To plan the surgical incision, you must determine whether the site of compression is above or below the elbow. If there is evidence of compression under an arcade of Struthers, center the surgical exposure at the radiographic projection of the supracondylar process. If the compression is below the elbow, extend the incision distal to the elbow flexion crease onto the forearm to expose the pronator and the arch of the FDS.

**Technique for Release of Compression at the Ligament of Struthers**

1. Center the incision over the supracondylar process and make it in line with the medial neurovascular bundle anterior to the medial intermuscular septum (Fig. 52.24).

   ![Figure 52.24](image)

   *Figure 52.24.* Entrapment of the median nerve (MN) under a ligament of Struthers. **A:** Initial appearance. **B:** The ligament divided and elevated (arrow). **C:** Supracondylar process (arrow).

2. Palpate the supracondylar process and expose the ligament of Struthers.
3. The median nerve, brachial artery, and sometimes the ulnar nerve lie within the proximity of the supracondylar process; therefore, proceed cautiously with dissection.
4. Divide the ligament of Struthers and excise the supracondylar process.
5. Continue distally and divide the lacertus fibrosus. This is done routinely in decompression of the median nerve for these cases and for others that do not involve compression at the supracondylar process. The lacertus fibrosus may act as a compressive band across the flexor muscle mass in supination and hence should be divided with any exploration of the median nerve.
6. If you do not find a ligament of Struthers, you must discover the area of compression by additional dissection distally.

**Technique for Release of Compression Distal to the Ligament of Struthers**

1. Begin the incision along the projection of the medial neurovascular bundle, 5 cm proximal to the elbow flexion crease. (Fig. 52.25).

   ![Figure 52.25](image)

   *Figure 52.25.* Extensile approach for the exposure of the median nerve at the elbow and proximal forearm.

2. Continue it in a gentle curve along the elbow flexure, and extend it distally past the superficialis arch.
3. Protect the median antebrachial cutaneous nerve from injury.
4. Raise full-thickness flaps radially and ulnarily off the forearm muscle fascia.
5. Identify the median nerve proximal to the lacertus fibrosus and the PT (Fig. 52.26A).
6. The lacertus fibrosus originates from the antebrachial aspect of the musculotendinous junction of the biceps and travels distally and medially, crossing the median nerve and brachial artery to blend into the fascia of the flexor pronator muscle mass. Divide it in line with the course of the median nerve.
7. Follow the median nerve distally as it passes between the two heads of the PT.
8. Detach the superficial head of the pronator from its distal conjointed tendon with the deep head, using a stepcut or long oblique incision designed to allow...
resistance, with the elbow flexed to neutralize the stronger PT. However, isolated paralysis of any one or a combination of these muscles has been reported. (Hyperextension attitude of the distal joints of these two digits makes it difficult or impossible for the patient to tip pinch with the index finger and thumb (i.e., to make the so-called OK sign). The lack of long flexors results in a

Findings on clinical examination include weakness or paralysis of the muscles innervated by the AIN (59). Olehnik et al. (95) described an oblique incision centered over the point of maximal tenderness in the proximal forearm (Fig. 52.27). The fascia was then split longitudinally to allow adequate access to the soft-tissue structures in the antecubital fossa to the midforearm. Deep digital palpation and dissection were used to evaluate for compression of the nerve proximally by a ligament of Struthers. They additionally released intramuscular fascial bands of the PT and FDS that crossed the nerve. The authors of this study point out the importance of tracing the nerve along its course, releasing all fibrous bands and vascular structures that are potential sites of compression.

Alternative incisions that are oriented fairly transversely, with a goal of minimizing unsightly scarring, have been described (38). These have been criticized for not providing adequate exposure of the nerve and the sites of compression (58). Olehnik et al. (95) described an oblique incision centered over the point of maximal tenderness in the proximal forearm (Fig. 52.27). The fascia was then split longitudinally to allow adequate access to the soft-tissue structures in the antecubital fossa to the midforearm. Deep digital palpation and dissection were used to evaluate for compression of the nerve proximally by a ligament of Struthers. They additionally released intramuscular fascial bands of the PT and FDS that crossed the nerve. The authors of this study point out the importance of tracing the nerve along its course, releasing all fibrous bands and vascular structures that are potential sites of compression.

**Postoperative Care and Rehabilitation**

After skin closure, apply a well-padded compression dressing and a posterior plaster splint with the elbow flexed at right angles and the forearm in semiflexion. Encourage shoulder and finger motion immediately after the operation. After 5 days, discontinue immobilization; allow the patient to resume elbow flexion and extension and forearm rotation and to gradually return to full activities as tolerated.

**Complications**

As for CTS, misdiagnosis and technical factors are responsible for most complications. The most important is failure to release constriction at one of the four sites of possible entrapment. You must also address all other potential sources of compression by visualizing the nerve along its course. Avoid accidental damage to branches of the median nerve by initially exposing and dissecting the nerve along its lateral aspect, which is free of branches.

**ANTERIOR INTEROSSEOUS NERVE SYNDROME**

**Pathophysiology and Anatomy**

The anterior interosseous nerve (AIN) is a branch of the median nerve that is essentially entirely motor except for a few terminal branches that are sensory to a portion of the carpus. The most common pattern of muscles innervated by the AIN includes the FDP to the index finger, the flexor pollicis longus (FPL), and the pronator quadratus (PQ). This innervation pattern varies significantly, which can cause confusion during clinical examination. The nerve arises from the dorsal aspect of the median nerve as it passes between the two heads of the PT. In some cases, it passes deep to the deep head of the PT. It passes beneath the arcade of the FDS and courses distally along the anterior surface of the interosseous membrane between the FDP and the FPL, accompanied by the anterior interosseous artery. The AIN gives branches to the FPL and the radial aspect of the FDP muscles approximately 4 cm distal to its origin from the median nerve (Fig. 52.28). Compression may be caused by one of many structures, including the deep head of the PT, the FDS, accessory muscles (e.g., Gantzer’s muscle, and an accessory FPL) (28-74), aberrant vessels (e.g., anomalous radial artery), and tendinous bands along the course of the nerve.

**Assessment**

Patients initially complain of vague, aching pain in the proximal forearm and sometimes in the wrist. This occurs at rest and is exacerbated by activities. There is no sensory deficit with AIN syndrome, which is different from carpal tunnel and pronator syndromes. Patients may note difficulty with activities such as writing, or weakness in tip pinch. Frequently, there is a history of a single episode of strong contraction of elbow, wrist, and finger flexors accompanied by pain and followed shorty thereafter by motor loss.

Findings on clinical examination include weakness or paralysis of the muscles innervated by the AIN (18). Weakness of the FPL and of the radial half of the FDP makes it difficult or impossible for the patient to tip pinch with the index finger and thumb (i.e., to make the so-called OK sign). The lack of long flexors results in a hyperextension attitude of the distal joints of these two digits (Fig. 52.28) (119). You can test the weakness of the PQ by asking the patient to pronate against resistance, with the elbow flexed to neutralize the stronger PT. However, isolated paralysis of any one or a combination of these muscles has been reported (59).
It is important to differentiate between an FDP or FPL rupture and AIN syndrome in the patient with acute presentation. This is done best by looking for the tenodesis effect of the FPL and index FDP (72). Innervation anomalies add variability to the classic examination findings. Martin-Gruber connection (median to ulnar motor nerve connection in the forearm) occurs in 15% of individuals; 50% of these arise from the AIN. The presence of this anomaly may cause weakness of additional intrinsic muscles of the hand in patients with AIN syndrome. Additionally, in 50% of individuals, the FDP to the index is innervated by branches from the median nerve, not the AIN (50). The diagnosis is usually confirmed by EMG studies. Nerve conduction studies are usually not affected, although side-to-side differences may be noted (Table 52.7).

**Preoperative or Nonoperative Management**

In a patient who presents acutely, obtain neurodiagnostic studies 2–3 weeks after injury, and again at 6 and 12 weeks if no clinical improvement is noted. Chronic cases, presenting after 6 weeks, should have neurodiagnostic examination performed initially and the patient should be followed clinically. If no improvement is noted, perform another study at 12 weeks after the injury. Although no specific protocols have been evaluated, nonoperative treatment may consist of avoidance of exacerbating activities, immobilization of the elbow in flexion and the forearm in pronation, and the use of NSAIDs.

**Surgical Indications and Relative Results**

Essentially all reported cases have gone on to spontaneous recovery, although in some instances this has taken up to 2 years. Most authors agree that recovery can be enhanced by surgical exploration when spontaneous recovery is not apparent or is slow (50). Recovery is generally complete within 6 months after surgery. Persistence of the motor symptoms without signs of significant improvement for 8–12 weeks is an indication for surgical exploration and decompression (122). Evidence of clinical motor recovery or signs of reinnervation on EMG would call for further observation.

**Operative Technique**

The surgical technique and postoperative management are very similar to those used in the pronator syndrome.

- Use the same incision as for pronator syndrome.
- Divide the lacertus fibrosus to allow access to the median nerve as it passes beneath the superficial head of the PT (Fig. 52.26A).
- The AIN branches from the median nerve just distal to the proximal border of the superficial head of the pronator. Trace it beneath this muscle. This is a common site of entrapment.
- If necessary for exposure, you may detach the superficial head of the pronator (Fig. 52.26B).
- Trace the nerve distally as it passes beneath the FDS. If necessary, detach the origin of this muscle or divide its fibrous arch, as in pronator syndrome exploration, to trace the nerve distally (Fig. 52.26C).
- Trace the nerve as it travels along the anterior interosseous membrane between the FPL and FDP muscles.
- Terminate the distal dissection when you visualize the branches to the deep flexors.
- Reattach the FDS muscle. (This may be done posterior to the median nerve if you feel that anterior transposition is necessary.)
- Reattach the PT superficial head deep to the median nerve and AIN.
- Close the skin and place a long-arm splint.

As in pronator syndrome, it is important to visualize the entire nerve and divide all suspected offending structures. The postoperative management is essentially identical to that after treatment of the pronator syndrome.

**Complications**

Possible complications are similar to those described for the carpal tunnel and PT syndromes. The main problem is an error in diagnosis, particularly for the patient with an incomplete syndrome involving either the thumb or the index long flexors, but not both (Fig. 52.29) (56). Such a presentation may lead to the erroneous diagnosis of tendon rupture and to a negative tendon exploration. Perform the tenodesis test with the wrist in maximal extension along with MP joint and PIP joint extension. This should produce slight flexion at the distal interphalangeal (DIP) joint of the index and the IP joint of the thumb with AIN syndrome but not with tendon rupture (79).

Suspect Parsonage–Turner syndrome (brachial neuritis) in cases with an acute onset of pain in the forearm followed by weakness in the muscles normally affected in AIN syndrome a few days to weeks later (at times associated with a febrile illness, vaccination, or unrelated surgery), especially in bilateral cases (145). In Parsonage–Turner syndrome, there will also be shoulder pain and involvement of the shoulder muscles at times. AIN compression syndrome generally presents after an acute injury or in conjunction with repetitive activity, whereas brachial neuritis is insidious in nature. In Parsonage–Turner syndrome there is pain not associated with an injury, which may involve more proximal areas of the upper extremity than that seen in AIN syndrome. Parsonage–Turner syndrome often produces EMG results similar to those of AIN syndrome in the FPL, FDP, and PQ. Sampling of more proximal muscles innervated by the brachial plexus, such as the deltoid, may also demonstrate EMG abnormalities, which is different from AIN entrapment (Table 52.8).
Table 52.8. AIN Syndrome versus Parsonage–Turner Syndrome

Complete recovery is seen in 90% of cases treated surgically or nonoperatively. Surgical exploration and decompression are reserved for cases associated with trauma.

COMPRESSION NEUROPATHIES OF THE ULNAR NERVE

CUBITAL TUNNEL SYNDROME

Pathophysiology and Anatomy

The most common location for entrapment of the ulnar nerve is about the elbow; this condition is known as cubital tunnel syndrome. There are five potential compression sites of the nerve that occur along its course. At the midarm level, the ulnar nerve pierces the medial intermuscular septum and runs distally posterior to it. Approximately 8 cm proximal to the medial epicondyle, the nerve may pass through an inconstant fibrous tunnel, the arcade of Struthers, formed by a band connecting the medial intermuscular septum to the tendon of the medial head of the triceps. This is the first potential site of compression. The nerve continues posterior to the intermuscular septum. The edge of the septum becomes a second potential site of compression, usually after failed anterior transposition. The nerve then comes to lie in the retrocondylar groove of the medial epicondyle, the third potential site of compression, where it gives off a few articular sensory branches to the elbow joint; it then enters the cubital tunnel, the fourth potential site of compression. The cubital tunnel is a fibro-osseous canal formed by the medial epicondyle anteriorly, the ulnohumeral ligament posterolaterally, and a structure termed the cubital tunnel retinaculum, which is superficial and forms the roof of the tunnel. The fifth potential site of compression occurs as the nerve passes under Osborne's fascia, a thick fascial layer that connects the heads of the FCU to the medial epicondyle and olecranon in nearly 80% of individuals and is often confluent with the cubital tunnel retinaculum. The nerve then courses to enter the forearm between the two heads of the FCU. At this level, it gives off several motor branches to the FCU. It comes to lie medial to the FDP, piercing the deep flexor pronator aponeurosis—a fascial structure serving as a common origin and aponeurosis of the humeral head of the FDS and the FCU—as it exits from the cubital tunnel. This aponeurosis is the sixth and most distal potential compression site, and it, like the medial intermuscular septum, is usually a site of secondary compression after anterior transposition.

Figure 52.30. The first five potential compression sites of the ulnar nerve in cubital tunnel syndrome: (a) arcade of Struthers, (b) medial intermuscular septum (considered a secondary site of compression), (c) medial epicondyle, (d) cubital tunnel, (e) Osborne's fascia. (From Osterman AL, Davis CA. Subcutaneous Transposition of the Ulnar Nerve for Treatment of Cubital Tunnel Syndrome. Hand Clin 1996;12:421, with permission.)

Figure 52.31. The sixth potential site of compression of the ulnar nerve in cubital tunnel syndrome, the flexor pronator aponeurosis.

Table 52.9. Potential Compression Sites of the Ulnar Nerve in Cubital Tunnel Syndrome

Compression of the nerve is often of a dynamic nature. Both constriction of the nerve and traction are implicated in its dysfunction. Flexion of the elbow has been shown to cause increased intraneural pressure in the ulnar nerve at the cubital tunnel and decreased volume in the cubital tunnel itself. The ulnar nerve at the
elbow normally glides to accommodate elbow flexion (\textcircled{5}). When tethered by scar or fibrosis, the ulnar nerve experiences traction forces, which affect nerve function.

Additional causes of compression include trauma, deformity (e.g., cubitus valgus), malunion or nonunion of the medial epicondyle, elbow instability, spurs or bone fragments within the floor of the cubital tunnel (Fig. 52.32), tumors, abnormal muscles (e.g., anconeus epitrochlearis), and a nerve that subluxates or dislocates repeatedly over the medial epicondyle.

\textbf{Figure 52.32.} \textbf{A:} Compression of the ulnar nerve at the elbow by a large osteochondral body (arrow). \textbf{B:} Severe nerve constriction (between arrows) after removal of the osteochondral fragment.

\section*{Assessment}

The presenting complaint is usually numbness and paresthesias along the ulnar nerve distribution, the small finger, the ulnar half of the ring finger, and the ulnar aspect of the hand (Fig. 52.3). This is exacerbated by leaning on the elbow or positioning it in flexion. Aching pain may be referred to the medial aspect of the elbow. Numbness on the medial half of the forearm is not usually present. Weakness of grip or loss of dexterity in the fingers may accompany these symptoms.

Physical examination includes sensory evaluation, provocative testing, and motor examination. Threshold sensory evaluation, including Semmes–Weinstein monofilaments and vibratory testing, is most sensitive and is recommended. Two-point discrimination yields abnormal results in more advanced cases. Sensation is decreased in the ring and small fingers as well as in the ulnar half of the dorsum of the hand, which indicates compression proximal to the origin of the dorsal cutaneous branch of the ulnar nerve and therefore proximal to the wrist.

Employ provocative testing to help localize the site of compression, as well as uncover dynamic forms of the disorder. Tinel's test is positive if paresthesias are elicited in the distribution of the nerve when it is gently percussed. The location of percussion with maximal elicitation of symptoms may indicate the site of compression. Tinel's test is sensitive but not specific, giving a high rate of false positive results at the cubital tunnel (\textcircled{23}). The elbow flexion test described by Buehler and Thayer (\textcircled{17}) and others (\textcircled{101}), which is flexion of the elbow beyond 90° with the forearm in supination and the wrist in extension, is positive when symptoms are produced within 1 minute, and it may localize compression to the level of the elbow. Novak et al. (\textcircled{80}) modified this test to include direct compression of the ulnar nerve with the examiner's finger just proximal to the cubital tunnel while the elbow is flexed maximally (Fig. 52.33). The test is considered positive when paresthesia symptoms are produced in the ulnar nerve distribution within 30 seconds. This test is reported to have 0.91 sensitivity and 0.97 specificity. Evaluate potential subluxation of the ulnar nerve over the medial epicondyle by direct palpation while the elbow is brought from full extension to full flexion. Ulnar nerve subluxation is seen in 16% of normal individuals (\textcircled{20}) and therefore is not considered pathologic per se. If associated with neuritic symptoms, it may be the cause of injury to the nerve. Palpation may also elicit tenderness and disclose an enlarged, sensitive nerve.

\textbf{Figure 52.33.} The flexion compression test for cubital tunnel syndrome.

Motor examination is helpful in patients with more advanced disease. Atrophy may be seen most commonly in the hypothenar musculature and in the first dorsal interosseous muscle. When weakness is present, it involves not only the ulnar innervated intrinsic muscles but typically the FDP to the ring and small fingers. When both ulnar innervated intrinsic and extrinsic muscles are involved, the ulnar claw hand, a sign of intrinsic–extrinsic imbalance, does not appear as severe. Grip strength testing is often normal unless there is significant loss of power to the long flexors of the ring and small finger. Pinch strength, especially key pinch, is decreased as a result of loss of strength to the flexor pollicis brevis (FPB), the adductor pollicis, and the first dorsal interosseous muscle. Froment's sign (hyperflexion of the MP joint of the thumb) and Jeanne's sign (hyperextension of the MP joint of the thumb) are elicited during key pinch (Fig. 52.34). Weakness or paralysis of the FDP concentrates the flexion force of the FPL at the IP joint, causing hyperflexion of this joint (\textcircled{11}). The EPL compensates for the adductor pollicis and enhances hyperextension of the MP joint of the thumb because it is unopposed by the intrinsic flexor of the thumb (the EPB).

\textbf{Figure 52.34.} Froment's sign and Jeanne's sign, seen with intrinsic muscle weakness in ulnar nerve palsy.

For subjective evaluation, directly test the strength of the first dorsal interosseous muscle against resistance, and measure it by side-to-side comparison in unilateral cases. In some individuals, contribution of innervation to this muscle from the median nerve can occur (\textcircled{109}), and therefore this test is not specific. Evaluation of the abductor digiti quinti is also subjective. Side-to-side comparison is facilitated by a confrontation test. Ask the patient to maximally abduct her fingers while holding her hands out in front, palms facing her. She brings the tips of her small fingers together and, while she resists collapse of the abducted small fingers, she brings her hands
together. In unilateral cases with abductor weakness, the weak hand’s small finger collapses to the side of the ring finger (Fig. 52.35).

Figure 52.35. The confrontation test.

Wartenberg's sign is abduction of the small finger with extension of the fingers at the MP joint level. It indicates interosseous dysfunction. The cross finger test (30) is very useful and also evaluates function of the interossei. Ask the patient to cross his index and long fingers. Patients with ulnar nerve dysfunction often have trouble performing this task. Atrophy and weakness of intrinsic muscles innervated by the ulnar nerve indicate a moderate to severe lesion of the nerve (Table 52.10).

Table 52.10. Provocative Tests for Cubital Tunnel Syndrome

Radiographs are indicated in cases of previous trauma, deformity, and suspected arthritis, and where there is incomplete range of motion. AP, lateral, and oblique views are obtained, as well as axial views of the distal humerus and olecranon for evaluation of the ulnar groove.

Neurodiagnostic studies include NCV and EMG evaluation. These are helpful in confirming the diagnosis and in classifying the case for treatment and prognostic purposes. NCV evaluations of the segment of the ulnar nerve across the elbow are considered significant if conduction values are reduced by 33% (33). Segmental “inching” studies may be helpful in localizing the site of compression, especially in previously operated cases with recurrence of symptoms. EMG evaluation of the ulnar innervated muscles can provide information on chronicity and progression as well as severity, and it may indicate the approximate site of compression. More importantly, EMG needle examination coupled with somatosensory evoked potential (SSEP) evaluates for radiculopathies and more proximal lesions, including thoracic outlet syndrome (TOS), which is suspected especially in cases of bilateral ulnar nerve symptoms (Table 52.11).

Table 52.11. Cubital Tunnel Syndrome Summary

Classification

Dellon (26) developed a useful classification system for cubital tunnel syndrome (Table 52.12). He classified patients into mild, moderate, and severe categories depending on physical and electrodiagnostic findings. Surgical treatment options and the relative results with respect to the patient classification will be discussed.

Table 52.12. Staging of Ulnar Nerve Compression at the Elbow

Preoperative or Nonoperative Management

Neither vitamin B6 nor NSAIDs have been shown to have an effect on cubital tunnel syndrome. Injections are advocated by some. Two of us (MNH and JT)
occasionally use them. Water-soluble steroid is injected at the proximal aspect of the cubital tunnel, not into the tunnel. Take great care to avoid injury to the ulnar nerve, which is at risk. Most agree, though, that injection is to be avoided because of the great risk of injury to the nerve, especially if injection is made into the cubital tunnel where the nerve is tightly confined.

The most effective nonsurgical management of cubital tunnel syndrome includes patient education and splinting. The occupational or physical therapist instructs the patient in nerve protection. This includes avoidance of repetitive flexion and extension of the elbow, of prolonged positioning of the elbow in the flexed position, and of leaning on the medial aspect of the elbow. Adjustments are made in the height of work stations and seats when indicated, so that the elbow is flexed no more than 30° during work. Elbow pads may be worn to prevent direct pressure on the nerve in its subcutaneous position (Fig. 52.36). Hand therapists can provide Thermoplast or pillow extension splints that hold the elbow in 30° to 45° of flexion during sleep to prevent hyperflexion (Fig. 52.37). Recheck the patient after 3 months of treatment. In mild cases and some moderate ones, patients who comply with these instructions may have a good response and be able to avoid surgery.

Figure 52.36. Commercially available elbow pads worn to protect the ulnar nerve from mechanical irritation.

Figure 52.37. Thermoplast night splints custom fabricated by a hand therapist.

Surgical Indications and Relative Results

Progression or inadequate amelioration of symptoms with nonsurgical care is an indication for surgery. Inability of the patient to comply with nonsurgical care in mild or moderate cases is a relative indication. Severe involvement, including motor dysfunction, requires surgical intervention. Ulnar neuropathies associated with deformity, bony lesions, tumors, and elbow instabilities, among others, require attention to the pathology contributing to the nerve compression as well as the nerve itself.

The severity of disease, its chronicity, and the general condition of the patient all influence the outcome of treatment. Patients with intermittent symptoms, no atrophy, and mild electrodiagnostic findings respond well to nonoperative treatment (52). The choice of surgical procedure in some instances may also have an effect. In most uncomplicated cases, return of sensation and motor function occurs within 6 months. Nouhan and Kleiner (89) evaluated 33 limbs that had been followed for an average of 49 months. Preoperative nerve compression was classified as mild in 6, moderate in 7, and severe in 20. Surgical treatment consisted of submuscular transposition with Z-lengthening of the flexor pronator mass. There were 97% good to excellent results overall; the preoperative classification did not influence the final result.

Sersadge and Willis (114) evaluated the results of 160 cases undergoing cubital tunnel release and medial epicondylectomy. Preoperative severity of compression was mild in 7%, moderate in 66%, and severe in 3%. There were 87% good, 12% fair, and 1% poor results (failure of treatment). Factors that increased the rates of symptom recurrence in their patients included female sex, the presence of concomitant CTS or TOS in the same extremity, age in the third or fourth decade, and patients who did not return to work within 3 months after surgery. Limb dominance, length of preoperative conservative care, and EMG results did not have a relationship to recurrence rate.

In a literature review by Dellon (25), patients in the mild group had excellent results from surgery no matter what technique was used. Patients in the moderate group did not improve without surgery, and decompression in situ was not effective. Mediial epicondylectomy produced 50% excellent results with a high recurrence rate, whereas submuscular transposition gave 80% excellent results with the lowest recurrence rate. In severe patients, surgery resulted in less than 50% excellent results for sensory recovery and up to 25% for motor recovery. Recurrence developed in 30% of these patients. In this group, the poorest results were in those undergoing intramuscular transposition, and the best were in those receiving submuscular transposition and internal neurolysis.

Preoperative Planning

When a particular condition contributes to compression of the ulnar nerve, consider additional diagnostic studies to further delineate the pathology. Computed tomography (CT) scans can further characterize suspected bony abnormalities, including space-occupying spicules or fragments, fracture callus, and malunions or nonunions. Suspected tumors are best visualized by magnetic resonance imaging (MRI) evaluation. Progressive deformities (e.g., cubitus valgus due to nonunion of the lateral condyle) must be stabilized at the time of decompression and transposition of the nerve, or in a staged fashion. Patients with previously failed decompressions should undergo inching nerve conduction velocities to better localize the site of compression, most often in the most proximal or distal portion of the previous surgical exposure.

Better than 80% to 90% good results are obtainable with any of the commonly employed operative methods. The choice of operative technique is greatly influenced by the cause of the compression, the patient's age, and systemic conditions such as diabetes or alcoholism. Operative techniques include simple decompression, medial epicondylectomy, subcubaneous transposition, intramuscular transposition, and submuscular transposition. The nerve may be decompressed by simple division of the arch of origin of the FCU (or the cubital tunnel) in the following cases: (a) if clinical findings (e.g., a localized nerve percussion sign) suggest isolated entrapment of the nerve beneath the arch (or cubital tunnel retinaculum), (b) if the nerve presents a constricting groove caused by this arch (or retinaculum), as visualized during operation (Fig. 52.38), or (c) if the nerve is vulnerable to manipulation (e.g., in older patients or patients with diabetic or alcoholic neuropathy) (138).
Anterior submuscular transposition is best suited for neuropathies associated with elbow deformity, abnormalities of the cubital canal, and the subluxing or dislocating ulnar nerve, particularly in the younger population and in the more severe cases with evidence of motor involvement (68,69). A particular indication for medial epicondylectomy is the ulnar neuropathy associated with nonunion of a fracture of the medial epicondyle. Routine use of this technique has been shown to be effective (48,60). Some prefer anterior subcutaneous transposition over submuscular transposition (1,31,99,104). Subcutaneous transposition is commonly employed as part of other operative procedures about the elbow, including fracture reduction, elbow arthroplasty, and neurotomy of the ulnar nerve in cases where there is loss of nerve length.

Dissection of the ulnar nerve is delicate and requires patience and diligence to prevent damage to the nerve, its branches, and its accompanying blood supply. This is aided by use of magnification, fine instruments, and bipolar cautery. A trained surgical assistant is invaluable in facilitating these procedures and in adding a level of safety to prevent potential complications related to nerve injury.

In Situ Decompression

- Start the skin incision equidistant between the olecranon and the medial epicondyle; extend it 3–4 cm proximally and 6–8 cm distally (Fig. 52.39A).

- Isolate the ulnar nerve before it enters the cubital canal.
- Delineate the arch of origin of the FCU, elevate it from the nerve, and divide both it and Osborne’s fascia while protecting the nerve under direct visualization (Fig. 52.39B).
- Extend this division distally between the two heads of the FCU to allow room for the nerve (Fig. 52.39C).
- Flex and extend the elbow, and make sure the nerve does not sublux. If subluxation occurs, be prepared to transpose the nerve or perform a medial epicondylectomy.
- Release the tourniquet for careful hemostasis.
- Do not close the FCU heads beneath the ulnar nerve.
- Close only the skin.
- Apply a well-padded dressing.

Support the arm in a sling for a few days. Encourage immediate active flexion and extension of the elbow. Subluxation of the nerve after decompression is rare. On the contrary, nerves that are as tense as bow strings proximal to the constricting tendinous arch, snapping over the medial epicondyle during elbow flexion and extension, recover a normal excursion after decompression.

Medial Epicondylectomy

- Center the incision over the medial epicondyle, and extend it proximally and distally far enough to expose all potential compression sites (Fig. 52.40).

- Isolate the ulnar nerve as it enters the cubital tunnel.
- Decompress the nerve in the cubital tunnel; lift the retinaculum off the nerve; protect the nerve and directly visualize it to prevent formation of a painful neuroma. Divide the retinaculum.
- Trace the nerve into the FCU muscle. Divide the origin of the arch of the FCU.
- Continue decompression of the nerve between the heads of the FCU; do not damage the multiple muscular branches in this area.
- Divide the deep flexor pronator aponeurosis until the nerve has been dissected 8 cm distal to the medial epicondyle.
- Trace the nerve approximately 6 cm proximally.
- Release the arcade of Struthers.
- Excise the distal 8 cm of the intermuscular septum in the arm, taking care not to damage any of the vessels associated with the nerve. (Multiple vascular leashes exist near the insertion of the septum into the medial epicondyle.)
- Make an incision directly over the medial epicondyle. Elevate the flexor pronator mass subperiosteally, both radially and ulnarily, while preserving the proximal attachments of the muscle mass (Fig. 52.41A).

- Perforate the base of the epicondyle where you will make the osteotomy with a small drill, Kirschner wire (K-wire), or osteotome.
- Preserve the medial collateral ligament, which arises from the distal, inferior portion of the epicondyle.
- Remove the epicondyle, cutting it in line with the medial cortex of the distal humerus (Fig. 52.41B). Perforating the planned osteotomy line with drill holes may be helpful.
- Cover the raw bone surface with bone wax, and close the tendon of the flexor pronator mass (Fig. 52.41C). We recommend decompression of the nerve proximally and distally at all sites of potential compression.
- Check that the ulnar nerve glides unimpeded during flexion–extension of the elbow.
- Release the tourniquet and obtain hemostasis.
- Close only the skin after this.
- Apply a well-padded dressing and a long arm posterior splint.

Postoperatively, leave the splint in place for 3–5 days. Then remove it and begin active range-of-motion exercises. Use a sling to protect the arm when it is not engaged in therapy. Full range of the elbow should be achieved by 3–4 weeks. At that time, begin progressive, gentle strengthening. Theoretically, the nerve will slowly transpose itself anteriorly and come to rest in a position without tension, anterior to or on the flexion–extension axis of the elbow. Seradge (112) demonstrated a decreased incidence of elbow contracture and a decrease in return-to-work time of 50% in patients who had mobilization of their elbows within 3 days of surgery following medial epicondylectomy versus those who were immobilized for 14 days postoperatively.

Anterior Transposition

The three methods of anterior transposition—subcutaneous, intramuscular, and submuscular—are essentially similar in their means of initial decompression and mobilization of the nerve, and this is described here. Both the way the transposition is maintained and the rehabilitation vary with the method, however, so they will be described under separate headings.

- Center the incision between the olecranon and the medial epicondyle, and extend it along the axes of the humerus and ulna 8–10 cm proximally and distally.
- Expose the deep fascia, and elevate the radial flap along this plane over the origin of the flexor–pronator muscles. Extend the exposure to adequately visualize the ulnar nerve along its course from the arcade of Struthers to well into the interval between the heads of the FCU and, laterally, to visualize the median nerve.
- Isolate the ulnar nerve as it enters the cubital tunnel.
- Decompress the nerve in the cubital tunnel; lift the retinaculum off the nerve, protect the nerve and directly visualize it, then divide the retinaculum.
- Trace the nerve into the FCU muscle. Divide the origin of the arch of the FCU (Fig. 52.42A).

- Continue decompression of the nerve between the heads of the FCU (do not damage the multiple muscular branches in this area), releasing Osborne’s fascia, the fascia of the heads of the FCU, and the pronator aponeurosis.
- Divide the deep flexor pronator aponeurosis 8 cm distal to the medial epicondyle.
- Trace the nerve approximately 8 cm proximally.
- Release the arcade of Struthers (Fig. 52.42B).
- Excise the distal 8 cm of the intermuscular septum of the arm to prevent secondary impingement on the nerve after anterior transposition. Take care not to damage any of the vessels associated with the nerve. Multiple vascular leashes exist near the insertion of the septum into the medial epicondyle (Fig. 52.42C).
- Mobilize the nerve from the cubital tunnel, preserving the small longitudinal vessels accompanying it.
- You may need to divide small branches arising from the nerve to the joint; branches to the ulnar head of the FCU must be preserved. Carefully separate them proximally from the main trunk by interfascicular dissection, to allow mobilization of the nerve.
- Make sure the nerve can be brought anterior to the medial epicondyle so that it lies in a relaxed course anterior to the flexion–extension axis of the elbow, none of the muscular branches to the FCU are under tension, and there is no kinking of the nerve proximally or distally.

Subcutaneous Transposition

Eaton et al. (31) described a technique (described next) that employs a fasciodermal sling fashioned from the fascia of the medial epicondyle and sutured into the dermis of the anterior skin flap (Fig. 52.43). The nerve comes to lie in the plane between the dermis and fat of the anterior flap, and the fascia of the flexor–pronator muscles, and it is maintained there by the sling. An alternative method for creation of a sling to maintain the anterior position of the nerve employs the medial intermuscular septum as described by Pribyl and Robinson (89). One of us (RMS) avoids the use of fascial slings and prefers to suture the fat of the lateral skin flap to the medial fascia to create a broad-based tunnel.
Intramuscular Transposition

This technique was described by Adson at the turn of the century, and it was evaluated in a series published by Kleinman and Bishop in 1989 (63), from which the following description is derived. We do not use this technique as part of routine treatment for cubital tunnel syndrome.

- Decompress and mobilize the ulnar nerve (Fig. 52.44). Transpose it anteriorly to a position where it will lie without kinking or tension, and mark or note its position on the fascia of the flexor–pronator mass (Fig. 52.44B).

![Figure 52.44. Intramuscular transposition. A: Decompression and mobilization of the ulnar nerve. B: Transposition of the nerve to the flexor pronator fascia. C: Laying the nerve in a trough. D: Closing the fascia over the nerve. (From Kleinman WB. Anterior Intramuscular Transposition. In: Gelberman RH, ed. Operative Nerve Repair and Reconstruction. Philadelphia: Lippincott, 1991:1069, with permission.)](image1)

- Return the nerve to the ulnar groove, and make an incision in the fascia of the flexor–pronator musculature where the nerve lay in the previous step.
- Along this incision, create a 5- to 10-mm-deep trough in the substance of the muscles. Sharply excise portions of the fibrous septae that cross the trough from within the bellies of the muscles so that the tissue contacted by the nerve will be muscle.
- Lay the nerve in the trough. Ensure that its course is without sharp angles at the proximal and distal extents of the trough, and that it rests easily in the trough, beneath the level of the fascia (Fig. 52.44C).
- Close the fascia over the nerve, and test the excursion of the nerve under the closure; it should glide without hindrance. Fascial closure is facilitated by placing the forearm in full pronation and the elbow in 90° of flexion (Fig. 52.44D).
- Release the tourniquet and obtain hemostasis.
- Close the skin.
- Place the arm in a bulky splint that holds the forearm in 45° of pronation and the elbow in 90° of flexion.

Postoperatively, hold the forearm in the semipronated position and the elbow in flexion for 3 weeks, then institute progressive range of motion exercises. Permit unrestricted use by 6 weeks.

Submuscular Transposition

Learmonth (66,69) provided the classical description of the technique of submuscular transposition of the ulnar nerve. He lengthened the flexor–pronator muscle mass by a stepcut, or Z-lengthening, of the common tendinous origin from the medial epicondyle to decrease the tension on the nerve in its anterior position on the fascia of the brachialis muscle and anterior capsule of the elbow (89).

- Identify the lateral border of the flexor–pronator origin, and raise the anterior skin flap adequately to visualize it.
- Identify the median nerve, which lies lateral to the flexor–pronator origin. The goal of the procedure is to place the ulnar nerve alongside the median nerve.
- To gain access to the lateral margin of the muscles, cut the fascial reflection at this margin.
- Using blunt dissection, elevate the flexor–pronator muscles from lateral to medial. This dissection begins distal to the flexor–pronator origin and proceeds between the flexor–pronator muscle group and the brachialis muscle and anterior elbow capsule.
- The appropriate medial exit of this dissection is in the interval between the humeral and ulnar heads of the FCU. To facilitate completion of the lateral-to-medial dissection in this plane, identify the interval medially.
- After the entire muscle mass is raised, detach it from its origin by creating a 90° stepcut in the common tendon, and turn it distally (Fig. 52.45A). Leave the posterior limb of the stepcut long and based on the epicondyle. To avoid damage to the medial collateral ligament complex of the elbow, you may use an elevator to dissect the muscle off the anterior elbow capsule. At this stage, ensure that the deep pronator aponeurosis, which forms a common intermuscular septum between the FCU and the humeral head of the FDS (Fig. 52.31), is divided adequately to avoid kinking of the nerve distally when it is transposed.

![Figure 52.45. Detachment of the flexor pronator mass from the medial epicondylye using a stepcut. A: Making the stepcut. B: Reattachment of the flexor pronator mass after transposition of the nerve. (From Rayan GM. Proximal Ulnar Nerve Compression: Cubital Tunnel Syndrome. Hand Clin 1992;8:325, with permission.)](image2)

- Transpose the nerve anteriorly so that it lies next to the median nerve on the anterior surface of the brachialis muscle and tendon and the anterior joint capsule.
where it will be deep to the flexor pronator mass.

- Make certain there is no kinking of the nerve proximally at the arcade of Struthers (or the medial intermuscular septum) or distally at the deep pronator aponeurosis, and that the muscular branches of the nerve are not under tension (Fig. 52.46). Protect the posterior branch of the medial antebrachial cutaneous nerve.

Figure 52.46. Anterior submuscular transposition. A: Extensile incision, allowing visualization of all potential compression sites. Note the proximity of the posterior branch of the medial antebrachial cutaneous nerve. B: Transposition of the nerve and reattachment of the muscles to the epicondyle. (From Spinner M, Linscheid RL. Nerve Entrapment Syndromes. In: Morrey BF, ed. The Elbow and its Disorders, 2nd ed. Philadelphia: Saunders, 1993:813; and from Spinner M. Injuries to the Major Branches of the Forearm, 2nd ed. Philadelphia: Saunders, 1978, with permission.)

- Release the tourniquet and carefully secure hemostasis.
- Reattach the stepcut flexor–pronator origin in a lengthened position over the ulnar nerve with nonabsorbable suture, and reapproximate the heads of the FCU with absorbable suture (Fig. 52.46B) (25).
- Close the skin.
- Apply a well-padded dressing from the hand to the upper arm, with a posterior plaster splint.

Postoperatively, maintain the arm in plaster immobilization for 7–12 days. Then remove the immobilization, place the arm in a sling, and institute active range-of-motion exercises. The wrist can be protected from extending with a removable Velcro splint. Full elbow range is expected by 3 weeks, when the sling is removed. Restrict the patient from forceful gripping with the hand for an additional 1–3 weeks, but encourage light activities. Begin strengthening 4–6 weeks postoperatively, and have the patient return to nearly full activities at 6–8 weeks, with unrestricted use at 9–12 weeks depending on individual progress and demands.

Complications

The most common causes of recurrent cubital tunnel syndrome are incomplete decompression and inadequate mobilization of the nerve at the time of transposition. Failure to decompress the nerve at the site of entrapment often results in failure to relieve symptoms, and this can be avoided by carefully evaluating all potential sites of compression. When initial relief of symptoms is followed by recurrence, common causes are kinking of the nerve proximally at the arcade of Struthers or on the margin of the intermuscular septum, and distally at the deep pronator aponeurosis. You can avoid this by making the incisions adequate for exposure and by examining the nerve at surgery, before closing the wound, to ensure that it is not entrapped by the procedure anywhere along its length.

Reoperation should be preceded by nonoperative care and repeat neurodiagnostics, including the inching studies previously mentioned, to evaluate for the potential site of secondary compression. When revision surgery is appropriate, the procedure of choice is submuscular transposition (26) unless this was the initial procedure. In that case, the choice of revision surgical technique is often determined at surgery, at which time the status of the nerve and its bed can be evaluated. The results of repeat decompression are poor in comparison to those of initial decompression (6.106). The medial antebrachial cutaneous nerve (particularly the posterior branch) is at risk for injury during the dissection. This injury commonly results in pain and an unhappy patient.

ULNAR TUNNEL SYNDROME

Pathophysiology and Anatomy

Ulnar tunnel syndrome is caused by the compression of the motor, sensory, or motor and sensory portions of the ulnar nerve in the canal of Guyon. The canal of Guyon is a confined fibro-osseous triangular space on the ulnar aspect of the volar wrist (Fig. 52.47). The roof of this space is formed by the volar carpal ligament proximally (the thickened distal extension of the antebrachial fascia, which becomes confluent with the tendinous insertion of the FCU onto the pisiform) and the pisohamate ligament distally (which is the extension of the FCU from the pisiform onto the hook of the hamate). The lateral wall is formed by the TCL proximally and the hook of the hamate distally. The medial wall is formed by the pisiform and its associated fibrous structures, and the abductor digitii minimi. The ulnar artery and nerve enter the canal of Guyon at the wrist, deep and radial to the FCU tendon, the artery lying radial to the nerve. In the proximal portion of the canal, the motor and sensory bundles of the nerve lie side by side as one nerve. Just at the distal origin of the pisiform, the nerve divides into deep and superficial branches. The deep branch, which is the motor division, dives through a fibrous arch formed by the origins of the abductor digitii minimi and flexor digitii minimi at the base of the hypothenar muscle group. It continues on to innervate the intrinsic muscles of the hand. The superficial branch continues on through the canal, beneath the pisohamate ligament, to course along the palmar surface of the hypothenar musculature and become, in its terminal branches, the proper digital nerves of the ulnar and radial small finger and the ulnar ring finger.

Figure 52.47. The anatomy of the ulnar tunnel and the course of the ulnar nerve from the forearm into the wrist as seen in a palmar view of the medial side of the wrist. ODQ, opponens digitii quinti muscle; FDQ, flexor digitii quinti muscle; ADQ, abductor digitii quinti muscle; H, hook of hamate; P, pisiform; FCU, flexor carpi ulnaris tendon. (From Eversmann WW Jr. Entrapment and Compression Neuropathies. In: Green DP, ed. Operative Hand Surgery, 3rd ed. New York: Churchill Livingstone, 1993:1341, with permission.)

Gross and Gelberman (45) described the ulnar tunnel and divided it into clinically relevant zones (Fig. 52.48). Zone I is the area of the canal from the proximal margin of the volar carpal ligament to the distal margin of the pisiform—more specifically, where the nerve bifurcates. It is defined by the presence of both the motor and the sensory divisions of the ulnar nerve. With division of the nerve into motor and sensory branches, zones II and III are defined; the former is associated with the motor and the latter with the sensory division. These last two divisions run side by side in the canal up to the level of the hypothenar fibrous arch.
Entrapment of the ulnar nerve in the ulnar tunnel may be a result of space-occupying lesions. Ganglions arising from the triquetrohamate joint are the most common cause. Others include aneurysms (Fig. 52.49), lipomas, fractures of the bony walls (particularly the hook of the hamate) of the canal of Guyon, anatomic variations of the canal, and accessory or aberrant muscles. Repeated blunt trauma to the hypothenar region is the second most common cause (10,116). Compression in zones I and II is most often caused by ganglions and fractures of the hook of the hamate. Zone III is most often affected by a vascular lesion of the ulnar artery (116,128).

Classification

Entrapment at the wrist may produce pure motor, sensory, or mixed symptoms (10). Shea and McClain (116) described three ulnar nerve compression syndromes at and distal to the wrist. These correspond to the three anatomic areas of the canal. In type I, the entrapment takes place in the proximal zone, resulting in mixed motor and sensory deficit. Type II is purely motor, secondary to compression in the canal of Guyon or at the hook of the hamate in association with the origins of the abductor digiti minimi and the flexor digiti minimi and within the substrate of the opponens digiti quinti. Type III is caused by pressure on the superficial branch of the ulnar nerve, producing a sensory deficit in the ring and small fingers without associated muscle weakness or atrophy (Table 52.13).

Assessment

Ulnar tunnel syndrome may be difficult to distinguish from cubital tunnel syndrome. One difference is the sparing of sensation of the dorsal ulnar half of the hand in ulnar tunnel syndrome. This area is innervated by the dorsal branch of the ulnar nerve, which arises variably from the ulnar nerve, but always proximal to the wrist crease, and does not enter the canal. Another difference is sparing of the long flexors of the ring and small fingers, leading to a more pronounced ulnar claw deformity in patients with ulnar tunnel versus cubital tunnel syndrome. Additionally, a history of repeated trauma to the hypothenar region may direct special attention to evaluation of this area in patients who present with ulnar-nerve-related symptoms (Table 52.14).

A careful examination is extremely helpful in precisely localizing the site of compression. Palpation of the deep structures within the hypothenar region may suggest a mass, not infrequently a ganglion within the canal. Allen's test (an evaluation of the contributions made by the radial and ulnar arteries to the blood supply of the hand)
is performed because thrombosis or aneurysm of the ulnar artery may be the cause of the neuropathy. Tinel's test over the ulnar nerve at the level of the wrist and compression of the nerve over zone I may be helpful in distinguishing ulnar tunnel from cubital tunnel syndrome, although this has not been verified by studies. Phalen's test may also be positive in ulnar tunnel syndrome.

Because of the high incidence of space-occupying lesions and fractures associated with compression of the ulnar nerve in the canal of Guyon, obtain radiographs. Plain radiographs, including PA, lateral, and carpal tunnel (ulnar tunnel) views, can be used to screen for fractures, dislocations, and arthritis. If a hook-of-the-hamate fracture is suspected but not proven in plain radiographs, a CT scan is the diagnostic study of choice. Mass lesions include ganglia and aneurysms and are best evaluated by MRI. In some cases of vascular lesions, arteriograms may be of additional help. Electrodiagnostic studies show slowing of the NCV across the wrist of the sensory and/or motor portions of the nerve. In theory, isolated slowing in the sensory portion is not diagnostic of isolated sensory division compression because the sensory fibers of the nerve are more susceptible to compression than are the motor fibers. If EMG evaluation shows abnormalities in the FCU and FDP muscles in addition to the intrinsics, compression of the ulnar nerve is present proximally (Table 52.15).

Preoperative or Nonoperative Management

Except for cases resulting from repeated blunt trauma, in which cessation of trauma may lead to complete resolution of symptoms, and for the mild type II neuropathy, the ulnar tunnel syndrome is best treated surgically. In the absence of identifiable lesions causing compression of the nerve in the ulnar tunnel, nonoperative treatment consists of splinting, NSAIDs, and avoidance of activities that aggravate or precipitate symptoms. Failure to adequately improve symptoms is an indication for surgery.

Surgical Indications and Relative Results

As noted in the preceding section, most cases of ulnar tunnel syndrome are treated operatively because there is often a mass lesion or a vascular injury or anomaly causing compression of the nerve. Vascular reconstruction may be necessary in ulnar artery aneurysms and thrombosis. Ganglia must be identified and excised. If no injury before exploration. It is reasonable to treat acute, traumatic ulnar tunnel syndrome expectantly in cases of incomplete or mild neurologic deficit, and to reserve urgent operative decompression for those cases with dense sensory deficits and/or paralysis of intrinsic muscles. Results of operative management are generally good, and recurrence is rare. Return of muscle function is adequate to avoid the need for tendon transfer. The rate and extent of recovery are likely related to the preoperative duration and severity of symptoms.

Preoperative Planning

Identification of the cause and site of compression is essential to treat the offending lesion at surgery. Plan for and inform the patient of excision of a fractured hook of the hamate or arthritic pisiform. Vascular reconstruction may be necessary in ulnar artery aneurysms and thrombosis. Ganglia must be identified and excised. If no particular lesion is identifiable, suspicion of a particular zone of compression will help direct particular attention to the segment of the nerve corresponding to that zone.

Operative Technique

The choice of incision and extent of exposure vary according to the particular pathology suspected as the cause of compression. The technique of exploration and decompression of the nerve through its course in the ulnar tunnel is described here.

- Center a zigzag incision over the canal of Guyon, beginning just proximal to the proximal wrist crease at the radial border of the FCU tendon (Fig. 52.50). Or, in the case of concomitant CTS, use the incision for carpal tunnel release described earlier in this chapter and carry the dissection ulnarly to expose the canal of Guyon.

- Begin dissection proximally. Incise the fascia along the lateral border of the FCU.
- Identify the ulnar artery and nerve after retracting the FCU medially; the artery lies lateral to the nerve.
- Trace the ulnar nerve and artery distally, and incise (in order) the overlying palmaris brevis muscle, the hypothenar fat, any fibrous bands, and the palmar carpal ligament.
- Identify the pisiform. The ulnar nerve bifurcates as it passes by the pisiform; the sensory branch continues distally, and the motor branch dives toward the origin of the hypothenar muscles.
- Trace the sensory branch onto the hypothenar muscles, dividing any crossing and potentially constrictive structures.
- Trace the motor branch into the fibrous arch of the hypothenars and several interossei distally, again dividing any potentially constricting fibrous structures.
- Inspect the floor, walls, and contents of the canal, and identify any masses, aberrant muscles, fractures, or offending structures.
- Identify and inspect the ulnar artery for any abnormalities.
- One of us (JT) performs release of the carpal tunnel routinely at this time.
- Close the skin.
- Apply a padded hand dressing similar to that for carpal tunnel release.

Postoperative care is as for carpal tunnel release. If you treated other pathology simultaneously, institute specific rehabilitation and advise precautions as indicated.

Complications

Complications are similar to those associated with CTS. Incomplete release is potentially a problem if the nerve is not traced distally enough into zone III, between the
pisohamate and pisometacarpal ligaments. An additional pitfall is failure to recognize the existence of a vascular component within this syndrome.

COMPRESSION NEUROPATHIES OF THE RADIAL NERVE

The radial nerve can be entrapped as it crosses the lateral intermuscular septum in the arm (most frequently in conjunction with displaced fractures of the humerus) or compressed proximal to the elbow in association with a fibrous arch from the lateral head of the triceps (a rare form of compression) (72). Evaluation of these two conditions reveals involvement of the muscles innervated by the posterior interosseous nerve as well as those by the radial nerve prior to its branching into motor and sensory divisions—typically the brachioradialis and extensor carpi radialis longus (ECRL) muscles. Additionally, sensory disturbances in the radial nerve distribution are common with these disorders. EMG evaluation is often diagnostic, and observation is the treatment of choice. If recovery is not spontaneous within 3 months, exploration and decompression are warranted.

The two more distal compressions are the posterior interosseous nerve (PIN) syndrome and the radial tunnel syndrome (RTS) (143). Additionally, the superficial, sensory branch of the radial nerve (SBR) can be compressed in the distal forearm, causing pain and sensory disturbances in the radial nerve sensory distribution.

POSTERIOR INTEROSSEOUS NERVE SYNDROME

Pathophysiology and Anatomy

The radial nerve travels along the posterior aspect of the middle third of the humerus in a diagonal course between the lateral and medial heads of the triceps. At the distal third of the humerus, the nerve pierces the lateral intermuscular septum and then travels anteriorly and distally between the brachialis and brachioradialis muscles. Just proximal to the elbow, the nerve bifurcates into superficial and deep branches. The superficial branch, the sensory division, continues distally, traveling between the brachioradialis and supinator muscles. The posterior interosseous (deep) branch, essentially a purely motor nerve, passes between the two heads of the supinator muscle under an inverted fibrous arch, the arcade of Frohse, which is formed by the thickened edge of origin of the superficial head and is seen readily (55). It continues beneath the supinator muscle, exiting under its distal edge. The PIN innervates the muscles of the posterior forearm (Fig. 52.52).

Figure 52.51. A: Composite drawing of dissections of the forearm at the level of the elbow. B: Enlarged view of the posterior interosseous nerve and its relationship to the supinator muscle. The motor supply to the extensor carpi radialis brevis arises most frequently from the superficial radial nerve. (From Spinner M. Injuries to the Major Branches of Peripheral Nerves of the Forearm. Philadelphia: Saunders, 1972, with permission.)

Figure 52.52. Innervations of the posterior interosseous nerve. Not labeled in the diagram are the distal innervations, from radial to ulnar: abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, and terminal sensory branches to the dorsal carpus. (From Spinner M, Linscheid RL. Nerve Entrapment Syndromes. In: Morrey BF, ed. The Elbow and Its Disorders, 2nd ed. Philadelphia: Saunders, 1993:813; and from Spinner M. Injuries to the Major Branches of the Forearm, 2nd ed. Philadelphia: Saunders, 1978, with permission.)

There are five classic potential compression sites of the PIN (Fig. 52.53). Just proximal to the radiocapitellar joint, after branching from the radial nerve, the PIN travels through fibrous tissue that is associated with the anterior capsule of the radiocapitellar joint. This fibrous tissue may form bands that can cause constriction of the nerve (37). The nerve continues distally and is crossed by the leash of Henry, small radial recurrent vessels that have been reported to be a source of compression (70). The fibrous leading edge of the extensor carpi radialis brevis (ECRB) muscle travels diagonally across the proximal edge of the supinator muscle and can cause compression of the PIN just prior to its entrance under the arcade of Frohse (70,107,118). The edge of the ECRB and the fibrous arcade of Frohse, the thickened proximal edge of the supinator muscle, are the most common sites of compression in PIN syndrome (Table 52.16). The nerve wraps around the proximal radius between the two heads of the supinator and may also be compressed as it exits from beneath the superficial head on its distal margin of this muscle.

Figure 52.53. The five potential compression sites of the posterior interosseous nerve: fibrous bands on the anterior radiocapitellar joint capsule, the vascular leash of Henry (radial recurrent vessels), the proximal edge of the extensor carpi radialis brevis, the arcade of Frohse (proximal edge of the supinator), and the distal edge of the supinator. (From Hynes DE, Peimer CA. Compression Neuropathies: Radial. In: Peimer CA, ed. Surgery of the Hand and Upper Extremity. New York: McGraw-Hill, 1996:1291, with permission.)

Other causes of PIN compression include space-occupying lesions such as lipomas (103) and ganglions (77,93), radiocapitellar synovitis in patients with rheumatoid arthritis (78,147), fractures of the radial neck, and dislocations of the radial head (80). PIN compression may also be iatrogenic, as after internal fixation of fractures of the proximal radius, in which the nerve is extremely vulnerable because it may lie directly on the periosteum opposite the tuberosity of the radius (Figs. 52.54) (120).

Figure 52.54. A: In supination with a bare area of the proximal radius, the posterior interosseous nerve comes to lie against the periosteum of the radius. B: Details of the bare area. (From Spinner M. Injuries to the Major Branches of Peripheral Nerves of the Forearm. Philadelphia: Saunders, 1972, with permission.)

Assessment

The PIN syndrome is purely motor. Onset is usually insidious. There may be a history of trauma to the radial head or neck. Symptoms include weakness of the PIN-innervated muscles, and pain but not sensory dysfunction. The bra-chioradialis and the ECRL are not involved because they are innervated by the radial nerve. The ECRB may be spared because its innervation may originate more proximally, or it may appear to arise from the superficial bifurcation of the radial nerve (Fig. 52.51). The complete syndrome involves loss of extension of all digits and of the extensor carpi ulnaris. The patient can dorsiflex the wrist but with radial deviation. Middle and distal digital joints may still be extended through their intact intrinsics. Partial syndromes may involve just the extensor digitorum communis (EDC), with extension of the thumb and index finger preserved (Fig. 52.55). Early in the compression syndrome, a less striking clinical picture may exist, with paresis or paralysis of isolated digits. Patients with rheumatoid arthritis may present the same attitude of the hand whether the cause is a PIN compression or rupture or dislocation of the EDC tendons. A careful examination assists the clinician in differentiating between these two entities (75,78).

Figure 52.55. Incomplete dorsal interosseous nerve syndrome.

Diagnostic studies include routine radiographs of the elbow, especially in cases of trauma or arthritis. Soft-tissue masses may stretch or compress the PIN near the proximal radius. Functional loss of finger extension may be present, even though the patient is completely unaware of the presence of a mass. MRI examinations are extremely helpful in these patients, for preoperative evaluation of the size, shape, and location of the mass. Electrodiagnostic studies are imperative. The EMG portion of the examination is usually diagnostic (Table 52.17).

Brachioradialis Muscle–Splitting Approach

Methods

Surgical decompression for the treatment of PIN syndrome produces good to excellent results in 85% of patients (54). Patients generally recover motor function, although improvement may take 18 months to complete. If the paralysis has been longstanding (more than 12–18 months), so that end organ innervation of the muscle has atrophied, there will be residual loss or inadequate recovery. These patients can be treated with appropriate tendon transfers (see Chapter 55 on radial nerve palsy) (54).

Preoperative Planning

Be prepared to address concomitant fractures and dislocations. You must delineate the sizes and locations of masses to optimize the choice of approach. This requires a preoperative MRI. In cases of suspected malignancy, perform a metastatic workup and choose a treatment appropriate for the neoplasm. In patients with rheumatoid arthritis and radiocapitellar disease, radial head excision may be indicated.

There are several approaches to the radial nerve in the proximal forearm. Use the one that allows complete visualization of the potential compression sites of the nerve and that allows treatment of any associated conditions. Three popular approaches are the anterolateral extensile, posterior, and brachioradialis muscle–splitting approaches. Perform the surgery under tourniquet control and regional or general anesthetic.

Anterolateral Approach

- Begin the incision 5 cm above the flexor crease on the lateral aspect of the arm, over the interval of the brachioradialis and biceps. Extend it distally, across the flexor crease, along the ulnar border of the brachioradialis muscle (Fig. 52.56).

![Figure 52.56. The anterolateral approach to the radial nerve. (From Eversmann WW Jr. Entrapment and Compression Neuropathies. In: Green DP, ed. Operative Hand Surgery, 3rd ed. New York: Churchill Livingstone, 1993:1341, with permission.)](image)

- Develop the skin flaps to the level of the muscle fascia. Protect the lateral brachial and lateral antebrachial cutaneous (LABC) nerves as well as the cephalic vein in the subcutaneous tissues.
- Deepen the dissection proximally and identify the radial nerve in the interval between the brachialis and brachioradialis just proximal to the flexion crease of the elbow.
- Trace the nerve distally onto the anterior capsule of the radiocapitellar joint, the first site of potential compression, where fibrous bands may compress the nerve. Release all substantial structures crossing the nerve.
- Continue tracing the nerve distally. The fan-shaped leash of vessels from the radial recurrent artery cross the nerve as they travel to the brachioradialis. With bipolar cautery, coagulate the vessels and divide them.
- While visualizing the nerve, pronate the forearm and flex the wrist. This will tighten the leading edge of the ECRB and may demonstrate its compression of the PIN. Remove a portion of the fibrous edge of the muscle in the region of the nerve.
- Continue following the nerve as it enters the arcade of Frohse. Divide the fibrous arch while protecting the underlying PIN.
- The superficial head of the supinator often has a tough fascial envelope. Because of this and for the benefit of exploration of the nerve as it travels through the supinator, it may be preferable to divide the superficial head of the supinator as it crosses the PIN.
- Trace the nerve as it branches and exit the supinator. Divide the distal margin of the superficial head of the supinator.

Posterior Approach of Thompson

- Make an incision along the line connecting the lateral epicondy and Lister's tubercle with the forearm in pronation. Begin it 2 cm distal to the lateral epicondyly, and extend it 8 cm.
- Locate the interval between the ECRB and EDC muscles in the distal portion of the wound. Develop this interval and extend it proximally.
- Identify the transverse-oblique fibers of the supinator muscle (Fig. 52.67).

![Figure 52.57. The posterior muscle-splitting approach to the radial tunnel and the arcade of Frohse. ECU, extensor carpi ulnaris; ECRB, extensor carpi radialis brevis; ECRL, extensor carpi radialis longus; EDC, extensor digitorum communis. (From Eversmann WW Jr. Entrapment and Compression Neuropathies. In: Green DP, ed. Operative Hand Surgery. New York: Churchill Livingstone, 1982:1341, with permission.)](image)

- Increase exposure by developing the interval between the ECRB and the supinator. Avoid dissection between the EDC and the supinator, which would place the motor innervation of the EDC at risk (120).
- Explore the nerve as previously described, beginning proximally. It may be difficult to isolate the fibrous bands of the first site of compression, which is a disadvantage of this approach. (One can extend this approach proximally by developing the interval on the medial and lateral aspects of the brachioradialis muscle.)

Brachioradialis Muscle–Splitting Approach

- Make an incision centered over the mobile wad at the level of the radiocapitellar joint (Fig. 52.58).
Develop the skin flaps to the level of the muscle fascia. Protect the lateral brachial and LABC nerves in the subcutaneous tissues.

Make an incision in the brachioradialis fascia in line with the muscle fibers.

Palpate the radial head.

Bluntly dissect through the substance of the muscle, separating its fibers and heading toward the radial head. Continually locate the radial head by palpation.

Identify the transverse-oblique fibers of the supinator. The superficial branch of the radial nerve will be on the underside of the brachioradialis (Fig. 52.59).

Identify the PIN as it enters the arcade of Frohse.

Dissect the nerve, evaluating the five potential sites of compression and dividing all potential offending structures. (Pronate the forearm and flex the wrist to evaluate ECRB compression of the nerve.) Carry decompression out to the distal margin of the supinator.

If more proximal exposure is desired, extend the skin incision along the interval between the brachioradialis and the biceps on the arm. Proceed with deeper exposure as described in the anterolateral approach.

If more distal exposure is desired, extend the incision so that you can reach the interval between the ECRB and EDC muscles. Proceed with deeper dissection as described in the posterior approach.

Loosely approximate the fascia of the brachioradialis before closing the skin.

Authors’ Preferred Method

Start the incision 4–5 cm proximal to the elbow flexion crease, at the interval between the brachioradialis laterally and the brachialis medially.

Distally, continue the incision to the interval between the ECRB and the ECRL laterally and to the EDC medially (Fig. 52.60).

Begin deep dissection at the proximal end of the incision.

Identify the radial nerve and tag it with a moist, wide Penrose drain.

At the distal end of the incision, develop the plane between the ECRB and the EDC, exposing the oblique fibers of the supinator muscle (Fig. 52.57).

Accomplish wider exposure by partially detaching the ECRB from the lateral epicondyle.

Dissection to increase exposure is between the ECRB and the supinator, as in the posterior approach. (Do not dissect between the EDC and the supinator.)

Trace the nerve from proximal to distal, using the proximal and distal intervals for exposure.

Divide all potential compressing structures as previously noted.

After decompression of the nerve, release the tourniquet and obtain hemostasis. Do not close any deep structures except as noted for the brachioradialis-splitting technique. Suture the skin in layers. Apply a padded dressing and a long-arm splint with the forearm in supination and with the elbow flexed 90°.

Postoperative Care and Rehabilitation

Immediately postoperatively, encourage shoulder and finger range-of-motion exercises. Because these approaches are carried out between anatomic planes, you may discontinue immobilization as early as 3–5 days and no later than 7–10 days. Depending on individual patient recovery, slings or wrist splints may be used for up to 3 weeks for comfort. Formal therapy for strengthening and range of motion is not routinely implemented but should be used when the patient is slow to progress. Return-to-work time is influenced by the severity of the syndrome and the particular job demands.

Complications

In addition to the pitfalls common to other entrapment syndromes, differentiation of the PIN syndrome from extensor tendon ruptures or dislocations in the patient with rheumatoid arthritis is important. Make this distinction by performing a tenodesis test. When the wrist is passively flexed, the fingers will not extend at the MP joints if the tendons are ruptured. If the tendons are intact, as in PIN syndrome, extension of the MP joints will occur as the wrist falls into flexion.

Avoid forceful dissection between the supinator muscle and the extensor diptor, because this will jeopardize the innervation of the EDC muscle. Identification and resection of the fibrous leading edge of the ECRB where it crosses the PIN, as well as separate division of the arcade of Frohse, are critical because these are the common sites of compression of the nerve. “Recurrence,” or rather failure of operative treatment, is caused by incomplete decompression of the nerve at all the potential sites of entrapment.
RADIAL TUNNEL SYNDROME

Pathophysiology and Anatomy

The radial tunnel is the region along the course of the radial nerve and its posterior interosseous (deep) branch, beginning proximally where the radial nerve lies deep between the brachioradialis and the brachialis, and extending distally to the distal border of the supinator muscle (107). The five sites of compression are the same as those for PIN syndrome (97,107), easily remembered by the mnemonic FREAS (Table 52.16). Unlike in PIN syndrome, the compression of the PIN in RTS is not caused by masses, fractures, and disturbances of the radiocapitellar joint. It is associated with repetitive elbow flexion and extension and forearm rotation. It is likely a dynamic form of compression of the PIN (57).

Assessment

Radial tunnel syndrome is a painful condition, without motor deficit and usually without sensory changes. Patients present with a dull, aching or burning pain over the lateral aspect of the elbow in the region of the proximal extensor–supinator muscle mass. Symptoms may radiate distally along the course of the extensor muscles to the radial aspect of the hand or proximally to the shoulder. In some cases, there may be paresthesias in the radial nerve distribution. Symptoms are worsened by activities, especially those requiring forceful and repetitive elbow motion or wrist flexion and extension and forearm pronosupination, and are relieved by rest. The association between lateral epicondyritis, or “tennis elbow,” and RTS has been noted (107,141). Patients may present with tennis elbow symptoms and evidence of lateral epicondyritis, which may respond to local steroid injections followed by localization of discomfort several centimeters distal to the lateral epicondyte over the radial tunnel. The resultant RTS can then exist solely or concurrently with the tennis elbow; 5% of patients with lateral epicondyritis also have RTS (128). The diagnosis of RTS is differentiated from tennis elbow by examination.

Physical examination will reveal tenderness centered over the radial head and neck along the course of the radial nerve. Comparison of the opposite, unaffected side is recommended because many normal individuals find this area exquisitely tender to deep palpation. Distal radiation of symptoms can occur with manual compression of the nerve in this region. Limitation of elbow extension and weakness of grip further suggest RTS. Sensory deficits in the distribution of the superficial radial branch may be seen in RTS and suggest compression of the nerve in the proximal aspect of the tunnel at a point where both divisions of the main trunk are simultaneously vulnerable, such as beneath the fibrous bands proximal to the arcade of Frohse. Because of its dynamic or exertional nature, provocative testing is invaluable in detecting RTS and may give clues to the site of compression of the nerve within the radial tunnel. Described provocative tests for RTS include the elbow flexion test, the middle finger extension test (107), passive pronation of the forearm (33), and the supination test (70) (Table 52.18). In the elbow flexion test (Fig. 52.61), ask the patient to flex his elbow against resistance. Reproduction of pain with this maneuver indicates compression of the nerve by fibrous bands on the capsule of the radiocapitellar joint. In the middle finger extension test (Fig. 52.62), ask the patient to extend his middle finger against resistance applied by you over the proximal phalanx. Hold his forearm in full pronation and his elbow extended. Reproduction of pain in the radial tunnel region with this maneuver indicates entrapment of the PIN at the ECRB tendon.

Table 52.18. Provocative Tests for Radial Tunnel Syndrome (RTS)

Figure 52.61. The elbow flexion test for radial tunnel syndrome.

Figure 52.62. The middle finger extension test for radial tunnel syndrome.

Electrodiagnostic studies are not generally helpful in diagnosis of RTS. Conduction velocities are often normal, and EMG changes are present in patients with clinically evident weakness or atrophy and therefore carry the diagnosis of PIN syndrome. There may be a place for dynamic electrodiagnostic studies to detect subtle changes in nerve function (64,100). We believe that a localized injection of anesthetic, with or without steroid, into the radial tunnel, which produces a PIN palsy and relieves symptoms, is diagnostic for RTS. Localized steroid injection may also assist in differentiating RTS from tennis elbow (Table 52.19).

Superficial Radial Nerve Compression Syndrome (Cheiralgia Paresthetica)

Compression neuropathy of the SBR was first described by Wartenberg in 1932 (143). He suggested that the condition be named cheiralgia paresthetica because of its

Pathophysiology and Anatomy
The radial nerve bifurcates just proximal to the elbow, in the interval between the brachioradialis and brachialis muscles. The superficial sensory branch continues toward the wrist under cover of the brachioradialis and medial to the ECRL muscle. It courses superficially to the supinator in the proximal forearm, and then to the PT insertion in the midforearm. In the distal third of the forearm, the nerve pierces the antebrachial fascia between the tendons of the brachioradialis and ECRL muscles. The nerve passes superficially to the extensor retinaculum and divides into terminal branches to provide cutaneous innervation to the dorso-radial aspect of the hand (Fig. 52.8).

When the forearm is in supination, the sensory branch lies deep to the fascia, without compression from the tendons of the brachioradialis and ECRL muscles. As the forearm pronates, the ECRL tendon crosses beneath the brachioradialis tendon in a scissors-like fashion, pinching or compressing the nerve (Fig. 52.64A). Palmar-ulnar deviation of the wrist places traction on the nerve (Fig. 52.64B). Repetitive traumatization of the nerve causes swelling, which inhibits its normal gliding through the fascia, leading to a traction injury (27).

**Figure 52.64.** A: Pronation of the forearm causes a pinching of the superficial branch of the radial nerve. B: Palmar-ulnar flexion of the wrist puts the superficial radial nerve in maximal traction. (From Dellon AL, MacKinnon SE. Radial Sensory Nerve Entrapment in the Forearm. J Hand Surg [Am] 1989;11:199, with permission.)

**Assessment**

Usually, a history of repeated, job-related forearm pronosupination is given. Affected patients complain of pain, numbness, tingling, and dysesthesias over the dorso-radial aspect of the hand. Symptoms are brought on by wrist movement and are intensified when the patient makes a tight grip with the thumb and index finger. Nighttime awakening caused by symptoms is not common. Sensory examination reveals alterations in two-point and vibratory sensation. There is no motor dysfunction of radially innervated muscles, although grip and pinch strength may be decreased secondary to pain. Percussion along the course of the nerve, particularly as it emerges between the brachioradialis and ECRL tendons, produces paresthesias. Dellon and MacKinnon (27) described a provocative test for eliciting symptoms in which the patient is instructed to pronate the forearm with the elbow in extension. If within 30–60 seconds the symptoms of paresthesias or dysesthesias are evoked or exacerbated over the dorsal radial aspect of the hand, entrapment is confirmed (Fig. 52.65).

**Figure 52.65.** The provocative test for entrapment of the superficial branch of the radial nerve, consisting of forced pronation of the forearm. (From Dellon AL, MacKinnon SE. Radial Sensory Nerve Entrapment in the Forearm. J Hand Surg [Am] 1989;11:199, with permission.)

The entity most commonly confused with superficial radial nerve entrapment is de Quervain's stenosing tenovaginitis of the first dorsal wrist compartment. Finkelstein's test (i.e., pain on quick ulnar deviation of the hand with the patient's thumb grasped in the palm) is positive in both entities. The presence or absence of swelling over the first dorsal compartment, a nerve compression test over the course of the superficial radial nerve, and careful sensory testing are used to differentiate these two entities. Electrodiagnostic testing is rarely useful, although it often shows abnormalities in conduction velocity or amplitude (27). Injury to the LABC nerve as a source of the patient's symptoms must also be excluded because there is overlap in the innervation of the LABC and the SBR nerves in the mid and distal forearm in 75% of patients (27). Exclude it by performing serial blocks with local anesthetic. First block the LABC nerve at the lateral arm, then block the SBR at the site of suspected entrapment. Improvement in symptoms subsequent to the second injection but not the first implicates the SBR as the cause (Table 52.20).

<tbody>
<tr>
<td>Nonoperative treatment includes avoidance of pronosupination and radiocubital deviation of the wrist, splinting of the wrist with or without inclusion of the thumb and forearm, and NSAIDs. Physiotherapy, including tissue mobilization and nerve gliding exercises, steroid iontophoresis, and progressive gentle stretching, may be helpful. Administer steroid injections subfascially, and use them judiciously because of the potential for depigmentation of the skin and subcutaneous fat atrophy. Patients with long-term symptoms or onset of symptoms associated with a fracture or crush injury tend not to improve with nonoperative treatment.</td>
</tr>
</tbody>
</table>

**Surgical Indications and Relative Results**
Failure to improve, or inadequate improvement, after prolonged nonoperative treatment is an indication for surgery.

In the series reported by Dellon and MacKinnon (27), pain relief was good or excellent in 86% of patients undergoing surgery. Of these patients, 43% returned to their regular jobs, 22% returned to modified work, and 35% remained disabled because of associated injuries. Objectively, marked improvement was noted in grip and pinch strength.

Operative Technique

- Make an 8 cm curvilinear incision just volar to the mid-radial aspect of the radius, centered in relation to the point where the nerve pierces the antebrachial fascia (Fig. 52.66A). (The location of the positive Tinel’s sign may also be used.) To prevent scarring about the nerve, avoid placing the incision directly over the nerve.

- Identify and protect cutaneous branches of the LABC nerve.
- Identify the SBR and the fascia between the BR and ECRL.
- Release the fascia joining the BR and ECRL distally out to the insertion of the BR (Fig. 52.66B).
- Release the fascia at least 6 cm proximal to the nerve (Fig. 52.66C).
- Ensure that the nerve lies loosely in the subcutaneous tissue and that the BR and ECRL glide independently without constriction of the SBR (Fig. 52.66D).
- Close the wound, and apply a bulky compression dressing with a volar splint.

Postoperative Care and Rehabilitation

Remove the postoperative dressing after 7–10 days. We discourage splinting. Begin a home program of scar therapy and tissue mobilization. Encourage the patient to use the hand progressively in regular activities.

Complications

As with the majority of compression neuropathies, accurate diagnosis and good surgical technique will prevent complications. You must differentiate between SBR entrapment and de Quervain's tendovaginitis by physical examination. If concomitant de Quervain's exists, treat it appropriately. Exclusion of entrapment of the LABC nerve by differential anesthetic blocks is also imperative. Avoid excessive handling of the nerve at surgery to prevent neuroma formation.

LATERAL ANTEBRACHIAL CUTANEOUS NERVE COMPRESSSION

Pathophysiology and Anatomy

The LABC nerve is the terminal, sensory portion of the musculocutaneous nerve. Arising from the musculocutaneous nerve in the interval between the biceps and brachialis muscles, it continues distally under cover of the biceps muscle and then the lateral border of the biceps tendon to the elbow flexion crease. At this level, the nerve lies on top of the brachialis, lateral to the biceps and medial to the brachioradialis. It pierces the brachial fascia lateral to the biceps tendon. It divides into an anterior branch and a posterior branch, the former traveling with the cephalic vein to innervate the anterior surface of the radial forearm to the thenar eminence, and the latter continuing to innervate the radial and posterior aspect of the distal forearm to the wrist (Fig. 52.67). The anterior branch of the LABC nerve communicates with the superficial radial nerve above the wrist (6). Compression of the LABC nerve is rare but can occur where it emerges from beneath the lateral border of the biceps tendon just medial to the brachioradialis. The nerve is compressed between the brachialis fascia and the tendon of the biceps when the elbow is extended. Compression of the nerve can be further accentuated with pronation of the forearm (8-91).

Assessment

Characteristically, the history includes repetitive, forceful exercise of the elbow in a position of extension. Patients complain of pain over the lateral aspect of the elbow on active motion of the elbow, with accompanying burning or numbness in the radial forearm. Examination reveals decreased sensibility distally along the radial aspect of the forearm. Elbow extension is limited with the forearm fully pronated. Point tenderness is found lateral to the biceps tendon at the elbow crease. Compression may be confirmed with sensory NCV studies measured between the elbow flexion crease and the axilla. A nerve block with local anesthetic that produces numbness along the nerve's cutaneous distribution and eliminates symptoms aids in the diagnosis. The nerve lies between the cephalic and median cubital veins 1.5 cm lateral to the biceps tendon, and the injection is best placed just distal to the cubital crease (Table 52.21).
Preoperative or Nonoperative Management

Conservative treatment initially consists of splinting and anti-inflammatory medication. If symptoms persist or worsen over the first few weeks, administer a local injection of corticosteroids around the nerve. Nonoperative treatment has limited success.

Surgical Indications and Relative Results

Consider surgical decompression if symptoms do not resolve within 3 months.

Davidson et al. (22) reviewed 15 patients with a diagnosis of LABC nerve entrapment. Average follow-up was 13.4 years, with a minimum of 2 years. Eleven of these patients underwent surgical decompression. Of these, none had recurrence of hypesthesia, and all had complete relief of pain and full range of motion. One patient subsequently underwent release of the lateral epicondyle. Of the four patients who were treated nonoperatively, one had persistent hypesthesia but full range of motion and complete pain relief.

Preoperative Planning

If surgery is planned, obtain radiographs of the elbow to rule out bony pathology. Examine the patient on more than one occasion to confirm consistent findings. Consider all extraarticular and intraarticular elbow conditions when evaluating the patient.

Operative Technique

- Begin the incision proximal to the elbow flexion crease along the lateral border of the biceps muscle. Curve it laterally at the elbow flexion crease to head toward the radial tunnel. Do not cross the cubital flexion crease at right angles.
- Identify the LABC nerve 1.5 cm lateral to the tendon at the level of the medial condyle (Fig. 52.68A).
- Trace the nerve proximally several centimeters.
- Demonstrate the area of entrapment by pronating the arm in extension. Look for flattening of the nerve and loss of vascular markings.
- Excise a triangular wedge of biceps tendon (1×3 cm) where the nerve is compressed by the edge of the biceps and the brachialis (Fig. 52.68B).
- Ensure that the decompression is complete by pronating and supinating the elbow while it is in extension.
- Apply a bulky dressing, and splint the elbow at 90° in neutral rotation.

Figure 52.68. A: The lateral antebrachial nerve emerging from beneath the lateral border of the biceps tendon. B: A wedge-shaped section taken out of the overlying biceps tendon to decompress the nerve. (From Nunley JA, Howson P. Lateral Antebrachial Nerve Compression. In: Szabo RM, ed. Nerve Compression Syndromes: Diagnosis and Treatment. Thorofare, NJ: Slack, 1989:201, with permission.)

Postoperative Care and Rehabilitation

At 2–3 weeks postoperatively, remove the splint and allow full, unrestricted activity to tolerance.

After nerve injury, the regenerating axons proximal to the injury site seek to grow and reestablish contact with their respective end organs. Continuity or repair of the Schwann cell endoneurial tube aids this process. Regenerating axons that do not grow through the zone of injury and into the distal segment of endoneurial tube become encased in scar and constitute a forme fruste of peripheral nerve regeneration.

The resulting nodule formed within the zone of injury in an intact crushed or stretched nerve, or in the terminal end of the proximal segment of a lacerated nerve, is called a neuroma. The neuroma is usually well circumscribed, white, and rubbery or firm in consistency. It may adhere to adjacent scar, skin, muscle, fascia, tendon, periosteum, or bone.

All peripheral nerves form neuromas in response to injury, but only neuromas containing sensory nerve fibers can be symptomatic. The digital nerves of the hand, the palmar and ulnar cutaneous nerves, and the dorsal sensory branches of the radial and ulnar nerves are pure sensory nerves and are especially prone to form painful neuromas. As many as 30% of neuromas formed by these nerves become symptomatic (7). Common digital nerves in ray amputations appear more inclined to be painful than those of digital amputations, possibly because the former contain more sensory fibers.

HISTOLOGY

Microscopically, a neuroma is a neural swelling consisting of randomly directed axons in a matrix of proliferative mesothelial elements, primarily epineurium and endoneurium. There is a disorganized mixture of axons with a predominance of small-diameter unmyelinated fibers, frequently in whorl-type patterns surrounded by Schwann cells, fibroblasts, collagen, macrophages, and capillaries. Myofibroblasts have been consistently identified by electron microscopy in painful neuromas. These cells may serve as histologic markers of a symptomatic neuroma, but their pathophysiologic role remains undetermined (1, 5).

CLASSIFICATION (SUNDERLAND)

Sunderland classified neuromas into three major categories (Table 53.1): neuroma-in-continuity; neuromas in completely severed, unrepaired nerves; and amputation stump neuromas (28). Neuromas-in-continuity include those with intact perineurium, those with partial nerve division, and those that form after nerve repair or grafting.

Table 53.1. Classification (Sunderland)

PATHOPHYSIOLOGY OF NEUROMA PAIN

The central perception of pain from neuromas is transmitted by afferent small unmyelinated C and A delta fibers. This picture is sometimes confounded by the involvement of additional adjacent afferent axons contained within the same sensory nerve (Table 53.2). Afferent impulses are biochemically mediated and may occur spontaneously or be triggered physically (Table 53.3). In the gate theory of pain, nociceptors do not appear to override other nociceptors, whereas touch or pressure may do so. Proximity of a neuroma to skin, to bony prominences, and to the working surface (palm) of the hand renders it more vulnerable to mechanical impulses (19, 26, 31).

Table 53.2. Pathophysiology of Neuroma Pain
Table 53.3. Biochemically Mediated Afferent Impulses

There may be a genetic or sex-related (hormonal) predisposition to heightened pain sensitivity and perception. Psychosocial factors may also play a variable role in the perception and expression of pain. Such factors include individual personality, pain tolerance, and secondary gain. These elements may be difficult to sort out and may confound diagnosis, treatment, and outcome.

Although symptomatic neuromas alone can be disabling, a diathesis similar to that seen in patients who develop chronic regional complex pain occurs more frequently than expected by chance alone. Symptomatic neuromas of the hand may be complicated by sympathetically or independently mediated pain. There may be combinations of pain involvement (see Table 53.2, Table 53.6). Pain patterns are often refractory to treatment until the noxious stimulation of the nociceptors is eliminated. Chronicity may lead to dystrophic tissue changes. The impairment and consequent outcome of a symptomatic neuroma are worsened by the complexity of such additional afferent nerve fiber involvement.

Table 53.6. Relating Diagnostic Discriminators to Pain Type, Etiology, and Pathophysiology

DIAGNOSIS

Patients who form symptomatic neuromas have a focus of burning, aching pain, strongest at the site of the nerve injury (Table 53.4). The pain may radiate peripherally in the sensory distribution of the injured nerve, or proximally in the distribution of the nerve trunk. A dysesthetic “trigger area” found in the same site may radiate pain peripherally in the distribution of the injured nerve on percussion. This pain is equivalent to a nonadvancing Tinel’s sign and may be called a neuroma sign.

Table 53.4. Diagnosis of Neuroma

Relief of these symptoms with an injection of a local anesthetic helps to confirm the diagnosis. Often there is corresponding sensory deficiency or loss. The history, physical examination, peripheral and sympathetic nerve blocks, and standardized pain and psychosocial analysis in various combinations aid in establishing the diagnosis, sorting out confounding factors, and predicting outcome.

TREATMENT

Iatrogenic sensory nerve injury may be unavoidable. Knowledge of sensory nerve anatomy in the hand and digits helps to minimize such injuries. In both traumatic and iatrogenic lacerations, careful identification of transected nerve ends and their repair at the time of primary wound treatment improves the likelihood of functional nerve recovery and decreases the risk of symptomatic neuroma formation. In cases of segmental nerve injury with an identifiable and reparable distal end, and in a clean and adequately vascularized bed, nerve grafting accomplishes the same goals. In instances where nerve repair or reconstruction is not possible and in some amputations, painful neuromas may develop. The signs are identifiable early, and prompt treatment is usually more effective than later measures.

NONSURGICAL TREATMENT

Nonsurgical measures are more likely to succeed when a painful neuroma is mild and is treated early. Medications, therapy, physical modalities, and consultation with a pain management specialist may be helpful (Table 53.5). If injections of the neuroma are used, adding triamcinolone acetate to the injection solution may produce a collagenase effect and soften adjacent scar sufficiently to be curative or palliative in some cases (23). Use as much as 10 mg of triamcinolone acetate (i.e., a 10 mg/ml concentration diluted 1:1 or more with 1% lidocaine) and repeat three times at 1- to 3-week intervals as needed. Advise patients that depigmentation of the skin and atrophy of the subcutaneous fat may accompany triamcinolone injection (15).
Table 53.5. Nonoperative Treatment

Although inhibition of neuroma formation has been demonstrated histologically after application of triamcinolone on a freshly severed nerve, there is no histologic response to the application of this steroid in the chronic neuroma. The reason for improvement or resolution of neuroma pain after steroid injection in the chronic neuroma remains unclear. The use of collagenase inhibitors and gangliocidal agents on freshly cut nerve ends is an area of ongoing investigation that may have future clinical impact (3).

SURGICAL TECHNIQUES

Operative intervention for symptomatic neuromas is indicated after confirmation of the diagnosis by injection of local anesthetic and when physical measures such as desensitization and injection with triamcinolone acetate fail to provide relief. The more clearly the diagnostic discriminators demonstrate a pure neuroma pain picture, the better are the outcome expectations following surgery (Table 53.6).

Neurorrhaphy and Nerve Grafting

It is easier to prevent symptomatic neuromas than to heal them. Take particular care when operating in the vicinity of the major sensory nerves of the hand, in excision of ganglions. Other tricky surgeries include decompression of de Quervain's stenosing tenosynovitis of the first dorsal compartment, carpal tunnel decompression, palmar fasciotomy or fasciectomy for Dupuytren's disease, A1 pulley release for trigger digits, and tendon repair and reconstruction.

For optimal recovery, posttraumatic and iatrogenic transections of the nerves should be identified and repaired early whenever possible. Secondary identified lacerations may merit nerve grafting if direct suture cannot be performed (6). In either instance, the preferred treatment for prevention of painful neuromas is to restore the continuity of the nerve, allowing successful axonal regeneration across the injury site.

Current investigations with neurotrophic hormones, electric current, a variety of artificial (e.g., polyglycolic acid, collagen-filled) and autogenous (e.g., vein and muscle) conduits, and the use of nerve allografts with immunosuppressors may soon play a larger, more definitive role in secondary neuroma treatment by means of nerve reconstruction (19,20). Neurovascular island flaps and toe–hand transfers have been successful for management of refractory digital neuromas when the distal portion of the involved nerve is not available, when sensory restoration is important, and in the reconstruction of an amputated digit (17,27).

Decompression and Translocation

Consider decompression of the nerve if a neuroma-in-continuity forms with the intact perineurium as a result of repetitive or cumulative trauma (e.g., bowler's, jeweler's, or surgeon's thumb) and does not respond to nonsurgical measures. A neurolysis may be performed and the perineural sleeve of scar removed. In some instances, the nerve may be translocated intact, deep to muscle such as the thumb abductor or a lumbrical muscle in the palm (Fig. 53.1) (14).

Figure 53.1. Submuscular transposition. A: Exposing the radial digital neuroma. B: Division of the lumbrical muscle. C: Mobilization of the lumbrical muscle and digital nerve.

- Expose the radial digital neuroma at the base of the index fingers adjacent to the lumbrical muscle.
- Divide the lumbrical muscle near its insertion.
- Mobilize the lumbrical muscle and digital nerve.
- Translocate the digital nerve beneath the muscle.
- Reapproximate the muscle insertion by suture.
- The lumbrical muscle now overlies and protects the neuroma-in-continuity.

Translocation methods may also have merit in the treatment of chronic symptomatic Sunderland type II neuromas.

Simple Excisional Neurectomy

After digital amputation, traditional recommendations are that each digital nerve end be identified, mobilized, and placed under gentle tension, and that the sharply divided end be allowed to retract 6–10 mm into healthy tissue proximal to the amputation stump (Fig. 53.2) (30).
Figure 53.2. Simple immediate or early primary excisional neurectomy.

- Identify and ligate the digital arteries.
- Place the digital nerve under gentle tension.
- Cut the digital nerve as far proximal as possible.
- Allow the cut nerve end to retract 6–10 mm proximal to the amputated bone end.

Crushing, coagulation, freezing, chemical injections, nerve ligation, and capping of the nerve end have been tried with varying success and are not recommended.

Surgery may be indicated if a symptomatic neuroma forms and does not respond satisfactorily to triamcinolone acetate injection, desensitization, transcutaneous electrical nerve stimulation, or other nonoperative measures. For excisional neurectomy to be successful in the treatment of amputation neuromas, a stump revision must be performed if there is a bony prominence representing a potential source of trauma to the nerve end. Simple neuroma resection has become a benchmark by which other measures may be gauged (Fig. 53.3).

Figure 53.3. Funicular excision with epineural ligation. A: Mobilization of the epineurium. B: Cutting the funicular ends. C,D: Restoration and suturing of the epineurium.

- Dissect the digital nerve and its neuroma away from the digital artery.
- Place the digital nerve and its neuroma under gentle tension.
- Resect the neuroma by cutting the digital nerve as far proximal as possible.
- Allow the cut nerve end to retract into unscarred soft tissue 6–10 mm from the amputated bone end.

In some patients treated by this method, the course after simple excisional neurectomy is one of initial improvement followed by recurrent symptoms as the anatomic neuroma reforms in its new position. A second excisional neurectomy may occasionally be helpful after a failed initial procedure, but subsequent procedures offer diminishing returns (30).

Transposition

Neuroma formation has been linked to the neurohormonal influences of sensory end organs, particularly those of the skin. Transposition may remove the nerve end from local neurohormonal influences at the site of injury. Transposition of a severed nerve end to a protected environment away from skin, bony prominences, and the working surface of the hand and avoidance of tension on the nerve may provide the best physical protection of the severed proximal nerve end. It may prevent, improve, or eliminate symptoms.

Although cut nerve ends or symptomatic neuromas with poor full-thickness skin coverage may often be protected by submuscular translocation or by local or distal flap coverage, it may be easier and more practical to transpose the nerve to a protected environment. An area with better blood supply, less scar, and less tension seems to have a salutary effect on a painful neuroma. Transposition has the additional benefits of physically removing the nerve end from areas of direct trauma, such as the working surface of the hand, bony prominences (especially amputated bone ends), severely scarred areas, and local neurohormonal influences. There are three types of translocation procedures for cut nerve ends: subcutaneous, intramuscular, and intraosseous.

- To protect the nerve end or the neuroma from direct trauma in the area to which it is transposed, place a resorbable suture through the epineurium without violating the nerve, or through the capsule without violating the neuroma (Fig. 53.4, Fig. 53.5) (4).

Figure 53.4. Suture techniques for nerve transposition. A: Unligated nerve end. B: Ligated nerve end.

Figure 53.5. Subcutaneous dorsal web space transposition. A: Dissection and mobilization of the digital nerve and its neuroma. B: Suturing the perineurium. C: Tying the suture over a dental roll.

- Tie a knot 3–4 mm distal to the freshly cut nerve end or neuroma to prevent its direct contact with the structures to which it is transposed.
- After transposition of any type, inspect the nerve trunk to be certain it is neither under tension nor kinked.
In diffusely dysesthetic digital amputation stumps with one palpable sensitive digital neuroma and one nonpalpable insensitive neuroma, consider transposing both nerves. If transposition is not done, the remaining digital neuroma sometimes becomes significantly more painful, even though the transposed neuroma becomes asymptomatic.

The following three procedures are optional for neurectomy or transposition.

- Mobilize the epineurium proximally exposing the funicular ends.
- Cut the funicular ends proximally.
- Restore and suture the epineurium over the cut funicular ends without injuring them.

Dorsal Subcutaneous Transposition

- Dissect and mobilize the digital nerve and its neuroma. Dissect the neuroma and its fibrous capsule in continuity with its nerve proximally and mobilize it so that it can be translocated without tension.
- Protect the digital artery.
- Ensure hemostasis.
- Resect the neuroma. Select a dorsal, scar-free site away from bony prominences and local pressure or trauma. The area chosen should place the neuroma dorsal to muscle, positioning the muscle between the neuroma and the surface of the hand (Fig. 53.4, Fig. 53.5 and Fig. 53.6).
- Ensure hemostasis.
- Dissociate the epineurium and its perineurium from the nerve substance. The neuroma is then mobilized, and an initial hole is made in the cortex adjacent to the initial drill hole (Fig. 53.5). The depth of this initial hole must be adequate to accommodate one or two suture ends through the bone. A small burr or Kirschner wire may be used. The proximal end of a sensory nerve is exposed by a short incision over the proximal end of the metacarpal bone.
- Drill two small holes in the near cortex distal to the initial drill hole. The proximal end of the nerve is carefully mobilized, and a small Kirschner wire is used to drill holes for the suture ends and the nerve. The nerve is then passed through the bone and tied over a dental roll or left free within the bone. Be sure the nerve is not under excessive tension.
- Tunnel under or into the subcutaneous fat in the adjacent dorsal web space.
- Bring the needles and suture ends through these holes. Tie a knot 3–4 mm distal to the nerve fascicles to prevent them from directly abutting soft tissues, muscle, or bone after transposition.
- Attach the suture over a dental roll.

Intradigital Transposition Although intradigital transposition has long been advocated, there is now evidence from both laboratory and clinical studies that neuroma formation is suppressed by placing the transected proximal nerve end directly into muscle substance (19). The operative technique is similar to that of dorsal subcutaneous transposition. Although the procedure of neuroma excision and implantation of the transected nerve end into the brachioradialis has been a successful method of treating symptomatic neuromas of the superficial radial nerve, similar procedures repositioning the digital nerves into the intrinsic muscles of the hand have been disappointing. Perhaps muscle contracture, a relatively large muscle excursion in relation to muscle size, pressure, traction on the nerve during use, or some combination of these is at fault. Therefore, this procedure is not currently recommended.

Intrasosseous Transposition Intramuscular transposition of the cut proximal end of a sensory nerve or of a neuroma with sensory neuroma resection produces results at least comparable to those of subcutaneous transposition (2,9,12,21,22). Either of two techniques for intrasosseous transposition may be used (Fig. 53.7).

Intrasosseous Transposition

- Drill two small holes in the near cortex opposite the initial drill hole. The proximal end of the nerve is carefully mobilized, and a small Kirschner wire is used to drill holes for the suture ends and the nerve. The nerve is then passed through the bone and tied over a dental roll or left free within the bone. Be sure the nerve is not under excessive tension.
- Drill a hole in the adjacent phalanx large enough to accommodate the nerve without constriction and proximal enough to avoid excessive nerve tension.
- Drill two small holes in the far cortex opposite the initial drill hole using a small Kirschner wire or drill. Pass the needles and suture ends through these holes. Tie the suture over a dental roll or make a small skin incision prior to passing the suture ends and tie them directly on the bone. Two alternative methods follow:
  - Alternative A: Drill two small holes in the near cortex distal to the initial drill hole using a small Kirschner wire or drill. Pass the needles and suture ends through these holes. Tie the sutures directly on the bone.
  - Alternative B: Suture the epineurium to the periosteum adjacent to the initial hole and leave the nerve end free within the bone. Be sure the nerve is not kinked. Be sure the nerve is not under excessive tension.

An obstructing knot prevents compression of the proximal nerve end against intramedullary bone. The epineurium may also be sutured to the periosteum or to the bone at the site of its entry into the intramedullary canal. In either technique, there should be no tension on the nerve at any point. The angle that the transposed nerve makes as it enters and courses through the bone should not be too acute. In transposing a transected nerve into bone, it is important to avoid tension on the proximal stump in any position in the arc of motion of adjacent joints.

Centrocentral Coaptation

Centrocentral coaptation is the joining of two nerves or fascicles of the same diameter to either end of an autologous nerve or fascicle transplant, artificially created by sharply dividing and then resuturing one of the nerves or fascicles 5–10 mm from its cut end (Fig. 53.8).
Ligate the digital arteries.
- When done as a secondary procedure, resect the neuromas.
- Intercalate a section of digital nerve graft (from the amputated finger or other donor site) between the digital nerves of the index finger.
- The nerve graft should be at least 5–10 mm in length and of similar diameter to the digital nerves.
- Allow no tension at the suture lines.
- Protect with adequate cover.
- Keep away from skin suture lines.
- Primary centrocentral coaptation is preferred, although secondary centrocentral coaptation can be done.

The junctures should be performed between the central nerve or fascicle and the transplant, so that the physiologic regeneration of the central axons course past the suture lines and bypass each other at the midportion of the transplant (Fig. 53.9).

The axons recognize each other as “nontarget structures.” Therefore, the neuroma is small and nonsensitive.

Increased intraneural pressure reduces axoplasmic flow, centrally inhibiting neural protein synthesis and stopping axonal growth after 3–5 mm of axonal overlap.

The nerve fascicles’ insulation from neurotrophic growth factors also inhibits neuroma formation.

If more than one centrocentral fascicular junction is performed at the same area, the suture lines may be offset stepwise to minimize the chances of axonal compression by interfascicular connective tissue proliferation. Protect the centrocentral junction by adequate full-thickness cover and place it as far from the skin suture lines as possible. This procedure is excellent for cases of digital or ray amputation. It can be performed as a primary or secondary procedure (8,10,11,15,26,27,29).

Axonal regeneration appears to cease after an overlap of 2–5 mm within the midportion of the transplant, as the increased intraneural pressure created by this juncture mechanically reduces its axoplasmic flow; this centrally inhibits neural protein synthesis. This mechanism also minimizes the size of the intraneural neuroma within the transplant.

Another theory explaining the inhibition of symptomatic neuroma formation by centrocentral union is that macromolecular proteins in the distal nerve stump and sensory receptors (i.e., target-derived neurotrophic factors) stimulate axonal regeneration locally at the site of injury and centrally at the nerve cell body by retrograde axoplasmic transport. They may also guide the regenerating axons to their target end organs after nerve repair or grafting is performed. In the case of an unsatisfied proximal nerve end, these neurotrophic factors may contribute to neuroma formation and its symptoms. Centrocentral coaptation may insulate the central nerve segment or the fascicle stumps from neurotrophic influences and confine the regenerating axons to a nontarget environment, allowing the regenerative process to cease.

POSTOPERATIVE CARE AND REHABILITATION

After skin closure, provide a supportive and protective dressing until pain at the operative site is minimal. In the case of a successful operation, it takes 3 to 6 weeks for the pain to subside. Thereafter, have the patient remove the protective dressing or splint 3 to 4 times each day for therapy. Therapy includes joint motion and tendon excursion exercises, as well as scar softening, mobilization, and desensitizing measures. Use warm water soaks, massage, and active range-of-motion exercises.

It is becoming apparent that nerves, much like tendons, are capable of gliding a limited distance in the tissue that surrounds them. To the extent that this gliding is impaired by scar adhesion, traction on the nerve may occur and may produce symptoms. We attempt to restore gliding by early motion, scar massage, softening, mobilization, and desensitization after neuroma surgery. Aerobic conditioning has proven helpful to some patients (Table 53.7).

The Jobst pump (Jobst Institute, Toledo, OH) or an Isotoner glove (Aris Isotoner, New York, NY) may be used to diminish swelling. The Isotoner glove is worn at night. Vibration may be soothing and softens, mobilizes, and desensitizes the scar area. Other physical measures to soften and desensitize the scar include Silastic...
elastomer (Smith & Nephew, Menomonee Falls, WI), maintained in place with Coban (Medical Products Division of 3M, St. Paul, MN), which may be worn at night. Paraffin wax bath and phonophoresis deliver deep heat and may be soothing. Carefully combined with massage, they may help to stretch and soften scar. Continue these methods until the patient's pain is well within tolerance, resolved, or has reached a point of maximum medical improvement.

A positive supportive attitude by the therapist and the physician and a program directed at functional recovery, desensitization of the stump and scar, and early return to manual activities (including work and recreation) play a very important role in patient recovery.

OUTCOMES

Primary or early neurorrhaphy is probably the best single measure to prevent a symptomatic neuroma. Nerve grafting and neurorolized tissue transfer are a close second. These methods may also restore sensory loss. Decompression and translocation of an intact neuroma in continuity is also a highly reliable procedure. Each of these procedures reestablishes nerve continuity. They are at least 90% to 90% successful in avoiding or eliminating symptoms or making them tolerable.

Simple excisional neurectomy is about 65% reliable. Repetition of this procedure for initial failure is also about 65% effective. After two unsuccessful attempts at simple excisional neurectomy, there is little yield from repeating the procedure again.

Nerve transposition and centrocentral coaptation are usually used as salvage procedures for symptomatic neuromas in which the distal nerve segment is not available and in which the reestablishment of sensation is not critical. These procedures are 60% to 90% successful.

Patients with pure neuroma pain fare better than those with complex pain. Patients who do not have adverse psychosocial factors fare better than those who have them (25).

PITFALLS AND COMPLICATIONS

Prevention of a symptomatic neuroma in cases of nerve division can be achieved by repair using direct suture in freshly lacerated lesions and by nerve grafting, primarily or secondarily, in cases with nerve loss and those in which direct suture cannot be accomplished without tension. In elective digital amputations or ray resection, centrocentral coaptation or transposition may be selected for digital nerve management. For traumatic amputations, the condition of the wound at the time of surgery may dictate whether the transected nerves are managed by simple excision or by a nerve-manipulating procedure. If the wound is contaminated or if additional dissection would jeopardize tissue viability, the transected nerve ends should be managed by simple excision. Centrocentral coaptation or transposition of the neuroma may be deferred and performed as a delayed primary procedure when wound conditions permit or secondarily if a symptomatic neuroma develops. Naturally, prevention of a symptomatic neuroma is preferable to treatment of one.

Treatment possibilities for a symptomatic neuroma include nerve grafting if a distal nerve end is available. Decompression and submuscular translocation are quite reliable in managing neuromas caused by repetitive or cumulative trauma that form in continuity with the perineurium intact. Dorsal subcutaneous or intraosseous transposition is effective in treating symptomatic neuromas when no suitable distal nerve exists. Centrocentral coaptation is an excellent method of managing transected digital nerves. Although setting the standard for comparison, simple excision does not provide as good or as reliable results for established neuromas as do the other procedures described in this chapter.

The principles of nerve transposition in instances of symptomatic neuromas include removing the free nerve end from areas of scarring, bony prominences, and the working surface of the hand. Translocation or transposition can also remove a freshly cut nerve end from local neurohormonal influences arising from denervated cutaneous sensory end organs. The free nerve end must be under no tension and should lie in or adjacent to well-vascularized tissues. There must be no kinking of the translocated nerves.

In the case of nerve transposition failure, the reason may be excessive nerve tension, pullout, or kinking. Consider performing a second surgical procedure to investigate the causes and redo the transposition or relocate the nerve. The same is true in failure of centrocentral coaptation.

Although neuroma formation elsewhere in the body is suppressed by intramuscular transposition of the proximally transected nerve, this method has proved ineffective for controlling neuroma pain in the hand. Intrinsic muscle contracture causes a relatively large excursion in relation to muscle size; pressure and traction have been implicated.

Successful intervention for a symptomatic neuroma correlates with the time from its formation. Chronic pain syndromes and the establishment of central pain are time related and often involve psychosocial and economic factors. The longer a painful neuroma goes untreated, the less likely it is that any modality can be effective. Treatment should be completed expeditiously, and the patient should return to work, even if performing only light duty, as soon as possible.

Reoperation after a failure of initial surgical treatment of a painful neuroma may be successful and is indicated. If a second operation does not solve the problem, additional surgery produces sharply diminished returns. Although another operation is sometimes indicated, the physician should also consider alternatives. The patient can, for example, be referred to a multidisciplinary pain clinic as an alternative to additional surgery. These clinics provide diagnostic and therapeutic nerve blocks. They are particularly helpful with complex regional independent and sympathetically mediated pain.

Regional and stellate ganglion sympathetic blocks have moderated symptoms in some patients with complex pain components. There has also been some success related and often involve psychosocial and economic factors. The longer a painful neuroma goes untreated, the less likely it is that any modality can be effective. Treatment should be completed expeditiously, and the patient should return to work, even if performing only light duty, as soon as possible.

WORK AND ATTITUDE OF THE PATIENT

A surgeon can move muscles around and attach tendons to new insertions. Therapists can help the patient to understand new patterns of control of the hand. Only the patient can heal the wound and make the hand work. In this process, one of the most important variables is the attitude of the patient and her willingness to accept the disciplines of recovery.

The very best results occur when the patient is self-employed, has no one to blame but himself for the injury, and has everything to gain by a speedy return to work. The poorest results occur when a patient blames someone else for the injury, and is angry and resentful. This problem is compounded when the patient expects to obtain a larger financial reward if she has residual disability. The outlook is still worse if the patient already has a poor self-image, has been a failure, and now views the injury as a lasting excuse for continued dependency.

No plan for reconstructive surgery should be finalized until the patient’s own attitudes and personality have been evaluated and until he has been brought fully into the picture. Before outlining any program, the surgeon must encourage patients to talk and present their own ideas about the future. It is important to know how the patient has been influenced by others, including family, employer, and attorney. If the patient has been fortunate enough to see a surgeon before talking to a lawyer, it may be possible for the surgeon to recommend a legal advisor who works for a fee rather than for a proportion of any potential award and who understands the harm that is done to the process of recovery by delays in the financial settlement and by suggestions that it may be financially beneficial to the patient to maximize the disability.

If a patient is angry, it is worthwhile to spend time with the patient or to get help for the patient to come to terms with these emotions, enabling the process of rehabilitation to start with a single-minded and uncomplicated determination to do well.

The physician must also determine the patient’s attitude about the worth of any complex procedure. An operation that would be obviously indicated for a young manual worker may be inappropriate for a retired person who can manage what he needs to do with the ranges of useful motion that remain.

In planning tendon transfers, there is often a choice between a simple procedure, using synergistic transfers, and one that is more complex, requiring the retraining of non-synergists. Age must be taken into account. Children and young people can easily bring back into their consciousness the mechanisms of control of any muscle in the upper limb and can reprogram their nervous system to make it fit a different pattern. This may, however, be almost impossible for some elderly people of even the highest intelligence. Their neuronal pathways have created “ruts” that have deepened over years of efficient use. The ruts remain even when new pathways are established, and it is not good use of mental concentration to direct it constantly away from useful activity to control the new pathways. For these patients, synergistic muscles should be used, and only one movement should be restored at a time.

QUANTITATIVE EVALUATION OF MUSCLES

Every muscle has two major variables that identify its potential. The first is its capability for creating tension, and the second is the distance, or excursion, through which it can be sustained.

No surgeon who is unable to work out the mechanical effect of her proposed actions should move muscles or tendons. I do not suggest that a mathematical equation needs to be worked out in each case. However, the surgeon and therapist should use approximate figures that can inform them whether any given tendon transfer can provide enough but not too much tension to restore balance and whether a given muscle is capable of providing the range of motion needed by the joints.

Accounts of the way in which muscles can be evaluated are available elsewhere (1, 2). A summary is provided in Table 54-1, and a composite graph of all the muscles of the forearm and hand is given in Fig. 54.1. Figure 54.1 shows the tension capability on the vertical scale and the potential range of excursion on the horizontal scale. Both of these scales are relative. The numbers for tension represent each muscle as a percentage of the combined tensions of all muscles below the elbow. The excursions are the average of the fiber lengths of each muscle in a medium-sized forearm or hand, measured while all muscles are in their position of physiologic rest.

Table 54.1. Normal Mean Fiber Lengths, Mass Fractions, and Tension Fractions for Adult Muscles
Most muscles whose tendons cross only one joint actually use only one half to two thirds of the excursions that are calculated from the fiber lengths. Muscles whose tendons cross several joints more often use their whole potential excursion, but even these muscles manage to work within the central half to two thirds of their potential most of the time by means of extending one of the joints while allowing others to flex.

No surgeon should assume that a given nerve injury must result in the classic pattern of muscle loss for that injury. There are many patterns of innervation and of injury and disease, and the only reliable way to evaluate patterns of paralysis is to have a hands-on clinical test of every movement while the examiner’s fingers feel for the tightening of the tendons. During surgery, some clinical testing can be performed while the tendons are exposed if the patient is awake, or at least a needle electrode should be used to stimulate the muscles that are about to be used to confirm their vitality, strength, and potential for excursion.

CHANGES IN MUSCLE STRENGTH AFTER TRANSFER

It has been commonly taught that muscles can be expected to lose one grade of strength after transfer. This rule is based on the Medical Research Council (MRC) system of grading of muscle tension, which was developed in Britain during World War II and has been widely used ever since. The grades are 0 to 5; 5 is normal, and 1 is a twitch without movement of a joint. Three of the grades refer to the ability of a muscle to oppose gravity: unable to move against gravity, able to move against gravity, and able to move against gravity and resistance. Because the effect of gravity on muscle varies depending on what limb segment has to be moved, and because movement against gravity is a very small part of the work of muscles in the upper limb, the MRC scale gives a much wider spread at the lower end of the scale. For this and other reasons, Yahr and Beebe suggested that it would be more reasonable to use a simple percentage scale in which 100% is normal (3). Some may prefer to use a scale of 0 to 10, in which 0 is equal to 100%. Grade 1 on the MRC scale is about 5%; 2 is perhaps 10%; 3 is approximately 25%; 4 is 60% to 70%; and 5 is 100%.

The old “rule” that said a muscle would lose 1 grade of strength (MRC scale) on transfer was never a quantitative statement but, rather, a warning to expect less tension out of a muscle after it has been transferred than it had before. However, the basic concept of loss of strength is wrong. A muscle has the same nerve supply, the same blood supply, and the same number of sarcomeres after it has been rerouted as it had before.

There is a change in the effectiveness of a muscle after transfer. This change is due not to loss of active muscle tension but to the increased passive drag on the muscle caused by the changed elastic properties of passive soft tissue. All the soft tissue in and around a muscle must be lengthened with the muscle as it moves and exerts an elastic restraint. In the normal situation of a muscle, the length-tension curve of this tissue is low (Fig. 54.2) and becomes steeper only toward extremes of movement. After a muscle is moved to another part of the limb, it becomes surrounded by scar tissue that binds it to the tissues along the new pathway. Scar tissue has a short, steep length-tension curve and may severely limit the excursion of a muscle after transfer. If great care is taken to pass the tendon through yielding fatty tissue only, without using a large wound of access, the postoperative scar will bind the tendon only to tissues that can be easily moved and stretched and will have a low length-tension curve. If an open wound of access cuts through fascia or retinaculum, or if bone is scratched or periosteum is cut, the scar may bind the tendon directly to an immovable structure and the postoperative range of excursion will be very short. In either case, the actual tension produced by the muscle is the same as it was before repositioning. The change is that the tension will be useful only for a shorter distance on either side of the position in which the muscle and tendon rested while the wound was healing. When wider excursion is attempted, part of the energy of the muscle is used in stretching or attempting to stretch scar tissue.

Whenever possible, no fascia or other immobile tissue should be cut in the same wound as a transferred tendon. This is why it is wise to use only a small wound proximally where the muscle or tendon is to change direction and only a small wound distally where the tendon is to be attached. The tendon should be tunneled between the two incisions with no open wound. Find detach the tendon from its original site of insertion. After the tendon has been freed from other tissues, if necessary, pull it out through the proximal incision. Then pass tendon-tunneling forceps from the incision of proposed insertion to the proximal incision. Open the jaws to receive the tendon end, and withdraw the forceps distally with the tendon following.

Several factors help ensure success. The tendon-tunneling forceps should have a smooth, rounded nose, widening to a viper head, quite close to the nose, and then narrowing back to a straight shaft as far as the handles. This ensures that any resistance that is felt during passage will be at or near the advancing end (Fig. 54.3). It should be possible to open the jaws of the tunneling forceps without increasing the width of the tunnel. It is essential that the surgeon know the anatomy of the pathway, having passed forceps of the same pattern along the chosen path previously, at least in a fresh cadaver arm, so the feel of the structures is familiar.
The forces must never be forced through if resistance is felt. It must be withdrawn a little and probed until yielding tissue is found. If a tendon or graft is to be passed through the carpal tunnel (often a good path), the nose of the tunnel must be deep to all tendons and sheaths. The feel of the floor of the tunnel is hard, irregular, and quite unmistakable; it is safe for the tunneler to press on the floor. If passage of the tunneler pulls the fingers into flexion, it means that the tunnel is in among the tendons. It must be pulled back and rerouted more deeply on the floor. I have never known adhesions to be a problem in this uninjured skeletal plane; this plane also is clear of the median nerve.

If a muscle is used for transfer that is weaker than the original muscle it is to replace and if it is not blocked by adhesions, it may eventually become stronger until it is able to match the requirements of its new responsibilities.

It is true that all muscles, with or without surgical interference, respond to repeated strong contractions by becoming stronger. This is accomplished by the addition of sarcomeres in new muscle fibrils in parallel with the old. The condition for this hypertrophy is that the weak muscle must actually contract as strongly as it is able, in phase with its new task. I have seen many transferred muscles that have become progressively weaker after surgery and have been regarded as failures. In a few cases, this has been because it has become rigidly adherent in its new pathway; however, this has often been because the muscle was never reeducated to contract in phase with its new action. The hand therapist must not be content to see the transferred muscle contracting on command or in the sequence of postoperative exercises that are planned to involve contraction of that muscle. The muscle must be seen to contract during activities of daily living or at a work bench where the patient is thinking of work rather than of the hand.

**CHANGES IN EXCURSION OF MUSCLE AFTER TRANSFER**

Surgeons often wonder what happens if they transfer a muscle that has short fibers to replace a muscle that had long fibers. Assuming that the new muscle will have a shorter excursion, will it eventually develop longer fibers to match the requirement of its new task?

The answer is that it will not. If the patient exercises well and uses the muscle effectively, the result is gradual lengthening of the paratendinous soft tissues to maximize available excursion. However, the number of sarcomeres in series in each fiber remain the same. The only way to lengthen a muscle fiber is to keep it on stretch at rest. The only way to do this without shortening the fibers on the opposite side of the limb is to operate and attach the tendon at a higher relative tension. Muscle fibers respond to constant tension by adding sarcomeres in series until normal resting tension is reestablished.

There is a danger in attaching transferred muscles at high tension, because the muscle may respond by involuntary contractions that cause avulsion at the suture line. The best way to handle the problem is to make the attachment of a transferred tendon at a tension just above normal resting tension (for a wrist-moving muscle, this may be 1 cm of distal pulling of tendon from its relaxed position), and to place the limb in the postoperative cast in a posture to relax that tension until the wound has healed, usually in 3 to 4 weeks. After the posture is allowed to return to normal, the transferred muscle tends to give electromyographic discharges for 1 or 2 weeks until new sarcomeres have grown and relaxed the tension. This whole process brings the new muscle enough into consciousness to be of some assistance in the process of reeducation.

**MECHANICAL BALANCE AT EACH JOINT**

The calculation that is needed for balance involves moment or torque at a joint. This is the product of the tension of the muscle and the lever arm or moment arm at the joint. A weak muscle may produce a high torque at a joint if it crosses the joint far enough from its axis to have a long lever. In so doing, however, it uses a lot of excursion and may be able to produce only a limited range of motion of the joint. A stronger muscle may produce the same torque by crossing the joint nearer to the axis; it requires less excursion, thus allowing a wider range of joint motion.

If one knows the leverage or moment arm of a tendon at each joint that it crosses, the excursion needed at that joint may be calculated by multiplying the moment arm in centimeters by the number of degrees of required motion of the joint measured in radians (1 radian = 57.3°) (Fig. 54.4). This also may be checked at surgery when a tendon is transferred. The joint is moved through some multiple of 60° (approximately 1 radian), checked by a geometric triangle (Fig. 54.5), and the resulting motion of the tendon is measured on a millimeter scale. For example, after performing a tendon transfer for intrinsic muscle function at the metacarpophalangeal joint of the middle finger, the surgeon may hold the proximal part of the tendon, pulling it gently, while he flexes the metacarpophalangeal joint through 90° (1.5 radians). If the tendon moves 15 mm, it is lying 10 mm in front of the axis of the metacarpophalangeal joint. By doing this, the surgeon is able to make sure that the tendon is positioned correctly. If, with the same metacarpophalangeal angular motion, the tendon moves only 8 mm, the surgeon has inadvertently passed the tendon behind the metacarpal ligament rather than in front of it; in that case, the tendon will be a weak metacarpophalangeal flexor unless it is rerouted (Fig. 54.6).

**Figure 54.3.** A tendon tunneler is illustrated. A tendon tunneler must have a smooth blunt nose; its thickest point should be just behind the nose (the “viper” head); and it should be possible to open the jaws and the handles without stretching or tearing the tissues of the tunnel. (From Brand PW. Muscles—The Motors of the Hand. In: Rob C, Smith R, eds. Operative Surgery, 3rd ed. Stoneham, MA: Butterworth Publishers, 1977, with permission.)

**Figure 54.4.** A: A radian is shown. The length of a radius, measured on the circumference, is joined to the center by two radii. B: The way in which the lengthwise movement of a tendon may be used to measure the moment arm of a joint. If the joint moves 57.29°, the length of rope that runs off the pulley must be equal to its moment arm at the joint (i.e., radius of pulley). (From Brand PW. Clinical Mechanics of the Hand. St. Louis: CV Mosby, 1985, with permission.)

**Figure 54.5.** A 30° to 60° to 90° triangle. The corners are cut off to allow the triangle to be tucked into web spaces, where the actual joint axis is deep in tissue. (From Brand PW. Clinical Mechanics of the Hand. St. Louis: CV Mosby, 1985, with permission.)
One of the remarkable features of the hand is that tissues in close proximity to each other exhibit sharply contrasting responses to imposed mechanical stress. Tendons, tendon sheaths, and ligaments respond to repetitive tensile stress by a steep elastic curve of resistance before 10% of elongation has occurred. Paratenon and areolar tissue between tendons respond to repetitive tensile stress by allowing more than 100% lengthening with minimal elastic resistance. Skin occupies an intermediate position, and muscle allows about 100% of passive lengthening from its fully relaxed position. The last 50% of muscle lengthening requires significant tension, the energy of which is stored and used to supplement the active contraction of the stretched muscle.

If one muscle is used to provide tension to two different tendon insertions, the surgeon must make sure that the excursion required of each tendon is the same for each range of motion. Otherwise, the tendon with the bigger moment arm will fall slack and exert no tension, because it is linked to a tendon that moves less, having a smaller moment arm. For example, in radial palsy, a pronator teres attached to both extensor carpi radialis longus and extensor carpi radialis brevis is effective for extension only through the extensor carpi radialis longus insertion, which is the least effective extensor. The pronator should be attached only to the extensor carpi radialis brevis or to a better balanced pair of insertions.

**CHANGES IN PASSIVE STRUCTURES AFTER PARALYSIS**

One of the remarkable features of the hand is that tissues in close proximity to each other exhibit sharply contrasting responses to imposed mechanical stress. Tendons, tendon sheaths, and ligaments respond to repetitive tensile stress by a steep elastic curve of resistance before 10% of elongation has occurred. Paratenon and areolar tissue between tendons respond to repetitive tensile stress by allowing more than 100% lengthening with minimal elastic resistance. Skin occupies an intermediate position, and muscle allows about 100% of passive lengthening from its fully relaxed position. The last 50% of muscle lengthening requires significant tension, the energy of which is stored and used to supplement the active contraction of the stretched muscle.

In contrast to the highly variable responses to repetitive stress, all of these tissues have a rather constant response to long-term changes in their resting tension. If muscle, ligament, or skin is held in a slightly stretched position for several days at a time, the tissue begins to undergo structural change to adapt to the new length. Conversely, if any of these tissues are allowed to rest in a totally slack and loose position, the tissue elements begin to be absorbed and reoriented in a shortened position. Muscle fibers lose sarcomeres until normal physiologic resting tension is restored in the new posture.

The normal physiology of muscle-joint interaction largely depends on the harmony between active muscle contraction and the viscoelastic changes in the passive soft tissues. For example, a stretched muscle uses elastic recoil to provide most of the force when it begins to contract; most of the active contractile force of a muscle, as it nears its limit of shortening, is consumed in stretching out its opposing muscles and is not available for its primary function of moving the joints. Similarly, the elastic stretching and recoil of skin and connective tissue participates in all joint motion, and the feedback of its sensory nerves provides the best monitor of joint position and proprioception.

One of the first effects of paralysis is to unbalance the hand. This results in a collapse of joints toward the posture in which the unparalyzed muscles are shortened and in which the soft tissues on the paralyzed side are stretched to the point at which their elastic tension equals the diminished tone of the shortened unparalyzed muscles.
This new position of equilibrium is unstable. The unparalyzed muscles rest at a tension below their normal resting tension and begin losing sarcomeres to restore tension in the shortened position. The stretched skin and other soft tissues begin to grow to reduce their unnatural state of tension.

These initial compensations result in further destabilization of the equilibrium until some joints reach a point beyond which they cannot move. This process is seen in ulnar palsy, where there may be minimal clawing soon after injury but severe deformity after several months. It is also seen in radial palsy if the wrist is not supported night and day. And this process is seen in the thumb in median palsy, in which the dorsal tissues of the thumb tend to become progressively narrower and the ligaments at the base of the thumb change their length and density; after 1 or 2 years it may become impossible to oppose the thumb fully even after effective tendon transfers.

Muscle balance has been emphasized here because it is often neglected. A recognition of its importance results in a greater insistence on maintaining a normal functional position of the hand at rest as well as during activity until muscle balance is restored. This discussion should also stimulate the surgeon to operate earlier to restore muscle balance.

TRICK MOVEMENTS DEVELOPED AFTER PARALYSIS

So-called trick movements are the various attempts by an active person to get things done despite the limitations of paralysis. It is the good patient who finds a way around her disability, and it is only a foolish surgeon or therapist who decries these efforts unless there is a serious reason for preventing their use.

A trick movement is a way of using the hand that would never be done if the hand were normal. When the normal way to hold an object or to perform an action is no longer possible, some people read passively and wait for the doctor to do something. Others are determined to move ahead and find a way to do the job with whatever resources remain in the hand. These unorthodox patterns of movement indicate that the will to work is maintained. When patients succeed in accomplishing objectives, they gain confidence and maintain personal pride. These are assets beyond price. The quality of muscles, skin, and joint motion are maintained in better condition than if the limb is passive in a splint.

Two possible problems may result from trick movements. The tissues may become stretched or contracted as a result, and the trick may persist after tendons have been transferred. Tissue changes have already been mentioned, and examples have been given from paralysis of each of the three main nerve paralyses. Of the trick movements that may be troublesome as a habit after tendon transfer, one of the worst is the lateral squeeze pinch that is developed by almost every patient who has a low ulnar median palsy (Fig. 54.9). These patients cannot easily use their thumbs except by simultaneous contraction of the extensor pollicis longus and flexor pollicis longus. Each of these muscles, although opposing each other at the interphalangeal and metacarpophalangeal joints, has a common vector for adduction at the carpometacarpal joint of the thumb. To make this work, the two muscles must contract together. The flexor pollicis longus overcomes the extensor pollicis longus at the two distal joints where its moment arms are greater, and the extensor pollicis longus keeps the carpometacarpal joint in extension for which it has a better leverage than the flexor pollicis longus has for flexion. The resulting ugly pinch is strong and becomes frequently used.

The late deformities are flexion contracture of the interphalangeal joint and shortening of the dorsal skin and fascia of the web. Even if these deformities are corrected by surgery, the habit of using the extensor pollicis longus for pinch tends to persist. It is most difficult to get rid of if it has been used for many months or years and by older patients. The problem of this abnormal pinch is that it is the opposite of the new pattern that the surgeon uses to restore normal pinch. The newly transferred abductor-opponent by transfer may be hard to recombine, but the extensor pollicis longus is easy to use by force of habit. The extensor pollicis longus also has a better moment arm to pull into supination than the new transfer has for pronation. The patient's instinctive tendency to contract the extensor pollicis longus on attempted pinch is the cause of many failures of opponents transfers.

To prevent the development of this habit pattern, the thumb may be splinted forward or held out by a C-splint. If a tendon transfer is to be delayed many months, however, it is not likely that a patient will agree to remain restrained. If the pattern is already firmly established at the time surgery is planned, consider using the habit, rather than fighting it, by transferring the extensor pollicis longus through the distal forearm between radius and ulna to be attached to the stump of its own tendon to serve as an abductor-extensor of the thumb. The attempt to use the trick movement then enhances the true opponents action. This transfer leaves the thumb with the hand.

Tissue homeostasis may be judged by a return of normal skin mobility, joint mobility, hand volume, and skin temperature. I suggest the use of a skin thermometer for comparing the affected side with the normal side. A hand volumeter is also a useful instrument for monitoring the resolution of any inflammatory state in the tissues of the hand. The patient should notice the progress in the graph of these records, which can also be used after surgery to mark progress in recovery from the operation and the mobilizing of joints and tendons. The patient learns to associate raised temperatures with inflammation and notices how his hand volume increases when the hand is hanging down and how it decreases after a period of elevation and moderate exercise.

If tendon transfers are performed while there is still tissue inflammation as marked by lack of free skin mobility, elevated local temperature, and hand volume, the postoperative inflammation is likely to be more severe and the adhesions around transferred tendons more difficult to resolve. The patient must have time before surgery to learn about and understand the implications of the operation and to identify the muscle and tendon to be transferred, so that there may be no loss of time in the critical period after the postoperative cast is removed.

Timing of surgical intervention is more difficult if the nerve has been repaired and is in process of recovery. Too many surgeons assume that they have to wait until they are absolutely certain that no recovery is possible before they decide to operate for restoration of muscle balance. They are afraid of some recovery occurring after they have performed a tendon transfer and of being told that their operation was unnecessary and possibly harmful.

The treatment plan is dominated more by the fear of lawsuits than by the good of the patient. The correct approach to this problem is first to make a realistic estimate of the probability of good recovery of the involved muscles, recognizing that muscle recovery is good if the nerve repair is accurate and without tension, and is in the same limb segment as the affected muscle. The likelihood of good recovery is fair if the nerve injury and repair is in the limb segment proximal to the muscle, and it is poor if the injury is two segments proximal. An ulnar nerve division above the elbow, for example, rarely results in good recovery of the intrinsic muscles in the hand. A median nerve above the elbow has a slightly better likelihood of recovery, but the secondary stiffness and contracture that results from the necessary 1- to 2-year wait to make sure is more harmful than any disability that may result from an early transfer followed 1 or 2 years later by recovery of the thenar muscles.

If an operation is to be performed early although later recovery is possible, it is wise to select a tendon for transfer that will not leave a significant defect by its loss from the donor site. For example, in a high median palsy, although the thumb is fully mobile passively, it is appropriate to use the extensor indicus proprius around the ulnar...
border of the wrist to restore abduction to the thumb. This muscle might be inadequate if it had to oppose contracted tissues and a negative pattern of use after 1 or 2 years. Similarly, a palmaris longus, extended by free grafts through the carpal tunnel, is appropriate for a new case of intrinsic palsy of the fingers before the support of the volar plates and other tissues is lost by being stretched and before the interphalangeal joints become stiff in flexion.

The whole situation must be fully explained to the patient and the pros and cons offered in writing so that the patient may understand and choose between the possible harm of operating early and the more probable harm of waiting until much later.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study. 

1. 
Radial nerve palsy most frequently results from penetrating injuries to the lower arm and the upper forearm and from fractures of the middle to distal third of the humerus. The major functional impairment is an alteration in the ability to grasp and release.

Riordan separated grasp into three phases (28):

- **Phase 1** constitutes opening the hand widely and requires the long extensors of the fingers and the thumb, abduction of the first metacarpal, and intrinsic muscle action.
- **Phase 2** involves surrounding the object and requires combined long flexors and intrinsic action.
- **Phase 3** is gripping the object between the fingers and the palm or between the fingers and the thumb and requires strong action of the long flexors.

Opening the hand for release requires the long extensors and the intrinsic muscles to perform as in phase 1 of grasp. In high radial nerve palsy, grasp phases 1 and 3 and the ability to release are severely impaired. In posterior interosseous nerve palsy, at least one of the radial wrist extensors is intact for wrist stability during phase 3 of grasp, and only grasp phase 1 and release are affected. Reconstruction for radial nerve palsy is directed at rebalancing the grasp-release mechanism necessary for normal hand function.

**ANATOMY**

The radial nerve (Fig. 55.1) originates from the posterior cord of the brachial plexus. Contributing nerve fibers can be traced from the fifth through the eighth cervical roots, with the largest contribution usually from the seventh. The nerve enters the upper arm posteriorly, accompanying the deep brachial artery between the long and medial heads of the triceps. The radial nerve does not travel in the spiral groove of the humerus but lies instead on the upper part of the medial triceps, separated from the underlying bone by a layer of muscle approximately 3.4 mm thick (40). The nerve is in direct contact with the humerus only in the distal arm, where it pierces the lateral intermuscular septum.

Innervation of the triceps varies. Linell suggested four branches to the triceps; a branch to the long head arising about 9.5 cm below the acromion, the nerve to the lateral head arising about 10.1 cm, and another larger branch to the medial head about 11.2 cm below the acromial tip (19). Sunderland reported more variability, with 5 to 10 branches typically found (38). Because the branches to the triceps arise high in the arm, paralysis of the triceps from a fracture of the humerus is unlikely.

The radial nerve pierces the lateral intermuscular septum about 10 cm proximal to the lateral epicondyle and enters the anterior arm between the brachialis and the brachioradialis. The motor branches to the brachioradialis and the extensor carpi radialis longus are given off in this area above the elbow. A branch is often extended to the brachialis, but the predominant innervation of this muscle is the musculocutaneous nerve (29).

The radial nerve divides into a superficial and deep branch at about the level of the lateral epicondyle. The level of bifurcation varies from 4.5 cm above the lateral epicondyle to 4 cm below, with division at or below the epicondyle more common (19). At about this same level, the radial nerve gives a branch to the extensor carpi radialis brevis. Sahliyri found this branch to arise from the superficial branch of the radial nerve in 56% of specimens, from the deep branch in 36%, and from the angle formed by the two in 8% (29). With the exception of the frequent branch to the extensor carpi radialis brevis, the superficial branch of the radial nerve is purely sensory.

After the bifurcation of the superficial and deep branches, the superficial branch continues distally and dorsally under the cover of the brachioradialis. It emerges from under this muscle at the junction of the middle and distal thirds of the forearm to continue subcutaneously along the dorsoradial aspect of the forearm to supply skin on the lateral part of the dorsum of the wrist and hand.

The deep branch of the radial nerve is often referred to as the posterior interosseous nerve. Its function is purely motor, except for several branches to the wrist joint at its most terminal extent, which are sensory. The posterior interosseous nerve passes from the proximal anterior forearm to the posterior forearm through the supinator muscle, which it innervates. The proximal margin of the supinator forms a fibrous arch, referred to as the arcade of Frohse, through which the nerve passes (12).

The posterior interosseous nerve exits the supinator approximately 8 cm below the elbow joint, and it immediately divides into multiple branches. Spinner observed that the branches seem to be arranged into two major groups (34). The first group supplies the superficial layer of extensor muscles (the extensor digitorum communis, extensor digiti minimi, and extensor carpi ulnaris), and the second group supplies the deep layer (the abductor pollicis longus, extensor pollicis longus and brevis, and...
In planning incisions for tendon transfers, consider the resulting effects on tendon gliding from the adhesions that inevitably form. Avoid longitudinal incisions along the biomechanics (see Figure 55.2).

Initial treatment of radial nerve palsy depends on the nature and severity of the inciting injury. Closed injuries, such as crush injuries, low-velocity gunshot wounds, and closed fractures, result in neurapraxia or axonotmesis, and they should simply be observed initially. In open injuries, such as open fractures and lacerations, the nerve should be explored during the initial irrigation and debridement of the wound.

The reported incidence of high radial nerve palsy associated with humeral shaft fractures is 2% to 15% (8,13,14,17,18,20,23,25,31,33). Several factors influence prognosis for patients with such fractures. Partial paralysis indicates continuity of the nerve and is a good prognostic sign. Functional recovery can be expected. Kaiser et al. believe that a comminuted, middle-third fracture of the humerus with immediate onset radial nerve palsy offers the poorest prognosis for nerve recovery (17). This poor prognosis is related to the high energy involved in this fracture. They suggest early exploration of nerves with this fracture pattern.

Holstein and Lewis suggested that a spiral oblique fracture of the distal humerus places the radial nerve at particular risk for entrapment in the fracture site (14). They think early exploration is indicated if this fracture pattern is associated with a radial nerve palsy. In contrast, Pollock and colleagues, who noted a 93% spontaneous recovery rate irrespective of the fracture pattern, recommend initial observation in all closed humerus fractures with associated radial nerve palsy (23). If nerve function shows no signs of improvement in 3 to 4 months, explore the nerve with neurolysis or neurorrhaphy. In a more recent study, Foster et al. examined a series of 14 patients with radial nerve palsy caused by open humeral shaft fractures. The nerve was either lacerated or interposed in the fracture in 64% of patients (15).

Our experience suggests spontaneous recovery in most fractures. For all closed fractures of the humerus associated with a radial nerve palsy, we treat the nerve injury expectantly if the fracture can be reduced closed. Most patients can be expected to recover in 1 to 4 months. In 3 to 4 weeks, if recovery has not begun, assess the extent of the nerve damage by electromyography. If no neurologic recovery is observed in 3 to 4 months, we explore the nerve with neurolysis or neurorrhaphy. If reduction is blocked by any soft-tissue interposition, especially if the fracture is of the distal spiral oblique type, we explore the nerve and reduce and internally fix the fracture.

If manipulation results in an acute radial nerve palsy of immediate onset, early exploration should be considered. Radial nerve palsies that are delayed in onset, even after manipulation, may be observed. In open fractures, the nerve should be explored during irrigation and debridement of the fracture. Repair nerves and fix rigid fractures. Repair segmental defects with interfascicular grafts. Functional nerve return can be expected in as many as 77% of patients (21).

We have observed return of muscle function, even after grafting defects as large as 15 cm. As a general rule, nerve regeneration progresses at a rate of 1 mm per day (22). Lesions above the elbow may progress at a slower rate. After giving up on a nerve repair, we have occasionally been surprised to find some muscle function return several months after that predicted by the 1-mm-per-day formula.

The importance of maintaining supple joints free of deformity cannot be overemphasized. Use splints and physical therapy while awaiting nerve recovery and before considering tendon transfers. Splinting must be individualized. A simple palmar cock-up splint may increase the grip strength 3 to 5 times (8). Most patients are well served by such a splint. A patient requiring greater excursion of the fingers may prefer a dynamic splint with extension assists for the wrist and metacarpophalangeal joints (Fig. 55.2) (24-37,38).

**Figure 55.2. A dynamic splint with an extension assist for the wrist metacarpophalangeal joints of the fingers and abduction or extension assist for the thumb are shown.**

**Surgical Techniques**

The surgeon considering the operative treatment of a patient with radial nerve palsy should be familiar with the fundamental principles of tendon transfers and biomechanics (see Chapter 54). In selecting radial nerve transfers, approach each patient individually, with attention to age, occupation, and recreational goals. Become familiar with the limitations and uses of the different available transfers (Table 55.1). The transfers discussed here assume an isolated radial nerve palsy.

In planning incisions for tendon transfers, consider the resulting effects on tendon gliding from the adhesions that inevitably form. Avoid longitudinal incisions along the...
path of the transfer, which tend to form adhesions through their entire length between the transferred tendon and the overlying fascia and skin. Incisions passing directly over tendon junctures are especially troublesome and may inhibit the transferred tendon from gliding. Make small transverse incisions to mobilize muscle-tendon units if the unit is freely dissectible from its surrounding structures. If the muscle to be transferred requires significant dissection, avoid incisions that run in a direct line with the proposed path of the transfer. The skin is fairly mobile in the forearm, and adequate exposure can often be obtained by simple retraction without extensive skin incisions.

Little controversy exists in regard to choosing the motor tendons to restore wrist extension. Transfer the insertion of the pronator teres to the extensor carpi radialis brevis at its musculotendinous junction. Avoid the dual insertion of the pronator teres to the extensor carpi radialis brevis and extensor carpi radialis longus. Brand described the biomechanical reasons for avoiding dual insertion.

Consider both radial wrist extensors as ropes attached to two different-sized pulleys on the same shaft (Fig. 55.3). If each rope is wrapped around its respective pulley and pulled separately, more rope unwraps from the larger pulley, which has a larger moment arm. If the two ropes are tied together and tension is placed on the knot, the rope around the larger pulley (larger moment arm) becomes loose because a longer length of rope is pulled off the larger pulley than the smaller one. The rope to the smaller pulley remains tight and is therefore the only one effective in turning the shaft. The extensor carpi radialis longus has a smaller moment arm for wrist extension than does the extensor carpi radialis brevis. With insertion of the pronator teres into both radial wrist extensors, as the pronator teres begins to contract, the extensor carpi radialis brevis with its larger moment arm for wrist extension becomes slack, and the extensor carpi radialis longus provides the only effective wrist extensor.

![Figure 55.3](image)

Wrist extension will be weaker than if the pronator teres had only been transferred to the extensor carpi radialis brevis. The extensor carpi radialis longus has a larger moment arm for radial deviation of the wrist than for wrist extension, and with a dual insertion of the pronator teres, attempted wrist extension results in significant radial deviation.

**STANDARD OR FLEXOR CARPI ULNARIS TRANSFER**

In older patients and in those who are difficult to rehabilitate or have less need for independent digital control, use what is known as the standard or flexor carpi ulnaris (FCU) transfer. Transfer the pronator teres to the extensor carpi radialis brevis for restoration of wrist extension; the flexor carpi ulnaris around the ulnar side of the forearm to the extensor digitorum communis for finger extension; and the palmaris longus to the rerouted extensor pollicis longus for thumb extension (Fig. 55.4). If the two ropes are tied together and tension is placed on the knot, the rope around the larger pulley (larger moment arm) becomes loose because a longer length of rope is pulled off the larger pulley than the smaller one. The rope to the smaller pulley remains tight and is therefore the only one effective in turning the shaft. The extensor carpi radialis longus has a smaller moment arm for wrist extension than does the extensor carpi radialis brevis. With insertion of the pronator teres into both radial wrist extensors, as the pronator teres begins to contract, the extensor carpi radialis brevis with its larger moment arm for wrist extension becomes slack, and the extensor carpi radialis longus provides the only effective wrist extensor.

The incisions for the flexor carpi ulnaris transfer are shown in Figure 55.4. Under tourniquet control, expose the pronator teres insertion through a 7 cm longitudinal midaxial incision (incision 1) over the middle third of the radius while the forearm is held in neutral rotation.

![Figure 55.4](image)

Identify the insertion of the pronator teres by developing the interval between the brachioradialis and the extensor carpi radialis longus, carefully protecting the sensory branch of the radial nerve. Even in radial nerve palsy, trauma to the sensory branch may produce a painful neuroma. The insertion of the pronator teres is predominantly muscular, with very little tendinous component.

To gain sufficient tendon length, elevate the pronator teres off the radius with a 3 cm strip of periosteum (Fig. 55.5). The periosteum in adults is thin, and this strip is usually small; handle it with care.

![Figure 55.5](image)
Flexor carpi ulnaris also has a greater excursion than the flexor carpi radialis brevis. Simply pronate the forearm to expose the extensor carpi radialis brevis. The periosteal strip of the pronator teres will later be woven through the extensor carpi radialis brevis tendon just distal to the musculotendinous junction. Mobilize all the muscle-tendon units, however, before completing any junctures.

To expose the flexor carpi ulnaris (Fig. 55.7A), make a longitudinal incision (incision 2) along the palmar ulnar forearm directly overlying the flexor carpi ulnaris muscle belly. Distally, start the incision at the proximal wrist crease just proximal to the pisiform. Continue the incision proximally to the junction of the middle and proximal thirds of the forearm.

Place a tag suture in the flexor carpi ulnaris tendon, and detach it from its insertion on the pisiform. Use the tag suture to provide traction on the tendon and to mobilize the flexor carpi ulnaris from its underlying extensive origin from the ulna and its overlying origin from the fascia. Stop this mobilization 5 cm distal to the flexor carpi ulnaris origin to avoid damaging its innervation from the ulnar nerve.

Expose the extensor digitorum communis tendons through a 3 cm oblique incision (incision 4) in the distal forearm, cutting in a proximal–radial to distal–ulnar direction. Tunnel a tendon passer subcutaneously from the ulnar margin of incision 4 to the proximal extent of incision 2. With this tendon passer, bring the flexor carpi ulnaris subcutaneously around the ulnar side of the forearm to lie along the ulnar aspect of the extensor digitorum communis. If the bulk of the distal muscle belly of the flexor carpi ulnaris in its new position seems excessive, bring it out of its tunnel and trim it from its tendon.

If a palmaris longus exists, transfer it to the rerouted extensor pollicis longus (see Fig. 55.7B). Rout the extensor pollicis longus tendon subcutaneously along the radial border of the wrist, enabling the transfer to extend and radially abduct the thumb.

Expose the palmaris longus distal insertion into the palmar fascia through a 1 cm transverse incision (incision 3) at the proximal wrist crease. Expose the proximal tendon and muscle belly of the palmaris longus through the proximal portion of incision 2. Divide the palmaris longus tendon distally, and deliver it into the proximal portion of incision 2.

Make a 2 cm transverse incision (incision 5) over the radial aspect of the wrist just distal to the radial styloid, and expose the extensor pollicis longus tendon in the dorsal extent of this incision.

Identify and divide the extensor pollicis longus tendon proximal to the dorsal retinaculum (incision 4), and deliver this tendon from its dorsal compartment into incision 5.

Tunnel a tendon passer subcutaneously from incision 5 to the proximal extent of incision 2, and deliver the palmaris longus tendon across the palm aspect of the forearm into incision 5 to meet the rerouted extensor pollicis longus. Dilate the tourniquet, achieve hemostasis, and close incisions 2 and 3.

Make the junction between the pronator teres and the extensor carpi radialis brevis last, because the tenodesis effect caused by flexing and extending the wrist is used to make sure the tension of the finger and thumb transfers are appropriate and produce synchronous motion. The juncture of the periosteal strip of the pronator teres to the extensor carpi radialis brevis may be tenuous and intolerant of the repeated wrist manipulations involved with setting the tension of the finger and thumb transfers.

For the flexor carpi ulnaris to extensor digitorum communis transfer, we prefer an end-to-side juncture rather than an end-to-end juncture. Some patients have demonstrated improved motor function return even a few years after injury. Dividing the extensor digitorum communis tendons for an end-to-end juncture deprives the patient of a potentially superior result if any motor function returns after the transfers have been completed.

Pass the flexor carpi ulnaris tendon through a slit in each of the extensor digitorum communis tendons by fully flexing the wrist and fingers to make sure the juncture is proximal enough to remain unrestricted by the dorsal retinaculum. Suture each extensor digitorum communis tendon individually to the flexor carpi ulnaris with 4-0 nonabsorbable braided Dacron.

The tension under which the transfers are sutured is critical. Set the tension by placing the metacarpophalangeal joints and the wrist joint in full extension, and suture the flexor carpi ulnaris tendon under slight tension.

For the palmaris longus to extensor pollicis longus transfer, place the thumb, interphalangeal, and metacarpophalangeal joints in full extension and the carpophalangeal joint in full radial abduction. Weave the palmaris longus tendon three times through the extensor pollicis longus tendon and suture it with 4-0 nonabsorbable braided Dacron, as described by Pulvertaft (Fig. 55.7C). Pull the palmaris longus tendon distally under mild tension while completing this juncture. Move the wrist, fingers, and thumb through a full range of motion to ensure that motion is synchronous and no restrictions are caused by the junctures.

Set the tension for the wrist transfer by placing the wrist joint in maximal extension. Pull the pronator teres under slight tension to the extensor carpi radialis brevis tendon just distal to the musculotendinous junction. Weave the pronator teres through the extensor carpi radialis brevis tendon, and suture it in place (Fig. 55.5).

Assess the tension of all the transfers again by rotating the wrist through a range of motion. With the fingers fully extended with flexion of the wrist and with the fingers flexed into the palm with extension of the wrist, a synchronous tenodesis effect should be observed.

In older patients or in patients who may be difficult to reeducate, suture the musculotendinous units under moderate tension to provide an extra component of sensory feedback through the stretch reflex.

Close the remainder of the wounds while maintaining the wrist and fingers in maximal extension and the thumb in maximal extension and radial abduction. Apply dressings and splints as described under “Postoperative Care.”

If the palmaris longus is not available, use the flexor digitorum superficialis tendon to the ring finger to the rerouted extensor pollicis longus for thumb extension and abduction. Make a 1 cm transverse incision in the distal palm over the fourth metacarpophalangeal joint, and divide the flexor digitorum superficialis tendon between the A1 and A2 pulleys. Deliver the tendon into the middle forearm through incision 2, and tunnel it subcutaneously into incision 5 to meet the rerouted extensor pollicis longus. The juncture and tension are identical to those described for the palmaris longus transfer.

**FLEXOR CARPI RADIALIS TRANSFER**

Patients who wish to return to heavy labor may have difficulty if the flexor carpi ulnaris is sacrificed for transfer. The flexor carpi ulnaris is a strong ulnar deviator and an important wrist stabilizer, and it is necessary for activities like hammering. In these patients, select the flexor carpi radialis to provide finger extension (Fig. 55.8).

For wrist extension, the extensor teres to extensor carpi radialis brevis, which is exposed through a 7 cm longitudinal midaxial incision (incision 1) (Fig. 55.8), along the middle third of the forearm, as previously described.
For young patients who may require a greater range of motion in the fingers independent of wrist motion and who are cooperative rehabilitation candidates, a modification of the standard transfer described by Boyes (4, 10) is performed. The flexor digitorum superficialis tendons of the middle and ring fingers are passed through the interosseous membrane to act as finger extenders. The flexor digitorum superficialis tendons of the middle finger are sutured to the extensor digitorum communis tendons of all four fingers, and the flexor digitorum superficialis tendons of the ring finger to the rerouted extensor pollicis longus for thumb extension and abduction (see description under “Postoperative Care”). If the palmaris longus is not available, use the flexor digitorum superficialis tendon to the ring finger to the rerouted extensor pollicis longus for thumb extension and abduction (see description under “Standard or Flexor Carpi Ulnaris Transfer”).

MODIFIED BOYES TRANSFER

For young patients who may require a greater range of motion in the fingers independent of wrist motion and who are cooperative rehabilitation candidates, use a modification of the transfer described by Boyes (4, 10). The flexor digitorum superficialis tendons of the middle and ring fingers are passed through the interosseous membrane to act as finger extenders. The flexor digitorum superficialis tendon of the middle finger is sutured to the extensor digitorum communis tendons of all four fingers, and the flexor digitorum superficialis tendon of the ring finger to the rerouted extensor pollicis longus for thumb extension and abduction (see description under “Standard or Flexor Carpi Ulnaris Transfer”).

This method provides independent control of the index finger and thumb from the other fingers for the pinch function. The flexor carpi radialis is brought around the radial side of the forearm to the abductor pollicis longus to provide independent control of the index finger and thumb from the other fingers for the pinch function. The flexor carpi radialis tendon is sutured to the extensor pollicis longus. The flexor digitorum superficialis tendons of the middle and ring fingers are sutured to the extensor digitorum communis tendons of all four fingers, and the flexor digitorum superficialis tendon of the ring finger to the rerouted extensor pollicis longus for thumb extension and abduction (see description under “Standard or Flexor Carpi Ulnaris Transfer”).

Under tourniquet control, expose the pronator teres insertion through a 7 cm longitudinal midaxial incision (incision 1) over the middle third of the radius while the forearm is held in neutral rotation.
The importance of synergistic transfers becomes an issue when the flexor digitorum superficialis (a finger flexor) is transferred to the extensor digitorum communis or A1 and A2 pulleys instead of at its insertion (Fig. 55.11). As with any tendon transfer, early transfers cannot be considered until a full or near-full passive range of motion has been achieved and tissue equilibrium exists. EARLY TENDON TRANSFERS

Burkhalter suggests transfer of the pronator teres to the extensor carpi radialis brevis as an "internal splint" while awaiting nerve recovery (Fig. 55.11). This transfer allows the patient to remain brace free. If neurologic return does not occur, nothing has been lost and the remainder of the definitive transfers can be completed. This transfer is useful in selected cases. Patients with a poor prognosis for relatively early nerve recovery because of a high radial nerve laceration, a large defect requiring a long compartment tunnel.

Complete the pronator teres to extensor carpi radialis brevis juncture, as previously described. Close the remainder of the incisions, and apply dressings and splints as described under "Postoperative Care."

POSTERIOR INTEROSSEOUS NERVE PALSY

In isolated posterior interosseous nerve palsy, the brachioradialis, extensor carpi radialis longus, and in most cases, the extensor carpi radialis brevis innervations are intact. A wrist extensor need not be replaced in these patients. Because all of the radial wrist extensors are intact, a significant amount of radial deviation may occur with wrist extension. In this group of patients, use the flexor carpi radialis for finger extension.

The palmaris longus or flexor digitorum superficialis of the ring finger may be transferred to the rerouted extensor carpi radialis longus tendon to restore thumb extension and abduction. For patients requiring a greater range of finger motion, pass the flexor digitorum superficialis of the middle and ring fingers through windows in the interosseous membrane, to act as finger and thumb extensors. Use the flexor carpi radialis to provide thumb abduction. Sacrificing the ulnar deviating force of the flexor carpi ulnaris exaggerates radial deviation caused by the radial wrist extensors. Therefore, we do not use the flexor carpi ulnaris to obtain finger extension in posterior interosseous nerve palsy.

POSTOPERATIVE CARE

Immediate postoperative care is similar in each of the transfers. After the incisions have been closed, apply a bulky plaster-reinforced compression dressing that maintains the elbow at 90° of flexion, forearm in neutral, the wrist at 45° of dorsiflexion, the metacarpophalangeal, the proximal interphalangeal, and distal interphalangeal joints of the fingers at 0°, and the thumb at maximal extension and abduction. No immobilization of the fingers or thumb is required for the early transfer of the isolated pronator teres to extensor carpi radialis brevis.

Remove the dressing 10 days postoperatively for suture removal. Apply a long arm cast, maintaining forearm, wrist, and fingers in the same position. The patient wears the cast for approximately 3 more weeks. Then change to a removable short arm splint, maintaining the wrist in 45° of dorsiflexion and metacarpophalangeal joints in 20° of flexion, and leaving the proximal and distal interphalangeal joints free. Supervised physical therapy is started at this time.

Discontinue use of the splint 2 to 3 weeks later, unless an extensor lag at the metacarpophalangeal joints or the wrist occurs, for which nighttime splinting is continued until it resolves.

PITFALLS AND COMPLICATIONS

Use of the flexor digitorum superficialis may produce a flexion contracture or hyperextension deformity at the proximal interphalangeal joint. Litter suggested that these deformities can be eliminated, at least to the point where no functional impairment occurs, by dividing the flexor digitorum superficialis tendon proximally between the A1 and A2 pulleys instead of at its insertion (22).

The importance of synergistic transfers becomes an issue when the flexor digitorum superficialis (a finger flexor) is transferred to the extensor digitorum communis or the extensor pollicis longus (finge extensions). Many surgeons believe that the flexor digitorum superficialis is an easy muscle to retrain, and in young patients, this seems to be true (6,10). We avoid this transfer in older patients who may have difficulty with reeducation.
**CHAPTER 56**

**MEDIAN NERVE PALSY**

Steven M. Green

**INTRODUCTION**

Despite advances in the understanding, evaluation, and treatment of peripheral nerve disorders, surgical reconstruction for paralysis of median innervated muscles remains a common procedure. This chapter discusses the analysis of such problems and the concepts and techniques of rehabilitation.

The median nerve innervates muscles that originate within the hand (intrinsic) and those whose origin is more proximal (extrinsic). Table 56.1 lists these muscles and their primary functions. The ulnar and radial nerve may activate muscles usually innervated by the median nerve (11). These variations can lead to diagnostic confusion (11). The pronator teres and quadratus both pronate the forearm. Because the pronator teres is more effective if the elbow is extended, the individual force of these two muscles can be determined by testing the strength of pronation with the elbow in extension and then in flexion.

Table 56.1. Muscles Innervated by the Median Nerve

The ability of the flexor digitorum superficialis (FDS) to flex the proximal interphalangeal joint of a finger is examined by holding the other digits in extension, thereby inhibiting flexor digitorum profundus function. Because the ring and small fingers often share a common muscle belly, the power of proximal interphalangeal joint flexion of these two digits should be tested both individually and simultaneously. In testing the strength of distal joint flexion, one evaluates the function of the flexor pollicis longus (FPL) and the flexor digitorum profundus. Thumb opposition is a combined motion of palmar abduction, pronation, and flexion (7). This essential thumb motion brings the thumb pulp in contact with that of one or more fingers. Although prehension is achieved by the three thenar intrinsic muscles, the abductor pollicis brevis is the most important (5, 10).

Median nerve palsy is most often a result of trauma such as laceration, traction, fracture, gunshot wound, or chronic compression neuropathy. Diabetic peripheral neuropathy and viral and lepromatous infection are less common etiologies.

Median nerve palsy is frequently a rather disabling condition. Loss of active pronation adversely affects a person’s ability to use a computer keyboard or a tool such as a screwdriver. Weakness of the flexor carpi radialis is rarely a problem because the flexor carpi ulnaris is innervated by the ulnar nerve and can adequately perform wrist flexion. Of greater functional importance is the loss of digital flexion of the thumb, index, and middle fingers. The ring and small fingers are less affected because their profundi are usually innervated by the ulnar nerve. Loss of opposition severely affects one’s ability to grasp as well as engage in fine manipulation.

**NONSURGICAL TREATMENT**

In situations in which a median palsy is expected to resolve, make efforts to maintain joint flexibility to prevent contractures. Teach the patient to perform frequent range-of-motion exercises primarily to prevent extension deformity of the finger joints and fixed adduction of the thumb. Using Velcro loop straps to tie the affected finger and a normal finger together preserves joint motion and enhances hand function as well. An opposition splint maintains the thumb–index web space and places the thumb in a more useful position. If contractures have developed, a hand therapy program is required to restore digital flexibility. Avoid dynamic traction on the thumb, which can cause stretching of the ulnar collateral ligament rather than improvement of the adduction contracture. A better method uses a static thumb–index web space splint, which is modified as abduction is obtained.

**SURGICAL CONCEPTS**

A frequent etiology of median nerve palsy is chronic carpal tunnel syndrome that has caused thenar atrophy. In spite of modern microsurgical techniques, recovery of motor function after median nerve neurotomies is frequently poor. Performing a tendon transfer as an internal splint simultaneously with repair of proximal median nerve injuries is useful, because permanent thenar palsy is common. An opposition tendon transfer provides early functional recovery, avoids adduction contracture, and eliminates the need for splinting. Even if the intrinsic muscles are reinnervated, the recovered strength is rarely normal.

A thumb–index web space contracture that is resistant to splinting can be corrected by release of the deformity with skin plasties or skin grafts and release of the adductor and the first dorsal interosseous muscles and, if necessary, the trapeziometacarpal joint capsule. Joint fusion places a digit in a more functional position and...
is especially useful in treating palsy of the flexor digitorum profundus (provided that the FDS is of normal strength) and for weakness of the FPL. Although joint fusions are technically simple, improve dexterly, and do not require postoperative rehabilitation, they neither restore mobility nor improve weakness. Tendon transfers require more surgical skill and patient cooperation than does joint fusion, but they have the potential of providing active joint motion and regaining strength.

Although tendon transfers to restore opposition are commonplace today, it was not until 1918 that Steindler (24) suggested rerouting the FPL to restore thumb mobility. Bunnell (4), in his classic article of 1938, outlined the basic principles of opposition reconstruction and emphasized that surgery must be individualized to meet the patient’s needs, because “each hand is a problem in itself.” He wrote that candidates for tendon transfer surgery must have adequate sensibility, the thumb joints should be stable, and the skin and joints must be supple.

In restoring opposition, consider the excursion and force of the tendon to be transferred, the direction of its pull, and the axis of insertion into the thumb (6) (see Chapter 56). Although it may not be possible to replace the function of several weakened intrinsic muscles fully with one tendon transfer, the replacement should match as closely as possible the normal force and excursion of the paralyzed muscles. The force generated by a muscle is proportional to its cross-sectional area, which is 6.0 cm² for the median innervated thenar intrinsics (3).

The long finger superficialis (cross section of 5.8 cm²) and the extensor carpi ulnaris (ECU) (6.2 cm²) most closely match the thenar forces. Although the ring finger superficialis (3.2 cm²), the extensor indicis proprius (EIP) (1.7 cm²), the palmaris longus (PL) (1.8 cm²), and the abductor digitii quinti (2.1 cm²) are frequently used for tendon transfers, their potential force of contraction is significantly less. Excursion, or the change in length between full relaxation and contraction, depends on mean fiber length, which averages 3.5 cm for the thenar muscles. This figure is surpassed by all the commonly used transfers.

In selecting a tendon for transfer, the surgeon must not substitute one imbalance for another. Choosing a strong motor may improve thumb function, but if a finger flexor is used, the improvement occurs at the expense of power grip. To produce the motion of opposition, the transfer must pull from the direction of the pisiform, paralleling the fibers of the abductor pollicis brevis (7). Transfers that use a pulley distal to the pisiform encourage metacarpal flexion at the expense of palmar abduction. The reverse is true for transfers that pull more proximal and radial to the pisiform. Unless there exists a supple subcutaneous bed through which the transfer is to be passed, the motor will not be able to transmit its force of contraction. Therefore, skin resurfacing may be required before a tendon transfer is performed. Alternatively, a Silastic tendon prosthesis can be used to form an adequate pathway for eventual tendon transfer at a second stage.

The most predictable insertion is made into the tendon of the abductor pollicis brevis (13). Insertions into the ulnar base of the proximal phalanx do not produce greater rotation during opposition, and these insertions may slip about the metacarpophalangeal (MP) joint, causing unwanted extension or flexion of the proximal phalanx. Insertions into the extensor mechanism or the MP joint capsule increase thumb extension and stability, but they are recommended only for patients with combined nerve palsies in which a single insertion may result in stretching out of the thumb ulnar collateral ligament (1,2,20).

TENDON TRANSFERS FOR INTRINSIC PALSY

FLEXOR DIGITORUM SUPERFICIALIS (4,12,22,26)

- Incise the proximal flexor sheath, and divide the FDS (Fig. 56.1, Fig. 56.2, Fig. 56.3, Fig. 56.4, Fig. 56.5, Fig. 56.6, and Fig. 56.7). Be careful not to divide the FDS too distally, or hyperextension of the proximal interphalangeal (PIP) joint may occur.

Figure 56.1. The three incisions required for an opposition transfer using the ring finger superficialis are shown.

Figure 56.2. The flexor carpi ulnaris tendon stump has been created, the superficialis passed beneath the intact portion of the wrist flexor, and a subcutaneous pathway produced with the tendon passer.

Figure 56.3. The superficialis has been transferred and the tendon loop formed.
Figure 56.4. The superficialis has been passed through the substance of the thenar intrinsic tendon.

Figure 56.5. Lack of active opposition as a result of median nerve palsy.

Figure 56.6. Same patient is shown as in Figure 56.5 after superficialis transfer (palmar abduction).

Figure 56.7. The same patient is shown (opposition).

- At a point 2 cm proximal to the wrist, expose and withdraw the FDS.
- Transect the radial half of the FCU 2 cm from its insertion, leaving a distally based stump that is sutured to itself, forming a loop.
- Pass the FDS dorsal to the FCU, then through the loop of the FCU.
- Expose the intrinsic tendon on the radial side of the thumb metacarpal-phalangeal (MP) joint.
- Pass a large clamp from the thumb incision to retrieve the FDS.
- Place the thumb in opposition to the ring finger.
- Interweave the FDS into the intrinsic at half the potential excursion of the transfer.

EXTENSOR INDICIS PROPRIOUS (27)

- Expose and divide the extensor indicis proprius (EIP) with a thin strip of radial MP extensor hood. Suture the defect in the hood.
- Withdraw the EIP just proximal to the retinaculum.
- Place a large clamp into a 2 cm incision at the distal ulnar aspect of wrist.
- Retrieve the EIP and continue as for a FDS transfer.

If the MP hood is not closed, a loss of extension is possible. This transfer is not as powerful as a FDS transfer, but it has the advantage that it does not weaken the patient's grip (8).

EXTENSOR DIGITI QUINTI (23,25)

- Make sure that before the extensor digiti quinti (EDQ) is divided that there is a ring—to—small communis slip (Fig. 56.8).
Figure 56.8. The EDQ has been divided, and a clamp has been used to form a subcutaneous passage between the distal forearm and the thenar eminence.

- Divide the EDQ at the small finger MP and withdraw it via an additional incision proximal to the retinaculum.
- Complete the procedure as for an EIP transfer.

EXTENSOR CARPI ULNARIS (19)

- Expose the distal ECU and divide it at its insertion (Fig. 56.9, Fig. 56.10, Fig. 56.11 and Fig. 56.12).

Figure 56.9. The insertion of the ECU has been transsected.

Figure 56.10. The extensor pollicis brevis has been divided at its musculotendinous junction and its insertion exposed.

Figure 56.11. The transposed extensor pollicis brevis, without traction.

Figure 56.12. The extensor pollicis brevis, with traction.

- Divide the extensor pollicis brevis at the musculotendinous juncture and bring it out at the thumb MP.
- Transfer the EPB subcutaneously across the palm and suture it into the ECU.

Insufficient ECU excursion and less-than-optimal insertion of the EPB precludes full recovery of opposition.

PALMARIS LONGUS (5,16)

- Through a palmar incision, dissect the PL and elongate it with palmar fascia.
Pass the tendon subcutaneously and suture it into the APB tendon.

Although it is a useful adjunct to carpal tunnel release, PL transfer is a weak transfer that provides good abduction but poor pronation (Fig. 56.13).

**Figure 56.13.** The palmeris longus has been exposed and prolonged with a strip of palmar fascia.

**ABDUCTOR DIGITI QUINTI (HUBER TRANSFER)**

- Expose the entire muscle and tendon to the ADQ.
- Identify the ulnar artery or nerve and neurovascular pedicle to the ADQ.
- Divide the insertion and attachments to the FCU and pisiform.
- Turn the muscle like the page of a book, and pass it through a generous tunnel toward the thumb. Suture it into the abductor pollicis brevis (APB).

This difficult operation will be ineffective if the neurovascular pedicle is damaged or kinked (Fig. 56.14, Fig. 56.15, and Fig. 56.16).

**Figure 56.14.** The ADQ muscle has been exposed and the ulnar nerve and artery carefully dissected and retracted with vessel loops.

**Figure 56.15.** The origin and insertion of the ADQ have been divided and the conjoined thenar intrinsic tendon exposed.

**Figure 56.16.** Active palmar abduction regained after ADQ transfer.

**FLEXOR POLLICIS LONGUS**

- Reroute the FPL after osteotomy of the proximal phalanx or before interphalangeal joint fusion.

Although this procedure avoids division of the FPL, palmar abduction rather than true opposition is obtained. Better results occur with FPL transfer using the FDS technique.

**TENDON TRANSFERS FOR FLEXOR POLLICIS LONGUS PALSY**

**FLEXOR DIGITORUM SUPERFICIALIS**

- Expose the FPL and the FDS through a midvolar forearm incision.
Divide the FDS and interweave it into the FPL so that the interphalangeal joint of the thumb rests in 30° of flexion. Usually with high median palsy, the FDS is weakened and not available for transfer. Interphalangeal fusion is more reliable.

BRACHIORADIALIS
- Release the extensive insertion and fully mobilize the brachioradialis (BR) well up the forearm. The BR does not have equivalent excursion to the FPL and requires a large incision to release the insertion fully.
- Attach the BR tendon to the FPL with an interweave technique.

TENDON TRANSFERS FOR FLEXOR PROFUNDUS PALSY

FLEXOR PROFUNDUS TRANSFERS
- Expose all of the FDP tendons in the distal forearm.
- Suture side to side the weakened tendons to the active ones.

This procedure will increase distal joint mobility, but not strength. If the FDS are functioning, distal interphalangeal (DIP) joint fusions are preferable.

EXTENSOR CARPI RADIALIS BREVIS
- Divide the extensor carpi radialis brevis (ECRB) at the 3rd metacarpal.
- Pass it through a large window in the interosseous membrane.
- Interweave into the paralyzed FDP.

A wrist extensor has significantly less excursion than the profundi, so only incomplete digital mobility is achievable.

POSTOPERATIVE REHABILITATION

Tendon transfers require 4 weeks of constant postoperative immobilization. If the purpose of the surgery is to regain digital flexion, place the wrist in 30° of palmar flexion, the MP joint in maximal flexion, and the interphalangeal joint flexed approximately 20°. Protect opposition transfers for 1 month by immobilizing the thumb in maximal palmar abduction with the wrist in a neutral position unless an extensor was transferred. Extensor transfer requires mild wrist flexion to relieve sulature line tension.

After 4 weeks, the splint can be removed and the reeducation process begun. The patient should exercise for 5 to 10 minutes every 1 to 2 hours. More prolonged activity may fatigue the transfer. Encourage active motion to activate the transfer and permit passive motion, which does not stress the tendon juncture. Gentle resistance, such as squeezing a wet sponge or crumpling a newspaper, is permitted at postoperative week 6. Muscle reeducation can be encouraged by having the patient activate both hands simultaneously. Muscle massage and biofeedback may be helpful. If after 6 weeks adequate digital motion has not been achieved, splint the MP joint in extension in order to generate more power at the interphalangeal joint.

Subsequent to opposition transfer, some patients continue to flex rather than abduct the thumb. Inhibit this tendency by splinting the interphalangeal joint in extension. Eight weeks after tendon transfer surgery, encourage the strengthening process using putty and free weights. At this time, passive stretching of the transfer can be prescribed if the resting tension of the transfer is too high or if contractions are developing.

PITFALLS AND COMPLICATIONS

Poor functional recovery after tendon transfer usually occurs because of uncorrected preoperative joint stiffness, errors in surgical technique, or inability of the muscle to be reeducated. If adequate mobility is caused by either excessive or inadequate tension of the transfer, revision surgery can be done to alter the tension.

Occasionally, disruption of the transfer occurs, which is usually the consequence of excessive loading in the first few months after surgery. If you recognize this condition, perform an expeditious repair.

Deformity of the PIP joint can occur subsequent to transfer of the FDS. If this tendon is divided close to its insertion and the volar plate is or becomes lax, a swan-neck deformity can ensue. Minimize this problem by dividing the tendon in the palm, thereby retaining the distal portion of the superficialis tendon. Although this technique minimizes PIP hypertension, the reverse complication, i.e., PIP joint flexion contracture, can occur if the patient was not instructed to extend the joint fully subsequent to transfer injury.

If the PIP joint begins to hyperextend soon after FDS is divided, use an extension block splint. Conversely, if the finger develops a flexion contracture, apply a dynamic extension splint. Loss of index MP joint extension and radial subluxation of the extensor digitorum communis are known complications of the extensor digiti proprius (EIP) opposition transfer. Avoid these problems by careful closure of the extensor hood. Positioning the wrist in marked flexion after a simultaneous carpal tunnel release and tendon transfer to restore opposition can result in palmar subluxation of the median nerve and flexor tendons. Subluxation can produce scar entrapment of the nerve, bow-stringing of the flexor tendons, and a wrist flexion contracture. Excessive loss of finger extension may result after transfer of the extensor carpi radialis to the digital flexors because the excursion of a wrist motor is significantly less than that of a digital flexor. Avoid this problem by making sure that at the time of transfer, the fingers can be passively extended fully with the wrist in no more than 20° of flexion.

CHAPTER 57

ULNAR NERVE PARALYSIS

Paul W. Brand and Anne Hollister

CHAPTER 57

ULNAR NERVE PARALYSIS

P. W. Brand: Department of Orthopaedics, University of Washington, Seattle, Washington, 98195.
A. Hollister: Department of Orthopaedic Surgery, LSU Medical Center, Shreveport, Louisiana, 71130.

Damage to the ulnar nerve can affect the following motor functions:

- Flexion and ulnar deviation of the wrist
- Flexion of the ring finger and little fingers
- Independent flexion at the metacarpal (MP) joints of all fingers
- Interphalangeal (IP) extension of all fingers
- Abduction-adduction of all fingers
- Adduction-flexion of the carpometacarpal joint
- Adduction-vesting of the MP joint of the thumb

FLEXION AND ULNAR DEVIATION OF THE WRIST

High ulnar nerve palsy can result in paralysis of the flexor carpi ulnaris (FCU), the strongest muscle in the forearm. The FCU is an important element in many physical actions such as swinging an ax, hammer, or club; cutting with a knife; and pounding on a desk. Paralysis results in a general sense of weakness in a variety of actions, but there is no total loss of any action, nor is there a deformity at rest.

For this reason, most surgeons do not feel justified in performing tendon transfers to balance the wrist following high ulnar nerve palsy. For some manual workers, however, the loss of this powerful muscle is a handicap. For a carpenter, who might feel disabled by an ulnar-flexor quadrant weakness at the wrist, for example, it might be practical for the surgeon to transfer the flexor carpi radialis (FCR) to the insertion of the FCU, inasmuch as the radial-flexor quadrant is unaffected in ulnar palsy.

FLEXION OF THE RING FINGER AND LITTLE FINGER

Flexion of the ring finger and little finger is severely weakened in high ulnar palsy, with loss of flexor profundus function in both fingers, in particular because the strength of the surviving median-supplied flexor digitorum superficialis (FDS) to the little finger is less than one-third the strength of the profundus. In the ring finger, the FDS is two-thirds the strength of the profundus, so that only two fifths of the flexor strength of the ring finger survives. The flexor weakness of the ring finger, however, is partially masked by the fact that the paralyzed ulnar-supplied part of the profundus moves to some extent with the median-supplied profundus to the middle finger. This cross-finger support is variable and only partial, because the actual muscle fibers are not shared but are linked by connective tissue, which allows some independence.

Some extrinsic flexor power remains in the ulnar two fingers; for this reason, no deformity is caused by paralysis of the long flexors. Because deformity is more obvious than functional disability, substitution is rarely offered for the paralyzed long flexors. If the weakness seems really disabling, the profundus tendons of the ring finger and little finger may be sutured side-to-side to the profundus of the middle finger in the forearm so that they move together. This technique does not really add strength; it merely "shares" the weakness more evenly. If one adds the tension fractions (see Chapter 54, Fig. 54.1, Fig. 54.2) of all the muscles that normally combine to flex the little finger and ring finger, including the intrinsic muscles, the total is 14.6. Of these, only 2.9—or about one fifth—survive in high ulnar palsy.

Even when the deformity of claw hand has been corrected by replacing the intrinsic muscles by transfers, the total tension fraction is commonly 1.0 to 3.0, shared between four fingers. The result is a gross weakness of ulnar-side grip, only about 25% of normal strength. Yet most forearm muscles remain unparalyzed, and the forearm and hand retain at least 70% of their total tension capability.

Even when grip strength as a whole is acceptable, a specific weakness of ulnar-side grip results in a significant disability for all actions that use the width of the hand to control radial-ulnar torque. One of the most common of these actions of the hand is the use of a hammer (Fig. 57.1). All hand movements that require a twist or turn, either in a pronation-to-supination direction or in ulnar deviation, require that the object be held in such a way as to transmit a torque, by means of a force couple. The handle of a hammer is moved by a force couple when one force (F2) pulls upward and a simultaneous force (F1) pushes downward, with a distance between them, along the handle. The hammer head is forced down while the end of the handle may move up, or the whole hammer may move, with F1 moving more than F2. This produces a torque on the hammer proportional to the magnitude of the forces multiplied by the perpendicular distance between them.

Figure 57.1. To strike with a hammer, it is necessary to produce a force couple. Two forces move in opposite directions.
As with all forms of torque, the length of the lever arm is just as important as the amount of force. In the case of a couple, twice as much total force is needed to produce the same torque if the two components are moved 50% closer together. In a medium-sized hand, the width of an effective grip is about 10 cm (Fig. 57.2). In the same hand, if only the index and middle fingers are strong, the effective width of the hand is reduced to about 5 cm (Fig. 57.3).

![Figure 57.2](Image)

**Figure 57.2.** A normal hand may be about 10 cm wide where it holds a hammer. In the force stroke, the thumb web pushes while the little and ring fingers pull. In retracting the hammer, the hypothenar mass pushes, and the index and middle fingers pull.

![Figure 57.3](Image)

**Figure 57.3.** In high ulnar palsy, the little and ring fingers may be so weak that only the middle finger can pull firmly enough to complete the couple. This is only half as wide as in a normal hand. The hammer is unstable and its action is weak. For many tasks involving torque, it is better to have strong index and little fingers, even if the middle finger is weak.

Even though such a hand may retain 50% of its power to grip an object, it will have only 25% of its power to turn, twist, or swing an object. The patient has difficulty describing the weakness, saying only, “I feel my hand is weak.” The dynamometer is not a measure of the dexterity strength of a hand, but only of squeeze power. Most manual tasks demand multidirectional torque, which requires a broad hand with strength at each of its borders.

A further problem associated with paralysis of the finger flexors is the reversal of the metacarpal arch, usually thought of as being caused by paralysis of the intrinsic muscles. The best muscles to control the arch, however, are those that cross the fifth carpometacarpal joint on the palmar side, thus serving as carpometacarpal flexors. These are the hypothenar muscles and the long flexors to the ring and little fingers. Brandsma has noted that patients with ulnar palsy who retain ulnar-supplied profundus rarely have severe arch reversal (W. Brandsma, Carville, Louisiana, personal communication, 1984).

Recognition of the importance of the loss of profundus in the ulnar-paralyzed hand should suggest rethinking the patterns of correction. An obvious method to increase ulnar-side grip strength is to use the extensor carpi radialis longus (ECRL) to reactivate the flexor profundus tendons to the ring finger and little finger. The muscle fibers of the ECRL are long enough to allow a good range of finger flexion with a little synergistic extension of the wrist. The ECRL is also strong enough to compensate for the ulnar profundus loss and helps to rebalance the wrist, which is relatively overpowered by the dorsal and radial side in high ulnar palsy.

**INDEPENDENT FLEXION AT THE METACARPAL JOINTS OF ALL FINGERS**

The most significant functional loss in ulnar nerve palsy is independent flexion at the MP joints. This loss of flexion is important because it is the basis for the deformity of claw hand. Uncontrolled extension of the MP joints results in failure of the long extensor tendons to extend the IP joints. It also changes the sequence of flexion of the fingers, making it impossible to flex the proximal segment ahead of the distal segments. Therefore, when the hand closes on an object, the force of grasp is transmitted only through the fingertips rather than through the whole palmar surface of the fingers. High localized tip pressure results, leading to inhibition of the use of strength in sensitive fingers, or to pressure sores and injuries to fingertips in insensitive fingers (Fig. 57.4 and Fig. 57.5).

![Figure 57.4](Image)

**Figure 57.4.** A: Normal hand grasping a cylinder. The area of skin contact is shaded. B: Claw hand grasping a cylinder. The area of contact is limited to the fingertips and the metacarpal heads. (From Brand PW. Clinical Mechanics of the Hand, 3rd ed. St. Louis: CV Mosby, 1999:215–216.)

![Figure 57.5](Image)

**Figure 57.5.** This patient had loss of sensation from Hansen’s disease. The little ulcers and scars are in the most characteristic position for a patient with functional
Ultrasound results in MP flexion weakness in all fingers, not just in the ring and little fingers. Clawing may occur earliest and most obviously in the ulnar-side fingers, because they lose all intrinsic muscles in ulnar palsy, whereas the index and middle fingers usually have median-supplied lumbricals. The lumbricals, however, can exert only about one tenth the tension of the combined interossei. The presence of intact lumbricals may delay the onset of clawing or make it less severe; however, when the end of the finger is pushed backward, as when pinching against the thumb, the MP joint retreats into extension and the proximal interphalangeal (PIP) joints hyperflex.

This mechanism is similar to Froment's sign in the thumb. It can be tested in a patient who has no clawing of the index and middle fingers by asking her to hold the intrinsic-plus position (MP joint flexed and IP joints extended) while the examiner pushes backward with a finger against the middle of the front of the proximal phalanx of the patient's finger. If this test causes the finger to buckle into PIP flexion, weakness of the intrinsic muscles is indicated, as is a need to rebalance the finger to compensate for present weakness and to prevent clawing later.

Operations to restore MP flexion will be considered in the next section, but first let us emphasize that we are recommending the restoration of active flexion, not just the provision of a block to limit extension of the MP joints.

The deformity of claw hand may be easily corrected simply by providing a passive block to prevent hyperextension, thus allowing the long extensors to extend the IP joints. Surgery proposed to provide a passive block includes tenodesis, capsulodesis, bone block, or even an extensive scar on the palmar side of the MP joint. The result in each case is a beautiful, straight hand.

The real problem with ulnar palsy is functional, not cosmetic, in that as the hand begins to close on an object the sequence of closure is reversed. The proximal segment should flex first, followed by the distal segments, each making contact with the object and accepting a share of the load and the pressure; in ulnar palsy, the tips flex first, and the fingers curl down into the fist, tips first. Thus the object is grasped with all the pressure on the fingertips (Fig. 57.6).

INTERPHALANGEAL EXTENSION OF ALL FINGERS

In the normal hand, the intrinsic muscles extend or help to extend the IP joints by three mechanisms:

1. Direct action of the lumbricals together with those interosseus muscles that insert into the lateral band create direct extension of the PIP and distal interphalangeal (DIP) joints. This mechanism is effective even in radial nerve palsy, which inactivates the long extensors.
2. The intrinsic muscles hold the MP joint flexed without flexing the IP joints. Thus the long extensors can be prevented from extending the MP joints, while they remain effective on the IP joints.
3. The unique action of the lumbricals pulls the profundus tendons distally (by their origins on profundus tendons), while pulling the lateral bands proximally to facilitate IP extension with MP flexion.

This third action, the weakest of the three, cannot be reproduced by tendon transfer, so we shall consider only the other two mechanisms. By bringing the tendon of any muscle across the palmar side of the intermetacarpal ligament and attaching it to the lateral band, both extension mechanisms are accomplished. Such a transfer, which flexes the MP joints and extends the IP joints, corrects both elements of the claw hand deformity (Fig. 57.6). We have found this pattern most successful.

In the normal hand, however, only part of the force of the intrinsic muscles is transferred into the lateral bands. The greater part moves directly into bone and flexes only the MP joint. Thus the forces are free to flex at the MP joint with or without IP extension. Following tendon transfer into the lateral band, with no intrinsic transfer into the proximal phalanx, the total force of the transfer for MP flexion must also provide tension for IP extension. In hypermobile fingers, this constant pull on the lateral bands may result in a degree of progressive hyperextension of the PIP joints that can become a true swan-neck deformity—most common in cases where the FDS tendon has been removed and used for transfer to the lateral band (1). The PIP joint is thus deprived of its prime flexor, which has then become an uncontrolled extensor.

Because of this complication, we have given up using the Stiles–Bunnell transfer of the superficialis tendons for claw hand correction except in cases where the PIP joints have become so stiff in flexion, even after preoperative therapy, that hyperextension is very unlikely to develop. Do not perform attachment of any transfer for intrinsic replacement to the lateral band in fingers that have hypermobile PIP joints. In such cases, and especially in those deprived of their FDS, it is better to attach the tendon transfer to the flexor tendon sheath, as suggested by Brooks (4) and Zancolli (13, 14). In such cases, the long extensors hold the IP joints in extension in the first stage of total finger flexion, although at a higher total cost of energy (because the intrinsic MP flexors must work against and overcome the MP extension moment from the extrinsic extensors).

ADDITION–ABDUCTION OF ALL FINGERS

Adduction–abduction of all fingers is a function of the intrinsic muscles supplied by the ulnar nerve. The median-supplied lumbricals are weak enough and are near enough to the adduction–abduction axis of the MP joints that they have only a small active abduction capability.

Fingers should not be provided with an effective abductor (away from the midline of the hand) unless there is an effective adductor to restore the side-by-side position of all fingers. Most tasks can be accomplished by side-by-side fingers, as long as they have independent flexion and extension. Fingers that can abduct but not adduct look strange, and the projecting fingers become caught on the edges of pockets or bags and are subject to injury in the workplace.

To control both adduction and abduction, eight separate tendons are needed, one to each side of each finger. The first editions of Bunnell's famous book on hand surgery (15) described how all superficialis tendons should be split to give the required eight tendon insertions, and instructed us to transfer both slips of any one tendon to the same side of adjacent fingers.

If on a personal note (P.W.B.), while I was working in India in 1948, the first edition of Bunnell was my "bible" and I faithfully did as instructed, and my therapists struggled without success to teach my leprosy patients how to spread and adduct their fingers after surgery. Years later, I visited Bunnell and asked if I could see his results. He confessed that he had never succeeded in getting any patient to control abduction and adduction with the split-superficialis operation that formed the frontispiece of the first edition of his book. It had just seemed a sensible pattern to use. Nevertheless, I am grateful for the book.

Unless there is an unusual need for individual control of lateral movement of fingers, we now recommend that all intrinsic replacement tendons or grafts should be
attached on the side of the finger that will pull it toward the line between the index and middle fingers. Thus, the middle, ring, and little fingers are moved radially by the insertions on their radial sides, and the index finger is moved toward the ulna by its ulnar-side insertion. The result will be that all fingers will ordinarily be held side by side. In addition, a replacement for the first dorsal interosseous muscle may be added to the radial side of the index finger, if deemed necessary (Fig. 57.7).

Figure 57.7. For correction of ulnar paralysis, a single motor may be used for the radial side of the middle, ring, and little fingers and the ulnar side of the index finger. A separate motor may be used for the radial side of the index finger if necessary. (From Brand PW. Clinical Mechanics of the Hand, 3rd ed. St. Louis: CV Mosby, 1999:291.)

There are two reasons for adding an index finger abductor. The first is to facilitate spreading of the fingers, as a piano player or typist might require. This motion does not need a strong muscle, and even the extensor indicis proprius (EIP), properly rerouted, might be adequate. The second is to stabilize the index finger against the thrust of the thumb in pinch. A normal pinch is not “square,” pulp to pulp. There is at least a 30° angle between the thumb and index finger, so the transverse vector of the thumb force that pushes the finger across the palm is perhaps half as great as the vector that pushes the finger dorsally from palmarly (Fig. 57.8A).

Figure 57.8. A: Normal pinch angle of about 30° between markers on thumbnail and fingernail. Pinch is stable by action of intrinsic muscles. B: With index finger abducted, the angle between thumbnail and fingernail is greater, making an unstable pinch. C: Desirable pinch in an ulnar palsy patient. An ulnar-side intrinsic transfer to the index finger acts like a first palmar interosseous and circumducts the index MP joint so as to oppose the thumb pulp. This results in a true square pinch that needs no other intrinsic muscle support. D: Key pinch does not demand much intrinsic muscle support of the index finger, providing it is supported by all the fingers flexed together.

It would seem necessary, therefore, to have an index finger abductor about half as strong as the flexors. The first dorsal interosseous muscle, at a tension fraction of 3.2, is about right. The index finger has no true adduction-abduction axis, however, but moves around a variable cone (2). There is also a link between abduction and rotation. Thus, a replacement for the first dorsal interosseous will twist the finger while it abducts, so that it faces more across the palm than before, providing a pinch that is less square.

The more the first dorsal interosseous pulls, the more it increases the angle between the line of thrust of the thumb and that of the index finger (Fig. 57.6B). This configuration makes the pinch more unstable, requiring support by a force vector that opposes the result of the two major flexion forces of the thumb and index finger. In effect, the first dorsal interosseous muscle, by being a rotator, increases the need for itself as an abductor.

The converse of this fact is that if no replacement is made for the first dorsal interosseous muscle, but one is provided for the first palmar interosseous on the ulnar side of the finger, the result will be to twist the finger into external rotation and diminish the angle by which the index finger meets the thumb. The result of an “ulnar-side only” attachment of an intrinsic replacement to the index finger is that the thumb and index finger meet in a true square pinch, with fingernail and thumbnail parallel and with thumb flexors opposing finger flexors squarely, so that no lateral stabilization is necessary (Fig. 57.8C).

For these reasons, routine replacement for the first dorsal interosseous is not advised, except as a device for spreading the fingers apart. For the purposes of pinch, the first palmar interosseous (we may call it “the opponens indicis”) is all that is needed.

If the patient uses key pinch a lot, rather than a tip or pulp pinch, then there is more reason for a first dorsal interosseous replacement, since it directly supports the side of the index finger against the thumb. Even in key pinch, however, this is unnecessary if the patient usually pinches against an index finger, which is supported by all four fingers flexed together (Fig. 57.8D).

In most cases of paralysis of the intrinsic muscles of the hand, therefore, it is best to use one muscle only as a replacement for the intrinsics to all four fingers, and to extend it by four strands of tendon or tendon graft. Attach the tendon to the lateral band on the radial side of the middle, ring, and little fingers, and to the ulnar-side lateral band of the index finger.

CHOICE OF MOTOR FOR INTRINSIC TRANSFERS

The total tension capability of all the intrinsic muscles to the fingers is greater than the total of the flexor profundus. Thus, it would seem that a powerful muscle would be required for each finger to replace the lost tension. In the normal hand, however, the total intrinsic tension to any finger is divided between multiple insertions, and it would lead to gross imbalance to apply that total tension to any one insertion on only one side of a finger.

Most surgeons use much less total tension, and use only one muscle, such as a single superficialis tendon, split into four strands in the proximal palm and taken to one lateral band of each finger. The ECRL (tension fraction, 3.5) is our favorite. It may be used, with a free graft split into four insertions; or two weaker muscles, such as the EIP and the extensor digiti quinti (EDQ) may be used, with two insertions each (6).

Following the experience of Fritsch (6,7), we have sometimes used the palmaris longus (PL) (average tension fraction, 1.2) with grafts to all four fingers; we have found that it does correct the claw deformity in cases that are operated on early, before bad habit patterns have developed and before the palmar plate has become grossly stretched. The advantage of using the PL is that the operation may be done immediately after any ulnar nerve injury in the arm or upper forearm with the confidence that nothing has been lost, even if the intrinsic muscles recover later. This is an important advantage. Early surgery prevents the development of any deformity and leaves the option of adding a stronger muscle a year or two later, if the intrinsic muscles have not recovered and if the patient needs more grasp strength.

Zancolli (13,14) popularized a technique for moving the FDS tendons from their insertion on the middle phalanx to be attached to the flexor sheath in front of the MP joint. This “lasso” operation deprives the PIP joint of its prime flexor, but it leaves the muscle as a flexor of the MP joint. This is similar to the old Stiles operation, except that the insertion is central rather than to the lateral band (12). It is also rather simple to perform, but it may create long-term problems because the PIP joint is deprived
of a flexor except by contraction of the profundus, which is more effective at the DIP joint than at the PIP joint when working against resistance (2).

The same problem results in hyperflexion of the IP joint of the thumb in Froment's sign of ulnar palsy. In the fingers, the deformity develops slowly, but finally a hyperflexed DIP joint and a hyperextended PIP joint give rise to a swan-neck deformity. The lasso operation should be reserved for the late correction of clawed fingers that have become somewhat stiff in PIP joint flexion and therefore are unlikely to become fully corrected or hyperextended.

If a lasso operation has been performed (or a Stiles–Bunnell with transfer of superficialis tendons) and the DIP joints begin to show signs of persistent flexion, it is best to intervene early with a profundus tenodesis in the middle segment with the DIP joint just short of full extension. This technique transfers profundus power from DIP joints to PIP joints and provides a more satisfactory hand, even though active flexion of the DIP joints is lost (Fig. 57.9).

STRENGTH

Various muscles have been used with success for the correction of claw hand. It is easy to misunderstand the relative usefulness of each. Since surgeons and patients are so often concerned about deformity, procedures such as the Stiles–Bunnell (12) or the lasso of Zancolli (13) are often preferred because they are "strong" correctors of deformity. They do not really add strength to the fingers, however; they take strength away from PIP flexion and move it proximally to the MP joint.

Even a weak tendon transfer such as a PL from the wrist area is relatively stronger because it adds something to the fingers from an area that is unaffected by paralysis. From the point of view of added strength, Fowler's operation using the EIP and EDQ (tension fractions 1 plus 1 equal 2) is better, and the transfer of the ECRL or the extensor carpi radialis brevis (ECRB) (tension, 3.5 or 4.2) may be the best of all (11).

In the immediate postoperative phase, both surgeon and patient appreciate quick correction of deformity. It is in the long term, however, that the patient realizes the extent of the weakness and how the removal of a strong flexor from the PIP joint is a high price to pay for the flexion of the MP joint.

PATHWAY OF TRANSFERRED TENDONS

An advantage of the Stiles–Bunnell (5,12), Fowler (11), and lasso (13) operations is that the tendons are all long enough for direct transfer without grafts. If a single superficialis tendon is to be used for four fingers (modified Stiles–Bunnell), the tendon should be withdrawn in the proximal palm, just distal to the roof of the carpal tunnel, so that each tendon strand can be passed to its own finger without having to cross a palmar septum (2).

FOWLER'S OR MODIFIED FOWLER'S OPERATION

- Divide the tendons of the EIP or EDQ over the back of the MP joints, and withdraw them back to the carpal area. Split each into two strands.
- Pick up each strand by its tip, using a curved tunneler that has been passed from the base of one side of each finger, in front of the transverse metacarpal ligament, through an intermetacarpal space, appearing in the dorsal incision to pick up its tendon and withdraw it to its point of insertion. Accomplish this tunneling without penetrating the dorsal fascia that overlies the extensor tendons. Some strands of fascia that lie on the palmar and dorsal surfaces of the interosseous muscles in each space may have to be penetrated. Most, however, may be avoided by gentle and sensitive passage of the rounded nose of the tendon tunneler; feel for weak areas or gaps in the fascia.
- It is best to pass the tendon strands to the index and middle fingers through the second intermetacarpal space, and the two strands to the ring and little fingers through the third space. The strand to the little finger crosses the neck of the fourth metacarpal on the palmar side on its way to the proximal phalanx of the little finger.
- This route to the little finger sounds complex, and there may be concern that adhesions will occur as the tendon hugs the neck of the fourth metacarpal bone. It is not difficult, however, if a curved, blunt-nosed tunneler is passed empty from the little finger and angled across until the bone of the fourth metacarpal neck is felt. Then slip the tunneler between the bone and the flexor tendons, and turn immediately dorsally, through the intermetacarpal space, and then proximally to the rerouting incision over the wrist where the tendon is grasped and pulled through, back to the finger.

This pathway is less likely to result in two deformities that are common in the original Fowler's operation: reversal of the metacarpal arch and continued abduction of the little finger. If adhesions form in this modification of Fowler's operation, they occur at the point of perforation of the fascia in the interosseous space, not to the bone.

ECRL OR PL TRANSFER

For most cases that need transfer for intrinsic palsy, we prefer to use a wrist-moving muscle, such as the ECRL or the PL, extended by grafts. The fingers are approached through the carpal tunnel and along the lumbrical canals. The junction between the tendon and the grafts is made in the distal forearm, proximal to the carpal tunnel.

- Divide the ECRL tendon near its insertion and withdraw it proximally through a transverse incision. Make a second transverse incision in the anterior distal forearm about 5 cm proximal to the wrist crease, centered over the PL.
- Pass a blunt-nosed tunneler into this incision and direct it proximally beneath the tendons of PL, FCR, and brachioradialis (BR) to appear in the proximal incision over the ECRL.
- Grasp the end of the tendon and pull it through to the distal incision, where it is joined to a four-tailed graft, either of a plantaris tendon (folded in two and each limb split in two) or to a 12 mm wide strip of fascia lata, taken from the lateral thigh and split into four tails in its distal two thirds.
- Make a rerouting incision in the center of the proximal palm, just distal to the carpal tunnel. Pass a curved tunneler through a split in the palmar fascia, deep and proximally, until the bony-ligamentous floor of the carpal tunnel is felt, deep to all tendons and sheaths. Then direct the tunneler toward the distal forearm incision, between the FCU and the flexor tendons to the fingers, until it appears in the wound.
- Grasp all the ends of the four tendon strands with the tunneler and pull them into the palm. From here, pull each strand separately to each finger, and attach it to the lateral band (Fig. 57.6), or else to the flexor sheath in front of the MP joint, as suggested by Brooks (1).
- If the ECRB is to be used as a motor, divide it at its insertion and withdraw it 10 cm up the forearm, pulling a black thread behind it to identify its sheath. Remove the distal 1–2 cm if required and attach a four-tailed graft to the stump.
- Grasp the four graft tails with tunneling forceps and pull them back through the sheath, following the thread marker. From there, tunnel each graft through an interosseous space to its own finger. Grafts to the index and middle fingers pass through the second intermetacarpal space, and grafts to the ring and little fingers pass through the third space, using the same technique described for the modified Fowler's operation.
- Suture all grafts into position with the wrist flexed (for tendons that pass through the carpal tunnel) or extended (for the ECRB and the dorsal route). The MP joints are flexed and the IP joints extended (Fig. 57.6). In this position, tendon tension should be minimal or even zero.

REVERSAL OF THE METACARPAL ARCH

Figure 57.9. Profundus tenodesis in the middle segment. A: The profundus tendon is split, and half divided distally. The proximal end of the middle phalanx has a 2 mm drill hole in the anterior cortex and two 1 mm holes in the dorsal cortex. B: The cut end of the profundus slip is drawn into bone, leaving half of the profundus in continuity.

In the postoperative splint, position the wrist straight and the fingers in full MP flexion and IP extension.
A real disadvantage of Fowler’s operation and of the use of the ECRB as a motor is that both the tendon or the tendon grafts cross the carpometacarpal joints on the dorsal side. The result is an increase of extensor torque on these joints for the ring and little fingers, where there is already severe loss of flexor torque due to high ulnar paralysis.

The result is often a constant extensor posture at these joints, especially in the fifth ray, producing a marked reversal of the carpometacarpal arch. This is one more reason we prefer to route transfers for intrinsic replacement across the palmar side of the hand, where, in addition to their effect on the fingers, they can help stabilize the mobile metacarpals and may even make it possible to cup the palm.

**THE THUMB IN ULNAR NERVE PALSY**

Ulnar palsy results in thumb weakness in pinch and grip and usually results in deformities with hyperextension of the metacarpophalangeal (MCP) joint (Jeanne’s sign) and hyperflexion of the IP joint (Froment’s sign). These deformities result from loss of the intrinsic muscles, which are strong MCP and carpometacarpal (CMC) flexors (Fig. 57.10). The basic imbalance producing these deformities is loss of flexion power at the proximal and middle joints in the chain. There is also a loss of adduction power at the CMC and MCP joints.

**Figure 57.10.** The mechanics of the thumb in ulnar palsy. The thumb is comprised of four bones linked by three joints. Each joint moves about one or more axes of rotation. The carpometacarpal joint has two axes, a flexion–extension axis in the trapezium and an abduction–adduction axis in the metacarpal. The metacarpophalangeal joint has two axes of rotation, a flexion–extension (FE) axis in the metacarpal head and an abduction–adduction (AA) axis in the proximal phalanx. The interphalangeal joint has one axis in the distal proximal phalanx. The muscles of the thumb and the external loads act across these axes, and the balance of the thumb depends on the balance of the torques about all of the axes of rotation of the thumb. The force the muscles can generate is determined by their cross-sectional area. The mechanical advantage of the muscles is determined by their distances from, and directions of pull relative to, the axes. Cross sections of each thumb joint showing the bones, muscles, and axes of rotation are a good way to conceptualize the actions of the muscles on each axis. We can see that the FPL crosses the CMC joint palmar to the FE axis and just ulnar to the AA axis. It is a flexor and an adductor, but it has a small mechanical advantage at either axis. At the MCP joint, it lies palmar to the FE axis, and the AA axis passes through the tendon. The FPL has a good mechanical advantage for flexion of the MCP joint, but it does not have any effect on AA motions or torques since the axis passes through it. It is a flexor of the IP joint. In these cross sections, the ulnar-innervated muscles are stippled and the median and radial innervated muscles are shaded or black to illustrate the effect of ulnar palsy on the thumb mechanism. The deficit is the paralysis of the first dorsal interosseous, adductor pollicis, and flexor pollicis brevis. This leads to loss of flexor torques at the MCP and CMC joints, loss of adductor torques at the CMC and MCP joints, and weakness of IP extension. (From Brand PW, Hollister AM. Clinical Mechanics of the Hand, 2nd ed. Chicago: Mosby, 1982:25.)

There are three joints at which the thumb may be flexed: the CMC, MCP, and IP joints. The moment arms of the flexor pollicis longus (FPL) at the IP and the MCP joints are 0.75 and 1.0, respectively (Fig. 57.11). For equilibrium at the IP joint, a 2 kg load on the thumb pulp may require 5.33 kg of tension in the FPL tendon. At the MCP joint, the added moments of the adductor pollicis (AP) and the flexor pollicis brevis (FPB) maintain equilibrium. For equilibrium at the MCP joint, a 2 kg load on the thumb pulp needs a 12.0 kg tension in the FPL tendon if other muscles are paralyzed. The 12.0 kg tension that is needed to stabilize the MCP joint is much too great at the IP joint. The latter goes into sharp flexion. Once the IP joint goes into flexion, the moment arm of the load is shortened and may even run through the axis. This is the mechanics of Froment’s sign for ulnar palsy.

The shortage of flexor power at the MCP joint allows the external load to push it to the limits of MCP extension. This is the mechanics of Jeanne’s sign.

**Figure 57.11.** The mechanics of Froment’s sign. The ulnar-palsied thumb will collapse with IP joint hyperflexion (Froment’s sign) and MCP hyperextension when lateral pinch is attempted. The loss of flexor torque at the MCP joint is particularly pronounced since the short flexor and adductor have the largest tension fractions and mechanical advantages for flexion of the MCP joint.

The balance of torques about each joint of the thumb is dependent on the magnitude of the force and its distance from the axis of rotation (A). We can see that both the external load and the tendons act across multiple joints simultaneously. The moment arms for the FPL increase only slightly as one moves from the IP (0.75 cm) to the MCP joint (1.0 cm), but the moment arm for the external load applied at the tip increase from 2 cm at the IP joint to 6 cm at the MCP joint (B,C). The flexor moments needed to stabilize the MCP joints are three times greater than those needed to stabilize the IP joints. If the FPL is the only flexor for the two joints, there will be an excessive flexor torque at the IP joint and insufficient flexor torque at the MCP joint, resulting in hyperflexion of the IP joint and hyperextension of the MCP joint (D). The imbalance can be treated by fusion of the MCP joint, by tendon transfers to increase the flexion torque at the MCP joint, or by a combination of these procedures.

The thumb imbalance for a patient with ulnar palsy can be analyzed by considering the mechanics of the thumb joints individually and as a chain. Any muscle or tendon transfer acts on the axes of rotation of the joints of the thumb (Fig. 57.11) with the muscles crossing them, showing ulnar palsy. The CMC and the MCP joints have two axes of rotation each, one for flexion–extension (FE) movements and one for abduction–adduction (AA) movements (B).

In each joint, the axis for AA movements is not perpendicular to the FE axis or the bones. As a result, the path of the bones when they move is cone shaped, producing combined AA and pronation and supination movements. The IP joint has only one axis. The effects of a generic ulnar nerve palsy on the joints of the thumb can be seen in Fig. 57.10. In this specific case, there is loss of flexion and adduction at the proximal thumb joints.

There is a great deal of variation in the pattern of innervation of the short flexor and adductor muscles of the thumb. Sometimes, the median nerve supplies enough of the short flexor muscles so that ulnar palsy does not leave much deficit. In other cases, the FPL is the only thumb flexor that survives ulnar palsy. More commonly, enough of the short flexor is paralyzed to produce weakness in flexion of the proximal joints. In the latter two instances, any attempt at firm pinch results in flexion of the IP joint and extension of the MP joint. This functional test may be used to determine the need for tendon transfer. If the patient can pinch strongly without IP flexion, there is probably no need for a transfer.
FLEXOR DIGITORUM SUPERFICIALIS TRANSFER

- If a transfer is needed, the best tendon to use is the FDS of the middle finger. Divide it in the middle of the proximal segment of the finger and withdraw it into the palm through an incision parallel to, and just to the ulnar side of, the thenar crease, just distal to the midpalm. The palmar fascia must be split (not cut), leaving a significant strand to the radial side of the split.

- In the middle segment of the thumb, through an incision on its dorsoradial aspect, expose the edge of the dorsal expansion. Insert tendon-tunneling forceps halfway between the MP and IP joints and direct them subcutaneously to the palmar incision. The nose of the forceps must appear in the palmar incision superficial to the palmar fascia. Thus, when the tendon is pulled into the thumb, the radial strand of palmar fascia serves as a pulley, preventing the tendon from losing its angle of approach to the thumb (Fig. 57.12).

**Figure 57.12.** The flexor digitorum superficialis tendon is divided through the finger incision and withdrawn in the palmar incision. The tunneling forceps picks it up there and takes it to the thumb. Note that in the palmar incision (A), the tunneling forceps lies superficial to the palmar fascia. The tendon comes from deep to the fascia but turns around the fascia edge and uses that edge as a pulley. (B) Insertion points of the transferred tendon.

Of the thumb’s three joints, the CMC-1 and the MCP-2 joints both have two axes of rotation. The IP-2 joint has one axis or hinge. None of the hinges are perpendicular to the bones or to one another, so there are conjunct rotations with flexion-extension at all of the joints and with abduction-adduction at the CMC and MCP joints. The mechanical advantage of the muscles is determined by their distance from, and angle of pull relative to, the axes of rotation. For instance, the FPL is a flexor and adductor of the CMC joint, and a pure flexor of the MCP and IP joints (3).

Ulnar palsy produces paralysis of the first dorsal interosseus, the adductor, and a variable portion of the short flexor. This results in a loss of power for CMC and MCP flexion and adduction.

The tendon transfer may be passed ulnar to the CMC joint and attached to the extensor pollicis longus (EPL) tendon while the IP joint is fully extended. Alternatively, half the tendon transfer may be attached to the EPL and the other half closer to the MP joint, to the tendon of attachment of the abductor pollicis brevis. This double insertion (or yoke) (Fig. 57.12B) serves as a check to prevent excessive MP flexion and abduction.

If the paralysis involves most of the short flexors or if the MCP joint is hypermobile, the double insertion should be used or it may be better to fuse the MCP joint just short of extension and with some medial rotation of the phalanx on the metacarpal. The transfer will still act as a flexor and adductor of the CMC joint, allowing good lateral and tip pinch.

In those cases with extensive paralysis of the short flexors in which only the FPL is left for CMC and MCP flexion, the transfer may not be able to add sufficient flexor force to the CMC joint to prevent IP joint hyperflexion, even when the MCP joint has been fused. In these cases, tenodesis of the IP joint with suture of the FPL to the A1 pulley will give a stable IP joint in a useful position as well as preserving the FPL as a CMC flexor and adductor.

- Immobilize the hand with the IP joint extended, the MP joint slightly flexed, and the thumb in a pinching position. The middle (or donor) finger should be splinted in IP extension to discourage proximal attachment of the stump of the superficialis tendon.

**FDS TRANSFER (TECHNIQUE OF SOZEN)**

If a transfer is needed, the best tendon to use is the FDS of the middle finger. We always regret having to deprive any finger of its superficialis tendon, for reasons already discussed. Dr. Selcuc Sozen (11a) has demonstrated a way to avoid the development of a swan-neck deformity in a finger after removal of its superficialis tendon.

- Divide the tendon only halfway through, just proximal to the PIP joint, and then split it back to the level of the A1 pulley, at which level the other half of the tendon is divided. Now attach the half-thickness tendon that remains in the finger to the A1 pulley at a tension just enough to hold the PIP joint short of full extension. This tenodesis prevents any hyperextension of the PIP joint and thus of any gross deformity (3).

- Now withdraw the main tendon proximally through a longitudinal incision parallel to and just to the ulnar side of the thenar crease, just distal to the midpalm. Split the palmar fascia (do not cut it), leaving a good strand of palmar fascia radial to the split.

- Using an incision on the dorsoradial aspect of the middle segment of the thumb, expose the edge of the dorsal expansion. Insert the tendon-tunneling forceps halfway between the MP and IP joints and direct them subcutaneously to the palmar incision. The nose of the forceps must appear in the palmar incision superficial to the palmar fascia. Thus, when the tendon is pulled into the thumb, the radial strand of palmar fascia serves as a pulley, preventing the tendon from losing its angle of approach to the thumb (Fig. 57.10).

The tendon transfer may be attached to the EPL tendon while the IP joint is fully extended. Alternatively, half the tendon transfer may be attached to the EPL and the other half closer to the MP joint, to the tendon of attachment of the abductor pollicis brevis. This double insertion (or yoke) serves as a check to prevent excessive MP flexion.

- Immobilize the hand with the IP joint extended, the MP joint flexed, and the thumb in a pinching position. Splint the middle (or donor) finger just short of IP extension.

**POSTOPERATIVE CARE**

In the early postoperative reeducation phase of all these operations, exercise only one of the two joints in each digit. Apply cylindrical plaster casts to the IP joints (finger and thumb) in the corrected position, while encouraging the MP joints to move. After a few days, free up the IP joints, and prevent the MP joints from extending with a knuckle-bender splint.

Only when reeducation is proceeding well should both MP and IP joints be released at the same time. Even then, if there is a tendency to MP hyperextension or clawing, reimpose the alternating restrictions. In the thumb, the MP joint is difficult to immobilize, and IP extension may be continued longer if needed.

TENDON TRANSFERS IN COMBINED NERVE PALSIES OF THE FOREARM AND HAND

George E. Omer, Jr. and William F. Blair

CHAPTER 58

PRINCIPLES

Combined nerve palsies in the forearm and hand result in severe functional loss. Multiple nerve palsies usually result from extensive trauma. There may be skeletal instability with loss of normal motion. Circulation is usually impaired, and the result is ischemic pain and increased fibrosis. Muscle–tendon units are often lacerated and sometimes avulsed; consequently, neuromotor function is impaired, and the resulting fibrotic infiltration complicates normal muscle function.

Combined nerve palsies impose not only complex muscle weakness and diminished sensibility but also poor proprioception on the forearm and hand, with a loss of position sense and other normal feedback mechanisms. As joints stiffen and muscles atrophy, maintaining a mobile extremity without deformity or contracture demands persistent rehabilitation and meticulous splinting. The most important aspect of a rehabilitation program is the patient's acceptance of the responsibility and initiative for recovery. Reconstructive surgical procedures should not be undertaken until appropriate joint motion returns and skeletal alignment is stable.

Abnormal patterns of motor activity enhance the distortion of sensibility that accompanies a peripheral nerve deficit. Sensibility loss is more profound in combined nerve palsies, and motor return rarely passes two major joints distal to the injury. Make nerve repairs as soon as clinically appropriate, but delay surgical reconstruction to restore sensibility until all indicated tendon transfers have been performed and the patient has supple tissues with an established range of motion. Precise sensibility first requires precise motion, which may be obtained through surgical reconstruction and focused rehabilitation. The motion expected after tendon transfer cannot exceed the passive motion present preoperatively.

The preoperative action of the selected motor muscle should be synergistic with the anticipated postoperative action, or at least retrainable by conscious control. Electromyographic studies indicate that a new activity pattern can be developed to correspond with a new mechanical function, but the old activity pattern is not lost. Furthermore, the longer the surgeon waits for clinical nerve recovery, the more difficult it is to prevent gradual deformity.

Muscles with only temporary loss of function, such as those with neurapraxic lesions, may not regain normal strength for elective transfer procedures. Previously repaired tendons may be used for transfer only under optimal conditions. Reconstruction for combined nerve palsies is made more difficult by the smaller number of motor tendons that are available to stabilize residual function, or to provide additional function while awaiting potential nerve recovery following neurorrhaphy. It is usually inappropriate, therefore, to use intact muscle–tendon units as internal splints to enhance patterns of motion in combined nerve palsies. Use as few transfers as necessary. The objective of reconstructive surgery in the extremity with combined nerve injuries is limited. Strive for a balanced, functional hand, because tendon transfers redistribute existing assets rather than create new ones. The motor muscle for transfer is selected on the basis of its current clinical function.

Tendon transfers in combined nerve palsies are more complicated than those in isolated nerve palsy for a number of reasons: Extremity injuries are often complex; the patient has poor proprioception and distorted sensibility; fewer muscles are available for transfer and the ones that are available for potential transfer are weak. In addition, combined palsies require multiple operations, and longer follow-up time is required to make valid outcome-based decisions regarding tissue or tendon transfer than in isolated palsies. (Principles for tendon transfers are presented in Chapter 54.)

PATIENT EVALUATION

Evaluate the involved extremity for the level and extent of injury. Return of good muscle power across two joints distal to the nerve injury is rare. Ongoing assessment requires multiple quantitative tests that are repeated at regular intervals of 3 to 4 weeks. They include the following:

- A voluntary muscle test with recorded range of motion
- A test for light-touch two-point discrimination distance over autonomous zones for pertinent peripheral nerves
- A wrinkle test for sudomotor function
- Gross grip and finger-pinch strength tests
- Timed pick-up test for median or ulnar nerve lesions

In high (proximal) nerve palsy, the motor function potential is better than the sensibility potential.

Age and intelligence are pertinent because the patient must have developed the cerebral imprint for the proposed neuromuscular function to be reconstructed, and he must comprehend what is to be done and accept the postoperative discipline for rehabilitation. If the patient is an adult, it is relevant to determine whether he desires an increase in functional performance or only cosmetic improvement.

Combined nerve palsies, almost always combinations of either high or low injuries, can present at mixed levels, as in, for example, a low ulnar and high radial palsy. A combined nerve palsy that presents at mixed levels requires a systematic but individualized approach. These unusual combinations are not discussed in this chapter. Surgeons reconstructing extremities with multiple nerve injuries should be experienced enough to select the appropriate procedures for each individual case.

PREOPERATIVE MANAGEMENT

Immovilize the extremity in an appropriate position to maintain the desired result. After either median or ulnar palsy, the thumb–index web must be maintained to prevent thumb adduction and supination contracture. Wrist extension is a priority in radial palsy. Maintaining a mobile extremity without deforming contracture demands a vigorous rehabilitation program. Use progressive static splints or dynamic splints when full passive range of motion is not present. As stated, the functional range of motion achievable after tendon transfer depends on passive movement present before surgery.

Do elective tendon transfers only when tissue homeostasis and equilibrium are present. Chronic wounds are contraindications to elective surgery. Soft tissues should be free of scar contracture. The timing of tendon transfers varies with the level of the nerve injuries, as well as with the severity of the extremity injury.
GENERAL

- Position the patient supine with the involved extremity on an arm table.
- Using tourniquet control, place the incision so that the tendon junctures are beneath skin flaps and away from subcutaneous scars. Make the incisions transverse to the subcutaneous path of the transferred tendon. The subcutaneous pathway must glide with the transferred tendon.
- Mobilize the motor muscle to protect its neurovascular bundle, which usually enters the proximal third of the muscle. The selected muscle–tendon unit should have amplitude adequate for the anticipated motion (2). Reevaluate the texture, vascularity, and excursion of the selected muscle under direct vision at the operating table (23).
- Do not cross bare bone with the transferred tendon. Muscle–tendon units that must move through fascial planes, such as an interosseous membrane, must have as large an opening in the fascia as practical. Place the muscle in the fascial window, as the exterior muscle fibers will adhere to the edges of the window while the interior muscle fibers will retain motion. If the tendon is placed in the fascial window, it will bind fast and motion will be lost (17). The motor muscle selected must be strong enough for its new task, because it will have to pull itself free of the healing fibrosis after surgery and will usually lose one grade of strength on Lovett’s clinical scale (17).
- Select an appropriate moment arm for the direction of muscle–tendon action (6). Most muscles are parallel to bone, and the angle of approach between the transferred tendon and its insertion should be small. The greater the angle of approach that the tendon takes to its insertion point, the greater the force the muscle can exert, but the result is a “bowstring.” When a pulley is required to increase the approach angle to more than 45°, a loss of force secondary to friction occurs. Eventually, a bowstring tendon will shift to a straight line and then become too slack for effective action. The more distal to the joint’s axis of motion the transfer is anchored, the more the force the muscle can exert on the joint, but also the more the excursion is required of the tendon to provide a normal range of motion in the joint. If the insertion of a transferred tendon is split, the motor will act primarily on the slip under greater tension.
- A tendon transfer is more effective when it crosses only one joint. If the tendon bowstrings across a proximal joint, its mechanical advantage at that joint will be so great that it may force that joint into unwanted movement or use up all its amplitude so that it cannot move the distal joint. An example is the transfer of the brachioradialis (BR) into the flexor pollicis longus (FPL): When the elbow and wrist are extended, the patient can hold an object tightly, but when the elbow is fully flexed, the muscle–tendon power is dissipated at the elbow, and the patient drops the object. A second example is an unstable bony nonunion where tendon transfers fail because the telescoping skeleton prevents the development of adequate amplitude for functional power.
- Use synthetic sutures for tendon fixation to minimize tissue reaction. The suture can be relatively large, such as 2-0 for forearm transfers. Some tendon ischemia is prevented by inserting the suture through the center of the tendon and then circling only half the tendon; when suturing along the length of the tendon, protect circulation further by alternating these half-tendon circles from side to side. Avoid “lacing” a transferred tendon into a group of paralyzed muscle–tendon units; lacing creates bulk, with twist and scar, and increases friction. Select a precise insertion point, and at that point, suture a short length of the mobile paralyzed tendons and the transferred tendons side to side to prevent a shifting moment-arm, or “whipsawing,” of the tendons. Alternatively, leave the paralyzed tendon in its bed and pass the transferred tendon across it, as can be done with the flexor carpi ulnaris (FCU) to the extensor digitorum communis (EDC). This is an oblique transfer, and there should be a double line of nonabsorbable sutures to prevent shifting of the four slips of the EDC. You can disconnect the paralyzed tendon from its fibrotic muscle and connect it directly to the transferred muscle. Complete excision of the paralyzed muscle mass, however, may bring unwelcome hemorrhage and should not be done unless the paralyzed muscle belly is causing deformity.
- Deflate the tourniquet when final tension is set for the transfer so that muscle ischemia does not contract the muscle to such a degree that the tension is set too loose. The tension of a tendon transfer is best judged when the hand is in the position it will assume when the transferred tendon contracts. For extensor transfers, resting tension should be strong enough to passively hold the extremity in functional position against gravity; at the same time, be sure that the wrist has the potential for a normal arc of flexion. Flexor tendons often cross more than one joint and should be fixed at somewhat greater than normal tension against gravity. Appropriate tension brings perception of the new muscle more readily into consciousness, because stretch reflexes and other feedback mechanisms are stimulated when opposing muscles work to restore the neutral position of the extremity (4).

COMBINED LOW (DISTAL) MEDIAN AND ULNAR PALSY

Low (distal) median–ulnar palsy is the most common combined nerve palsy. The complete loss of palmar sensibility and intrinsic motor muscles produce an almost useless claw hand (Table 58.1). Examination demonstrates a flat transverse palmar metacarpal arch, with hyperextension at the metacarpophalangeal (MP) joints and hyperflexion at the proximal interphalangeal (PIP) joints. An abucted little finger may be associated with the flat transverse metacarpal arch. The patient flexes the useless claw hand (Fig. 58.1).

<tbody>
<tr>
<td>Adduction deformity of the thumb can be prevented by immobilizing it in radiopalmar abduction. If possible, abduct the thumb on a swivel splint (C-bar), which will add rotation to abduction and prevent carpometacarpal joint contracture (27).</td>
</tr>
<tr>
<td>An inadvertent contracture can be relieved by a Z-plasty of the skin web. A local dorsal free skin flap may be necessary. If Z-plasty release is necessary, identify the superficial radial nerve and preserve it for possible sensory reconstruction.</td>
</tr>
<tr>
<td>Excise tightened fascia over the thenar intrinsic muscles. It may be necessary to strip the adductor pollicis from the third metacarpal in fixed contractures.</td>
</tr>
<tr>
<td>Additional strength in a palised power train requires a new muscle–tendon unit, and in median–ulnar palsy, additional strength must be added by radial-innervated muscle–tendon units (18,21,24-33). This is most important for the thumb.</td>
</tr>
<tr>
<td>Use the extensor carpi radialis brevis (ECRB) to enhance thumb adduction for key pinch (Fig. 58.1) (35). Through a dorsal longitudinal zigzag incision (1.5 cm) that extends from the base of the third metacarpal to the dorsal retinaculum, identify the ECRB and transect it at its insertion.</td>
</tr>
<tr>
<td>Through a longitudinal incision between the distal thirds of the third and fourth metacarpals, expose the dorsal interosseous fascia and make a small window</td>

</tbody>
</table>

**Figure 58.1.** Transfer of the extensor carpi radialis brevis extended with a free tendon graft to add power to key pinch, as well as to align and provide power to wrist extension.
between the paralyzed interosseous muscles.

- Harvest a tendon graft (palmaris longus or plantaris). Attach this graft to the distal end of the ECRB and pass it volarly between the third and fourth metacarpals into the palmar space. A short incision in the palmar crease will identify the free graft and the adductor pollicis muscle. Then tunnel the tendon graft radiallyward just superficial (volar) to the adductor pollicis and deep (dorsal) to the flexor tendons and neurovascular structures. Make a short incision over the adductor tubercle of the first metacarpal. Attach the graft to the fascia over the adductor tubercle of the first metacarpal, and to the tendon of the adductor pollicis brevis, which improves pronation.

- Test the length of the transfer graft. With the wrist in dorsiflexion, the thumb should be against the palm; with the wrist in palmar flexion, the thumb should fall into abduction.

- Postoperatively, immobilize the hand with the thumb in neutral position (not adducted) and the wrist in 40° of dorsiflexion (13). The average strength of key pinch is doubled by this operation (1,38).

- Use the extensor indicis proprius (EIP) to increase thumb abduction and opposition (Fig. 58.2) (6,22). Identify the EIP through a short dorsal longitudinal or small zigzag incision over the MP joint of the index finger. If identified, preserve the superficial radial nerve for sensory reconstruction.

**Figure 58.2.** Transfer of the extensor indicis proprius to add power for abduction of the thumb.

- Extend the EIP tendon by removing a slice of the extensor apparatus in line with the tendon, and then meticulously repair the extensor apparatus with nonabsorbable sutures.

- Make a short incision over the dorsum of the hand distal to the dorsal retinaculum in line with the EIP tendon. Free the EIP from the EDC to the index and deliver it into the forearm longitudinal incision. Free the muscle bluntly from surrounding soft tissues.

- Make a short transverse incision just distal to the pisiform. Use a tendon passer to tunnel the EIP tendon subcutaneously around the ulnar border of the forearm, using the pisiform and its ligaments as a pulley. Apply intermittent tension on the EIP tendon to assess the range of functional motion.

- Make a short incision along the radial border of the thumb MP joint, and identify the tendon of the adductor pollicis brevis (APB). Use a tendon passer to develop a subcutaneous tunnel across the palm from the pisiform to the thumb MP joint. For the patient anticipating considerable palmar pressure in daily activities, make a short incision over the thenar muscle area and create an intramuscular tunnel for the EIP tendon. The tunnel results in less bowstringing across the base of the palm (17,21,22,27). Attach the transfer to the APB tendon, the joint capsule, and the extensor pollicis longus (EPL) over the proximal phalanx of the thumb. Set the tension with the wrist in neutral flexion–extension and the thumb in maximal abduction.

- The abductor pollicis longus (APL) can provide additional second-MP-joint stability for thumb–index tip pinch (Fig. 58.3) (16,20). Identify the slips of the APL at the radial styloid of the radius through a short incision. Identify and protect the sensory branches of the radial nerve. Distal to the dorsal retinaculum, identify the extensor pollicis brevis (EPB). Then apply traction to each abductor tendon to determine which one inserts on the metacarpal. Preserve this slip and detach one of the remaining slips at its insertion. Obtain a tendon graft from the palmaris longus or plantaris. Make a short incision along the radial border of the thumb MP joint. Suture the graft to the tendon of the first dorsal interosseous muscle and pass it subcutaneously to the radial styloid and suture it to the previously selected slip of the APL tendon. Tension is proper when the index finger and the wrist are in neutral position (16). Follow-up studies indicate that tendon transfers to the first dorsal interosseous muscle tendon do not add significant strength to pinch (31).

**Figure 58.3.** Transfer of the abductor pollicis longus extended with a free tendon graft to improve stability for thumb–index tip pinch.

- Arthrodesis of the MP joint of the thumb will strengthen both key and tip pinch (13). The chevron arthrodesis is the most effective procedure for fusion of the MP and PIP joints (Fig. 58.4) (17,35). Through a dorsal longitudinal incision, widely expose the joint. Point the apex of the chevron proximally. The apex of the distal bone is perpendicular to the coronal plane of the bone. Angle the cuts of the apex of the proximal bone to the desired degree of flexion at the arthrodesis site. An appropriate position is 15° of flexion, 5° of abduction, and some pronation so that the pulp of the thumb faces the pulp of the index finger. Immobilize for approximately 8 weeks (36).

**Figure 58.4.** Arthrodesis of the metacarpophalangeal joint of the thumb utilizing a chevron-shaped mortise cut.

Patients with a persistently abducted little finger usually have a flat transverse (palmar) arch. The extensor digiti minimi (EDM) has the potential to abduct the little finger through its indirect insertion into the abductor tubercle on the proximal phalanx (Fig. 58.5) (1). The EDM, however, should not be transferred unless there is an active EDC to the little finger.
The involved hand will rarely be used for precision activities after such a severe injury as high median–ulnar palsy (Table 58.2). The most important clinical problem is the total loss of volar sensibility, while atrophy of the finger pulps will discourage both precision and power grip. If the other hand is normal, focus on improving key pinch and simple grasp.

METHODS FOR SENSATION RECONSTRUCTION

There are no standard recommendations for restoring sensation. Motor reconstruction is concentrated on the thumb, but few patients gain enough precise motor function to have good sensibility. Methods for restoration of sensation include free nerve grafts, free vascularized nerve grafts, digital nerve translocation, neurocutaneous flaps, neurovascular cutaneous island pedicles, and free neurovascular cutaneous islands. We prefer microsurgical digital nerve translocation and restoration of sensibility. Methods for restoration of sensation include free nerve grafts, free vascularized nerve grafts, digital nerve translocation, neurocutaneous flaps, neurovascular cutaneous island pedicles, and free neurovascular cutaneous islands. We prefer microsurgical digital nerve translocation and restoration of sensibility.

The most reliable method for increasing power for gross grasp is to add an extra muscle–tendon unit to the power train for flexion of the proximal phalanges. Prolong the extensor carpi radialis longus (ECRL) or the brachioradialis (BR) with palmaris longus, plantaris, or toe extensor tendon slips (29-31) (Fig. 58.6). Make an incision along the ulnar aspect of the thumb; detach the ulnar half of the EDM from the dorsal apparatus; dissect proximally to the distal edge of the extensor retinaculum (the dorsal carpal ligament). Expose the nerve to the base of the thumb–index web, if a Z-plasty of the index and long finger (A) should be added between the second and third metacarpals to achieve full power of the transfer. (This addition is not illustrated.)

The most practical procedure in median–ulnar palsy is translocation of the superficial radial nerve. Expose the superficial radial nerve through a longitudinal zigzag incision over the radial dorsal aspect of the index phalanx and dorsum of the hand. Expose the nerve to the base of the thumb–index web, if a Z-plasty of the web has not been done. Expose the ulnar proper volar digital nerve of the thumb using microsurgical techniques. A major advantage is that the nerve translocation procedure may be done at the same time as the tendon transfers for median–ulnar palsy.

An alternative procedure to a nerve translocation is to create a neurovascular cutaneous island pedicle. Raise an island of skin over the proximal digital crease to expose the deep transverse metacarpal ligament and the flexor sheath of the little finger. Pass the ulnar half of the EDM between the fourth and fifth metacarpals into the palmar wound. If the little finger is clawed as well as abducted, insert the tendon slip into the radial aspect of the A1 pulley, or a radially based flap of the flexor tendon sheath just distal to the proximal pulley.

If the little finger is not clawed, pass the tendon slip beneath the deep transverse metacarpal ligament and suture it into the phalangeal attachment of the radial collateral ligament of the MP joint of the little finger. Set the tension with the wrist in neutral flexion–extension and the MP joint in 20° of flexion. Split the ring and little fingers for 4 weeks with the wrist extended and the MP joint flexed; leave the interphalangeal joints free to prevent adhesions of the flexor tendons.

The brachioradialis (BR) also may be used to motor thumb adduction.

The most practical procedure in median–ulnar palsy is translocation of the superficial radial nerve. Expose the superficial radial nerve through a longitudinal zigzag incision over the radial dorsal aspect of the index phalanx and dorsum of the hand. Expose the nerve to the base of the thumb–index web, if a Z-plasty of the web has not been done. Expose the ulnar proper volar digital nerve of the thumb using microsurgical techniques. A major advantage is that the nerve translocation procedure may be done at the same time as the tendon transfers for median–ulnar palsy.

An alternative procedure to a nerve translocation is to create a neurovascular cutaneous island pedicle. Raise an island of skin over the distal edge of the extensor retinaculum (the dorsal carpal ligament). Make a palmar incision obliquely from the distal palmar crease to the proximal digital crease to expose the deep transverse metacarpal ligament and the flexor sheath of the little finger. Pass the ulnar half of the EDM between the fourth and fifth metacarpals into the palmar wound. If the little finger is clawed as well as abducted, insert the tendon slip into the radial aspect of the A1 pulley, or a radially based flap of the flexor tendon sheath just distal to the proximal pulley.

If the little finger is not clawed, pass the tendon slip beneath the deep transverse metacarpal ligament and suture it into the phalangeal attachment of the radial collateral ligament of the MP joint of the little finger. Set the tension with the wrist in neutral flexion–extension and the MP joint in 20° of flexion. Split the ring and little fingers for 4 weeks with the wrist extended and the MP joint flexed; leave the interphalangeal joints free to prevent adhesions of the flexor tendons.

The most reliable method for increasing power for gross grasp is to add an extra muscle–tendon unit to the power train for flexion of the proximal phalanges. Prolong the extensor carpi radialis longus (ECRL) or the brachioradialis (BR) with palmaris longus, plantaris, or toe extensor tendon slips (29-31) (Fig. 58.6). Make an incision along the ulnar aspect of the thumb; detach the ulnar half of the EDM from the dorsal apparatus; dissect proximally to the distal edge of the extensor retinaculum (the dorsal carpal ligament). Expose the nerve to the base of the thumb–index web, if a Z-plasty of the index and long finger (A) should be added between the second and third metacarpals to achieve full power of the transfer. (This addition is not illustrated.)

The most practical procedure in median–ulnar palsy is translocation of the superficial radial nerve. Expose the superficial radial nerve through a longitudinal zigzag incision over the radial dorsal aspect of the index phalanx and dorsum of the hand. Expose the nerve to the base of the thumb–index web, if a Z-plasty of the web has not been done. Expose the ulnar proper volar digital nerve of the thumb using microsurgical techniques. A major advantage is that the nerve translocation procedure may be done at the same time as the tendon transfers for median–ulnar palsy.

An alternative procedure to a nerve translocation is to create a neurovascular cutaneous island pedicle. Raise an island of skin over the distal edge of the extensor retinaculum (the dorsal carpal ligament). Make a palmar incision obliquely from the distal palmar crease to the proximal digital crease to expose the deep transverse metacarpal ligament and the flexor sheath of the little finger. Pass the ulnar half of the EDM between the fourth and fifth metacarpals into the palmar wound. If the little finger is clawed as well as abducted, insert the tendon slip into the radial aspect of the A1 pulley, or a radially based flap of the flexor tendon sheath just distal to the proximal pulley.

If the little finger is not clawed, pass the tendon slip beneath the deep transverse metacarpal ligament and suture it into the phalangeal attachment of the radial collateral ligament of the MP joint of the little finger. Set the tension with the wrist in neutral flexion–extension and the MP joint in 20° of flexion. Split the ring and little fingers for 4 weeks with the wrist extended and the MP joint flexed; leave the interphalangeal joints free to prevent adhesions of the flexor tendons.

The most reliable method for increasing power for gross grasp is to add an extra muscle–tendon unit to the power train for flexion of the proximal phalanges. Prolong the extensor carpi radialis longus (ECRL) or the brachioradialis (BR) with palmaris longus, plantaris, or toe extensor tendon slips (29-31) (Fig. 58.6). Make an incision along the ulnar aspect of the thumb; detach the ulnar half of the EDM from the dorsal apparatus; dissect proximally to the distal edge of the extensor retinaculum (the dorsal carpal ligament). Expose the nerve to the base of the thumb–index web, if a Z-plasty of the web has not been done. Expose the ulnar proper volar digital nerve of the thumb using microsurgical techniques. A major advantage is that the nerve translocation procedure may be done at the same time as the tendon transfers for median–ulnar palsy.

An alternative procedure to a nerve translocation is to create a neurovascular cutaneous island pedicle. Raise an island of skin over the distal edge of the extensor retinaculum (the dorsal carpal ligament). Make a palmar incision obliquely from the distal palmar crease to the proximal digital crease to expose the deep transverse metacarpal ligament and the flexor sheath of the little finger. Pass the ulnar half of the EDM between the fourth and fifth metacarpals into the palmar wound. If the little finger is clawed as well as abducted, insert the tendon slip into the radial aspect of the A1 pulley, or a radially based flap of the flexor tendon sheath just distal to the proximal pulley.

If the little finger is not clawed, pass the tendon slip beneath the deep transverse metacarpal ligament and suture it into the phalangeal attachment of the radial collateral ligament of the MP joint of the little finger. Set the tension with the wrist in neutral flexion–extension and the MP joint in 20° of flexion. Split the ring and little fingers for 4 weeks with the wrist extended and the MP joint flexed; leave the interphalangeal joints free to prevent adhesions of the flexor tendons.

The most reliable method for increasing power for gross grasp is to add an extra muscle–tendon unit to the power train for flexion of the proximal phalanges. Prolong the extensor carpi radialis longus (ECRL) or the brachioradialis (BR) with palmaris longus, plantaris, or toe extensor tendon slips (29-31) (Fig. 58.6). Make an incision along the ulnar aspect of the thumb; detach the ulnar half of the EDM from the dorsal apparatus; dissect proximally to the distal edge of the extensor retinaculum (the dorsal carpal ligament). Expose the nerve to the base of the thumb–index web, if a Z-plasty of the web has not been done. Expose the ulnar proper volar digital nerve of the thumb using microsurgical techniques. A major advantage is that the nerve translocation procedure may be done at the same time as the tendon transfers for median–ulnar palsy.

An alternative procedure to a nerve translocation is to create a neurovascular cutaneous island pedicle. Raise an island of skin over the distal edge of the extensor retinaculum (the dorsal carpal ligament). Make a palmar incision obliquely from the distal palmar crease to the proximal digital crease to expose the deep transverse metacarpal ligament and the flexor sheath of the little finger. Pass the ulnar half of the EDM between the fourth and fifth metacarpals into the palmar wound. If the little finger is clawed as well as abducted, insert the tendon slip into the radial aspect of the A1 pulley, or a radially based flap of the flexor tendon sheath just distal to the proximal pulley.

If the little finger is not clawed, pass the tendon slip beneath the deep transverse metacarpal ligament and suture it into the phalangeal attachment of the radial collateral ligament of the MP joint of the little finger. Set the tension with the wrist in neutral flexion–extension and the MP joint in 20° of flexion. Split the ring and little fingers for 4 weeks with the wrist extended and the MP joint flexed; leave the interphalangeal joints free to prevent adhesions of the flexor tendons.
Table 58.2. Combined High (Proximal) Median and Ulnar Palsy

Use the ECRB to retain wrist extension and to restore thumb adduction power for key pinch (Fig. 58.1), and the EIP to improve thumb abduction (Fig. 58.2). Extend a slip of the APL to the tendon of the first dorsal interosseous (Fig. 58.3), and employ arthrodesis of the MP joint of the thumb to strengthen thumb–index tip pinch. The surgical techniques are similar to those used in low combined median and ulnar palsy.

- Use the ECRL for finger flexion (Fig. 58.8). Make a midline longitudinal, slightly zigzag incision from a point approximately 2.5 cm above the volar wrist crease to the proximal third of the forearm. With traction, identify the tendon of the flexor carpi radialis (FCR). On the radial aspect of this tendon is the radial artery and the tendon of the BR. On the dorsal aspect of the FCR is the flexor digitorum superficialis (FDS) and the flexor pollicis longus (FPL). Tag the FPL, and displace the FDS ulnarward to reveal the flexor digitorum profundus (FDP). Detach the ECRL at its insertion and release it halfway or more up the forearm to obtain maximal muscle–tendon motion. Tunnel the ECRL around the radial side of the forearm across all four tendons of the FDP, which is left in its usual position. Flex the fingers and align them more transversely than obliquely to ensure equal tension for gross grasp. The change in resting position is approximately 2 cm for the index and long finger tendons. Suture the transfer well proximal to the transverse carpal ligament to allow adequate and free excursion. Each transfer junction has a proximal and distal suture to prevent whipsawing under tension. Align tension so that there is functional extension of the fingers with the wrist in 15° to 20° of flexion.

- Use the BR tendon to enhance thumb flexion (Fig. 58.9). Identify the BR in the volar forearm incision and release it near its insertion. Free it extensively from all tissue attachments so that it has approximately 5 cm of passive mobility (28). Also free the FPL so that it glides both proximally and distally to the wrist. Weave the BR tendon into the tendon of the FPL, and secure it with nonabsorbable sutures. Adjust tension so that there is full extension of the thumb when the wrist is in 20° of flexion and the thumb in full abduction (39). If thumb–index tip pinch is unstable with MP joint extension and IP joint flexion (the “crank-handle” effect), then thumb MP arthrodesis is indicated (3). As indicated previously, we routinely use arthrodesis of the MP joint of the thumb for the initial surgical reconstruction.

Before reconstruction, it may appear that restoration of the intrinsic function will not be necessary, but when flexion is restored to the IP joints, the fingers will gradually assume a clawed position. Static techniques are used in most cases. Riordan (38) credits Fowler for developing a tenodesis of all four fingers utilizing free tendon grafts from the dorsal carpal ligament passed volar to the deep transverse metacarpal ligament to the lateral bands of the extensor apparatus (Fig. 58.10A). Wrist flexion increases the tension on the tenodesis so that the function is semiaactive. Parkes (34) placed a free tendon graft between the radial lateral band of the dorsal apparatus of the finger and the deep transverse metacarpal ligament (Fig. 58.10B). Riordan (37) split the FDS of the long finger into four slips; one slip is passed through the lumbrical canal of each finger and inserted into the lateral band of the dorsal apparatus. Zancolli (44) opened the proximal (A1) pulley of the flexor sheath and excised a flap from the volar plate (Fig. 58.10C).
There are not consistent recommendations for reconstruction of sensibility in this lesion. Two procedures to transfer sensibility to the thumb are described in the section on low median-ulnar nerve palsy. Sensibility can be transferred to the radial volar aspect of the hand (Fig. 58.11). Careful testing of the superficial radial nerve will demonstrate the distal level of sensibility on the dorsum of the index finger.

Figure 58.11. Fillet of index finger, with larger radial-innervated cutaneous island.

- Remove the skeleton of the index finger distal to the proximal third of the second metacarpal. Discard the insensitive distal skin. Then fit the filleted index finger flap into an additional volar defect created for it in the insensitive palmar skin (29,31,32). This procedure will provide protective sensibility within the thumb-middle web space.

In time, the wrist will translocate ulnarward on the radius secondary to the concentration of extrinsic forces to the radial side of the hand (26,29). A sequela of the carpal change is a decrease in the thumb-index web space, with loss of ability to grasp larger objects.

COMBINED HIGH (PROXIMAL) ULNAR AND RADIAL PALSY

Patients with high ulnar-radial palsy retain radiovolar sensibility, and reconstruction is useful to improve function. Surgery is often staged, however, and rehabilitation is difficult because surgical procedures need to be performed both for finger extension and flexion and for thumb adduction and abduction (Table 58.3).

Table 58.3. Combined High (Proximal) Ulnar and Radial Palsy

Use the pronator teres (PT) for wrist extension (Fig. 58.12). A major function of the PT transfer to the ECRB is stabilization of the wrist. Increasing dorsal extension power of the wrist by an increment of one may increase power grip three to five times (5).

Figure 58.12. Transfer of the pronator teres to the extensor carpi radialis brevis for wrist extension and stabilization.

- Through a longitudinal incision on the volar side of the radial aspect of the middle third of the forearm, expose the tendons of the PT, ECRB, and ECRL. Free the PT with a generous tongue of periosteum from the radius. Bluntly free the PT muscle belly, avoiding neurovascular injury. Pronate the forearm, and pass the PT subcutaneously and superficial to the BR and the ECRL muscle for attachment to the tendon of the ECRB. The wrist should rest in 30° of extension against gravity.

- Utilize the long FDS to improve the integration of MP and interphalangeal joint flexion, key pinch for the thumb, and the flattened metacarpal arch (Fig. 58.13) (22,24,30). The ring finger FDS cannot be used when the ulnar-innervated portion of the FDP is paralyzed. Expose the long finger FDS through a volar zigzag incision that extends from the PIP crease to the distal palmar crease. Release of the long FDS may result in a residual hyperextension deformity of the PIP joint. To prevent this problem, release the distal radial insertion of the FDS proximal to the PIP joint and perform tenodesis to prevent hyperextension of the joint after completion of the transfer. Release the ulnar half of the FDS at its terminal insertion. Retain the flexor sheath, especially the proximal A1 and A2 pulleys. The ulnar half of the long FDS tendon is split longitudinally again into two slips.
When increased power for grip is desired and the EDC will extend the PIP joint with the MP joint stabilized in flexion, insert a long FDS ulnar slip into each A2 pulley of the ring and little fingers (Fig. 58.13). Make a longitudinal zigzag incision on the volar side of the little and ring fingers. Expose the proximal edges of the flexor sheaths and pass the FDS ulnar slips distally through the flexor sheaths and volarly around the distal edge of the A2 pulley and suture them in place. The A2 pulley insertion does not extend the PIP joint, while active flexion returns to the MP joint of the ring and little fingers.

Extension of the fingers is usually weak, however, or absent in high combined ulnar and radial palsy. If preoperative testing indicates that the interphalangeal joints cannot be actively extended by the EDC when the MP joint is flexed, then insert the FDS slips into the dorsal apparatus (24,30). Make short longitudinal incisions over the dorsal aspect of the PIP joints of the right and little fingers. Direct the FDS ulnar slips radial to the ring and little fingers and volar to the deep transverse metacarpal ligament and then dorsally to be sutured at the insertion of the central slip of the dorsal apparatus on the middle phalanx (Fig. 58.13). Traction on the transferred FDS slips should flex the MP joints and extend the PIP joints.

Expose the abductor tubercle of the thumb through either a short longitudinal incision over the tendon of the APB, or a midline dorsal longitudinal incision for arthrodesis of the MP joint. Arthrodesis of the thumb MP joint gives improved strength for grip. Direct the radial half of the long FDS transversely over the volar surface of the adductor pollicis, but dorsal to the flexor tendons and neurovascular structures. Suture it into the insertion of the pollicis brevis (PB) tendon. The functional mechanism of this tendon transfer is similar to that of the Bunnell “tendon T” operation (20), except that the pulley for this transfer is the distal edge of the palmar fascia inserted into the third metacarpal rather than a free tendon graft between the first and fifth metacarpals. Tracton of the transferred long FDS tendon should adduct and pronate the first metacarpal, as well as increase the metacarpal (palmar) arch and depress the clawed fingers (30).

Use the index and ring FDS tendons to extend the fingers and the thumb (2,26) (Fig. 58.14). Expose the FDS tendons through volar zigzag incisions that extend from the PIP crease to the transverse palmar crease. Release the distal radial insertion of the FDS tendon proximal to the PIP joint and perform tenodesis to prevent hyperextension, or divide the FDS tendon proximal to the chiasma tendinum and deliver it into the longitudinal incision on the volar side of the radial aspect of the forearm. Proximal to the pronator quadratus, excise two windows from the interosseous membrane, one on each side of the anterior interosseous artery. The windows should be as large as possible for the patient's anatomy. If there is any indication of injury to either the anterior or posterior interosseous vessels, deflate the tourniquet and control hemorrhage. It is very difficult to establish hemostasis after the two FDS tendons are placed through the interosseous membrane.

The loss of balanced power across the PIP joints caused by removing the FDS may ultimately result in either a flexion contracture or a swan-neck deformity of these joints. Because it is not possible to accurately predict which of these deformities will occur in a given patient, we believe that it is preferable to wait for the onset of deformity before treating it. The most predictable corrective procedure may be arthrodesis of the PIP joint (13,25).

It is desirable to repower the APL, because incomplete abduction of the first metacarpal may cause awkwardness and loss of strong pinch. The FCR tendon can be used on the thumb if the MP joint is already streightened. The FCR tendon is a reliable source of power for the first metacarpal, because the adductor pollicis (AP) is only a voluntary muscle. It is a much more versatile muscle than the FDS tendon available to the index and ring fingers. A short strip from the FCR tendon is passed under the EPL tendon and sutured to the radial aspect of the EPL tendon (Fig. 58.15). The distal end of the FCR is then sutured to the radial aspect of the profundus muscle group (Fig. 58.15). The FCR is a very strong muscle and is not limited by any collagenous tissue. It is therefore well suited for the transfer to the thumb. The flexor digitorum profundus (FDP) tendon is passed under the EPL tendon and sutured to the radial aspect of the EPL tendon. The FDP tendon is then sutured to the radial aspect of the profundus muscle group (Fig. 58.15).

The distal end of the FCR tendon is sutured to the radial aspect of the profundus muscle group, because the FCR tendon is a very strong muscle and is not limited by any collagenous tissue. It is therefore well suited for the transfer to the thumb. The flexor digitorum profundus (FDP) tendon is passed under the EPL tendon and sutured to the radial aspect of the EPL tendon. The FDP tendon is then sutured to the radial aspect of the profundus muscle group (Fig. 58.15). The FCR tendon is a very strong muscle and is not limited by any collagenous tissue. It is therefore well suited for the transfer to the thumb. The flexor digitorum profundus (FDP) tendon is passed under the EPL tendon and sutured to the radial aspect of the EPL tendon. The FDP tendon is then sutured to the radial aspect of the profundus muscle group (Fig. 58.15). The FCR tendon is a very strong muscle and is not limited by any collagenous tissue.
Figure 58.16. Tenodesis of the denervated long and little flexor digitorum profundus (FDP) tendons to the innervated index and long FDP tendons for active flexion of all four fingers.

Restoration of sensation is the final stage of surgical reconstruction. In high ulnar–radial palsy, patients have median sensation and lack the precise ulnar motor function required for precise sensibility. Delay any procedure until all tendon transfers have healed and initial rehabilitation has been initiated.

COMBINED HIGH (PROXIMAL) MEDIAN AND RADIAL PALSY

Tendon transfers in patients with combined high median and radial palsy will result in a hand that functions only slightly more effectively than a prosthesis (24,25,31). All wrist motors are lost except the FCU. Radiocarpal (wrist) arthrodesis is indicated. When arthrodesis is performed on the wrist, finger flexion is not enhanced by wrist extension, and the total range of finger motion is limited (Table 58.4).

Table 58.4. Combined High (Proximal) Median and Radial Palsy

- The first priority in treatment is arthrodesis of the wrist, preferably using a low-profile plating technique.
- Utilize the ulnar innervated portion of the FDP for flexion of the fingers and thumb (Fig. 58.17). Approach the FDP through a longitudinal palmar incision on the ulnar aspect of the forearm. Because the radial portion of the FDP is denervated, the FDP tendons to the index and long fingers must be under greater tension than those to the ring and little fingers. A double line of proximal and distal sutures at the tendon junction is important to prevent shifting, or whipsawing, of the tendons when a power grip is applied. After suture, the finger pulps of all four digits are in transverse alignment instead of the usual oblique alignment.

Figure 58.17. Tenodesis of the denervated index and long flexor digitorum profundus (FDP) tendons to the innervated ring and little FDP tendons for active flexion of all four fingers.

To obtain maximal finger flexion and finger extension, we have usually done the FDP “group suture” before tendon transfers for finger extension. It is useful, however, to use dynamic finger extension splits with intrinsic stops for appropriate positioning in preparation for the surgical reconstruction of finger extension.

- Utilize the FCU for finger and thumb extension (Fig. 58.18). The oldest surgical procedure for digital extension used the FCU (2). Through the incision described for the FDP modification, transect the FCU just proximal to the pisiform and free it up proximally to obtain appropriate passive motion. A second longitudinal incision, 5–7 cm distal to the medial epicondyle, will facilitate the release of the muscle. The limiting factor in the dissection is the innervation of the FCU, which enters the muscle in its proximal 5 cm.

Figure 58.18. Transfer of the flexor carpi ulnaris (FCU) to the extensor digitorum communis (EDC) and extensor pollicis longus (EPL) for finger and thumb extension.

- Make a dorsal longitudinal incision in the midline of the forearm. Pass a tendon passer from the dorsal incision subcutaneously around the ulnar border of the forearm, and pull the tendon of the FCU into the dorsal incision. The FCU muscle belly can be trimmed distally; a bulky appearance, however, may be preferable to excessive bleeding when the tourniquet is released.
- For finger and thumb extension, bring the FCU well proximal to the dorsal retinaculum and suture it obliquely across the tendons of the EDC and the EPL. Leave the extensor tendons in their normal compartments, and place the FCU superficially across each tendon with a double suture line for stability. When the EDC slip to the little finger is absent, include the EDM in the tendon transfer. The junction increases tension on the EDC tendon slips until the fingers are held in a functional extension splay against gravity.
- After the tension is set for the EDC tendon slips, add the EPL tendon as the final insertion of the FCU transfer. Adjust tension against gravity so that the thumb fits into the extension splay demonstrated by the digits. In high median–radial palsy, however, finger flexion is inadequate, and the range of digit extension should be more modest to fit the potential range of flexion. Over time, and with balanced flexor tension, the patient can usually extend all fingers, or only the thumb. The occasional patient learns to show individual digits in extension through selective flexion (26). These FCU transfer functional activities are much more specific in isolated radial palsy, with normal wrist mobility and individual FDP flexor motion (23). The fused wrist, however, prevents radial deviation of the wrist, which is the most common long-term problem in isolated radial palsy with an FCU transfer.
REHABILITATION

The preoperative evaluation provides objective data to determine how much function has been lost and how much retained. Interview the patient to determine whether she desires an increase in function or in cosmesis. Document passive range of motion and initiate therapy before surgery if there are limitations in motion. Static and dynamic splints are useful to maintain or increase joint range of motion. For example, if the thumb–index web space is narrowed, a static thumb–web spacer may be fabricated and adjusted serially until full range of motion is obtained with a web space equal to the contralateral extremity. Sensibility evaluation is important because defects influence how the patients uses her hand. Conduct a functional assessment to document sensibility loss.

Preoperative training is valuable in the combined nerve palsies. It is important that the patient comprehend what is to be done and be ready to accept the postoperative discipline. Biofeedback is effective, and if possible, the patient should be able to palpate the major muscles to be transferred. The preoperative goals of rehabilitation are to maintain or achieve a supple hand and to enhance remaining hand function.

The pertinent consideration in postoperative splinting of the hand that has undergone tendon transfer procedures is identification of the points at which the relocated musculotendinous unit crosses the wrist and the digital joints. During the early postoperative period, direct splinting toward protection of the transfer, correction of stiffness secondary to postoperative immobilization, and controlled tension on the musculotendinous transfer. Brand (3) has recommended placing the hand in a volar slab cast with a very light unpadded cylindrical wrap to make a circular support that holds the fingers in the appropriate position during the postoperative period. A soft bulky dressing may be added.

Surgical procedures in low median–ulnar palsy emphasize transfers to improve intrinsic muscle function. All indicated surgery can be done at the same time. Immobilize the forearm in a light, compressive, bulky dressing with a volar plaster splint. Hold the wrist in 45° of extension, the MP joints (except the thumb) in full flexion, and the IP joints in full extension.

Change dressings in 14 days for suture removal and reaply a molded splint to hold the position of the joints. Initiate light strengthening at 6 weeks postoperatively. The MP arthrodesis of the thumb is immobilized for at least 8 weeks (33). Allow unrestricted use at 12–14 weeks postoperatively.

High median–ulnar palsy involves the elbow joint as well as more distal joints. Postoperatively, hold the hand and forearm in light, well-padded splints within a bulky dressing, with the wrist in 10° to 15° of extension, the thumb in opposition, the fingers supported in a “straight-line” position of full MP flexion, and the IP joints in 10° of flexion. Support the elbow in 90° of flexion (Munster level) (29). Start gentle active motion under supervision at 6 weeks postoperatively. Initiate strengthening at 8 weeks postoperatively. Elastic splinting can be used to support finger flexion, and static splints can be used to support thumb opposition. Gradually, change emphasis to functional use of the hand.

Some patients can benefit from multiple stages in reconstruction: First, do thumb and little-finger intrinsic procedures; second, do finger and thumb flexion procedures; third, correct residual claw fingers. These steps can be done at 3-month intervals, followed by any elective procedure for sensibility.

High ulnar–radial palsy is a rehabilitation problem. It is difficult to retrain flexion and extension simultaneously; consider staging the surgery for these cases. The first stage might include wrist and digit extension procedures, plus thumb abduction. The second stage might include digit flexion and thumb flexion. Arthrodesis of MP or IP joints can be done in either surgical stage, or the surgical stages could be reversed in order.

Sensibility procedures are the final stage of these surgical reconstructions. If done in the order just mentioned, the first phase is a radial nerve correction, and the wrist is immobilized in 45° of extension, the MP joints in 15° of flexion, and the thumb in maximal extension and abduction. Immobilize the elbow in a Munster-type above-elbow cast with 15° to 30° of pronation, leaving thePIP joints free. Remove the sutures at 14 days, but do not remove the long-arm cast until 6 weeks postoperatively. Use removable short-arm splints to hold the wrist, fingers, and thumb in extension.

Do the second phase, which involves finger flexion and intrinsic balance for the thumb. 12 weeks after the first phase. Hold the wrist in 45° of extension, the MP joints in full flexion, and the IP joints in extension (10° of flexion if tenodesis is done). Adduct the first metacarpal so that it is parallel with the plane of the second metacarpal. Maintain this intrinsic-plus position by immobilizing in plaster for 4 weeks before resuming active extension.

EVALUATION OF THE PATIENT

Symptoms of neurologic conditions of the shoulder include pain, weakness, or both. Obtain a complete history and perform a thorough physical examination; pay particular attention to testing and grading each muscle about the shoulder girdle and examining for specific local areas of tenderness. Then decide to what extent the pain is related to organic pathology. This decision making takes into consideration the patient’s credibility, whether worker’s compensation is a factor, and whether litigation is pending.

The diagnosis of shoulder pain is difficult, analogous to evaluating the source of low back pain. Most often, pathology resides in the rotator cuff or with intraarticular problems; take care not to fall into the trap of missing some of the less common diagnostic entities. The shoulder often is implicated in pain arising from the neck (1,8). This chapter does not discuss the qualities of cervical radiculopathy and arthritic changes about the neck, but I mention them here to remind you not to have tunnel vision when evaluating the shoulder.

Pain secondary to nerve compression can be caused by thoracic outlet syndrome, suprascalpular nerve compression syndrome, and quadrilateral space syndrome. See Chapter 61 for a complete discussion of thoracic outlet syndrome.

Pain can also be secondary to weakness or instability about the shoulder, due to palsies of the suprascalpular, axillary, long thoracic, and spinal accessory nerves, as well as palsy of the upper brachial plexus. Vague shoulder pain and weakness of the involved muscle groups are the main symptoms of isolated nerve injuries about the shoulder (44).

The purpose of this chapter is to review the diagnosis and treatment of specific nerve entrapments or palsies about the shoulder that result in pain, weakness, or both. Systemic conditions, such as arthrogryposis, muscular dystrophies, polio, and stroke, will not be discussed; instead, see the works of Saha (58) and Scholtissek et al. (60). Also see Chapter 67, Chapter 68, and Chapter 178.

PARSONAGE-TURNER SYNDROME

Before addressing specific conditions that can be traced to an isolated nerve insult, one must be aware of a syndrome comprising pain and flaccid paralysis of the muscles about the shoulder girdle. Parsonage and Turner first described it in 1948 (50), calling it neuralgic amyotrophy. The syndrome today is more often referred to by their names.

The essential clinical picture is simple: Without any constitutional disturbance, pain starts suddenly across the top of the shoulder blade and may radiate down the outer side of the upper arm or into the neck. This pain lasts from a few hours to a fortnight or more, and then a flaccid paralysis, of some of the muscles of the shoulder girdle and often of the arm, develops, and in some cases there is a patch of numbness over the outer side of the upper arm. When the paralysis appears, the severe pain usually stops, but a dull ache may persist considerably longer. This clinical picture is subject to modifications. (59)

In their series of 136 patients, Parsonage and Turner were able to identify a precipitating cause in 66 patients. Some of the causes cited were infection, trauma, or previous vaccination. They noted that local pain was almost always the presenting symptom, generally a constant severe ache that lasted for a few hours to a week or two and then stopped fairly suddenly as muscle paralysis appeared. Involvement of the long thoracic nerve leading to paralysis of the serratus anterior was the most common finding. The authors also reported cases in which the suprascalpular nerve, the axillary nerve, and C-5 and C-6 nerve root were involved. The prognosis for recovery was related to the amount of initial paralysis. Muscles not completely paralyzed or those showing some return during the first few weeks usually recovered completely in 6 months or less. With severe wasting occurring early and rapidly, the prognosis for useful return of function was poor. Recovery of voluntary power in completely paralyzed muscles was found 9 to 12 months after the onset, and recovery continued up to 2 years or longer. The only treatment recommended was to move the shoulder joint through its full range of motion on a regular basis to prevent stiffness.

The pathophysiology of this syndrome is not any better understood today than it was by Parsonage and Turner in 1948. It is important to keep this fact in mind when evaluating any new palsy about the shoulder, because early surgical treatment is not indicated (17). A history of severe pain preceding muscle paralysis or the close timing of a vaccination forms the basis for this diagnosis. Other than symptomatic therapy, no specific treatment is available.

SUPRASCAPULAR NERVE ENTRAPMENT

The suprascapular nerve may be compressed in the suprascalpular notch, resulting in little more than pain about the medial aspect of the scapula. The pain is usually diffuse, deep aching and may be localized to the posterior aspect of the shoulder. Adduction of the forward-flexed arm across the body produces traction on the nerve and may increase this pain (53). Deep palpation over the suprascalpular notch may show marked tenderness. With further compression or traction on this nerve, atrophy and loss of external rotator function will ensue (Figs. 59.1). The external rotation deficit limits the patient’s ability to perform activities with the arm in an overhead position. With prolonged compression and loss of all external rotator function, posterior shoulder instability may also result.
POSTERIOR APPROACH

The suprascapular nerve is a mixed peripheral nerve that arises from the upper trunk of the brachial plexus (C-4 to C-6) (Fig. 59.2). It courses laterally, deep to the trapezius and omohyoid muscles, and enters the supraspinous fossa passing under the transverse suprascapular ligament. The suprascapular artery and vein course with the nerve, but they pass above the transverse suprascapular ligament. The sensory component supplies the posterior capsule of the shoulder joint and has no cutaneous distribution (57). The suprascapular nerve courses deep to the supraspinatus muscle, innervating this muscle with two branches. The nerve continues to the lateral edge of the spine of the scapula, curving around it medially into the infraspinous fossa, deep to the infraspinatus muscle. As the nerve courses under the edge of the spine of the scapula, it commonly passes through an inferior transverse scapular ligament (the spinoglenoid ligament) that inserts at the lateral border of the scapular spine and the scapular neck.

More commonly, the site of entrapment is found to be underneath the transverse suprascapular ligament; isolated atrophy and weakness of the supraspinatus muscle, however, have been attributed to compressions underneath the inferior transverse scapular ligament (63,65). Demirhan et al. studied the anatomy and morphology in cadavers to determine the role of entrapment in the suprascapular nerve. They found the spinoglenoid ligament to be present in 60.8% of shoulders, and that it was wider at the superior entrance of the tunnel and fanned and twisted toward the inferior aspect (5). In all their specimens, the fibers inserted into the posterior shoulder capsule. During cross-body adduction and internal rotation of the glenohumeral joint, the suprascapular nerve moved laterally and stretched underneath the spinoglenoid ligament. In this position, the interaction of the spinoglenoid ligament and the posterior capsule resulted in stretching of the nerve (6).

Electromyography is critical for the diagnosis of compression of the suprascapular nerve. Diagnostic are denervation potentials in the supraspinatus and infraspinatus muscles and prolonged conduction time from Erb's point to the supraspinatus and infraspinatus muscles in the absence of involvement of other peripheral nerves (37). Root compression at the C-5 level can mimic suprascapular nerve entrapment syndrome; if C-5 root compression is the cause, however, electrodiagnostic studies of the deltoid and rhomboids will demonstrate abnormalities in these muscles. Magnetic resonance imaging is also useful not only for the detection of ganglion cysts but also for assessing the stage of paralysis (28).

Suprascapular nerve palsy can result from direct trauma such as fracture of the scapula or a blow to the shoulder region (70). It has been reported as well to result from compression by a ganglion cyst (26,47,54,62,65) or from a bone cyst (61). Rengachary et al. studied the anatomy of the suprascapular notch in cadavers and concluded that certain configurations might contribute to nerve entrapment (66). Ticker et al. found the ligament to be partially ossified in 18% of cadavers (66). It is debatable whether this entity is an actual nerve entrapment syndrome or a situation in which the nerve is fixed at a given point and the dysfunction is actually caused by traction.

Ferretti et al. studied 96 top-level volleyball players and in 12 found isolated paralysis of the infraspinatus on the dominant side (16). They attributed this denervation to the athlete’s repeated stressing and stretching of the nerve when serving (with the arm cocked) and following through. Sandow and Illic proposed that the infraspinatus branch of the suprascapular nerve can be directly compressed between the lateral border of the scapular spine and the medial margin of the rotator cuff during the extremes of shoulder motion during sports such as volleyball and baseball; they treat these athletes with a “notchplasty” in addition to release of both the superior and inferior suprascapular ligaments (59).

Most authors recommend decompression of the suprascapular nerve for severe pain or atrophy. Martin et al., however, reviewed their experience with nonsurgical treatment and concluded that “in the absence of a well-defined lesion producing mechanical compression of the suprascapular nerve, suprascapular neuropathy should be treated non-operatively” (43). Twenty percent of the patients in their study failed conservative treatment, however, and no predictors were found that would indicate the need for operative versus nonoperative care. For exposure of the nerve, posterior, anterior, and superior approaches have all been described (45,48,53,64). Most authors have abandoned the anterior approach because it is a more difficult dissection and has a higher risk of complications.

SURGICAL TECHNIQUES

POSTERIOR APPROACH

- Place the patient either prone or in the lateral decubitus position, with the involved side uppermost.
- Make the skin incision parallel to and 1 inch superior to the scapular spine, along its entire length.
- Elevate the trapezius muscle from the spine and reflect it superiority, exposing the supraspinatus muscle. Palpate the supraspinacular ligament overlying the supraspinacular notch.
- Clean the supraspinacular ligament with a blunt elevator. Protect the supraspinacular artery and vein, which are superficial to the ligament. Protect the supraspinacular nerve and sharply excise (not just release) the transverse suprascapular ligament.
- Enlarge the supraspinacular notch only if you find that the nerve is not completely free of impingement or traction. Inspect and palpate the surrounding region for any abnormal masses.
- Reattach the trapezius muscle to the spine of the scapula using nonabsorbable sutures placed through drill holes in the bone.
- Close the wound in routine fashion.
- Following surgery, immobilize the patient in a sling for 10 days. Then remove the sutures and initiate gradual progressive range-of-motion and shoulder-strengthening exercises.
SUPERIOR APPROACH FOR DECOMPRESSION OF THE SUPRASCAPULAR NERVE

Menon described the superior approach and claims that it offers ease of access to the suprascapular ligament while avoiding detachment of the trapezius muscle (Fig. 59.3) (45). I prefer this approach, as long as access to the spinoglenoid ligament is not required. It leaves a very cosmetically acceptable scar. This approach is, however, too limited to excise ganglions that originate from the glenohumeral joint. It may be combined with the posterior approach if a more extensile exposure is needed.

Figure 59.3. Superior surgical approach to the transverse suprascapular ligament. The trapezius is reflected medially to expose the suprascapular ligament and nerve. (Illustration courtesy of J. Menon.)

- Place the patient in a semi-sitting beach chair or a lateral position held by a vacuum bean bag.
- Start the incision over the distal third of the clavicle, extending it over the acromioclavicular joint to the lateral border of the spine of the scapula.
- Incise the subcutaneous tissue along the line of the incision.
- Detach the trapezius muscle from the distal third of the clavicle and the acromion process and reflect it medially.
- Palpate the superior border of the scapula, directing a finger toward the coracoid process. Move the fat pad underneath the trapezius to one side to expose the superior border of the scapula.
- Pass a right-angle clamp beneath the ligament and through the foramen, and then transect the ligament.
- Remove the ends of the ligament with a rongeur.
- Reattach the trapezius muscle to the lateral end of the acromion and the clavicle by passing sutures through drill holes; then close the skin.

ZACHARY PROCEDURE FOR RESTORATION OF SHOULDER EXTERNAL ROTATION

If the patient has longstanding weakness and irreparable damage of the supraspinatus and infraspinatus muscles, consider reconstructive substitution for the external rotators. The operation that I have found works best is the one described by Zachary and Leeds (73) [a modification of L’Episcopo’s (34) procedure], which is a transfer of the teres major and the latissimus dorsi to the lateral aspect of the humerus (Fig. 59.4).

Figure 59.4. Posterior view right shoulder. Transplantation of the teres major and latissimus dorsi muscles for restoration of external rotation at the shoulder. Retraction of the deltoid muscle superiorly and separation of the long and lateral heads of the triceps muscle expose the insertion of the teres major and latissimus dorsi. The tendons of the teres major and latissimus dorsi are passed through slots in the lateral head of the triceps muscle and fixed to the posterolateral aspect of the humerus through drill holes in the bone. (Adapted from Zachary RB, Leeds MB. Transplantation of Teres Major and Latissimus Dorsi for Loss of External Rotation at the Shoulder. Lancet 1947;253:758, with permission.)

- Place the patient prone with the arm in full internal rotation.
- Make a curvilinear incision over the posterior aspect of the upper third of the arm.
- Expose the insertion of the teres major and latissimus dorsi muscles by retracting the posterior border of the deltoid muscle superiorly; separate the long and lateral heads of the triceps muscle.
- Identify the radial nerve at the lower border of the teres major muscle. Detach the teres major and latissimus dorsi muscles together from their insertion on the humerus.
- Fully externally rotate the arm and pass the tendinous insertions of the teres major and latissimus dorsi muscles through a slit in the upper part of the lateral head of the triceps.
- Attach the latissimus dorsi and teres major muscles to the posterior lateral aspect of the humerus with mattress sutures passed through drill holes in the bone. Close the wound, and use a shoulder abduction splint to immobilize the patient in 90° of forward flexion and external rotation.
- Continue immobilization for 4 weeks, and then begin range-of-motion exercises.

AXILLARY NERVE COMPRESSION (QUADRILATERAL SPACE SYNDROME) AND INJURY

The axillary nerve contains fibers from C-5 and C-6 and is a terminal branch of the posterior cord. It lies on the subscapularis muscle behind the axillary artery and dips posteriorly just inferior to the glenohumeral joint before emerging in the quadrilateral space (Fig. 59.5). It innervates the teres minor and the deltoid muscles. The axillary nerve enters the quadrilateral space together with the posterior humeral circumflex artery.

Figure 59.5. Posterior view of the axillary nerve and posterior circumflex humeral vessels as they course through the quadrilateral space. (From Narakash A.)
The quadrilateral space is bounded anteriorly by the subscapularis fascia, superiorly by the teres minor, inferiorly by the teres major, and medially by the long head of the triceps (49). The axillary nerve is tethered in this space by muscular fascia, joint capsule, and periosteum. At the time of surgery, normally this space will admit an index finger along the neurovascular pedicle; the arm is in a relaxed position at the side. In abduction, this space is narrowed by the scissorlike effect of the triceps and the teres major, and the nerve is placed under tension by its distal site of innervation. Full forward flexion of the arm puts the subscapularis, teres major, and triceps muscles under tension, and it causes the humeral head to impinge on the axillary nerve. Abduction and external rotation further narrow the tunnel (49).

Idiopathic axillary nerve compression (the quadrilateral space syndrome) is a rare condition, and the diagnosis is often delayed (17). One case caused by a ganglion has been reported (18). Pain usually is described as being diffuse and anterior; extreme movements of the shoulder involving abduction and external rotation, however, exacerbate the symptoms. Typically, examination reveals tenderness over the posterior aspect of the quadrilateral space. Rarely is there any weakness of the deltoid or sensory deficit over the distribution of the axillary nerve. Electromyographic examinations are often normal and patients are often labeled neurotic.

Arteriography was once deemed necessary to confirm the diagnosis (3,4). This invasive procedure should be performed to document this syndrome only if surgery is contemplated. Perform a subclavian arteriogram by using the Seldinger technique with the humerus at the side and in abduction and external rotation (Fig. 59.6). Follow the dye distally to visualize the posterior humeral circumflex artery. In a positive arteriogram, the posterior humeral circumflex artery is patent with the arm at the side and occludes with the arm in external rotation and abduction. In normal extremities, the posterior humeral artery does not occlude in this position.

![Figure 59.6. Subclavian arteriogram of a patient with quadrilateral space syndrome. A: With the arm at the side, the posterior humeral circumflex artery is patent (arrow). B: With the arm in abduction and external rotation, occlusion of the posterior humeral circumflex artery is seen near its origin (arrow).](image)

Figure 59.6. Subclavian arteriogram of a patient with quadrilateral space syndrome. A: With the arm at the side, the posterior humeral circumflex artery is patent (arrow). B: With the arm in abduction and external rotation, occlusion of the posterior humeral circumflex artery is seen near its origin (arrow).

Francel et al. have found that arteriography is unnecessary and make the diagnosis on the basis of tenderness over the quadrilateral space, paresthesia over the lateral shoulder and upper posterior arm, and deltoid weakness associated with decreased shoulder abduction in the presence of a history of trauma (19). In addition, I have found that a diagnostic nerve block is more valuable in confirming the diagnosis than are any radiologic or electrodiagnostic studies. I inject 10 ml of 1% plain lidocaine into the quadrilateral space. If the injection produces numbness in the distribution of the axillary nerve, and the shoulder pain resolves in spite of provocative maneuvers, the diagnosis is more likely.

 Conservative therapy consists of avoiding aggravating movements, administration of antiinflammatory medication, steroid injections, and range-of-motion exercises. When this therapy has failed and diagnosis is confirmed, surgical decompression is recommended.

**DECOMPRESSION OF THE AXILLARY NERVE**

**Classic Approach**

- Make a skin incision parallel to and one fingerbreadth inferior to the scapular spine, and curve it along the posterior border of the deltoid muscle (Fig. 59.7).

![Figure 59.7. Skin incision for decompression of the quadrilateral space. The incision parallels and is just inferior to the spine of the scapula and curves inferiorly over the posterior humerus. The x marks the location of the quadrilateral space.](image)

Figure 59.7. Skin incision for decompression of the quadrilateral space. The incision parallels and is just inferior to the spine of the scapula and curves inferiorly over the posterior humerus. The x marks the location of the quadrilateral space.

- Dissect the fascia at the inferior border of the deltoid muscle starting inferior and laterally and proceeding superiorly and medially. Detach the deltoid muscle from the spine of the scapula, leaving a musculotendinous border for reattachment (Fig. 59.8).

![Figure 59.8. The deltoid muscle is dissected from the spine of the scapula and reflected laterally. The axillary nerve exits the quadrilateral space and is seen entering the deltoid (arrow).](image)

Figure 59.8. The deltoid muscle is dissected from the spine of the scapula and reflected laterally. The axillary nerve exits the quadrilateral space and is seen entering the deltoid (arrow).

- Elevate the teres minor muscle superiority. Cahill (3,4) recommends detaching the teres minor muscle from the humerus at this point, but I have never found it necessary to do so.
- Insert your index finger into the quadrilateral space, directing it anteriorly, and palpate the posterior humeral circumflex artery.
- Move the arm to extreme ranges of motion and feel for any compressing structures. You may find a scarred inferior glenohumeral ligament; tight teres minor, triceps, or teres major tendons; or tight subscapularis fascia. I have been impressed by the sharp scissorlike effect of the lateral head of the triceps tendon on the
axillary nerve and posterior humeral circumflex vessel; therefore, I incise part of this tendinous insertion to create more space in the tunnel.

- Reattach the deltoïd muscle to the scapular spine with nonabsorbable sutures through drill holes in the bone.
- Close the rest of the wound in the usual fashion. After surgery, place the arm in a sling for 7 to 10 days, then encourage gentle mobilization.
- Begin active deltoïd muscle exercises at 6 weeks. Do not start resistive exercises requiring full abduction and external rotation for 3 months.

**Limited Incision Approach for Decompression of the Axillary Nerve**

Franco et al. described a technique that does not require division of the deltoïd muscle and uses a smaller incision (18). I now routinely use this approach and have found exposure to be adequate and postoperative rehabilitation to be faster.

- Position the patient prone with the arm extended on an arm board.
- With the patient standing before induction of general anesthesia, determine the point of maximum tenderness over the quadrilateral space. Make a vertical or an S-shaped incision over this point.
- Raise skin flaps to expose the inferior border of the deltoïd.
- Incise the deltoïd fascia along the inferior border of the muscle and retract the deltoïd superiorly to expose the teres major and minor muscles.
- Dissect laterally and identify the tendon of the long head of the triceps.
- Open the fascia between the teres muscle bellies and explore the quadrilateral space.
- Identify the axillary nerve and the posterior circumflex humeral vascular bundle and tag them with rubber drains.
- Sharply divide any fibrous bands to decompress the space. (Although the authors do not mention this method, I incise the part of the tendinous insertion of the lateral head of the triceps if I find it compressing the axillary nerve and posterior humeral circumflex vessel when the arm is placed in abduction and external rotation.)
- Perform neurolysis if you find nerve fibrosis.
- Close the wound in layers. No drain is usually necessary.
- After surgery, place the arm in a sling for 7 to 10 days, then encourage mobilization and progress to resistive exercises as tolerated.

The axillary nerve’s relationship to the glenohumeral joint makes it particularly susceptible to injury from trauma to the shoulder joint. Coene and Narasak have reported that when diagnosed by electromyography, the incidence of axillary nerve injury in glenohumeral dislocations and humeral neck fractures is as high as 30% (6). These lesions, which are often overlooked, frequently are neurapraxias that resolve spontaneously. Persistent deltoïd muscle palsy due to lesions of the axillary nerve is rare, but when present it greatly affects the function of the upper limb. Atrophy of the deltoïd muscle and loss of shoulder abduction strength are evident on examination. Tinel’s sign may be positive in the infracavicular region, but this test is not reliable. Sensibility may be decreased over the lateral aspect of the upper arm. Deltoïd insufficiency may be masked by a strong rotator cuff.

Hertel et al. describe a more objective and reproducible method for assessing deltoïd function, which they have called the deltoïd extension lag sign (23). This test, which is based on the fact that no other muscle can compensate for insufficiency of the posterior part of the deltoïd, is performed with the following steps (23):

- Have the patient sit on an exam table, facing away from you.
- Grasp both wrists and elevate the upper extremities into full passive shoulder extension.
- Allow the shoulders to relax to submaximal extension to allow elastic recoil in the shoulder.
- Ask the patient to maintain this position as you let go.
- The sign is positive when a lag or angular drop occurs when you let go. Changes may be subtle, with a lag drop as little as 5°.

Electromyographic testing is diagnostic. If signs of reinnervation are absent by 6 months following injury, then surgical exploration is indicated (6, 52).

**APPROACH FOR AXILLARY NERVE REPAIR OR GRAFTING**

- Place the patient in the lateral position. Prepare and drape the shoulder widely to provide access both anteriorly and posteriorly. Make a skin incision along the anterior inferior border of the clavicle and extend it along the deltopectoral groove. Open the deltopectoral interval while protecting the cephalic vein.
- Detach the pectoralis minor muscle from the coracoid process and expose the branches of the brachial plexus. Leave a tendinous tag on the muscle for repair at closure.
- Isolate the posterior cord and identify the axillary nerve.
- Abduct and externally rotate the arm, and identify the inferior margin of the pectoralis major muscle insertion. Totally or partially release the tendinous portion of the pectoralis major muscle if necessary to better visualize the axillary nerve.
- The lesion usually cannot be addressed with only an anterior approach. Therefore, at this point perform a posterior approach, detaching the deltoïd as previously described for quadrilateral space syndrome.
- If a neurona-in-continuity is found, resect the neuroma back to normal-appearing neural tissue.
- Because repair of the nerve by direct apposition is usually not technically possible, obtain a sural nerve graft to bridge the gap.
- First, suture the sural nerve to the distal stump of the axillary nerve, and pass the nerve graft through the quadrilateral space and then suture to the proximal stump.
- Put the shoulder through a range of motion to demonstrate that there is no tension on the repair.
- Reattach the pectoralis major (if detached), the pectoralis minor, and the deltoïd muscles.
- Close the subcutaneous tissues and skin in the usual fashion.
- Postoperatively, immobilize the upper extremity for 3–4 weeks in a shoulder immobilizer. Initiate physical therapy as described for decompression of the quadrilateral space.

In cases of isolated deltoïd muscle palsy, either longstanding or with irreparable axillary nerve damage, consider a tendon transfer. Deltoïd muscle palsy is often associated with paralyzed rotator cuff muscles, and shoulder arthrodiesis becomes the best option. If at least one of the rotator cuff muscles is active and the usual prerequisites for tendon transfer are fulfilled (good passive range of motion of the shoulder joint, normal articular surfaces, and a strong muscle that is available for transfer), then consider restoring deltoïd function by tendon transfer. The trapezius transfer is most commonly used (31). Recently, the latissimus dorsi muscle, raised on its neurovascular pedicle and completely rotated, has been used to replace the anterior part of the deltoïd (28). Study the original description of the technique in detail if you plan to perform this operation (29).

The anterior deltoïd muscle can be damaged iatrogenically during operations about the shoulder where it is either detached from its origin or split. If the muscle is denervated, pain and weakness result. The posterior deltoïd muscle can be mobilized and advanced to assume the function of the anterior portion (30).

**LONG THORACIC NERVE (SERRATUS ANTERIOR) PALSY**

The long thoracic nerve is formed from the roots of C-5 to C-7. It passes posterior to the brachial plexus and lies on or penetrates the anterior surfaces of the scalenus medius, then angulates over the first or second ribs as it courses along the lateral thoracic wall downward and branches to supply the digitations of the serratus anterior muscle (30).

To avoid injury to the long thoracic nerve, it is important to be aware that it courses obliquely in an anterosuperior to posteroinferior direction as it progresses to the posterior angle of the second rib (14). Traction on the nerve is exerted when the shoulder is depressed or when the cervical spine is bent in a contralateral direction. Kaupalls's autopsy study suggests that the potential site for damage is anterior to the lower part of the scapula, where the nerve may be exposed to both compression and traction (53).

Isolated serratus anterior palsy may follow an injury such as a direct blow to the shoulder or a sudden jerk of the arm forward or backward (68). The nerve can be injured between the coracoid process and the first or second ribs. Injury to the nerve during surgery has been reported following auxiliary approaches for thoracotomy, radical mastectomy, and axillary node dissection (12, 40, 51). Repetitive trauma can also cause loss of serratus anterior function, particularly in laborers who carry heavy objects on their shoulders. Sustained compression has been described from the downward strain on the shoulder produced by carrying heavy knapsacks. A sudden forceful exertion such as lifting a heavy object or pushing with arms stretched overhead to support a ladder has also been reported as a cause. The prognosis is favorable if the nerve injury is from chronic minor trauma, but it seems to be less favorable if the nerve is injured by a single major episode (67). Gozna and Harris studied cadavers and showed that, when the underside of the scapula was coated with graphite and depressed forcefully downward against the thorax, a graphite imprint could be made along the long thoracic nerve at the level of the second rib (10). They concluded that this is the site of the nerve injury. Successful repair of this nerve is hampered by its surgically inaccessible location. Generally, one should wait for 1 or 2 years before considering operative treatment, as most patients improve slowly with time (17, 19).
Nerve injury must be differentiated from traumatic avulsion of the serratus anterior muscle, which also causes winging of the scapula \(21\); the latter injury is rare. Electromyography and radiographs are diagnostic.

Paralysis of the serratus anterior muscle causes scapular instability with attempts to elevate the shoulder. The scapula pulls away from the chest wall as the extremity moves into forward flexion or abduction. Normally, to elevate the shoulder fully, the scapula must remain stable and close to the chest wall; at the same time, the medial angle must depress and the inferior angle must rotate laterally and upward. Patients who have serratus anterior muscle palsy may be able to attain full shoulder motion in a supine position where the weight of the body supports and stabilizes the scapula; when they are standing upright, however, they cannot complete full shoulder flexion and abduction.

The serratus anterior muscle has two functions: Statically, it stabilizes the scapula to the thorax so that scapulothoracic muscles can work against a fixed point to achieve arm elevation; dynamically, it actively rotates the scapula anteriorly and dorsally to contribute to full arm elevation.

Examine the patient standing, at rest. If he has serratus anterior muscle paralysis, the medial rim of the scapula protrudes from the thoracic wall, and the inferior border of the scapula "wings." The winging of the scapula is more distinct if the patient lifts his arm into forward flexion and uses it for some sort of exertion, such as in doing a pushup against a wall (Fig. 59.9).

**Figure 59.9.** This patient demonstrates inferior scapula winging while doing a pushup against the wall. She has a longstanding serratus anterior palsy from a traction injury.

Nerve conduction studies and electromyography are both valuable in determining whether the lesion is partial or complete and whether regeneration is occurring after Wallerian degeneration. The rest of the upper brachial plexus requires electrodiagnostic study to confirm the diagnosis of isolated long thoracic nerve palsy.

**TREATMENT**

Conservative therapy consists of strengthening the remaining muscles around the shoulder girdle and avoiding activities that cause winging of the scapula. All exercises to strengthen the muscles should be performed with the scapula stabilized. Have the patient lie supine or stand upright with her back placed firmly against a wall. Patients can be taught to substitute movements to stabilize the scapula using a combination of trapezius and rhomboid muscle function. In addition, a custom-fabricated shoulder brace can be used to stabilize the scapula. Although these jacket-braces are usually not well tolerated, they are often appreciated by self-employed laborers who are highly motivated to use them in order to keep working.

When it is determined that recovery has ceased and the patient is sufficiently handicapped, consider surgical stabilization. There are two general approaches to scapular stabilization: static and dynamic. Static procedures have been described using various ligaments, fascia, or even bony scapulopexy with fixation of the scapula to the ribs \(11,20,33\). Although these procedures improve the winging of the scapula and allow the humeroscapular muscles to function against a fixed point during movement of the shoulder joint, they hinder motion of the scapular thoracic joint and make it impossible to obtain a full range of motion. Therefore, I prefer dynamic muscle stabilization if at all possible.

Muscles used for substitution of the serratus anterior muscle include the pectoralis major, pectoralis minor, and teres major muscles \(5,25,39,42,55,67,74\). The rhomboids and latissimus dorsi muscles have also been used, but few authors advocate transferring them to remediate serratus anterior muscle palsy \(24\). Pectoralis major transfer is probably the most common procedure, but it takes away a very strong axiohumeral muscle and thereby limits forward flexion, adduction, and internal rotation—functions already compromised by the absence of the serratus anterior muscle. Moreover, the pectoralis major tendon is too short to be directly sutured to the inferior tip of the scapula unless you use fascia to elongate it.

Similarly, the pectoralis minor tendon is too short to be directly attached to the tip of the scapula without the addition of fascia. Another reason not to choose the pectoralis minor muscle is that it serves as an antagonist to the serratus anterior muscle; it pulls the coracoid process down and forward and thus causes backward rotation of the scapula. The pectoralis minor muscle is active in downward movement of the arm, whereas the serratus anterior muscle acts in lifting the arm. Furthermore, the pectoralis minor muscle is relatively weak. The teres major muscle is a good substitute for the serratus anterior muscle for the following reasons:

- Its strength is equal to that of the serratus anterior.
- Its function as a depressor and internal rotator of the humerus is taken over by the latissimus dorsi.
- Its use does not further weaken the axioacromial muscle group.
- The course of its fibers corresponds to that of the serratus anterior muscle.
- It does not need to be elongated with fascia.
- The surgical scars are inconspicuous \(67\).

**TERES MAJOR TRANSFER**

Refer to **Figure 59.10**.

**Figure 59.10.** Surgical technique for teres major muscle transposition. **A:** An incision is made in the axilla parallel to the posterior fold, and the insertion of the teres major tendon on the humerus is exposed. Then a curved incision is made in the inframammary crease. **B:** The teres major tendon is dissected off the humerus and fed subperiosteally from its humeral insertion and tagged with a suture. **C:** The teres major tendon is passed deep to the latissimus dorsi into the inframammary incision and attached subperiosteally to the fifth and sixth ribs \(5,6\).
RHOMBOID AND LEVATOR SCAPULAE MUSCLE TRANSFER FOR ACCESSORY NERVE PALSY

- Place the patient in a lateral position.
- Make a skin incision parallel to the posterior axillary fold to expose the insertion of the teres major and the latissimus dorsi muscle. The insertion of the teres major is found 6 to 8 cm above the lateral border of the scapula.
- Identify the teres major tendon and detach it from the humerus while carefully retracting the neurovascular bundle laterally.
- Insert two heavy nonabsorbable sutures into the teres major tendon and bluntly dissect its muscle from the latissimus dorsi tendon.
- Make an incision, concave side up, below the breast in the inframammary fold.
- Create a blunt tunnel from the posterior to the anterior incision, using a finger to dissect deep to the latissimus dorsi muscle.
- Pass the sutures and the teres major tendon deep to the latissimus dorsi muscle into the anterior wound. Make sure that fascia is not binding the muscle and that the muscle is neither kinked nor twisted in the axillary wound.
- Expose the fifth and sixth ribs subperiosteally through the inframammary incision.
- Identify the tendons of the rhomboid major and minor muscles, and separate the superior slip from the inferior slip.
- Pass the superior slip into the fifth rib and the inferior slip into the sixth rib through drill holes in the bone.
- Determine tension by placing the arm in abduction and forward flexion with external rotation. In this position, the transferred teres major tendon should feel snug and draw the inferior pole of the scapula toward the chest wall. Secure this insertion with further nonabsorbable sutures into the periosteum and the teres major tendon.
- Close the wounds in routine fashion.
- After surgery, place the patient in a shoulder abduction splint, maintaining the arm in abduction, forward flexion, and external rotation for 6 weeks.
- Encourage motion of the elbow, wrist, and digits during the period of shoulder immobilization.
- After 6 weeks, initiate physical therapy to regain full range of motion in the shoulder along with gradual strengthening exercises.

SPINAL ACCESSORY NERVE PALSY

Spinal accessory nerve injury leads to trapezius muscle dysfunction. The trapezius muscle is important in stabilizing the scapula during forward elevation of the arm, and paralysis of it results in dropping, lateral displacement, and winging of the scapula, with weakness of forward elevation and abduction. Patients complain of pain in the shoulder and axilla. Pain and weakness increase with exertion of the arm. The pain may result from traction on the brachial plexus, causing a radiculitis; it has even been demonstrated that traction on the suprascapular nerve alone can be the cause of pain in trapezius palsy (46). The pain also may result from a neuroma (see Chapter 53), which is demonstrated by eliciting Tinel's sign in the posterior cervical triangle.

The accessory nerve exits the skull through the jugular foramen and passes inferior to the surface of the sternocleidomastoid muscle, which it innervates. As it passes underneath or penetrates the deep head of that muscle, it reappears under its posterior edge between the upper and middle thirds. It then enters the posterior cervical triangle, where it lies superficially. The nerve passes beneath the trapezius and forms a plexus with fibers from the third and fourth cervical nerves while innervating the trapezius muscle. The spinal accessory nerve runs a vertical course medial and parallel to the vertebral border of the scapula (29). They also found that three to six nerve branches also run a vertical course lying 33% to 50% of the distance from the tips of the vertebral spinous processes to the lateral tip of the acromion. They concluded that muscle-splitting incisions are relatively safe in the lateral half of the muscle (29).

The spinal accessory nerve's superficial position in the floor of the posterior cervical triangle renders it vulnerable to injury. Most commonly, the injury occurs during a surgical procedure such as surgical lymph node biopsy or removal of a benign tumor (13,71). It used to be that the nerve was frequently excised during radical neck dissection for malignant tumor, but more recently it is being spared when this operation is performed. The nerve may also be injured by penetrating or blunt trauma to the neck; I explored and grafted one patient's nerve that had been divided from a bite in the neck during a lovers' quarrel. Spontaneous palsy of the accessory nerve has been reported, but all known cases were due to heavy, repetitive work or were related to a particular incident of strenuous activity (41).

On examination, look for signs of surgical scars, and percuss to elicit Tinel's sign in the posterior cervical triangle. The patient may be unable to abduct the shoulder above 80°, and shrugging of the shoulder produces winging of the superior border of the scapula. An abduction test has been devised to further demonstrate the flaring of the vertebral border of the scapula. Hold the patient's wrist firmly at his side and ask him to attempt abduction against resistance. The test is considered positive if there is flaring of the entire vertebral border of the scapula (69).

Electrodiagnostic testing will confirm trapezius muscle palsy, help localize the lesion, and rule out other forms of neuropathy. Initially and up to 1 year, perform exploration of the nerve with neurolysis, repair, or grafting as necessary. After 1 year, consider reconstructive substitutions for the trapezius.

Conservative treatment is usually unsuccessful. Before surgery, however, I give the patient a trial of shoulder immobilization to see if removing the pull of the weight of the shoulder and axilla. Pain and weakness increase with exertion of the arm. The pain may result from traction on the brachial plexus, causing a radiculitis; it has even been demonstrated that traction on the suprascapular nerve alone can be the cause of pain in trapezius palsy (46). The pain also may result from a neuroma (see Chapter 53), which is demonstrated by eliciting Tinel's sign in the posterior cervical triangle.

On examination, look for signs of surgical scars, and percuss to elicit Tinel's sign in the posterior cervical triangle. The patient may be unable to abduct the shoulder above 80°, and shrugging of the shoulder produces winging of the superior border of the scapula. An abduction test has been devised to further demonstrate the flaring of the vertebral border of the scapula. Hold the patient's wrist firmly at his side and ask him to attempt abduction against resistance. The test is considered positive if there is flaring of the entire vertebral border of the scapula (69).

Electrodiagnostic testing will confirm trapezius muscle palsy, help localize the lesion, and rule out other forms of neuropathy. Initially and up to 1 year, perform exploration of the nerve with neurolysis, repair, or grafting as necessary. After 1 year, consider reconstructive substitutions for the trapezius.

Reconstructive options take the form of static or dynamic scapular stabilizations. Static stabilization procedures using fascia tend to stretch in time and are more often used in patients who have neuromuscular disorders and widespread weakness (10,22). The procedure of choice is an operation first described by Eden (19) in 1924, and later by Lange (39) in 1951. The Eden-Lange procedure is a lateral transfer of the levator scapulae and rhomboid major and minor muscles (36). The trapezius muscle has upper, middle, and lower components: The upper portion rotates and elevates the scapula, the middle portion stabilizes and adducts the scapula, and the lower portion down wardly rotates and depresses the scapula. The lateral transfer of the levator scapulae and rhomboid muscles allows them to approximate the function of the three portions of the trapezius muscle by changing the direction of their pull. The operation is well described by Biglani et al., whose technique follows (2).

Figure 59.11. Incisions for the transfer of the rhomboids and levator scapulae in the treatment of trapezius paralysis.
Figure 59.12. The levator scapulae, rhomboid minor and rhomboid major tendon are detached from their insertion on the medial border of the scapula and then transferred laterally.

- Separate the three individual muscles and dissect them proximally and medially, taking care to avoid injury to the dorsal scapular nerve. Tag the ends of each muscle with nonabsorbable sutures.
- Elevate the infraspinatus muscle from the inferior fossa of the scapula.
- Place six drill holes in the scapula, 1.5–2 cm apart, starting 4–5 cm lateral to the medial border of the scapula and 1 cm below its spine.
- Attach the rhomboid major and minor muscles to these drill holes with nonabsorbable heavy suture material.
- Tie the sutures with the scapula in the reduced position and the arm abducted 90°, and imbricate the infraspinatus muscle over the repair.
- Make a 4 cm incision over the scapular spine, starting 3 cm medial to the acromion process and extending medially.
- Dissect the trapezius, deltoid, and supraspinatus muscles subperiosteally and drill three holes through the spine of the scapula. Make a tunnel through the atrophied trapezius muscle, connecting the medial and lateral wounds in the line of the fibers of the upper trapezius.
- Pass the levator scapulae muscle through the tunnel and secure it to the spine of the scapula using nonabsorbable heavy suture material.
- Close the incisions in routine fashion and apply an abduction brace.
- Keep the patient in an abduction brace for 6 weeks after surgery. Allow her to perform passive assistive exercises.
- At 6 weeks, start her on a rehabilitation program to strengthen the shoulder.

UPPER BRACHIAL PLEXUS PALSY

With C5–C6 brachial plexus palsy, a patient will develop a flail shoulder. In time, the weight of the shoulder will cause inferior glenohumeral subluxation and pain. The pain may be secondary to traction on the brachial plexus or joint incongruity. In general, the treatment is reconstruction of the brachial plexus or a shoulder arthrodesis (see Chapter 60 and Chapter 103).

In a C5–C6 brachial plexus palsy, the function of elbow flexion is also absent. While constructing elbow flexion with either pectoralis major or latissimus dorsi tendon transfer, the shoulder may be stabilized if the transfer is performed by rotating the muscle completely on its new neurovascular pedicle. Since the primary function of these muscle transfers is elbow reconstruction, they will not be described in this chapter (see Chapter 58 and Chapter 60).

TYPES OF LESIONS

The typical patient with a brachial plexus injury has been injured in a motorcycle accident (Table 60.1). Other traffic accidents or sports accidents are less frequently the cause of a brachial plexus injury, and the resultant lesions are generally less severe. Open injuries to the brachial plexus may result from stabbing, but these lesions are rather rare. Gunshot wounds usually lead to only partial lesions.

A common mechanism of injury is compression trauma to the shoulder with fixation of the brachial plexus between the clavicle and the first rib. In such cases, the patient's head continues to move away from the shoulder, and a traction lesion results. The position of the arm at the time of injury influences which roots are most exposed to traction. The plexus may be compressed. If the humerus is fractured, the plexus is exposed to uncontrolled traction.

OPEN INJURY

In an open injury with clean transection of parts of the brachial plexus, primary repair is indicated. A blunt injury must be treated according to the rules of peripheral nerve surgery; in such cases, the brachial plexus should be repaired in a second stage.

CLOSED INJURY

In a fracture of the clavicle, compression of the brachial plexus by the fragments of the clavicle is possible. Repositioning and osteosynthesis are indicated if there is an ipsilateral plexus injury. A fracture of the transverse processes of the cervical vertebrae may also cause external compression of parts of the brachial plexus. Operative decompression is indicated.

With concomitant rupture of the subclavian artery and subclavian vein, a huge hematoma forms that compresses the brachial plexus. Vascular surgery to repair the artery or the vein is indicated as an emergency procedure. The question arises whether immediate repair of the brachial plexus should be performed. Usually, these patients have suffered severe trauma and severe loss of blood. Because a surgeon with experience in brachial plexus surgery might not be available, vascular repair should be performed, and the vascular surgeon should use an incision that will allow for later brachial plexus repair. Do not attempt to identify the individual parts of the brachial plexus other than what is necessary for the vascular repair, because this will increase the fibrosis and make the secondary operation more difficult.

In recent years, primary repair of the brachial plexus lesion by a competent brachial plexus surgeon has been undertaken. I have had the opportunity to see the results of some of these cases. My impression is that the repair performed under these acute circumstances tends to be less fastidious than early elective secondary repair and, consequently, the results are not as good.

Most patients with brachial plexus lesions have suffered a closed injury; however, they may also have suffered cranioencephalic trauma or other injuries of the extremities that require more immediate attention. Although there is no indication for emergency surgery for a brachial plexus injury, the question arises as to whether early exploration is indicated (3,4). An advantage of early surgery is that the lack of fibrous tissue makes exploration easier. On the other hand, the extent of the damage is much more difficult to assess because the damaged parts have not yet developed the inevitable fibrosis, making it more difficult to identify those lesions that may have
a chance for spontaneous recovery.

DIAGNOSIS
Lesions differ according to the location of the injury, the extension throughout the plexus, and the degree of damage.

LOCATION OF INJURY

Supraganglionic Lesions
In an avulsion of the nerve roots, the lesion is between the spinal ganglion and the medulla (a supraganglionic lesion). There is no proximal stump and no neuroma formation. The characteristics of these lesions are summarized in Table 60.2.

Table 60.2. Characteristics of Supraganglionic Brachial Plexus Injury with Avulsion of Roots

If the avulsed root can be extracted from the intervertebral canal and is situated outside, then the avulsion is recognized easily during surgical exploration. If, after a root avulsion, the spinal nerve remains within the intervertebral canal, the situation is not as clear. If such a spinal nerve is transected, part of the cross section may show fibrosis and degeneration but with the sensory fibers still intact. Measurement of evoked potentials can establish whether conduction to the central nervous system is possible.

Infraganglionic Lesions
With rupture, the spinal nerve is interrupted and the roots remain intact (an infraganglionic lesion). There is a proximal stump with neuroma formation. The characteristics of such lesions are summarized in Table 60.3.

Table 60.3. Characteristics of Rupture of Spinal Nerves with Roots Intact

Trunk Lesions
At the trunk level, a lesion may be proximal or distal. The long thoracic nerve, which exits the individual spinal nerves at a very proximal level, remains intact in these cases. The suprascapular nerve is usually involved. The pectoral nerves may or may not be damaged, depending on the level of injury (Table 60.4).

Table 60.4. Characteristics of Trunk Lesions in Brachial Plexus Injuries

Cord Lesions
When the lesion is at the level of the cords in the plexus, the long thoracic nerve, the suprascapular nerve, and the pectoral nerves are intact (Table 60.5). A cord lesion may be suspected if a Tinel Hoffmann sign is located in the infraclavicular fossa.
Table 60.5. Characteristics of Cord Lesions in Brachial Plexus Injuries

EXTENT OF LESIONS

Brachial plexus injuries often involve more than one specific lesion. For example, a single spinal nerve may have both a supraganglionic lesion and an infraganglionic lesion. One nerve root may have suffered an avulsion, and a neighboring one may have suffered a rupture. A common occurrence is the combination of a trunk lesion with a cord lesion. Such combinations lead to difficulties in diagnosis. Both false-positive and false-negative results occur with myelography and computed tomography.

A complete brachial plexus lesion involves all five roots (C-5, C-6, C-7, C-8, and T-1). The brachial plexus may receive a major additional source from C-4 or T-2. In the case of a prefixed plexus, the brachial plexus consists of roots C-4 to C-8; in the case of a postfixed plexus, it includes roots C-6 to T-2 (Table 60.6).

Table 60.6. Involvement of Individual Nerve Roots in 83 Patients with Complete Brachial Plexus Palsies*

Partial brachial plexus lesions are of two types. Type 1 lesions involve all roots but to different degrees. Initially there might be a complete brachial plexus lesion with partial recovery. Regard recovered muscles as weaker than normal muscles; this may be important if palliative surgery is being considered. In type 2 lesions, some roots are damaged whereas others are completely intact. In this case, perform palliative surgery according to the usual indications.

The following specific lesions are differentiated according to the extent of the injury:

- Upper brachial plexus lesion (C-5, C-6)
- Extended upper brachial plexus lesion (C-5, C-6, C-7)
- C-7 lesion
- Lower brachial plexus lesion (C-8, T-1)
- Peripheral lesion involving the suprascapular, the axillary, and the musculocutaneous nerves; this lesion simulates an upper brachial plexus lesion.

DEGREE OF DAMAGE

The extent of damage caused by a brachial plexus injury has been classified by Sunderland (33) into five degrees:

- First-degree lesions involve a conduction block without morphologic changes, which can be recognized by electrophysiologic examination. If after several days the conductivity of motor nerve fibers distal to the lesion remains intact despite paralysis, assume a first-degree lesion. Complete spontaneous recovery is possible.
- Second-degree lesions are typified by a loss of continuity of axons with other structures intact. This lesion cannot be recognized as easily as a first-degree lesion. Complete spontaneous recovery is still possible. There is no indication for surgery, but the occurrence of external compression and the development of fibrosis may hinder spontaneous recovery.
- Third-degree lesions are marked by a loss of continuity of axons and endoneurial structures with intact perineurium. Type A or B fibrosis is possible; the content of the fascicles may have become completely fibrotic (type C) if the lesion is very severe or if a long time has elapsed since the injury. With type A or B fibrosis, neurolysis is indicated. With type C fibrosis, neurolysis cannot effect regeneration, and resection with replacement of the involved fascicles by nerve grafts is indicated.
- Fourth-degree lesions, continuity is preserved only by connective tissue. This connective tissue can become completely fibrotic, in which case there is no chance for nerve fibers to grow beyond the lesion (type 4S; S = scar). In other cases, a neuroma may grow into the connective tissue that still unites the two stumps; in such instances, some nerve fibers may reach the distal stump, and therefore some conduction may be elicited during intraoperative stimulation (type 4N; N = neuroma). However, there is no chance for functional recovery. All fourth-degree lesions necessitate resection and repair by nerve grafts.
- Fifth-degree lesions, there is a complete loss of continuity.

Different degrees of involvement are possible in combined lesions. The differentiation between these degrees is made during intraoperative dissection with or without nerve stimulation (Table 60.7).
INDICATIONS FOR SURGERY AND EXPECTED RESULTS

Simple first- or second-degree brachial plexus lesions have good chances for spontaneous recovery, and no surgery is indicated. However, first- or second-degree lesions with epifascicular fibrosis (type 1A or 2A, respectively) usually have initial signs of recovery with subsequent failure to improve, or even some deterioration. Exploration is indicated, and after neurolysis a complete return of function is possible. The same is true for first- or second-degree lesions with interfascicular fibrosis (type 1B or 2B, respectively).

Third-degree lesions have some chance of spontaneous recovery, but this takes longer and the recovery will always be less than complete. Pure third-degree lesions without fibrosis are rare; usually there is a type A or B fibrosis. Such lesions can be converted into pure third-degree lesions by internal neurolysis, after which recovery may occur. If the endoneural space has become completely fibrotic (type 3C), however, there is no chance of spontaneous recovery. In such cases, resect the fascicles and repair continuity by nerve grafts.

In type 4N lesions with neuroma formation, some nerve fibers may get into the distal stump. Usually, regeneration takes a long time and the muscles may have already atrophied and fibrosed before regeneration can occur. Therefore, spontaneous recovery cannot be expected in these lesions, and surgical repair is indicated. This is also the case for fourth-degree lesions without neuroma formation (type 4S). Likewise, if there is a loss of continuity (type 5), there is no chance for spontaneous recovery.

In patients with complete loss of continuity, or type 3C, 4N, or 4S lesions, continuity must be restored. Because of the complexity of the structure of the brachial plexus and the long distance between the site of the lesion and the target organs, expect only partial recovery. Except in infants, the return of intrinsic hand function has not been observed.

The main goal of surgery is the return of active elbow flexion. If this occurs, the result can be regarded as satisfactory. In addition, some control of the shoulder joint, with the correction of subluxation, and the return of some protective sensation can be expected. If some forearm muscles become active, the result can be regarded as good. It is the experience of surgeons involved with brachial plexus surgery that the development of pain syndromes is less common in patients treated operatively than in those who are not treated. In some instances, pain is relieved by surgery.

BASIC APPROACHES TO BRACHIAL PLEXUS LESIONS

Strategies to deal with brachial plexus lesions are based in part on the historical development of brachial plexus surgery since the 1960s. In 1966, a roundtable discussion on brachial plexus surgery was held on the occasion of the tenth Societae Internationale de Chirurgie Orthopédique et Traumatologique (SICOT) congress in Paris. All roundtable members agreed that surgery has nothing to offer in the case of panplexus root lesions, except to verify the diagnosis. With the diagnosis of a root lesion, their recommendation was to not waste time with physiotherapy, and to perform early above-elbow amputation with arthrodesis of the shoulder joint, provided that there is a strong serratus anterior and trapezius muscle (31). Advances have occurred since that recommendation, however. Yeoman and Seddon (31,39) have performed an intercostal nerve transfer linking the third and fourth intercostal nerves with the musculocutaneous nerve via a nerve graft. This experience was furthered by Tsuyama et al. (35). The percentage of good functional recovery of the biceps muscle has constantly improved and has reached a very high standard in recent years (29,34). In the early 1960s, Millesi developed the combined approach to brachial plexus surgery based on the new, reliable technique of interfascicular nerve grafting. In recent years, two new trends have developed: the reimplantation of avulsed roots by Carlstedt et al. (8) and immediate free muscle grafting by Doi (13). These new trends are listed in more detail in the following paragraphs.

TREATMENT OF ROOT AVULSIONS BY INTERCOSTAL NERVE TRANSFER

In contrast to Seddon (31), who recommended intercostal nerve transfer only "if there is no shadow of doubt that the plexus is completely destroyed," Tsuyama et al. (35) applied this technique in all cases that showed signs of root avulsion (e.g., one or two meningocellalas in the myelogram), without convincing himself that really all roots were avulsed. The advantages of this strategy are that it is simple and the brachial plexus need not be explored. The disadvantage is that it neglects other possibilities to gain additional functions for the patient.

COMBINED APPROACH TO TREAT BRACHIAL PLEXUS LESIONS

When a reliable nerve grafting technique was available (18,19,22,23,24 and 25), the combined approach to treatment was immediately applied to brachial plexus lesions. This approach proved to be very helpful because brachial plexus lesions usually involve very long defects that cannot be treated by end-to-end coaptation. From the beginning, the goal was to restore the continuity of as many structures as possible in peripheral lesions, and to exploit not only the intercostal nerve transfer but also all other available nerve transfers, such as accessory nerve, cervical plexus, and so on. In these concepts, reconstructive procedures at a later stage are included (28). Early results of this approach were presented in February 1969 at a meeting in Lausanne, Switzerland (20).

REIMPLANTATION OF AVULSED ROOTS

In recent years, attempts have been made to reimplant avulsed roots, and considerable experimental successes have been presented by Carlstedt et al. (8). He applied this technique also in human cases with some success.

LAMINECTOMY FOR VERIFICATION OF ROOT AVULSIONS

Rootlets were explored within the vertebral canal by dorsal laminectomy to prove avulsion. After clarifying the diagnosis, the wound would be closed and the brachial plexus explored from an anterior approach. Information about the continuity for the dorsal roots but not for the ventral roots can be obtained more easily through intraoperative studies of evoked potentials.

Today, continuity of the ventral rootlets can be proven by the technique of central stimulation (36,37). With stimulation of the precentral gyrus of the cerebrum, action potentials reach all the peripheral nerves. Lack of a peripherally recorded potential indicates that the rootlets are avulsed. This is a reliable technique and it makes surgical exploration to verify root avulsion obsolete.

IMMEDIATE FREE MUSCLE GRAFTING

Doi (13) has treated fresh brachial plexus lesions by immediate free muscle grafting. In a first stage, the gracilis muscle was connected to the accessory nerve and used to activate the extensor digitorum communis tendons. At the same time, sensory fibers from the cervical plexus were transferred to the median nerve. In a second stage, a free muscle graft of the contralateral gracilis muscle was used to activate the flexor muscles of the fingers and also to produce flexion of the elbow joint. This muscle was connected to intercostal nerves II, III, and IV, for motor function. The sensory components of the intercostal nerves were transferred to the ulnar nerve. At the same stage, the motor components of intercostal nerves V and VI were transferred to the triceps muscle to achieve elbow extension. With this technique, elbow flexion and extension as well as finger flexion and extension were achieved.

In my opinion, this technique is very useful for older cases in which the original muscles of the arm are atrophic, but it may lead to a waste of muscle and nerves in cases less than 4 to 6 months old if no attempt is made to reinnervate them. In addition, nothing is done for shoulder abduction and external rotation. I feel that function of the shoulder joint is key to positioning the forearm and hand for function.

TECHNIQUES FOR EXPLORATION (COMBINED APPROACH)

BRACHIAL PlexUS Surgery IN THE BEACH-CHAIR POSITION
Many surgeons approach the brachial plexus anteriorly with the patient in a beach-chair position. This has the advantage that the surgeon sees all anatomic structures as they are depicted in the textbooks. The primary disadvantage, however, is that the clavicle is an obstacle for the exposure, and it is understandable that many surgeons do an osteotomy of the clavicle to facilitate the exposure. After the brachial plexus surgery, the clavicle is fixed with plate and screws (27,28).

ANTERIOR APPROACH IN THE SUPINE POSITION

- I prefer the supine position and an anterior approach for exploration. Place the patient supine with some support beneath the scapula to elevate the shoulder joint slightly. Turn the head to the contralateral side, prep the arm, and drape it free.
- For exploration of the supra- and infraclavicular fossae, sit between the head of the patient and the abducted arm. For exploration of the axilla and the upper arm, move into the angle between the trunk and the upper arm.

The advantages of this approach are that the supra- and infraclavicular fossae are approached from the cranial direction. The clavicle can be lifted and does not form an obstacle, and an osteotomy of the clavicle is never necessary. Also, the roots can be visualized from both the dorsal and anterior aspects. This is further facilitated by a sagittal incision, as outlined below. The only disadvantage is that the anatomy is seen upside down in relation to the usual anatomic illustrations.

- Make a sagittal incision directly across the supraclavicular fossa, crossing the clavicle at an oblique angle (Fig. 60.1). This incision has the advantage that it can be extended dorsally to the border of the trapezius muscle, and the supraclavicular fossa can be explored very dorsally. This also provides a good approach to the spinal nerves from a dorsal aspect (Fig. 60.2 and Fig. 60.3).

**Figure 60.1.** Approach to the brachial plexus by a sagittal incision. The figure shows the patient on his back. His head is on the right, the shoulder on the left side in the position of surgery.

**Figure 60.2.** The exploration of the upper, middle, and lower trunks through a sagittal incision in a patient with a lesion in continuity. The lesion is on the right side. Left is proximal and right distal.

**Figure 60.3.** The remaining scar of the patient from Figure 60.1.

- Always use a second curved incision, starting at the coracoid process and following the lines of tension to reach the anterior axillary fold. Where it turns to follow the anterior axillary fold, it can be continued to the middle aspect of the medial surface of the upper arm.
- Elevate the skin between these two incisions to unite the two fields. The only drawback to this approach is that the pedicled skin flap between these two incisions has to be moved in a medial or lateral direction to provide a proper field of vision.
- If spinal nerves C-5 and C-6 have to be explored, make a third incision in the transverse direction, again following the tension lines in the caudal third of the neck.
- In very rare instances, a fourth transverse incision far more cranially on the neck is necessary to provide access to the cervical plexus and the accessory nerve.
- Begin the exploration of the brachial plexus in the deltopectoral groove, sparing the cephalic vein. Transect the fascia beneath the muscle and find the lateral cord. Cranially, the posterior cord is seen; inferiorly, the artery is encountered. Medial to the artery, expose the medial cord. Proceeding in a lateral direction, the division of the lateral cord into the musculocutaneous nerve and the lateral root of the median nerve is seen. Follow the posterior cord, dorsal to the artery, to explore the division into the radial, axillary, and thoracodorsal nerves. Follow the medial cord distally to expose the ulnar nerve and the medial origin of the median nerve as well as the median antebrachial cutaneous nerve. Usually, this area is free of scar and the dissection is easy.
- If this part of the brachial plexus is damaged, it will be fibrotic. If it is scarred in, I do not dissect at this level. Lengthen the incision to the medial aspect of the upper arm and explore the nerves where they are normal, following them proximally into the area of injury.
- Having defined the aforementioned structures in the deltopectoral sulcus, dissect in a medial direction.
- Isolate and retract the pectoralis minor muscle to expose the plexus along its medial border.
- Continue the dissection to the area beneath the clavicle. This level is usually fibrotic.
- Next, enter the supraclavicular fossa by transecting the superficial cervical fascia. The external jugular vein is seen and spared, and the omohyoid muscle is identified.
- Dissect bluntly from both sides beneath the clavicle. Partially detach the clavicular origin of the pectoralis major muscle and isolate the subclavius muscle to facilitate this procedure.
- Follow the cords to define the divisions and to isolate the upper, middle, and lower trunks. Follow them up to the spinal nerves.
- The brachial plexus is now exposed in its full length and access is available through several windows:
  - The supraclavicular fossa cranial to the omohyoid muscle.
  - The space between the omohyoid muscle and the clavicle.
  - The space between the clavicle and the subclavian muscle.
  - The space between subclavian muscle and the pectoralis major muscle proximal to the pectoralis minor muscle.
  - The space between the pectoralis major and the deltopectoral fascia.
The axillary groove and the medial aspect of the arm.

To achieve this approach, no traversing structures need to be transected.

During the dissection, the minor structures of the brachial plexus are defined as well. This includes the suprascapular nerve in the suprascapular fossa, originating from the superior trunk at its division into the anterior and posterior division, the medial and the lateral pectoral nerves, going to the major pectoral muscles. The long thoracic nerve and the dorsal scapular nerve are met where they emerge from the scalenus medius muscle. The phrenic nerve is seen on the anterior aspect of the scalenus anterior muscle.

**EXPOSURE OF THE CERVICAL PLEXUS AND THE ACCESSORY NERVE**

- Using the third transverse incision in the lower part of the neck just described to approach the roots of C-5 and C-6, explore the plexus and the accessory nerve. In exceptional cases, make another cranially located transverse incision to facilitate the exposure, again undermining the skin between the two incisions.
- On the dorsal border of the sternocleidomastoid, define the nerves ascending around the border of this muscle. Here are found the transversus colli nerve, the major auricular nerve, and the minor occipital nerve. Follow these nerves in a central direction to reach the roots of C-4 and C-3. The C-4 root can also be reached by following the phrenic nerve after its exposure on the anterior surface of the scalenus anterior muscle. The different branches of the supraventricular nerves, followed in a central direction, lead to C-4. Use electric stimulation to recognize motor branches.
- Following the technique of Brunelli and Monini (8), expose the anterior motor branches of the cervical plexus.
- Slightly lateral and deep to the punctum nervosum, a group of lymph nodes is encountered. Deeper to these structures is the accessory nerve, emerging from a layer beneath the sternocleidomastoid muscle. Farther distally, the accessory nerve becomes more superficial. Before it enters the trapezius muscle, it gives off one branch to the muscle, which is able to maintain the function of the muscle even if the accessory nerve is transected distally to it. In this way, the function of the trapezius muscle can be preserved. Frequently, the trapezius muscle gets an additional innervation by a branch from the cervical plexus.

**EXPLORATION AND TRANSFER OF INTERCOSTAL NERVES**

The intercostal nerves I to VI consist of a motor component that innervates in its dorsal segment the serratus posterior superior and serratus posterior inferior muscles. Along their course, they give off branches to the intercostal muscles, and finally they innervate the transversus thoracis muscle. The sensory component leaves the nerve at the anterior border of the serratus anterior muscle, as lateral cutaneous rami, which reach the subcutaneous tissue and divide into a ventral and a dorsal branch. Close to the sternum, the anterior cutaneous branches leave the nerves and again divide into a ventral and a lateral branch. It is therefore obvious that these nerves contain a decreasing number of motor fibers as they progress distally. In the proximal segment before the lateral cutaneous branches leave the nerve, they contain more sensory fibers than after the departure of these nerves. Intercostal nerves VII to XII contain more motor fibers because they innervate the muscles of the abdominal wall.

Intercostal nerves III and IV, and sometimes also V, can be exposed to a very distal level, by the following technique:

- Make an incision that runs parallel to the ribs. The nerves can be transected far distally, isolated to a more proximal level, turned in the direction of the nerve to be neurorized (mainly the musculocutaneous nerve), and connected directly with this nerve. The advantage of this procedure is that only one coaptation is necessary. The disadvantage is that the incision has to be performed far in an anterior direction and the number of motor fibers is lower than in the midaxillary line, for example.

An alternative to this technique is the following:

- Perform a longitudinal incision in the lateral thoracic wall between the pectoralis major and the latissimus dorsi muscle.
- Split the fibers of the serratus anterior longitudinally along each rib, expose the ribs for a distance of 6–10 cm.
- Expose the intercostal nerves after dissecting off the external intercostal muscles, elevating the rib to gain access to the space beneath the lower border of the rib.
- Define the intercostal nerves here. Sometimes there are separate motor and sensory components.
- Use electric stimulation to identify the motor component for transfer to muscles and eventually the sensory component for transfer of sensory fibers.

If this is done in the midaxillary level, even if 5 or 6 cm of the nerve are isolated, the target nerve is not reached and a nerve graft has to be used in all cases. The disadvantage of this technique is that two lines of coaptation must be crossed by the nerve fibers. The advantage is that the incision is less conspicuous and the nerves contain relatively more motor fibers. It is obvious that from intercostal nerve V onwards, all further intercostal nerve transfers would need a graft because the distance between the thoracic wall and the proximal arm is too long. Because the motor fibers in general are small in number, three intercostal nerves are needed to neurotize a nerve of the caliber of the musculocutaneous nerve. Considering the high success rate of Tetsuya et al. (34) and Ogino and Naito (29), a transfer with end-to-end coaptation seems safer than a transfer by nerve graft. I recommend using intercostal nerves III and IV as nerve transfers by end-to-end repair; use intercostal nerves V, VI, and so forth via nerve grafts.

Another technique (19), which has not become popular, involves the following steps:

- Explore the intercostal nerves dorsally with the patient in a prone position.
- Bring the intercostal nerves above the pleura to the anterior side.
- Continue the operation after turning the patient on his or her back.

**TECHNIQUES FOR SURGICAL REPAIR**

**NEUROLEYSIS**

External neurolysis isolates the nerve trunks from adhesions to the surrounding tissues. An epifascicular epineuromyotony (single or multiple) is indicated to decompress the nerve trunk with type A fibrosis. If there is a moderate degree of interfascicular fibrosis (type B), epineuromyotony will not be sufficient. An epifascicular epineuromyotony (dissecting the epifascicular tissue) is then indicated. With more extensive interfascicular fibrosis (type C), the interfascicular tissue must be partially excised to achieve decompression (interfascicular epineuromyotony).

**NEURORHAPHY**

A neurorhaphy with end-to-end coaptation of nerve stumps is rarely possible with brachial plexus lesions. It is most appropriate in cases of clean transection (e.g., stab injuries) and follows the usual techniques.

**END-TO-SIDE COAPTATION**

Viterbo (38) discovered that a denervated nerve brought with its cross section end-to-side in contact with an innervated nerve may be neurorized from the innervated nerve. The neurolysis occurs across the perineurium if an epineurial window is created, and the neurolysis is even better, of course, when a perineural window is also made. The possibility of end-to-side coaptation offers many opportunities in brachial plexus surgery. I have successfully performed an end-to-side coaptation between a functioning dorsal scapular nerve and the denervated long thoracic nerve. Before that, my colleagues and I had transected the dorsal scapular nerve and sacrificed its function to achieve neurotization of a serratus anterior muscle, which is extremely important. By using end-to-side coaptation, we not only preserve the dorsal scapular function but also innervate the serratus anterior muscle. In a similar way, we have used nerve grafts that were coapted end-to-side to the phrenic nerve with its proximal end, and end-to-end to the lateral and medial pectoral nerves. In this way, the phrenic nerve could be used as an axon donor without sacrificing its function. Our results with end-to-side coaptation have been excellent in small nerves with one function. Whether it works in major nerves with multiple functions is not yet known (see the following discussion).

So far, we have made only epineurial windows. A perineural window does not seem to be necessary. It is obvious that this method offers a vast amplification of the possibilities in brachial plexus surgery. Its full value has yet to be shown in sufficient clinical cases.

**NERVE GRAFTING**

Restoration of continuity by free nerve grafting is performed using the sural nerve, the medial antebrachial cutaneous nerve, and occasionally the superficial branch of
the radial nerve. The use of cutaneous nerve segments for nerve grafting has the great advantage that well-defined points of the proximal stump can be coapted to well-defined points of the distal stump. Place the grafts individually to increase the spontaneous revascularization and to avoid central fibrosis. The grafts must be long enough to avoid longitudinal tension. Very few stitches are necessary to approximate the graft to the proximal and distal stumps. In recent years, the use of fibrin glues has been recommended to shorten the operative time considerably (27,28). If the grafts are long enough and the coaptations are absolutely tensionless, only a few sutures between the stumps and the grafts are necessary. In this case, the decrease of operative time by using tissue glue is minimal (Table 60.8).

Table 60.8. Donor Nerves for Free Nerve Grafts

In a root avulsion at C-8 and T-1, the ulnar nerve is available for use as a nerve graft. Bonney and Birch (4) have transplanted the ulnar nerve as a free vascularized graft based on the ulnar artery. Breidenbach and Terzis (6,7) have demonstrated that a free microvascular transfer is possible by using the superior ulnar collateral artery as the nutritive vessel without sacrificing the ulnar artery (Table 60.8).

Table 60.9. Donor Nerves for Vascularized Nerve Grafts

If there is a long superior collateral ulnar artery, the ulnar nerve can be transferred as an island flap without interrupting the blood supply. If the blood supply is not interrupted by a complication, this type of nerve graft offers the advantage that it is not dependent on the vascularity of the recipient bed. Achieving connections of well-defined spots on the proximal and the distal stumps is more difficult. Initial expectations that the qualitative result of regeneration would be significantly improved by this method have not been fulfilled. Most authors agree that the first signs of recovery might occur somewhat earlier but the final result is the same as with free nerve grafting with spontaneous revascularization (1,2,5,16,17,18).

The ulnar nerve can also be used as a donor of free graft after the epifascicular epineurium has been removed and the nerve trunk has been split into minor units by interfascicular dissection (19).

NERVE TRANSFER

By connecting the proximal stump of a normal nerve to the distal stump of a denervated nerve, nerve fibers can be transferred to the denervated nerve and will neurotize this denervated nerve. After reaching the target organ, functional recovery can be achieved; however, the patient must learn to use the stimuli from the donor nerve to perform a different movement with the newly reinnervated muscles. In the vast majority of cases, patients learn this quite easily. A correct term for this procedure would be nerve-fiber transfer. The term neurotization is widely used for this procedure, but this is incorrect because neurotization means to bring nerve fibers into a denervated area. Regardless of what type of transfer I do—end-to-end, end-to-side repair, or nerve grafting—I always neurotize a denervated nerve from an innervated proximal stump.

Another frequently used axon donor is the accessory nerve, especially after the first branch has left the nerve. The superior part of the trapezius muscle remains innervated by this branch and can even be used for a muscle transfer at a later stage. The trapezius muscle frequently has an additional innervation from the cervical plexus (ramus trapezius) and does not become totally denervated, even if the whole accessory nerve has been transected. Brunelli and Monini (8) described the use of the anterior nerves of the cervical plexus.

The dorsal scapular nerve is used now mainly in an end-to-side fashion. The phrenic nerve has also been suggested as an axon donor. The consequence of transecting the nerve would be the loss of function of the ipsilateral diaphragm. In a young patient, this might not do much harm if the thoracic muscles are intact. It should, however, never be combined with an intercostal nerve transfer. The phrenic nerve, of course, may easily be used if there is an accessory phrenic nerve available. Today, we use it in an end-to-side fashion. If there is a long superior collateral ulnar artery, the ulnar nerve can be transferred as an island flap without interrupting the blood supply. If the blood supply is not interrupted by a complication, this type of nerve graft offers the advantage that it is not dependent on the vascularity of the recipient bed. Achieving connections of well-defined spots on the proximal and the distal stumps is more difficult. Initial expectations that the qualitative result of regeneration would be significantly improved by this method have not been fulfilled. Most authors agree that the first signs of recovery might occur somewhat earlier but the final result is the same as with free nerve grafting with spontaneous revascularization (1,2,5,16,17,18).

The hypoglossal nerve has also been suggested as a source for the brachial plexus; however, this may cause some problems with tongue function.

Gu et al. (14) observed that a clean transection of C-7 does not create many adverse consequences, and contralateral transfers can be done. Usually after transection of C-7, the patient notes some weakness in the triceps as well as wrist and finger extensors. This weakness, however, disappears within a few weeks by compensatory hypertrophy of the remaining innervated fibers. The patient experiences some minimal sensory loss in the thumb and index finger, which does not create a long-term problem. Gu et al. (14) and Chuang et al. (11) performed a series of C-7 transfers that provided additional useful function. The only problem, however, is that the patient has to consciously use the nonparalyzed side to have an effect on the contralateral paralyzed side.

The problem with contralateral C-7 transfer is a major loss of function caused by a variation in the distribution of the nerve fibers. Intraoperative electric stimulation studies may avoid this, but in my opinion they are not reliable enough. Therefore, before a C-7 transfer, I perform an exposure of the contralateral root C-7 and place a ligature on the divisions. On the day after the operation, the real loss of function can be estimated very well and the patient can decide whether this functional loss, which decreases with time, is acceptable. If the patient accepts this condition, the C-7 transfer is performed at a second stage.

I performed my first C-7 transfer in 1993; after evaluating the functional result of the first three cases several years thereafter, I started to do it as a routine procedure. A C-7 transfer is appropriate in patients with avulsions of all five roots, or in patients with avulsion of several roots who have had the usual reconstructive procedures (restoration of continuity and ipsilateral nerve transfers) and who desire additional strength (Fig. 60.4).
decompression has been achieved, end the surgery. If not, the next step must be carried out until you are convinced that the damage makes spontaneous recovery

SELECTION OF SURGICAL TECHNIQUES ACCORDING TO THE SEVERITY OF THE NERVE LESION

For patients with avulsions of all five roots, initially perform nerve transfers to improve shoulder and elbow function. In a second stage, do a C-7 transfer to provide additional functional recovery in the forearm and finger flexors. With recovery of these muscles, reconstruct a gripping function of the hand.

In an initial series, we used the ulnar nerve as a vascularized graft to connect C-7 with the median nerve. In a follow-up series, we used the ulnar nerve as a vascularized graft to connect the anterior division of C-7 with the median nerve, and free nerve grafts to connect the posterior division of C-7 with the radial nerve distal to the branches to the triceps muscle.

In other cases when the radial nerve was neurotized by other donors, the anterior division was connected via a saphenous nerve graft with the median nerve, and the posterior division via a saphenous nerve graft with the ulnar nerve, attempting to restore the function of both the median and the ulnar nerves. So far, the results are encouraging, and late results will be available in a few years.

Complications were encountered in two cases. In one case, the biceps muscle became paralyzed after the ligature, in spite of the fact that this was not recognized during intraoperative electrostimulation. In this case, we opened the ligature and performed the C-7 transfer as an end-to-side coaptation between the now-preserved anterior and posterior division of C-7 and the grafts. This case is

Figure 60.5. This 7-year-old boy suffered a skiing accident that caused a complete lesion of the right brachial plexus, along with a lesion of the subclavian artery and a fracture of the clavicle. The artery was reconstructed by a vein graft and the brachial plexus was operated on in the boy's home town, but there was no recovery. I saw the patient for the first time 11 months after the accident. Avulsion of the C-7, C-8, and T-1 roots was diagnosed, and a reexploration with a C-7 transfer from the contralateral side was planned.

The left root C-7 was ligated, and there was no unexpected loss of function. Six days later, the right brachial plexus was explored, and the avulsion of C-7, C-8, and T-1 was confirmed. Only the right C-6 root could be used as a proximal stump. It was connected with the musculocutaneous nerve by a graft 18 cm long, with good success (biceps now M-4). Another graft was used to neurotize the axillary nerve (abduction with the shoulder joint now 30°), and two nerve grafts were interposed between C-6 and the radial nerve (with no recovery). A vascularized ulnar nerve segment 30 cm long was used to connect the contralateral C-7 and the ipsilateral median nerve.

These images represent the patient's hand at a follow-up examination 6 years after the initial surgery. A: On the patient's right side, note the scar of the sagittal incision and the somewhat broadened scar from the curved incision over the deltopectoral sulcus. On the patient's left, note a sagittal scar from the exploration of the C-7 contralateral. B,C,D: There is good functional return in the flexor digitorum superficialis and profundus, the flexor pollicis longus, the flexor carpi radialis, and the palmaris longus.

A tendon transfer for finger extension is scheduled.

especially interesting and we presently are awaiting the final result. If this end-to-side coaptation would work also with major nerve trunks, new possibilities would be available.

In the second case, the sensory loss of the thumb and the index finger was more than had been expected. In this case, the C-7 transfer was performed with only the dorsal division, and the anterior division was preserved. The area of loss of sensibility was reduced significantly.

SELECTION OF SURGICAL TECHNIQUES ACCORDING TO THE SEVERITY OF THE NERVE LESION

If nerve continuity is present, do a progressive intraneural neurolysis to define the degree of damage. If it becomes clear that the fascicular structure remains intact and decompression has been achieved, end the surgery. If not, the next step must be carried out until you are convinced that the damage makes spontaneous recovery
impossible. In this case, resect the damaged part and restore continuity by nerve grafting.

If nerve continuity is not present, prepare the proximal and distal stumps by resection or by interfascicular dissection until normal tissue is found. Then restore continuity by nerve grafts. In short defects (5–6 cm), direct end-to-end repair can be done. If, however, the defect is very large and extends, for example, from the trunk to the distal cord level, we prefer to do nerve grafts directly to the peripheral nerves (e.g., from C-5 directly to the axillary nerve, or from C-6 directly to the musculocutaneous nerve).

If a lesion is at the level of the spinal nerves, restoring continuity of all structures is usually impossible; you must then decide which parts are to be repaired. The highest priority is to restore elbow flexion. If possible, C-6 is united with distal structures leading to that part of the lateral cord that forms the musculocutaneous nerve, or in longer lesions we unite C-6 directly with the musculocutaneous nerve. The next important function is the control of the shoulder joint. Thus we try to neurorize the suprascapular nerve with fibers coming from C-5 or even C-4. Nerve fibers of the dorsal aspect of C-5, C-6, and C-7 are united with the posterior cord to provide nerve fibers to the axillary and radial nerves or in long defects with the nerves directly. C-8 and T-1 have a poor prognosis and therefore are the last priority.

In cases of root avulsion, an individual plan must be made for each patient. If the avulsion involves C-6 and T-1, the ulnar nerve can be used as a nerve graft. No attempt is made to neurorize the medial cord because of the low success rate (27), but this does not exclude neurorization of the ulnar nerve if a sufficient number of axon donors are available.

If C-6 is avulsed, C-5 can be used for the musculocutaneous nerve; in addition, it is connected with the scapular nerve. If C-7 is avulsed, the accessory nerve may be the donor for neurorization of the radial nerve.

If C-5 and C-6 are both avulsed, the accessory nerve may neurorize the suprascapular, and the axillary nerve and intercostal nerves are used for the musculocutaneous nerve. The musculocutaneous, however, can also be neurorized successfully by the accessory nerve (15). A similar approach is used in avulsion of C-5, C-6, and C-7. If all roots are avulsed, we prefer transfers at present, as suggested in Table 60.10, Table 60.11, Table 60.12 and Table 60.13.

POSTOPERATIVE CARE

After wound closure, immobilize the patient for 10 days in the intraoperative position by a plaster cast that includes the head, the trunk, and the arm. After this time, initiate passive and active mobilization for as wide a range of motion as possible. Electrotherapy of the denervated muscles is useful. Splinting should avoid overstretch of muscles, especially the biceps. There is still some question as to whether the shoulder joint should be immobilized in abduction to maintain full range of motion. In my experience, return of active motion in the shoulder joint is always limited; therefore, it is unnecessary to maintain a wide range of passive motion. The use of a custom orthosis is recommended.

SECONDARY RECONSTRUCTIVE SURGERY

In partial type II lesions with intact muscles, perform procedures to replace lost elbow flexion. Such procedures include the following:

- Transfer of the lateral segment of the pectoralis major muscle (12);
- Transfer of the latissimus dorsi muscle (40);
- Transfer of the common forearm flexor muscles from the medial epicondyle of the humerus to the shaft of the humerus (32).

In partial type I lesions, carefully evaluate the available muscle force. To improve the functional result in a regenerating biceps, a shortening of the biceps tendon some times helps. The biceps tendon can also be transferred 1 or 2 cm distally to provide a better lever arm and better flexion power by sacrificing supination. Simultaneous innervation of the biceps and triceps occurs quite often, and usually the triceps is the stronger muscle. In this case, mobilize the triceps, transfer its tendon to the anterior aspect, and unite it with the biceps tendon so that both muscles act as flexors. Sometimes the triceps has successfully replaced a nonfunctioning biceps, and
in some cases we have initially restored the function of the triceps by nerve transfer, planning a later muscle transfer. The control of shoulder function can be achieved by transferring the horizontal part of the trapezius muscle, including the bony insertion at the acromion, to the humerus, as described by Saha (30). Active gain of abduction is limited, but usually subluxation can be avoided and some control achieved. In some cases, after tenolysis and mobilization of the supraespinalus muscle and tendon, the horizontal part of the trapezius muscle was directly transferred to the supraespinalus tendon, proximal or in other cases distal to the acromion, passing beneath the acromion. There are cases in which the clavicular and posterior heads of the deltoide muscle recover but the acromial component does not. The clavicular head and the posterior third then act as adductors. In such cases, we have transferred successfully the clavicular and the posterior heads toward the median line of the shoulder joint (mediolization) to make both parts abductors.

Forceful recovery of elbow flexion does not help if the patient cannot externally rotate the shoulder. External rotation is a crucial function and must be considered from the beginning. We feel it is extremely important to achieve a strong pectoral major muscle. We transfer the pectoralis major muscle around the humerus shaft to the dorsal side along with the latissimus dorsi muscle, to act as an external rotator. If there is an internal rotation contracture, perform an osteotomy of the humerus at the same time to derotate the humerus by about 60°. The osteotomy is immobilized by plate and screws, and the pectoralis and the latissimus dorsi, if recovered, are transferred to the lateral aspect of the humeral shaft. Some patients develop a supination contracture, which has to be treated by mobilizing the radius and ulna with transsection of the interosseous membrane, ensuring that the radial tuberosity clears the ulna during pronation. The biceps tendon can be inserted into the coronoid process to avoid supination and pronation contracture.

If elbow flexion has returned but wrist and finger flexion are still paralyzed, we perform an arthrodesis or a tenodesis of the wrist joint. If one or two forearm muscles have returned, it is possible to restore simple gripping function (key grip) by tendon transfers. If all these procedures fail, and the local muscles are degenerated, a free muscle graft can still replace one or two important functions (13).

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

The signs and symptoms of thoracic outlet syndrome (TOS) result from compression of the neurovascular structures as they exit the chest and neck and pass through the costoclavicular interval and down into the axilla. The clinical presentation in each patient reflects the degree of compression of the brachial plexus and of the subclavian artery and vein. Historically, the interscalene area was considered the primary site of compression, but subsequent experience has shown that treatment of this disorder requires understanding the dynamic anatomy of the entire region of the neck and shoulder region.

Changes in the alignment of the shoulder girdle with normal development, age, and disease complicate the problem considerably but also provide a way to understand how signs and symptoms are produced (33). Specifically, exaggeration of the normal caudad descent of the shoulder girdle produced by poor posture or local injury can cause compression of the lower trunk of the brachial plexus and of the subclavian artery and vein (Fig. 61.1). This mechanism can explain the emergence of symptoms of TOS in patients who are asymptomatic before motor vehicle accidents (6,20,26). Congenital anatomic abnormalities such as cervical ribs, long transverse processes, or congenital bands can increase the severity of the effect.

Figure 61.1. This patient was asymptomatic before a motor vehicle accident in which she sustained what was termed a whiplash injury. This caused pain in the shoulder girdle, which led to a postural drop of her scapula and subsequent thoracic outlet compression. She was overweight with large breasts, which added to the downward pull on her shoulder girdle. Ultimately, after failure of conservative treatment, she underwent first rib resection with relief of her symptoms but required extensive postoperative muscle reeducation to correct her posture.

Although the incidence of cervical ribs in the general population has been reported in different studies to range from 0.056% to 1.5% (35), nine types of congenital fibrous bands have been described that can cause neurovascular compression within the thoracic outlet (30). Malunions and nonunions of the clavicle can also lead to thoracic outlet compression (14). Instability of the glenohumeral joint (33) can be associated with numbness and tingling within the limb or with secondary TOS (17). For reasons that are discussed further later, females with TOS outnumber males by about four to one. The disorder is seen most commonly between puberty and the fourth decade of life. Although there are scattered case reports of girls who have developed TOS in childhood, the authors do not report whether the patients had attained menarche. A postmenopausal woman who develops symptoms thought to be due to thoracic outlet compression should be carefully examined to be certain that the symptoms are not due to another condition.

CLINICAL PRESENTATION OF THORACIC OUTLET SYNDROME

For reasons that will become much clearer later in this chapter, I believe that the diagnosis of TOS is primarily clinical. Although some laboratory examinations are helpful, diagnosis is usually made on the basis of a careful history and physical examination.

The symptoms of TOS are quite variable, depending on which structures are being compressed. The majority of patients complain of pain and paresthesias that radiate from the neck, upper chest, or shoulder region, down the medial aspect of the arm and into the little and ring fingers, although some experience numbness of the entire upper limb. Much less commonly, it is the radial aspect of the arm and hand that is numb. Symptoms are often nocturnal; elevation of the arm in sleep or during activities aggravates them. Complaints such as the inability to hold a hair dryer or to work with the arms above the head are common. Some patients have numbness when driving or when carrying heavy objects. These symptoms are caused by compression of the lower trunk of the brachial plexus.

The signs are usually subtle and may be confined to weakness of the ulnar-innervated intrinsic muscles unless compression is severe. There may be weakness of all the intrinsic musculature and loss of power of the long flexors of the little and ring fingers. When the upper trunk of the brachial plexus is involved, differential diagnosis becomes more difficult, and there may be confusion with cervical radiculopathy or carpal tunnel syndrome.

Signs and symptoms of TOS may include acute arterial insufficiency or gangrene in the hand, but such severe symptoms are rarely seen in an orthopaedic practice. Such patients usually have acute occlusion of the subclavian or axillary arteries and often have aneurysms caused by compression by significant cervical ribs (13,27). This complication is more often found in older patients with long histories of often undiagnosed symptoms.

Venous compression can cause swelling of the hand and upper limb, which, if intermittent, is difficult to document until its severity motivates the patient to have it examined. Intermittent venous compression in the absence of thrombosis produces cyanosis as well as swelling in the limb.
Occasionally, a patient exhibits acute venous thrombosis, the so-called Paget-Schroetter syndrome (11,13,34). This “effort thrombosis” of the subclavian and axillary veins results from underlying subclavicular thoracic outlet compression and repetitive or strenuous use of the arms, particularly in the overhead position. The symptoms are acute pain and swelling of the limb and ipsilateral chest wall. Prompt recognition of the condition is imperative—delay may result in considerable disability due to chronic pain and swelling. Acute therapy consists of administration of intravenous thrombolytics by catheter with mechanical dilatation, if needed. Maintain the patient on anticoagulants for 3 or 4 months, and follow up with elective first rib resection to diminish the likelihood of recurrent thrombosis (35).

Unilateral Raynaud’s phenomenon has been occasionally diagnosed as being consistent with TOS. In this case, it is attributed to selective compression of the sympathetic innervation of the limb within the lower trunk of the brachial plexus. The etiology of unilateral Raynaud’s phenomenon is not collagen disease. More likely, this phenomenon represents episodes of distal embolization from an aneurysm located within the subclavian artery (13).

Patients with TOS may have significant neck or chest pain. When TOS is in the left hemithorax, such pain may mimic angina or myocardial infarction and bring the patient repeatedly to the emergency room or cardiac care unit (42).

**DIAGNOSES OF THORACIC OUTLET SYNDROME**

The physical examination is most important, not only to achieve a positive diagnosis but also to rule out other conditions that may be confused with TOS or that may coexist with it. Cervical radiculopathy is unusual in the C8—T1 distribution in the arm and hand (5). Nevertheless, when the symptoms are difficult to interpret, the cervical spine must be ruled out as a site of disease. There may be tenderness over the brachial plexus in the supravacular fossa, but this nonspecific finding may accompany either thoracic outlet compression or cervical radiculopathy.

Of the various provocative maneuvers used to elicit thoracic outlet compression, the overhead exercise test and Wright’s maneuver (49) are the most consistently positive. The first test is performed by having the patient, in the “hands-up” position, rapidly flex and extend the fingers. In susceptible patients, this exercise produces cramping on the affected side within 30 seconds. In addition, placing the arm in the abducted and laterally rotated position not only obliterates the pulse at the wrist but also reproduces the symptoms. Lowering the arm to the side restores the pulse and alleviates the symptoms.

The mere obliteration of a deep pulse with any of the provocative positions is not diagnostic of TOS, because in many young women, some position of the arm can obliterate a pulse. The reproduction of the symptoms is crucial! Sometimes they can be elicited by rotating the neck to the opposite side or by having the patient take a deep breath, particularly while the affected extremity is abducted and externally rotated at the shoulder.

Adequate radiographs are essential. It may be difficult to assess the lower cervical spine for the presence of adventitious ribs or long transverse processes at C7 because the patient’s identification plate may have been placed there. Hypoplastic, true first ribs can be confused with a hypoplastic, true first ribs unless you are sure of the vertebral level. Count from the atlas caudalward to establish that there is, in fact, a cervical rib. Look carefully at the disc spaces and the intervertebral foramina, and note abnormalities. In the lateral view of patients with droopy shoulders, the physician may be able to clearly define the second dorsal vertebra. Such patients may resemble those with TOS but may have no peripheral neural deficits in the limbs (37).

Apical lordotic radiographs of the chest can rule out lung tumors, which can mimic TOS in their presentation. Adequate radiographs of the shoulder are also necessary. When there is significant concern about possible cervical radiculopathy, magnetic resonance imaging (MRI) or myelography may be indicated. They are not needed in most cases.

Noninvasive vascular studies have been advocated as a reliable diagnostic test for TOS. In my experience, however, because pulses can be positional obliterated in many normal people, the incidence of false-positive results is substantial. Interpret such studies with caution. For patients with intrinsically vascular disease, noninvasive studies can be extremely useful.

Arteriography and venography have limited application in the general diagnosis of TOS, and I do not routinely use them. Because the occlusion of arterial outflow with the position of the arm may be observed in asymptomatic patients, an arteriogram would provide little information unless there is serious consideration of the presence of an aneurysm in the subclavian artery or intrinsically vascular disease. Patients with complete cervical ribs may have an increased incidence of such aneurysms (13,27).

Therefore, in such patients, it is prudent to obtain arteriographic studies if the surgeon intends to explore the thoracic outlet through the axilla. Venography is useful in demonstrating thrombosis of the axillary or subclavian vein and in following the process of recanalization, should it occur. Noninvasive testing may be of value in this situation as well.

Although some have claimed success using measurement of the velocity of conduction of the ulnar nerve through the thoracic outlet to diagnose TOS, the experience of many workers has failed to substantiate this claim (40,42,44). Reports from electrodiagnostic laboratories may say, “There is no evidence of TOS”; interpret such statements on nerve conduction velocity (NCV) with caution, however, because the test is not of value in this situation.

Where NCV is very useful is in differential diagnosis. Conditions such as ulnar neuropathy at the elbow and carpal tunnel syndrome are readily identified by means of NCV determinations. Because NCV determination is not a reliable means of assessing the plexus within the thoracic outlet, the use of somatosensory evoked potentials and F responses has received attention as a means of obtaining further objective evidence of neural dysfunction to diagnose TOS (19,23). Some workers have found the measurement of the amplitude of the evoked response of the medial cutaneous nerve of the forearm and C8 root stimulation to be of value in making the diagnosis (24). In my opinion, the diagnostic value of such measurements has not yet been firmly established, and the diagnosis remains clinical (4,44).

Electrographic examination of patients with TOS is usually not markedly abnormal unless there has been sufficient compression to cause denervation. In such cases, it is often possible clinically to detect atrophy and weakness of the ulnar-innervated interosseous and hypothenar muscles. In other patients, however, these muscles may show fibrillation potentials at rest that appear to be clinically normal (38).

The question of double-crush syndrome and TOS is controversial. Although Carroll and Hurst (7) have written that the coexistence of TOS and carpal tunnel syndrome is rare if it exists at all, patients are seen nonetheless with well-demonstrated signs of both entities (47). Ulnar neuropathy may coexist with TOS (19). Patients may have hard-to-distinguish combinations of signs and symptoms that appear to be the result of more than TOS. In these cases, look for additional lesions to explain the entire picture; otherwise treatment will fail.

**CONSERVATIVE THERAPY**

The general condition of patients with TOS is often poor. It is worthwhile to inquire about their level of physical activity; often, it is quite limited. Sometimes, patients are afraid to exercise for fear of worsening the condition, or they have been so advised by their physicians. If the patients have no other serious medical problems, make an effort to mobilize them with aerobic exercises. Probably the easiest generalized exercise for such patients is walking, because it does not usually cause much discomfort. Some patients may experience increased symptoms with walking, and in these cases, the use of a shoulder support such as the Biomet Hook.
Hemi-Harness (Biomet, Warsaw, IN) (Fig. 61.2) or the Roylan sling (Smith & Nephew, Germantown, WI) (Fig. 61.3) may help. Also, such patients may be able to benefit from use of a stationary bicycle.

Figure 61.2. The Biomet Hook Hemi-Harness as seen from behind is shown. It consists of two cloth sleeves with Velcro closures and an adjustable strap that can be tightened or loosened as needed to support the shoulder girdles. In addition to the height of the shoulders, the degree of retroversion is determined by where the strap is attached to the sleeves, and this, too, may be varied according to the correction required.

Figure 61.3. The Roylan sling as seen from the back (A) and the front (B).

The problem of obesity can be extremely difficult to manage; patients do not like to be told that they are overweight. Yet, excess soft tissue can place additional strain on the shoulders, particularly in women who have large breasts, which can aggravate TOS by increasing traction on the structures crossing the first rib. In cases of gigantomastia, reduction mammoplasty as a first step in the treatment of very debilitating TOS may be successful. Kay has reported on neurologic deficits in women with large breasts (15). The mechanism of thoracic outlet compression makes it likely that this is the locus of the problem. Even if weight reduction does not produce the desired alleviation of compression, the patient who is thinner will be easier and safer to operate on, especially through the axilla.

The most important part of the conservative management of TOS involves correcting postural abnormalities that can be identified as contributing to the compression, and exercises to strengthen the shoulder girdle when it is determined that weakened muscles are a significant factor (Fig. 61.4). Unfortunately, when the physician refers patients with TOS to a physical therapy department, it is not always guaranteed that the therapist caring for the patient will understand the genesis of the problem and apply appropriate therapy. Very often, stereotyped routines (25) such as stretching, soft-tissue massage, “nerve mobilization,” and cervical traction are used, and these methods will actually worsen the symptoms in many patients. The TOS patient must have a thorough analysis by a knowledgeable therapist, and an individual therapy program should be designed, implemented, and monitored to avoid provocative maneuvers (25).

Figure 61.4. A: The therapist is instructing the patient in the correct way to exercise. Note that the arms are held in front of the plane of the body and that they are below shoulder height. The trapezius, rhomboids, and levator scapulae can be strengthened in this way without bracing the shoulders back or provoking symptoms. The therapeutic plan must be individualized to the specific patient’s needs, and most often it can be carried out as a home program with occasional visits to the therapist. B: Exercises for the upper trapezius that are tolerated by most patients with TOS.

Patients with significant shoulder girdle disorders may not tolerate even the most gentle conservative program. Particularly in the case of anterior glenohumeral instability, the exercises often prove provocative because they tend to reproduce the subluxations. Such patients may be differentiated from those with dead arm syndrome. In all likelihood, many patients with the diagnosis of dead arm syndrome owing to glenohumeral instability really have TOS. If the condition goes unrecognized, the patients will continue to be symptomatic even after shoulder repair. Leffert and Gurnley studied an interesting series of patients in whom these two entities coexisted (17).

If an activity of daily living or employment seems to be related to symptoms of TOS, modify such activities, if possible. Overhead activities, the carrying of heavy loads, or the use of backpacks can be quite provocative to patients with compression within the thoracic outlet.

Use conservative measures and review progress periodically so that the condition does not drag on interminably. The conservative approach with periodic review is particularly important in patients whose cases are complicated by litigation, insurance, or open workers' compensation cases. Caregivers must try to be objective in interpreting symptoms so that patients are not unfairly deprived of the benefits of treatment. In addition to periodic reviews, set a time limit beyond which conservative therapy should be viewed as having failed. If there is no positive response, the clinician must decide whether to advise surgery or to accept the status quo with hopes that the condition may improve with time.

**INDICATIONS FOR SURGERY**

Failure of a carefully supervised program that includes the previously described treatment measures is the usual indication for surgery.

Patients with significant neurologic deficits—usually of the intrinsic muscles of the hand but sometimes in the long flexors as well—almost never respond positively to conservative therapy. If they are subjected to surgery, however, they should know preoperatively that postoperative improvement in the power of the long flexors may actually increase the muscle imbalance in the fingers and cause clawing or make it worse. Advise such patients that they may require secondary hand reconstruction.
for the muscle imbalance if it occurs. For those who have significant sensory loss, the outlook is somewhat unpredictable but generally favorable.

Patients with impending or established gangrene in the hand are candidates for immediate surgery. Fortunately, they are rare and usually are not seen primarily by the orthopaedic surgeon but more likely by vascular surgeons.

The most problematic indication for surgery in the thoracic outlet is intractable pain. Only the patient can feel and describe the pain; the surgeon must be able to interpret these reports appropriately. Constraints of daily routine, vocational or avocational adjustments, sleep disturbance, and history of analgesic use are all important avenues of inquiry necessary to formulate a decision for surgery. A complete and in-depth review of what was done in prior physical therapy sessions is most important, because the patient may not have had optimal care, or may actually have gotten worse because of provocative positioning the exercises require (25).

Patients with TOS often have very complicated medical records. Review the differential diagnosis very carefully before proceeding. Discuss with the patient and family the mechanics and objectives of surgery. Explain all possible complications in detail so that the patient can give an informed consent. If you believe that a second opinion would be useful, make certain that the surgeon or physician rendering this opinion has sufficient experience in the area to provide a valid opinion. Too often that opinion may be rendered on the basis of little personal experience or knowledge.

An obese patient who has made little genuine attempt to lose weight despite specific evaluation for the cause of obesity and instructions to correct it evinces poor cooperation. I have found it prudent to inform such patients that their surgery is elective and will not be done until they demonstrate genuine evidence of being willing or able to participate in their own rehabilitation.

Because of the possibility of significant intraoperative hemorrhage, the patient's blood should be typed and cross-matched before surgery. Whether to operate on a patient who will not accept blood transfusion or blood products, should they be needed intraoperatively, is a difficult and individual decision for which I do not have a confident answer.

Depending on the surgeon's training and inclinations and local custom, as well as the nature of the surgery to be performed, either a vascular or general thoracic surgeon may be part of the operating team. Although I have performed the vast majority of my surgeries without need for such assistance, it is valuable to ensure that such help is available on an if-needed basis. For patients who have particular problems such as successive surgeries in which complications can be anticipated, consultants may be invited to participate at the beginning of the case. In addition, the operating team should be experienced and adequate in number. I require three scrubbed assistants for surgery by the axillary route. Do not use overhead arm traction with weights, as is used in shoulder arthroscopy; it carries a risk of inducing an intraoperative traction injury of the brachial plexus.

Finally, make sure proper instruments are available and in working order before you make the skin incision. Have vascular and thoracic surgical instrument packs in the operating room should they be needed.

General anesthesia for surgery of the thoracic outlet by the transaxillary route requires that the patient be profoundly relaxed. The newer, short-acting muscle relaxants are particularly well suited to this situation. Discuss the time frame for the surgery with the anesthesiologist before commencing surgery so that muscular relaxation may be reversed by the time the incision is closed, thus allowing extubation without delay.

Surgeons with inadequate training or experience should not undertake thoracic outlet surgery because it has the potential for very serious complications. However, with proper identification of patients suffering from significant compression and technically adequate surgery, the results are very gratifying in most cases.

Surgical Techniques

There is no universal agreement as to which surgical procedure is best for the treatment of TOS. Scalenotomy was the first procedure to gain favor. If the pathology resided entirely between the scalene muscles (1,2 and 3), as was theorized, release of the anterior scalene should have permanently cured the condition. Unfortunately, the incidence of recurrence following scalenotomy was sufficiently high that surgeons had to develop other procedures.

Many workers have considered the first rib to be the common denominator of compression and have concentrated their efforts on eliminating it as well as adventitious ribs or congenital bands that might be encountered in the course of exploration (5). Since Roos reported his experience with the transaxillary first rib resection in 1966, this approach has been the procedure most often performed, and as the mainstay of the surgical approach to the problem, it is described in detail (28,29,30,31 and 32).

A variety of anatomic approaches, however, may be used for exploration of the thoracic outlet and removal of the first rib.

Significant reduction in the costoclavicular interval due to fracture angulation or hypertrophic subclavicular callus may occasionally necessitate clavulectomy. It is worth considerable effort to retain the clavicle if it does so does not materially increase the surgical risks (14). Removal of the strut function of the intact clavicle from a shoulder girdle with poor muscular support can markedly increase symptoms because of the superimposed traction effect of the ptotic shoulder. Patients with a good trapezius may function well following clavulectomy, but they experience weakness in overhead use of the arm. The enthusiasm for clavulectomy for uncomplicated thoracic outlet compression has been very limited. The procedure is not recommended (19).

The use of scalenectomy to treat TOS depends on the local pathology. Some authors consider it the preferred method of surgical treatment in certain cases (31). Although it is desirable to avoid reattachment of the scalenes to the bed of the first rib after it has been resected, I do not routinely resect a portion of the anterior and middle scalenes because of the possibility of injury to branches of the brachial plexus, which may actually pass through the middle scalene. The phrenic nerve must be out of harm's way if you elect to resect part of the anterior scalene.

Scalenectomy may be indicated in patients in whom a recurrence has been deemed due to scarring within the scalene muscles themselves. An anterior approach is best. In addition to obvious branches of the brachial plexus and phrenic nerve, the long thoracic nerve is particularly vulnerable, because it may not always be located lateral to the middle scalene. It may pierce the muscle or even present as two branches, each of which must be gently retracted and preserved.

In the next section, I describe in detail three operative approaches to the thoracic outlet specifically for resection of the first rib and then will comment briefly on the others.

The Transaxillary Approach (28,29,31,32)

Refer to Figure 61.5.

![Figure 61.5](https://example.com/figure615.png)

**Figure 61.5.** Anatomy of the right thoracic outlet from the axillary view with the upper extremity and shoulder elevated. (From Roos DB. Experience with First Rib Resection for Thoracic Outlet Syndrome. *Ann Surg* 1971;173:429, with permission.)
Relieve it by removing the middle third of the rib. At this point, retest the integrity of the pleura. Achieve complete hemostasis. Digitally explore the outlet and place the patient’s arm in all positions to assess.

There should be at least 1.5 cm of space behind the lower trunk of the brachial plexus; in most patients there will be 2 cm or less of posterior rib fragment.

After verifying that nothing has been caught in the jaws of the rib cutter, firmly close the blades and cut the rib. Then gently slide the instrument forward and open it, because trauma to the nerve can result in annoying dysesthesia on the posteromedial aspect of the upper arm and axilla.

Figure 61.6. Instruments for transaxillary first rib resection are shown. Penosteal elevator (A), rasp for first rib (B), and Roos rib cutter (C) are illustrated.

Failure to perform this part of the procedure properly will cause the line of section of the rib to lie at the level of the subclavian vein, where a sharp edge of bone may be overlapped in its insertion by the middle scalene. There may be additional vascular branches, or a cervical rib. A complete cervical rib may actually attach to the first rib. The intercostobrachial nerve arises from the second intercostal nerve and crosses the axilla embedded in fat to ultimately reach the medial aspect of the arm. If possible, mobilize and retract it, because trauma to the nerve can result in annoying dysesthesia on the posteromedial aspect of the upper arm and axilla.

Overhead lights will not provide sufficient illumination to perform the surgery safely. Use a headlight or lighted retractors.

Turn attention to the superior surface of the first rib. Define and detach the anterior scalene. The phevine nerve is not usually at risk with this approach, because it is located at least 2 cm cephalic to the tubercle. Using gentle, blunt dissection, tease the subclavian artery and vein away from the anterior scalene. Because the pleura may rise posteriorly and be adherent to the posterior surface of the muscle, it is helpful to use a long right-angled clamp to dissect behind the muscle and to shield each vessel in turn as, alternately, half of the muscle is cut sharply at its insertion to the bone. Obviously, all of this must be done very carefully under direct vision. When the muscle has been cut, it retracts.

At this stage, visualization is limited by the muscle (Fig. 61.5). The position of the middle scalene, which can be elevated off the first rib with the elevator. It is tempting to sharply divide this muscle at its insertion, but the possibility of injury to the nerve to the serratus anterior makes penetration inadvisable. As the muscle is elevated, it can also be partially retracted with the blunt retractor.

Using a rasp with a cutting edge that conforms to the outer curvature of the first rib, separate the soft tissues from the bone. Often, the first digitation of the serratus anterior muscle may overlap the insertion of the middle scalene on the first rib, but it must be bluntly separated. Alternate the rasp, the periosteal elevator, and gauze sponges to clear the surface of the rib of its muscle attachments. The undersurface should be similarly cleared, although it is not desirable to perform the entire dissection subperiosteally because of the possibility of later regeneration of the rib, particularly in young patients.

The peristeum of the first rib must be disrupted and as much of it removed as possible. This procedure may result in a tear in the adjacent pleura, causing a pneumothorax. During this maneuver, ask the anesthesiologist to control respiration so that the lung is retracted from the pleura in exhalation. About 30 seconds of apnea should be required. Then controlled respiration may be resumed.

In addition to fibrous bands of various types, other important variations in the local anatomy can be observed (Fig. 61.5). For example, the anterior scalene may also be overlapped in its insertion by the middle scalene. There may be additional vascular branches, or a cervical rib. A complete cervical rib may actually attach to the manubrium, but a lesser one may reach to the scapular tubercle. The attachment of the two ribs, which can be fibrous or actually fused, can create significant problems, especially if the subclavian artery is located at the junction.

I recently encountered such a situation that had resulted in a symptomatic aneurysm with emboli in the arm of a 24-year-old woman. After the bone had been removed, I had the valuable assistance of a vascular surgeon (prearranged) who did a vein graft to the thrombosed aneurysm, with an excellent clinical result.

The intercostobrachial nerve arises from the second intercostal nerve and crosses the axilla embedded in fat to ultimately reach the medial aspect of the arm. If possible, mobilize and retract it, because trauma to the nerve can result in annoying dysesthesia on the posteromedial aspect of the upper arm and axilla.

Retract the latissimus and pectoralis muscles. The intercostobrachial nerve arises from the second intercostal nerve and crosses the axilla embedded in fat to ultimately reach the medial aspect of the arm. If possible, mobilize and retract it, because trauma to the nerve can result in annoying dysesthesia on the posteromedial aspect of the upper arm and axilla.

Overhead lights will not provide sufficient illumination to perform the surgery safely. Use a headlight or lighted retractors.

The intercostobrachial nerve arises from the second intercostal nerve and crosses the axilla embedded in fat to ultimately reach the medial aspect of the arm. If possible, mobilize and retract it, because trauma to the nerve can result in annoying dysesthesia on the posteromedial aspect of the upper arm and axilla.
If there is a pneumothorax, insert a chest tube at this point and then prepare for closure. Give antibiotics if there has been a pleural leak but not in an otherwise uncomplicated case.

Return the arm, which the assistant has intermittently raised and lowered, to the side. Drains are not used, nor should they be needed.

Complete a subcutaneous closure, followed by a subcuticular closure using nonabsorbable suture, which is removed at 2 weeks postoperatively. Apply a small dressing. A sling is not needed.

POSTOPERATIVE CARE AND REHABILITATION

In uncomplicated exploration and decompression of the thoracic outlet by the axillary route, there is minimal blood loss and physiologic disturbance. Although there may be moderate postoperative pain, within a day most patients are sufficiently comfortable to move about without the support of a sling. If a pleural tear has occurred intraoperatively, then a chest tube is used for 24 hours. Most patients are discharged from the hospital on the second or third day after surgery.

Most patients are discharged from the hospital on the second or third day after surgery.

### POSTERIOR APPROACH

Adson advocated the supraclavicular approach for scalenotomy and resection of cervical ribs (1,3). It has the advantage of allowing relatively easy access to the anterior scalene muscle and the vessels.

#### ANTENOR APPROACHES TO THE THORACIC OUTLET

Anterior approaches to the structures within the thoracic outlet have been advised for resection of cervical ribs and resection of the first thoracic rib as well as for scalenectomy (3,9,21,22). In my experience, the exposure obtained for subtotal resection of the first rib is less satisfactory than that gained with the axillary approach, although this is not a universally held opinion.

Posterior approaches to the structures within the thoracic outlet have been advised for resection of cervical ribs and resection of the first thoracic rib as well as for scalenectomy (3,9,21,22). In my experience, the exposure obtained for subtotal resection of the first rib is less satisfactory than that gained with the axillary approach, although this is not a universally held opinion.

Although there may be moderate postoperative pain, within a day most patients are sufficiently comfortable to move about without the support of a sling. If a pleural tear has occurred intraoperatively, then a chest tube is used for 24 hours. Most patients are discharged from the hospital on the second or third day after surgery.
Within 48 hours of surgery, the dressing may be reduced to a single layer of gauze or removed altogether. Patients may shower as long as the wound is kept dry; underarm deodorants and powders are prohibited until the sutures are removed. Patients may be ambulatory at home but are cautioned against heavy lifting or any strenuous activities for 4 weeks after surgery. Then they may resume their preoperative exercise program, if there is no significant postural abnormality or weakness of the scapular muscles. It is most important that these exercises do not involve either overhead use of the arms or shoulder bracing, because both of these types of exercises essentially duplicate the provocative maneuvers that are used in diagnosis. Unfortunately, they are still prescribed and used in many physical therapy facilities (25).

**PITFALLS AND COMPLICATIONS**

**INADEQUATE RESECTION**

Inadequate resection of the first rib usually results from the surgeon's inexperience or timidity. Failure to resect the subclavius tendon anteriorly produces a line of resection of the first rib at the level of the subclavian vein that will then adhere and cause symptoms of venous compression. Because the vein has a thin wall and is easily torn, reoperation is hazardous. It is best performed, if necessary, by the transclavicular route.

Failure to resect sufficient rib posteriorly to clear the lower trunk of the brachial plexus by 2 cm is most common with an anterior approach, but it may also occur with a transaxillary procedure. In most cases, less than 2 cm of rib should remain from the level of the transverse process, but it is unnecessary to disarticulate the rib. If recurrence is believed to be due to adherences of the lower trunk of the plexus to the rib remnant, this procedure is best approached through a posterior, high thoracoplasty approach (8, 41). The hazards of this procedure stem from the difficulty of separating the periosteum and scar from the nerves, which must be carefully defined and lysed while the rib remnant is removed. Preliminary resection of the second rib is an aid to the dissection, which then proceeds to the bed of the first rib with a wider and clearer field.

**PNEUMOTHORAX**

Because an intact periosteal sleeve can result in regeneration of a resected rib, particularly in a young patient, it is advantageous to remove or displace as much of the periosteum as possible. The close adherence of the pleura, however, makes removal of this firm structure common during the course of the dissection. Because the pleura cannot be directly repaired, either a rubber catheter may be used to drain the pleural cavity during closure and then withdrawn, or a chest tube may be placed through a separate stab wound and connected to underwater suction for 24 hours. Then, after a radiograph confirms the absence of a pneumothorax, the tube may be removed. If a patient has sustained an intraoperative pneumothorax, he or she should be restricted from air travel for 7 to 10 days.

**INTERCOSTOBRACHIAL NEURALGIA**

The intercostobrachial nerve passes from the chest into the subcutaneous tissues of the arm and innervates the posterior brachium, in many patients, down to the level of the olecranon. Because it is located at the midpoint of the axillary incision made over the third interspace, it is liable to injury, either by laceration or traction. Even if care is taken to protect it, in many cases, there is some transient numbness along the posterior aspect of the arm, which gradually fades with time. If the nerve is cut, however, the patient may experience very annoying dysesthesia that can be permanent. Prevention is the best means of dealing with the problem. If there is a neuroma, local nerve blocks are of occasional value.

**BRACHIAL PLEXUS INJURY**

The most serious non-life-threatening complication of thoracic outlet surgery is injury to the brachial plexus (45). Occasionally, patients have varying degrees of neural dysfunction in excess of what was present preoperatively. The patient with increased postoperative loss of intrinsic function in the hand and numbness of the little and ring fingers may have sustained either a direct laceration of the lower trunk or a traction injury. In the first situation, repair is impossible, and no improvement is expected. In the second situation, often there is little spontaneous recovery, although it may occur. This complication can be avoided by gentle handling of the nerves with minimal or no direct retraction.

The patient who awakens from surgery with numbness of the entire arm and significant motor weakness that was not present preoperatively has sustained a traction injury to the brachial plexus, which usually results from excessive pull on the arm during surgery. This complication can result in permanent neurologic loss and pain, and can largely be avoided by carefully monitoring the amount of intraoperative traction. During the procedure, arm traction must be periodically lessened so that a constant pull is not maintained.

**LONG THORACIC NERVE INJURY**

Local injury to the nerve on the chest wall or as it comes around or through the middle scalene can result in permanent winging of the scapula owing to paralysis of the serratus anterior (49). The nerve should be sought and carefully protected. Sometimes, separate branches to the digitations of the serratus anterior are seen, in which case these must be preserved. This complication weakens the patient's ability to lift the arm in front of the plane of the body.

**VASULAR INJURY**

The subclavian artery and vein are clearly at risk in any procedure performed within the thoracic outlet. The surgeon must have available appropriate technical ability or surgical assistance for all eventualities. As stated earlier, appropriate instruments must be present in the room, and the sterile field should be draped to allow for additional procedures, including thoracotomy, if necessary.

**CONCLUSIONS**

The diagnosis and treatment of patients with TOS is demanding, sometimes frustrating, and technically challenging. However, many carefully selected patients get good results from surgical treatment when conservative therapy has been strenuously employed and failed. The nature of the patient population is such that attempting to compare the results of different series of surgically treated patients can lead to markedly divergent impressions of the effectiveness of surgery. In my own experience, about three quarters of the patients that I have operated on have had good to excellent results. Despite the fact that these surgical patients present less than 20% of all the patients I have seen with this entity, I believe that the surgery of TOS has a rightful place in the armamentarium of orthopaedics.

HISTORY

As early as 1614, Felix Plater described what may have been Dupuytren's contracture in the hands of a stone mason working in a quarry near Basel, Switzerland. He identified the disease in the flexor tendons and in fact could have been describing a rupture of the A1 pulley. Other well-known surgeons, such as Henry Cline and Sir Astley Cooper, described the condition during the next century and correctly located the disease in the palmar fascia.

In 1832, however, Baron Guillaume Dupuytren not only located the disease in the palmar fascia but also speculated that the etiology might be traumatic. He recommended surgical treatment of the diseased fascia through transverse incisions and postoperative splinting with the fingers held in extension. In addition to reporting the condition, he also lectured extensively on it. Thus, the choice of "Dupuytren" as an eponym, instead of a descriptive term such as "palmar fibromatosis," is justifiable.

Recent research has focused on several aspects of the disease, including the potential role of heredity, trauma, myofibroblasts, collagen, growth factors, and smooth muscle (which contributes to the contractile nature of the condition).

Surgical treatment is generally successful and rewarding, but careful consideration must be given to patient selection, history, physical findings, and the patient's ultimate goals from both functional and cosmetic perspectives.

For readers interested in a more in-depth history of the disease, the Groupe d'Etude de la Main (GEM) monograph edited by Hueston and Tubiana, an article by Whaley and Elliot in the British Journal of Hand Surgery, and Dupuytren's Disease: Biology and Treatment by McFarlane, McGeough, and Flint provide the complete history.

ETIOLOGY AND PATHOPHYSIOLOGY

TRAUMA

Larsen experimentally explored the role of trauma and believed that microhemorrhages and hemosiderin were part of the pathophysiology of Dupuytren's disease. He was able to produce similar histologic lesions in monkeys, but the animals never developed flexion contractures. Although trauma is often implicated in the etiology, studies have also shown that the disease occurs in almost equal frequency in manual and nonmanual workers.

FREE RADICALS

Free radicals may also play a role in "microtraumatizing" tissue and causing secondary contracture. Low levels of superoxide may stimulate fibroblast growth, which may also be important in wound healing and the evolution of scar.

MYOFIBROBLASTS AND FIBROBLASTS

In recent years, one of the most intriguing explanations regarding the pathophysiology of Dupuytren's contracture involves the myofibroblast. Gabbiani and Majno called attention to this cell in 1972. They were able to measure the contractile forces of myofibroblasts grown in tissue culture and found them comparable with that of rabbit skeletal muscle. They believed the myofibroblast was the driving force behind the palmar fascial contraction.

Chiu and McFarlane further elaborated on the pathophysiology, believing that the myofibroblasts contained elements of smooth muscle as well as collagen-producing fibroblasts. As the disease progressed, the contractile elements shortened the collagen. Concurrently, intercellular adhesion occurred in areas known as desmosomes, which contained fibronectin, a gluelike material that promotes intercellular adherence. Burch believed that proliferating fibroblasts were the consequence of an autoimmune response to collagen by "forbidden" lymphocytes.

Chiu and McFarlane further subclassified the disease into three stages: stage I, early disease with proliferation of perivascular fibroblasts; stage II, active disease, with nodular thickening of the palmar fascia, associated joint contracture, and hypertrophied fibroblasts as well as orderly deposition of collagen fibers; and stage III, advanced disease, with progressive joint contracture and diffuse fibrotic thickening of the palmar fascia. Histologically, wavy bundles of collagen fibers separating a sparse number of fibroblasts become apparent.

COLLAGEN

In addition to the abnormal array of fibroblasts and myofibroblasts with their contractile elements, the collagen found in Dupuytren's disease is identical to that which predominates in scar tissue. For example, normal palmar fascia contains almost no type III collagen. Approximately 30% of the collagen in Dupuytren's nodules is type III, in uninvolved regions of the palmar fascia in patients with Dupuytren's disease, 10% to 15% of the collagen is type III.

GLYCOSAMINOGLYCANs

The collagen in normal or abnormal tissue is embedded in a ground substance composed of proteoglycans, proteins, and hyaluronate. The exact molecular structure of
Coexistent trigger finger should be addressed surgically, with the Dupuytren's contracture removed if present. Conversely, Dupuytren's nodules need not be excised at contracture with subcutaneous fasciotomy while the patient was under local anesthesia. Figure 62.2. dorsal to the axis of PIP joint motion. should focus on maintaining the PIP joint in full extension as well as concomitant passive flexion of the DIP joint to pull the lateral bands to their more anatomic position (DIP) joint with associated PIP joint contracture in Dupuytren's disease should alert the examiner to the possibility of boutonniere. If the DIP joint can be passively released concomitantly, as did Gonzalez and Watson (16). Certain factors have been shown to predispose people to a more virulent form of Dupuytren's disease. For example, in patients in their teens or 20s, Hueston has referred to the disease as a “Dupuytren's diathesis” (21). This may include plantar fibromatosis (Ledderhose's disease), penile fibromatosis (Peyronie's disease), and knuckle pads. These conditions should be sought out during the history and physical examination of the patient because it has been found that they are predictive of a poorer prognosis.

Arguably, in these aggressive forms, the clinical course resembles that of an aggressive fibromatosis. When seen in children, this condition may resemble Dupuytren's disease histologically but predictably will have an extremely virulent clinical course. A similar condition, juvenile aponeurotic fibroma (31,39), has been noted to recur as fibrosarcoma with metastatic disease and death. Certainly, the combination of a young boy with a strong family history and an early onset of contracture carries a poor prognosis. Likewise, when the disease appears in young women, it tends to be more virulent and recurrent. Although this is generally true in younger women, in my experience older women do not fare much differently from men in terms of natural history. The presence of osteoarthritis in the proximal interphalangeal (PIP) or metacarpophalangeal (MP) joints compromises the final result by limiting the eventual range of motion (Fig. 62.1).

**Figure 62.1.** Persistent PIP flexion contracture in the right small finger with previous amputation of the left small finger in a 27-year-old man with seizure disorder.

**CONCOMITANT DISEASE**

Many diseases have been found in association with Dupuytren's disease—acquired immune deficiency syndrome (AIDS), for example. Free radicals have been linked to the apparent relationship between Dupuytren's disease and human immunodeficiency virus (HIV)—infected patients (3). Other frequently associated diseases include diabetes mellitus, tuberculosis, epilepsy, and alcoholism. Dupuytren's disease has been associated with many other diseases, with no clear causal relationship. It is particularly important to document these associated conditions in obtaining a patient history because some of these conditions may ultimately affect the prognosis (39).

Nissenbaum and Kleinert (39) were concerned that the coexistence of Dupuytren's disease with carpal tunnel syndrome might predispose to postoperative complications, such as increased swelling and complex regional pain syndrome. For this reason, they suggested minimizing complications by treating the more significant clinical problem—carpal tunnel syndrome or Dupuytren's disease—first. Michon (39) believed that carpal tunnel in Dupuytren's disease could safely be released concomitantly, as did Gonzalez and Watson (16).

Carefully evaluate the patient for coexistent boutonniere deformity (20), which would affect postoperative management. Hyperextension of the distal interphalangeal (DIP) joint with associated PIP joint contracture in Dupuytren's disease should alert the examiner to the possibility of boutonniere. If the DIP joint can be passively flexed following PIP joint release, then a PIP extension splint and a program of passive flexion should correct the boutonniere (Figs. 62.2). Postoperative management should focus on maintaining the PIP joint in full extension as well as concomitant passive flexion of the DIP joint to pull the lateral bands to their more anatomic position dorsal to the axis of PIP joint motion.

**Figure 62.2.** A: Persistent Dupuytren's contracture in the palm of a 71-year-old woman with severe arteriosclerotic cardiovascular disease. B: Z-plasty of skin contracture with subcutaneous fasciotomy while the patient was under local anesthesia. C: Improved extension postoperatively.

Coexistent trigger finger should be addressed surgically, with the Dupuytren's contracture removed if present. Conversely, Dupuytren's nodules need not be excised at
the time of A1 pulley release (5).

Finally, patients with significant coexisting diseases, such as coronary artery disease or history of cerebral vascular accident, need not cancel surgery but rather should have it done under local anesthesia, with appropriate sedation. The fasciotomy may be limited, if necessary, and only the affected digits released. Limited fasciotomy has occasionally been helpful for such patients (Fig. 62.3) (16,37).

Figure 62.3. A 27-year-old man with seizure disorder and recurrent Dupuytren's disease in both hands. Note previous amputation of the left small finger at the PIP joint level and recurrent flexion contracture of the PIP joint in the right small finger after two previous open fasciectomies. This patient was counseled to continue stretching his right hand and advised to use nonsteroidal medication. No further surgery has yet been required.

Diabetes concurrent with Dupuytren's disease may present problems of insulin management as well as a slight increased risk of postoperative wound infection. In the patient with diabetes, distinguishing between Dupuytren's disease and trigger finger is important. Finally, patients with seizure disorder have a high likelihood of recurrence and a tendency toward a more aggressive form of the disease (Fig. 62.4) (45).

Figure 62.4. Normal anatomy of the palm showing lattice-like arrangement of fascial bands surrounding the common digital nerve and artery at the level of bifurcation.

ANATOMY

The palmar fascia is a triangular-shaped structure on the volar surface of the hand, with four longitudinal thickened fascial segments corresponding to the individual finger metacarpals. There is a separate extension toward the thumb and thenar musculature. The fascia is attached to the skin of the palm by vertical septae and to the deeper structures of the hand, the flexor sheath, and intrinsic musculature through similar longitudinal septae, the ligaments of Legueu and Juvara.

The longitudinal fasciculi of the palmar fascia terminate at the proximal finger crease of the skin. The superficial transverse fasciculi, as well as a discrete deep transverse fiber layer, are proximal to the termination and perpendicular to the longitudinal fasciculi.

Between the superficial transverse metacarpal ligament distally and the finger flexion crease, the palmar fascia divides into smaller fascial elements extending onto the finger to join Cleland's ligament, Grayson's ligament, and the lateral digital sheath of Gosset (43) (Fig. 62.5). The fascia “spirals” around the neurovascular bundle in this region, and some authors refer to this normal fascial tissue as a “spiral band.” Located more transversely in the web space, the “natatory ligament” runs from the deeper palmar fascia across the skin of the web and becomes adherent to the skin within the web space.

Figure 62.5. Pathologic anatomy in which fascial bands have coalesced into fascial cords surrounding the neurovascular bundle. Depending on which bands are involved and to what extent, the neurovascular bundle may be drawn toward the midline in a subcutaneous position, making it vulnerable to surgical dissection.

I and others believe that no true spiral band exists (50; D. A. McGrouther, personal communication). Rather, the fascia reaches the finger through a confluence of attachments to tendon sheath, intrinsic muscle fascia, and skin. McGrouther has drawn the analogy between these fascial structures and a wooden lattice configuration that can flex and extend with the fingers, thereby becoming longer or shorter with normal function.

DISEASED FASCIA

In 1959, Luck suggested the term band for normal fascial structures and cord for those afflicted with Dupuytren's disease. These terms have endured (30). The central part of the finger is not covered by a fascial band but rather by a fibrofatty tissue that may become involved with Dupuytren's disease. Gosset described the continuation of the vertical septae of Legueu and Juvara and described them blending with the capsule and the MP joint and extending along the side of the finger to the lateral digital sheath. Continuations of the natatory ligament are confluent with this from the web space. Each of these structures can become involved in the contracture.

McFarlane's (33) description of the diseased fascia in Dupuytren's disease does not explain how a nodule becomes a cord but does quite clearly define the anatomy of the central cord, which is the diseased longitudinal band of the normal palmar fascia, known as the pretendinous band. This cord may extend to the finger, involving the fibrofatty tissue, with the volar surface of the finger becoming confluent with the central cord. This cord usually passes distally in the midline of the finger and may be
Although numerous surgical procedures have been described, I prefer the open-palm technique described by McCash. Completed within 2 hours and the tourniquet must be deflated, dissection becomes increasingly difficult. Bier block comparable to wrist block, digital block, or local anesthesia with monitored anesthesia care. Regardless of the choice of anesthetic, if the procedure is not experience the intravenous fluid from the anesthetic often compromises the surgical field. The patient rarely tolerates the tourniquet for more than 30 to 60 min, making anesthesia. Sedation with Diprovan (propothol) or Versed (midazolam hydrochloride) may be used. Bier block may be suitable in certain circumstances, but in my experience the intravenous fluid from the anesthetic often compromises the surgical field. The patient rarely tolerates the tourniquet for more than 30 to 60 min, making Bier block comparable to wrist block, digital block, or local anesthesia with monitored anesthesia care. Regardless of the choice of anesthetic, if the procedure is not completed within 2 hours and the tourniquet must be deflated, dissection becomes increasingly difficult.

SURGICAL TECHNIQUES

Although numerous surgical procedures have been described, I prefer the open-palm technique described by McCash. Make a transverse incision over the diseased ray or rays in or immediately adjacent to the distal palmar crease. Extensions of the incision toward the involved digit and proximally in the palm may be through either zigzag or straight-line incisions, with the straight-line incisions designed for later Z-plasty (Fig. 62.7).

Brurer-type incisions may be used when the PIP joint is not involved. When the incision must be extended distally on the finger to the PIP joint or further, use a straight, longitudinal incision broken into the appropriate number of Z-plasties. In the palm the Bruner-type incision lends itself well to the Y-Y closure (23).

When the longitudinal incision is used, and a PIP contracture is involved in Dupuytren’s disease, employ a classic 60° Z-plasty at the level of the PIP joint. This technique theoretically allows a 75% gain in length when the joint is mobilized. Once the joint has been mobilized, the transverse line of the Z-plasty should lie at or close to the level of the PIP joint.

Leave the wound open, like the distal palmar wound, to facilitate drainage and avoid tension on the wound closure. Normal skin has the potential for plastic deformation, but diseased skin of Dupuytren’s disease rarely does.

Begin exposing the diseased fascia through the proximal incision at the base of the palm, which should be extended to include normal fascia. Using the basic, general surgical principle of dissecting from normal toward abnormal tissue, identify the distal margin of the transverse carpal ligament, superficial palmar arch, and associated common digital arteries and nerves and trace them distally through the ulnar and radial canals. As you encounter diseased fascia, carefully separate it from the skin and underlying tissues, dividing the diseased superficial fibrous seape as well as the diseased tissue deep within the palm.

It is frequently possible to identify the ligaments of Legueu and Juvara. Divide them close to intrinsic muscle or tendon sheath, removing a small segment of normal tissue, particularly when dense adherence exists between the diseased tissue and the flexor sheath.

Perform the majority of the dissection with a #15 blade, beaver blade, or sharp tenotomy scissors. Maintain tension on the diseased fascia, holding it superficially with a single-tooth forceps, a Kocher clamp, or an Allis clamp (Fig. 62.7).

Maintain traction on the skin flaps using single- or double-hook retraction and with the aid of a specialized surgical hand table if an assistant is unavailable.
Alternative Surgical Treatments

The arterial supply of blood to the palm, combined with the dense fascial attachments between the skin and the palm that may be involved in Dupuytren’s disease, make rotation flaps difficult if not impossible. The central palmar skin has been shown by microangiography to have limited circulation (7). Any surgical procedure, therefore, should limit the amount of undermining of the skin in this region and avoid straight longitudinal incisions that may predispose to later contracture.

Many more surgical techniques and variations of surgical incisions to treat Dupuytren’s disease are described than are detailed here. In a recent textbook, McGrouther lists more than 40 surgical techniques that have been published since Dupuytren’s original description (34). All involve variations on zig-zag incisions, Z-plasties, local rotation flaps, and V-Y-plasty. This latter procedure, originally described by Palmen (40), has been more recently popularized by King et al. (23). The goal of this and any wound closure in Dupuytren’s disease should be to avoid tension while maintaining circulation to and viability of the flap.

Bedeschi (2) has modified the V-Y technique to the shape of a “honeycomb,” which is comparable to the V-Y-plasty. I have found that it works well for single-digit involvement, particularly at the MP joint.

1. Outline an incision from an area just proximal to the involved fascia in the involved finger and zig-zag distally at angles between 90° and 110° onto the finger and distal to the diseased fascia. Transverse incisions extend off the apex of the zig-zag incision (Fig. 62.8).

2. Use magnification, a 3.5-power loupe, or an operating microscope to better visualize the neurovascular bundle. Carefully protect the nerve and sharply dissect it longitudinally from the surrounding tissue. The nerve frequently turns acutely 45° or 90° as it is deformed by the diseased collagen, making dissection tedious.

3. As the dissection is carried onto the finger, mobilize the Z-plasty incisions, which should have been outlined before the surgical dissection. In general, cuts between 5 mm and 10 mm in length are sufficient and designed such that with closure of the Z-plasty the transverse limb lies at or near the PIP flexion crease.

4. Ideally, the entire segment of diseased fascia with the involved ray is removed in one segment from proximal to distal. The distal diseased fascia may adhere to the flexor sheath, collateral ligaments of the PIP joint, lateral digital sheet of Gossot, or Grayson’s ligaments. It rarely extends dorsally and should not involve Cieo’s ligaments.

5. Depending on the length of the procedure and your confidence in having maintained adequate hemostasis with bipolar electrocoagulation through the course of the procedure, you may elect to close a portion of the wound before deflating the tourniquet.

6. With the open-palm technique, leave the entire transverse incision open. With this technique, hematoma accumulation in the palm is unlikely; likewise with the fingers in the case of distal Z-plasty, where the transverse limb is left open. With a tighter closure, mitclicous hemostasis following tourniquet deflation and before wound closure is more important.

7. I prefer to close the wound with 5-0 nylon sutures placed in a horizontal or vertical mattress fashion.

8. Apply a bulky dressing loosely with a dorsal splint and encourage the patient to flex and extend the fingers when he awakens in the recovery room or when the axillary block wears off.

9. Change the dressing within 24 to 48 hours. Provide the patient detailed instructions for wound care and for a home exercise program. Remove sutures in 7 to 10 days. An outpatient hand therapy program is crucial in obtaining good results.

Skin Grafting

Hueston (19) and Gonzales (15) have popularized skin grafting in Dupuytren’s disease. In addition to providing wound coverage, the technique prevents recurrent disease from forming beneath the graft. A short period of immobilization is required, and there may be morbidity associated with a donor site. As with open-palm technique, full-thickness skin grafting at the site of Dupuytren’s resection allows the fingers to be brought into full extension with no tension, particularly at the level of the proximal interphalangeal joint. A skin graft here not only prevents recurrent disease but may also minimize tension on the incisional scar and further prevent contracture of the scar.

Gonzales’ choice for donor site is either the instep of the foot or the groin. The instep of the foot better resembles palmar skin, but local size constraints permit only small amounts of graft to be harvested. The groin has the added risk that the graft may bear hair, an equally undesirable outcome. The constraints have led me to use the upper inner portion of the arm or the lateral side of the leg (Fig. 62.9). Although it controls local recurrence in the area immediately beneath the flap, skin grafting does not prevent Dupuytren’s disease from occurring in other areas of the palm. Always consider skin grafting in recurrent disease where the skin is scarred from previous surgery in addition to being diseased.

Figure 62.9. A: Recurrent contracture (third time) in the palm of a 67-year-old retired avid golfer. Severe contralateral disease was present as well. This longitudinal
skin and fascial contracture caused pain when the patient was gripping a club. B: The site of excised skin and diseased fascia was covered by a full-thickness skin graft harvested from the lateral thigh with the donor defect closed primarily. C: Six months postoperatively, the hand in full extension. D: Full flexion. Note severe PIP flexion contracture in the contralateral hand in C. This hand was asymptomatic and, in fact, enabled the patient to grip a golf club better.

Although it requires some additional donor site morbidity, free-tissue transfer (25) may also have a role for some patients.

Postoperative rehabilitation following full-thickness skin grafting requires a 7- to 10-day period of splint immobilization to ensure graft adherence. During this time, the patient may remove the splint four or five times per day to gently flex and extend the involved fingers. Patients must be watched closely for signs of increasing edema, disproportionate pain, stiffness, infection, and signs of complex regional pain syndrome. Once the wound has healed, sutures are removed, and the skin graft has taken, have the patient begin a more active range-of-motion program. Some patients progress rapidly on their own but require the services of a trained hand physiotherapist. Many scars are erythematous, thick, hard, and painful. Elastomer supported by Coban helps to minimize the amount of redness and swelling that develops. Cortisone injection of the scar and regular use of nonsteroidal antiinflammatory drugs have also been beneficial in reducing edema and scar formation.

**PITFALLS AND COMPLICATIONS**

In preparing a surgical consent form for Dupuytren's disease, the most important complications to include are digital nerve injury, infection, and recurrence. The patient may be at greater risk for each of these complications, depending on certain preexisting conditions. For example, severe contractures or dimpling of the skin may increase the risk of digital nerve injury or digital nerve dysesthesia following fasciectomy. A strong family history of Dupuytren’s disease, surgery at an early age in men or women, or surgery in women may predispose to recurrence. Tenderness, chronic edema, reflex sympathetic dystrophy (more appropriately now called complex regional pain syndrome), and limited range of motion are less common with the open-palm technique (30).

Hematoma (Fig. 62.10), a fairly devastating complication, is more common when the palmar is closed. The surgeon needs to remember that the central portion of the palm is a relatively disvascular area (7). The creation of large flaps in the palm of the hand or significant dissection that undermines the wound margins may compromise the circulation temporarily or permanently, leading to skin slough and secondary contracture.

**Fig. 62.10.** Postoperative hematoma in the hand of a 42-year-old man whose fasciectomy was performed using the closed-palm technique. Although his ultimate result was satisfactory, additional therapy was required for PIP and MP joint stiffness secondary to hematoma resolution.

Severe edema, erythema, pain, swelling, and limited range of motion may occasionally occur after open palmar fasciectomy and have been referred to as a flare reaction. It occurs more often when a fairly acute presentation of palmar fibromatosis with a painful nodule initially exists. Should it develop, I recommend treatment with nonsteroidal antiinflammatory medication and therapy in the form of elastomer and edema control, intermittent protective splinting, and a general range-of-motion program. A strong family history of Dupuytren’s disease, surgery at an early age in men or women, or surgery in women may predispose to recurrence. Tenderness, chronic edema, reflex sympathetic dystrophy (more appropriately now called complex regional pain syndrome), and limited range of motion are less common with the open-palm technique (30).

**Fig. 62.11.** A: Inflamed palm of a 57-year-old man who was seen 3 months following fasciectomy for Dupuytren's disease in which the palmar skin was closed. He developed a local wound dehiscence and secondary infection. He also developed a secondary “flare” reaction and had been scheduled for revision surgery. Instead, he was treated with nonsteroidal antiinflammatory medication and therapy in the form of elastomer and edema control, intermittent protective splinting, and a general range-of-motion program. B: One year later, he underwent revision fasciectomy using the open-palm technique. C,D: Three months postoperatively, full extension and flexion. (Amputation of the contralateral small finger was from an industrial accident.)

In severe recurrent contracture, amputation is occasionally indicated. It is usually performed at the request of the patient who, for some reason, cannot tolerate an additional procedure on the involved finger. Amputation should be done with a caveat: Spread of the disease to other digits should not involve amputation of each of the fingers. Instead, resection of the contracture should be performed along with PIP joint arthrodesis, with shortening of the bone to correct the deformity and allow extension of the finger without severe damage to the neurovascular bundle. This is an excellent salvage procedure. In certain individuals, for whom motion is extremely important (a musician, for example), PIP joint replacement arthro-plasty, with a silicone-type prosthesis, may afford enough improved motion to alter the functional course.

Lings RS. The Genetic Factor in Dupuytren's Disease. Lancet 1834;2:222.

A balanced interaction of the intrinsic and extrinsic muscles provides the normal dexterity and power of the hand (8, 16, 17, 21, 22, 38). If an injury or pathologic condition affects one set of these muscles, the hand may become dysfunctional. Intrinsic muscle imbalance may be attributable to weakness, paralysis, loss of compliance, stiffness, or contracture (18, 36, 39). Contracture or stiffness of the hypothenar, lumbrical, or interosseous muscles leads to digital imbalance that disables the hand. This chapter focuses on the correction of hand problems caused by contracture of the intrinsic muscles. An understanding of the anatomy, as well as of the specific pathophysiology, is essential if the operating surgeon is to correct these problems (1, 13, 29). Although the causes of intrinsic contractures may vary, there are a number of typical pathologic patterns based on the common mechanisms of trauma, spasticity, and connective tissue diseases.

ANATOMY

The mid-axis of the hand, as viewed from the dorsum, is defined as the central axis of the third metacarpal. The dorsal interosseous muscles abduct the fingers from this axis, whereas the palmar interosseous muscles adduct them. There are four dorsal and three palmar interosseous muscles. In addition, there are three hypothenar muscles that function like dorsal interosseous muscles. Dorsal interosseous muscles arise from the metacarpal shafts and insert so as to achieve digital abduction; the designation of first dorsal interosseous muscle thus belongs to that muscle on the radial side of the index finger, and so on, in an ulnar direction. The little finger is actually abducted by the abductor digit quinti; the middle finger is abducted in both a radial and an ulnar direction and, therefore, has two dorsal interosseous muscles (2, 3, 6, 15, 20).

Except for the third, the dorsal interosseous muscles have two muscle bellies and therefore two (tendon) insertions—one into the base of the proximal phalanx and the other via the dorsal (tendon) mechanism (Fig. 63.1). The bony insertion deviates the digit and has a mild effect on proximal phalangeal (metacarpophalangeal (MP) joint) flexion. The tendon insertion produces MP joint flexion via the transverse fibers over the dorsum of the proximal phalanx. The tendon insertion also assists with proximal interphalangeal (PIP) and distal interphalangeal (DIP) extension via the oblique fibers that continue distally to join the lateral slips of the extensor tendon, forming the conjoint lateral band. The (radial and ulnar) lateral bands unite over the dorsum of the middle phalanx to become the terminal tendon. The abductor digiti quinti, the most dorsal of the three hypothenar muscles, has an unusual insertion into the ulnopalmar shaft of the fifth metacarpal, producing carpometacarpal flexion and supination when it contracts.

![Figure 63.1. Dorsal view of the anatomy of the interosseous muscles. Except for the third, all dorsal interossei have two muscle bellies and two tendon insertions. The dorsal interossei act as digital abductors. The hypothenar muscles function as dorsal interossei. Without exception, the palmar interosseous muscles, which have only one muscle belly, insert into the lateral band and oblique fibers.](image-url)

The lumbricals extend the PIP and DIP joints but also assist in flexing the MP joints. The lumbricals are unique in that they arise on their antagonist, originating from the tendons of the flexor digitorum profundus in the mid palm (Fig. 63.2). Lumbricals of the index and middle fingers originate from the radial side of the respective flexor digitorum profundus tendons. Lumbrical tendons course distally palmar to the deep transverse intermetacarpal ligaments, becoming part of the radial lateral bands at the midportion of the proximal phalanges. When the lumbrical muscles contract, they pull the flexor digitorum profundus tendon distally, decreasing its flexion effect (relaxing the antagonist), as well as pulling proximally on the lateral band and terminal tendon, thereby extending the PIP and DIP joints.
Figure 63.2. Lumbrical anatomy. The lumbrical is unique in that it both arises from and inserts into a tendon, relaxing its antagonist when functioning. Normal lumbrical contraction tightens the lateral band (interphalangeal extensor fibers); it also pulls the flexor digitorum profundus tendon distally, diminishing flexor tone.

The extrinsic extensor tendons are the only extensors of the proximal phalanges (MP joints), lying in the dorsal midline and inserting via the sagittal bands (Fig. 63.3). These aponeuroses pass in a palmar direction, attaching into the palmar plate and base of the proximal phalanges. The sagittal bands (extrinsic extensor fibers) are proximal and medial to the transverse fibers (intrinsic flexor fibers). It is important not to confuse the sagittal bands with the transverse fibers, since the sagittal bands arise from the extensor tendon, pass in a palmar direction, and extend the finger, whereas the more distal transverse fibers arise from the lateral band and pass dorsally, insert into the dorsal tendon mechanism (not bone), and flex the proximal phalanx (Fig. 63.4) (9,18,20,31,36).

Figure 63.3. Anatomy of the extrinsic extensor tendons. The dorsal tendon mechanism at the metacarpophalangeal (MP) and proximal interphalangeal joint is composed of MP joint extensor fibers from the sagittal bands and intrinsic flexor fibers via the transverse fibers. More distally, the interphalangeal extensor tendons are formed from both the intrinsic and extrinsic tendons.

Figure 63.4. Functional slings. At the metacarpophalangeal (MP) joint, the more proximal extrinsic extensor tendon extends the joint via the sagittal fibers, which course distally and in a palmar direction to insert on the palmar plate and flexor sheath. The intrinsic tendons act as flexors via the transverse fibers, coursing distally and dorsally over the base of the proximal phalanx. (From Smith RJ. Intrinsic Muscles of the Fingers: Function, Dysfunction and Surgical Reconstruction. Instr Course Lect 1975;24:200, with permission.)

DIAGNOSIS OF CONTRACTURE

Intrinsic muscles flex the MP joints, extend the interphalangeal joints, and deviate the fingers. Therefore, intrinsic contractures, with concomitant loss of compliance or elasticity, would be expected to interfere with interphalangeal joint flexion and MP joint extension. Less severe contractures tend to affect the interphalangeal joints, whereas more severe contractures produce deformity at both levels.

Intrinsic muscle tightness, or an intrinsic contracture, should be suspected when active PIP flexion is limited (Fig. 63.5). A simple physical test will usually confirm the diagnosis. Passive PIP flexion is tested by the examiner while the MP joint is held flexed; it is then tested again while the MP joint is held extended. A test of intrinsic tightness is positive if there is significantly less passive PIP flexion with the MP joint extended than with it flexed. Many authors have described this test, and it is often (confusingly) recorded eponymically (7,10,30,36). In contrast, extrinsic tightness (contracture of the extensor tendons) is present if passive PIP flexion is more limited when the MP joint is flexed than when it is held in extension. It may be impossible to perform these tests effectively if there are contractures in the MP or PIP joints, or if a joint is dislocated. If there are both intrinsic and extrinsic contractures simultaneously, one may obscure the other.

Figure 63.5. Intrinsic muscle tightness is tested by passively flexing the proximal interphalangeal joint while the metacarpophalangeal (MP) joint is held flexed; it is then tested again while the MP joint is held extended. The intrinsic tightness test is positive if there is significantly less passive proximal interphalangeal flexion with the MP joint extended than with it flexed.
The most common presentation of a functionally significant intrinsic contracture follows trauma, probably caused by muscle changes as a consequence of edema, anoxia, and immobilization. For example, a patient may complain that she cannot grasp objects; sometimes patients report weakness. A careful history and examination will reveal the intrinsic muscle pathology. When examined in the office, the patient may be almost able or fully able to make a fist with unrestricted simultaneous MP and PIP flexion. In attempting to grasp a hammer, however, the flexion of the MP joints is blocked by the hammer, and active flexion of the PIP joints is decreased. This activity is a functional test of intrinsic tightness.

**MILD INTRINSIC CONTRACTURE**

**NONSURGICAL TREATMENT IMMEDIATELY AFTER INJURY**

If a diagnosis of mild intrinsic tightness or of contracture is made soon after injury (after a Colles' fracture, for example), significant dysfunction may be avoided. Treat to reduce swelling, mobilize the intrinsic tendons, and stretch the muscle bellies. Institute elevation, fluid-flushing massage, and intrinsic muscle-stretching exercises.

Stretch the intrinsic muscles by gradually and repetitively performing an intrinsic tightness test, which involves simultaneous passive extension of the MP joints and passive flexion of the PIP joints. This home and supervised outpatient therapy program must be continued for several weeks to be fully effective.

**ACUTE POSTTRAUMATIC EDEMA: FASCIAL RELEASE**

During the immediate posttraumatic phase, if the hand is severely swollen, measure the pressure of the intrinsic muscle compartments. (See Chapter 13 and Chapter 65 for information on compartment syndromes.) In acute cases, surgical release of the fascial envelope about the intrinsic muscles, in addition to the adductor pollicis, and release of the carpal tunnel may be required (23,29).

- After applying a tourniquet, approach the intrinsic compartments of the swollen hand through longitudinal incisions about 5 cm long, centered over the mid shafts of the second and fourth metacarpals. Avoid injury to the dorsal veins and sensory nerves.
- Retract the extensor tendons and incise the interosseous fascia longitudinally at each intermetacarpal space. If the second metacarpal incision does not afford adequate access to the adductor pollicis in the first web, once the first dorsal interosseous muscle fascia has been released, make an additional 3 cm longitudinal incision just ulnar to the thumb MP joint, extending it proximally. Incise the fascia dorsal and palmar to the adductor.
- In severe injuries, it may be necessary to perform decompression of the hypothenar muscle via a longitudinal 3 cm incision at the ulnopalmar aspect of the hand and another incision over the thenar muscles, as well as carpal tunnel release.
- Pin the MP joints of severely swollen hands at about 70° of flexion with smooth 0.045 Kirschner wires (K-wires); pin the thumb metacarpal in wide palmar abduction and pronation. Do not close these longitudinal wounds while the hand remains swollen; they may be closed secondarily after several days, or by skin grafting.
- Keep the hand elevated and closely observe circulation. Begin hand therapy with bedside visits to encourage tendon gliding and small joint motion, except in those joints that are transfixed. Continue active exercises during the period of healing and maturation of skin grafts, if grafting has been required. Dynamic splints and closely supervised active exercises may be necessary. Remove the transfixion K-wires when the swelling has subsided adequately; in any event, remove wires within 21 to 28 days following insertion.

**MODERATE INTRINSIC CONTRACTURE**

After trauma, the moderately edematous hand is likely to develop intrinsic tightness that affects the PIP joints exclusively. When the hand is unprotected and swollen, MP joint flexion also becomes difficult. The intrinsic muscles, however, can achieve relatively unrestricted PIP extension because the capsule and collateral ligaments are initially more lax in that position. Continued PIP extension via tight intrinsic muscles results in limited PIP flexion; in severe cases, it may also be associated with actual capsular tightness at the PIP level. The intrinsic tightness test is positive in such cases.

**DISTAL INTRINSIC RELEASE**

To relieve the tightness—assuming that a program of intrinsic stretching exercises has failed—a distal intrinsic release is needed. The entire intrinsic mechanism need not be sacrificed, since only PIP flexion is impaired. This release of the oblique fibers of the lateral bands is known as a distal intrinsic release (i.e., it is distal to the transverse fibers) (23,15,18,39).

- Approach the lateral bands in the affected fingers through a dorsal, longitudinal incision 2–3 cm long over the middle third of the proximal phalanx. Carry the incision down to the dorsal mechanism, then elevate the skin flaps, first to the radial side and then to the ulnar side, exposing the lateral bands, the oblique fibers, and the central and lateral slips of the tendon mechanism.
- Divide the lateral bands and their oblique fibers near the distal edge of the wound as they insert into the central slip of the extensor mechanism (Fig. 63.6). Do not divide the lateral slip or the central slip of the extensor tendon; preserve the transverse fibers of the intrinsic tendon as well. Resect a 1 cm piece of the lateral band and its oblique fibers to correct the contracture completely.
- Repeat the intrinsic tightness test after both radial and ulnar lateral bands have been resected to verify the completeness of the procedure (Fig. 63.7). Close the wounds and split the MP joints in extension, taping the PIP joints into flexion.

**Figure 63.6.** Distal intrinsic release. For moderate intrinsic contracture that limits proximal interphalangeal flexion, resection of the oblique fibers and contiguous lateral bands is performed on both the radial and ulnar sides of the finger through a dorsal incision.

**Figure 63.7.** A–B: A 56-year-old woman had limited active proximal interphalangeal flexion 6 months after a Colles' wrist fracture. C–D: The intrinsic tightness test was positive. E: A distal intrinsic release was performed. F: Immediately after the surgical release of the intrinsic, the tightness test was negative. G–H: At 2 years after surgery, marked improvement in active proximal interphalangeal flexion continues, although motion is still imperfect.

- Begin active and passive PIP flexion exercises within a day or two of surgery. The MP flexion-block splint can generally be discontinued after 14 days, although intrinsic stretching and exercises should be continued for several weeks.
SEVERE POSTTRAUMATIC INTRINSIC CONTRACTURE

An extended anoxic injury, severe swelling, and prolonged elevated compartment pressure will produce intrinsic myonecrosis with secondary fibrosis, causing deformities at both the MP and the interphalangeal joints (2,3,18,19,34,36). These MP flexion contractures result only from marked and severe intrinsic fibrosis, as evidenced by the fact that most significant posttraumatic MP joint deformities are extension contractures resulting from tight collateral ligaments and secondary capsular scarring. The swollen MP joints strongly resist being flexed, and only in the presence of marked intrinsic muscle scarring will a contracture be severe enough to force the already tight, extended MP joints into a flexed position. Severe PIP extension or hyperextension may also be a part of this often static deformity. Secondary changes at both joints, with pericapsular fibrosis in the deformed position, are not uncommon. Often the first web is also limited because of contracture of the adductor pollicis and the first dorsal interosseous muscles. A significant degree of hand dysfunction results from these contractures.

PROXIMAL INTRINSIC RELEASE

Correction of severe contracture requires release of not only the distal intrinsic fibers, but also the transverse fibers of the dorsal tendons that normally flex the MP joints (Fig. 63.8). It is unlikely that these scarred intrinsic muscles will be functional to any extent; therefore, they are best handled by removing the tendons altogether, thus eliminating the deforming force. Overcorrection is rarely a problem, even with an aggressive and complete release. Indeed, full correction may be difficult to achieve.

- Make a dorsal transverse incision that extends from the radial mid-axis of the second metacarpal to the ulnar mid-axis of the fifth, just proximal to the MP joints. The dorsal approach prevents injury to the palmar neurovascular and tendon structures.
- Make a dorsal transverse incision that extends from the radial mid-axis of the second metacarpal to the ulnar mid-axis of the fifth, just proximal to the MP joints. The dorsal approach prevents injury to the palmar neurovascular and tendon structures.
- Make dorsal longitudinal incisions. Generally, incisions over the second and fourth metacarpals are sufficient. Avoid injury to sensory nerves, dorsal veins, and extensor tendons.
- Make dorsal longitudinal incisions. Generally, incisions over the second and fourth metacarpals are sufficient. Avoid injury to sensory nerves, dorsal veins, and extensor tendons.
- Verify relief of the combined MP flexion and PIP extension contractures by repeating the intrinsic tightness test.
- Verify relief of the combined MP flexion and PIP extension contractures by repeating the intrinsic tightness test.
- When residual capsular inelasticity hinders positioning of the MP joints in extension, it may be necessary to pin them in that position with obliquely placed, smooth K-wires for about 2 weeks. To correct PIP extension, it may also be necessary to release the lateral bands separately—in much the same manner as the distal intrinsic release was performed—at the time of the proximal intrinsic release. In such cases, individual dorsal incisions may also be required to relieve the PIP contractures completely.
- When residual capsular inelasticity hinders positioning of the MP joints in extension, it may be necessary to pin them in that position with obliquely placed, smooth K-wires for about 2 weeks. To correct PIP extension, it may also be necessary to release the lateral bands separately—in much the same manner as the distal intrinsic release was performed—at the time of the proximal intrinsic release. In such cases, individual dorsal incisions may also be required to relieve the PIP contractures completely.
- Postoperative care is essentially the same as it is for a distal intrinsic release, as described earlier.

With severe contractures, a release of the adductor pollicis muscle is also necessary (12,19). Since the skin is often tight, I have found that the most dependable way to relieve the first web contracture is by approaching the adductor via a standard Z-plasty or a Wolff four-flap Z-plasty in which the dorsal longitudinal limb can be extended as far proximally as necessary (5). The dorsal approach prevents injury to the palmar neurovascular and tendon structures.

- Use a small chisel or elevator to free the adductor from its third metacarpal origin.
- Use a small chisel or elevator to free the adductor from its third metacarpal origin.
- If necessary, pin the first metacarpal in wide palmar abduction and pronation for up to 3 weeks, depending on the ease of maintaining the corrected position with splints and dressings alone.
- If necessary, pin the first metacarpal in wide palmar abduction and pronation for up to 3 weeks, depending on the ease of maintaining the corrected position with splints and dressings alone.

SPASTIC CONTRACTURE

Intrinsic spasticity may cause dysfunctional deformities in patients with cerebral palsy; it may also occur following cerebrovascular accidents, and it may also affect patients with central nervous system diseases (11,19,24,26,27,33). At times, the intrinsic spasticity is not clinically evident until after the tighter and stronger finger and wrist flexors have been released surgically. Weeks or months after a flexor release or slide, the previously corrected digits may begin to assume an intrinsic-plus posture, with combined MP flexion and PIP extension or hyperextension, often appearing unexpectedly. Although this deformity is similar to that associated with severe posttraumatic contracture, the cause and treatment are different. This condition is attributable to overactive muscles, not scarred and necrotic tissue. The purpose of a surgical release is ideal to decrease the spasticity, and to lengthen the intrinsic muscle–tendon unit to correct the deformity and preserve function. Strictly speaking, the intrinsic muscle cannot be lengthened; however, such an effect is attainable via a muscle slide (31,32).

INTRINSIC MUSCLE SLIDE

- Make dorsal longitudinal incisions. Generally, incisions over the second and fourth metacarpals are sufficient. Avoid injury to sensory nerves, dorsal veins, and extensor tendons.
- Make dorsal longitudinal incisions. Generally, incisions over the second and fourth metacarpals are sufficient. Avoid injury to sensory nerves, dorsal veins, and extensor tendons.
- After incising the interosseus fascia longitudinally, completely release the metacarpal origins of the interosseus subperiosteally with an elevator. Place the fingers in the intrinsic-minus (claw) position, and slide the released muscles distally (Fig. 63.9).
- After incising the interosseus fascia longitudinally, completely release the metacarpal origins of the interosseus subperiosteally with an elevator. Place the fingers in the intrinsic-minus (claw) position, and slide the released muscles distally (Fig. 63.9).

- Make separate incisions over the ulnar portion of the first metacarpal for the superficial head of the first dorsal interosseus, avoiding trauma to the princeps pollicis artery, and at the ulnar aspect of the little-finger MP joint to transect the tendons of the flexor digiti quinti.
- Make separate incisions over the ulnar portion of the first metacarpal for the superficial head of the first dorsal interosseus, avoiding trauma to the princeps pollicis artery, and at the ulnar aspect of the little-finger MP joint to transect the tendons of the flexor digiti quinti.
- Make separate incisions over the ulnar portion of the first metacarpal for the superficial head of the first dorsal interosseus, avoiding trauma to the princeps pollicis artery, and at the ulnar aspect of the little-finger MP joint to transect the tendons of the flexor digiti quinti. The transsection of the abductor digiti quinti may also be necessary. In this situation, maintain splitting in the intrinsic-minus (claw) position of combined MP extension and PIP flexion for 2–3 weeks before initiating therapy and exercises, so as to encourage the released muscles to realign more distally.
ULNAR MOTOR NEURECTOMY

Certain spastic deformities are so severe that salvage by intrinsic muscle slide is precluded. Patients with such deformities may have associated capsular contractions and PIP hyperextension. The best operation in these cases is an ulnar motor neurectomy.

- Make a curvilinear, longitudinal, ulnar palmar incision extending distally from a point just proximal and radial to the pisiform, to a position distal and radial to the hamulus (hook) of the hamate.
- Identify the deep motor branch of the ulnar nerve as it courses dorsally and in a radial direction around (distal to) the hamulus. Excise a 1 cm segment of nerve.

Do not cut the sensory branches of the nerve. Contractures, if present, may be addressed appropriately at the same time.

Secondary small joint deformities necessitating ligament reconstruction or replacement may occur in the chronically spastic hand. For a discussion of the sublimis tenodesis and other similar procedures, see Chapter 68.

CONTRACTURE FOLLOWING TERMINAL TENDON INJURY: MALLET FINGER

When the terminal extensor tendon is divided or avulsed, the proximal part of the terminal tendon and contiguous conjoined lateral bands retract proximally, unbalancing the extensor forces at the PIP joint. A hyperextension deformity of the PIP joint may gradually develop, or the joint may merely become more difficult to flex actively (14,27). The intrinsic tightness test is typically positive.

Repair of the terminal tendon as well as intrinsic stretching exercises may be required to correct this problem. Digital rebalancing may have to be undertaken in resistant cases. The need for tendon transfer release or capsulodesis is determined by a careful assessment of the combined effects of the intrinsic and extrinsic tendon contributions to the PIP overpull.

LUMBRICAL CONTRACTURE

The lumbrical is a unique muscle that both arises from and inserts into a tendon, relaxing its antagonist when functioning. Normal PIP flexion depends on balanced flexor digitorum profundus contraction and lumbrical relaxation. Lumbrical scarring (shortening) and loss of elasticity cause transmission of flexor digitorum profundus traction into the lumbrical tendon, to which it has become tethered, rather than through the more distal portion of the flexor digitorum profundus tendon (Fig. 63.10A). Active pull on the flexor digitorum profundus tendon then causes PIP and DIP extension via the contracted lumbrical, rather than flexion, a situation Parkes termed the “paradoxical lumbrical-plus finger” (25).

Paradoxical lumbrical transmission of flexor forces may also be seen when the normal flexor digitorum profundus insertion is lost, as may occur in untreated distal tendon lacerations or distal joint amputations (Fig. 63.10B). The then-lax profundus tendon retracts proximally, and contraction of the flexor digitorum profundus muscle is transmitted to the dorsum of the PIP joint via the lumbrical tendon, producing paradoxical extension or limited active flexion. A loosely inserted tendon graft would have the same effect. The intrinsic tightness test is positive in such cases.

Resection of the radial lateral band will cure this problem. Indeed, I am careful to test patients with DIP amputations for intrinsic tightness, and I often perform an acute radial lateral band release. Intrinsic stretching exercises become a regular part of the rehabilitation program.

INTRINSIC CONTRACTURE AND CONNECTIVE TISSUE DISEASE

Interosseous contracture is common in the patient with rheumatoid arthritis. Unlike posttraumatic deformities, contracture may be associated with painful synovitis, ulnar digital drift, joint subluxation, and joint destruction. Secondary deformities are common and may require a combination of joint and tendon reconstruction and releases (5,8,35,37). It is beyond the scope of this chapter to discuss correction of rheumatoid ulnar drift, intrinsic tenodesis, and spiral oblique retinacular ligament reconstruction (see Chapter 70).

SWAN-NECK DEFORMITIES

Swan-neck deformities are more common in the arthritic hand but may develop after trauma, with severe intrinsic tightness. In general, there must be a physiologic predisposition to (passive) PIP joint hyperextension (present in many patients with connective tissue inflammatory diseases). In addition, intrinsic tightness, whether clinical or subclinical, is a requirement for this deformity, characterized by the combination of PIP joint hyperextension and DIP joint flexion. At the PIP joint, there is (secondary) laxity of the volar plate, dorsal subluxation of the lateral bands, and contracture of the collateral ligaments, which makes it difficult for the patient to initiate PIP flexion, at first. With time, the deformities may become fixed.

In addition to intrinsic muscle imbalance, there are other causes of swan-neck deformity in patients with systemic arthritis. Extrinsic tightness in a patient with palmar subluxation of the proximal phalanx but no ulnar drift increases tension in the extrinsic extensor central slip, producing PIP hyperextension. In such a case, the intrinsic tightness test will be negative, but the extrinsic tightness test is positive. Further, there are patients who have coexisting intrinsic and extrinsic tightness. Such individuals demonstrate marked resistance or inhibition of passive PIP joint flexion at the extremes of both the intrinsic and extrinsic tightness tests. In these, the PIP joint is “least tight” when the MP joint is held at about 30° to 40° of flexion; and it is “most tight” at maximal MP flexion and also at maximal MP extension. Flexor tendon rupture (especially of the flexor superficialis), PIP joint volar plate laxity, and DIP joint destruction resulting in terminal extensor tendon rupture all may produce swan-neck deformities. In such problems, testing for intrinsic and extrinsic tightness will not necessarily limit passive PIP joint flexion until and unless the PIP deformity becomes fixed.

Operative Technique

Static swan-neck deformity results from secondary contracture of the PIP joint collateral ligaments and fixed dorsal laxation of the lateral bands. Release of the intrinsics alone will not restore normal balance and physiologic tendon function. Such fingers need intrinsic release (proximal or distal release, as appropriate), restoration of DIP joint extension—or tenodesis in an extended position—and correction of the volar plate–ligament incompetence at the PIP joint. If the PIP joint extension contracture is fixed, perform dorsal capsulectomy and serial sectioning of some, or the majority, of the collateral ligaments. To achieve treatment goals, combine the PIP joint and intrinsic releases with an intrinsic tenodesis (Fox, 63.11).
Intrinsic contractures are far more common than generally appreciated. Adequate correction requires accurate diagnosis. When active PIP flexion is limited as a result of posttraumatic hand edema, suspect intrinsic tightness and impending contractures and perform an intrinsic tightness test. Prompt institution of intrinsic muscle-stretching exercises and regular supervised therapy will often prevent the development of deformity and fixed contractures.

This operation reverses intrinsic tightness, releases the PIP joint, creates a volar check-rein (ligament) at the PIP joint, and increases extensor tenodesis in the terminal tendon to improve DIP joint extension.

In a particular case, the tissue condition (or surgeon preference) may dictate using the ulnar lateral band rather than the radial one, and there is not a significant technical difference. The goal of the operation is to tenodese the PIP joint in about 30° flexion. Postoperative dressings protect this position.

Begin a therapy program within a very few days of operation—this is critical to prevent fixed PIP joint contracture and tendon adhesions. Hand therapists can fabricate a custom digital extension-block splint that allows active PIP flexion and extension to about 30° to 35° during active and passive exercises. Beginning at about 4–5 weeks after surgery, allow active PIP joint extension out of the splint, but continue splint protection for 6–8 weeks after surgery.

Alternative Operative Technique

An alternative to intrinsic tenodesis is the creation of a spiral oblique retinacular ligament (SORL), but this requires a free tendon graft.

- Suture the graft into the normal insertion of the terminal extensor tendon at the distal phalanx, and then pass proximally, but diagonally, across the palmar surface of the fibro-osseous canal, staying dorsal to the neurovascular bundles.
- Suture it into the proximal phalanx, volar and proximal to the PIP joint (Fig. 63.12).

This reconstruction needs a more extensive dissection than intrinsic tenodesis, in addition to the need for a tendon graft, and probably should be reserved for patients who do not otherwise have adequate stability of Cleland's ligament to act as a check to retain an intrinsic tendon palmar to the axis of PIP motion. Alternatively, one can reasonably consider passing the native intrinsic tendon, if available (as described earlier), across the flexor surface, as with the SORL, to avoid tendon graft where dorsal tissues allow native correction but Cleland's ligament still does not provide a useful check-rein.

PITFALLS AND COMPLICATIONS

The most common problem accompanying intrinsic tightness and contractures is failure to recognize the underlying cause of limited PIP motion following injury. Intrinsic contractures are far more common than generally appreciated. Adequate correction requires accurate diagnosis. When active PIP flexion is limited as a result of postruamous hand edema, suspect intrinsic tightness and impending contractures and perform an intrinsic tightness test. Prompt institution of intrinsic muscle-stretching exercises and regular supervised therapy will often prevent the development of deformity and fixed contractures.

Surgical release of the intrinsic muscles, when required, should not be considered an end in itself, but rather a means to an end—a second chance at therapy. Intrinsic contracture destroys the delicate balance of the hand. Intrinsic release will not achieve functional improvement unless these very demanding and unforgiving small joints and tendons are made to glide in order to regain the full range of motion in the postoperative interval. Select patients carefully, and make every effort to help them understand the crucial role they will play in their own recovery. Patients who are not intellectually and emotionally committed to a recovery that requires tediously repetitive therapeutic exercises, including frequent hand therapy and office visits, should not undergo the procedure.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Burns are a major health hazard, second only to motor vehicle accidents as the leading cause of accidental death in the United States (19). Despite aggressive techniques of acute burn wound management, crippling hand deformities occur. In a severe burn, the hand, which accounts for 5% of the total body surface area, is often neglected as attention is focused on helping the burn victim to survive. By the time it has been ascertained that the patient will survive, fixed contractures that are functionally disabling and aesthetically displeasing often have developed, and surgical reconstruction may be indicated (1,12,22,24).

First-degree and superficial second-degree burns heal satisfactorily without tissue replacement. Deep second-degree (i.e., partial-thickness), third-degree (i.e., full-thickness), and fourth-degree (i.e., tendon, bone, nerve, or joint) burns that are not debrided and covered with skin grafts or flaps heal by granulation tissue, producing scar and contractures. Early wound closure and splinting are essential to prevent contractures during the acute burn period and to minimize the necessity for secondary reconstruction. Beasley observed that the triad of edema, inflammation, and especially immobility is responsible for the deformities produced by thermal injuries (7). He further pointed out that the severity of the deformities is directly proportional to the amount of time a wound remains open.

Before undertaking upper extremity burn reconstruction, several factors require consideration. First, the surgeon must assess the functional needs of the patient. There is no reason to launch a series of reconstructive procedures if a patient has fully adjusted to his condition and is able to carry out the activities of daily living as easily as before the burn (17). Having decided to proceed with reconstruction, remember that other priority areas, particularly the head and neck, may require surgical correction; if a large area of body surface has been burned, unscarred skin may be at a premium. Therefore, the surgeon must plan for the appropriate allocation of skin. Preoperative radiographs are mandatory before any procedure involving the mobilization of joints.

Complete restoration of joint motion may not be possible with a soft-tissue release, because the articular surfaces may be incongruous on account of sepsis, dislocation, or heterotopic ossification. Although both extremities may be burned and require reconstruction, it may be practical to reconstruct only one extremity because of limited skin availability, leaving the other as an assistive appendage. If the entire extremity including the axilla is burned, reconstruction should proceed in a proximal to distal fashion; shoulder and elbow mobility should be restored before hand procedures are performed. Full hand motion is useless if elbow and axillary contractures preclude positioning the hand in space (23). Reconstructive procedures should preferably not be performed through scar that is hypertrophic and red. Wait until the scar has matured, a process that can be accelerated with the use of elastic pressure garments.

**PRINCIPLES OF SOFT-TISSUE COVERAGE**

The surgeon must understand certain principles of soft-tissue coverage before reconstruction of specific anatomic locations can be accomplished (Fig. 64.1). Burn contractures are corrected by scar incision, excision, or a combination of both procedures. Afterward, a soft-tissue defect exists.

![Figure 64.1. Outline of the surgical treatment of burn contractures.](image-url)

Most defects in the hand can be covered by a skin graft, a local flap, or a combination of the two. After a burn release, local flaps, such as Z-plasties, have limited application and should be considered for coverage only if the flap consists of pliable, unburned skin. Scarred skin usually does not tolerate the stress of being rotated as a local flap, and a significant portion of the flap may become necrotic. Local flaps, however, have the advantages of providing a good color match and usually obviate the need for a skin graft.

Skin grafting is the mainstay of treatment after contracture release or excision. Skin grafts adhere only to a well-vascularized surface. A tendon denuded of paratenon, bone without periosseum, and articular cartilage do not accept a skin graft; they require flap coverage. If simultaneous or future bone, nerve, or tendon reconstruction is being considered, a skin graft alone provides insufficient coverage.

After deciding to use a skin graft, the next choices depend on the size and location of the defect and the availability of unburned donor skin. A donor site should be inconspicuous and should match the recipient defect as closely as possible. For example, a defect on the palm should ideally be covered with adjacent, unscarred palmar skin, but transfer is rarely possible because of the limited availability of palmar skin. Unscarred skin is usually available from the lateral, hair-free portion of the groin or from the buttocks, or even from the instep of the foot. After selecting a donor site, the physician must next choose between a split-thickness skin graft and a full-thickness skin graft.

A full-thickness skin graft has several advantages in burned hand reconstruction. It is durable and is particularly suited for contact areas, such as the palm and the mobile palmar surface of the fingers. It contracts less than a split-thickness skin graft and is less conspicuous. The donor site for a full-thickness skin graft is closed primarily, so there is considerably less postoperative pain than occurs after a split-thickness skin graft, in which the reepithelializing donor site may be painful for
several days after graft harvesting.

Two circumstances in burn reconstruction make a split-thickness graft a more practical choice for coverage than a full-thickness skin graft. If the area to be covered is large, a split-thickness skin graft is indicated. The donor site for a split-thickness skin graft does not require primary closure, and more skin is available for grafting. The split-thickness skin graft can be expanded by meshing, although meshed skin is aesthetically displeasing and it tends to contract more than a nonmeshed graft. A split-thickness graft is also indicated if the recipient bed has poor vascularity, as occurs following radiation burns or with burns in which there is residual skin ulceration and low-grade sepsis.

Under certain conditions, skin grafting is not applicable. Fourth-degree burns, particularly if untreated during the acute burn period, tend to leave the extremity in a contracted, fibrotic condition (21). After the scar has been excised, there is often exposed bone, tendon, or joint, and these structures will not accept skin grafting of any kind. Furthermore, with deep fourth-degree burns, it is often necessary to perform reconstructive procedures involving the tendons (e.g., tenolysis or tendon graft) or joints (e.g., capsulotomy); coverage with a skin graft is not appropriate because the graft, even if it does take, adheres tightly to the tendon or joint, limiting mobility. Always perform scar release or scar excision before elevation of a flap. After excision of the burn cicatrix, the recipient bed may be three to four times larger than it was before. Knowing the dimensions of the recipient bed, the surgeon can better design an appropriate-size flap.

In most cases, skin flaps are unnecessary. Most burns involve injury to the skin alone, and a flap is usually not indicated. If mobile structures are exposed, however, or if future reconstruction is anticipated, do not hesitate to apply a flap.

**THUMB RECONSTRUCTION**

Because the thumb contributes 40% to 50% of the function of the hand, its functional restoration is a primary goal in upper-extremity reconstruction after burns. For normal thumb function, there must be adequate length, sensibility, mobility, stability, and strength, and a satisfactory appearance. Most thermal injuries produce skin contractures that limit thumb mobility and use. In severe burns, loss of thumb length is usually secondary to a fourth-degree injury in which the distal portion or more of the thumb becomes necrotic, necessitating amputation. In children, longitudinal growth may be restricted because of a dermal contracture or direct thermal injury to the growth plates.

**ADDUCTION CONTRACTURE**

Adduction contracture of the thumb, in which the thumb metacarpal is adducted toward the index metacarpal in a plane perpendicular to the palm, is the most common contracture of the burned thumb (26). In its mildest form, it is produced by dorsal scarring over the thumb–index web, and the palmar skin is usually not burned. Reconstruction of the thumb–index cleft can be accomplished by several techniques.

**Z-Plasty**

Z-plasty is indicated in circumstances where the flaps to be rotated are not severely scarred (33).

- Design it so that the palmar limb generally follows the thenar crease, the middle limb parallels the leading edge of the thumb–index cleft, and the dorsal limb parallels the ulnar aspect of the thumb metacarpal. All limbs should be of equal length.
- After incision, elevate the flaps, making them as thick as possible, and preserve any blood vessels that penetrate the base of the flap.
- Take care to avoid dividing the radial neuromascular bundle to the index finger that lies immediately beneath the palmar flap.
- After the flaps have been raised, release the previously inflated tourniquet and secure meticulous hemostasis.
- Rotate the flaps and sew them into position. Be sure that the flaps are vascularized. A flap that is dark and congested (e.g., in venous insufficiency) or one that is pale and white (e.g., in arterial insufficiency) invariably becomes necrotic. If not vascularized, return the flap to its original position and consider an alternative form of coverage, such as skin grafting.

A Z-plasty is indicated for the correction of mild linear contractures and can be performed only when the burn being rotated is relatively pliable and unburned. If the skin is scarred and fibrotic, seek alternative techniques of coverage.

**Skin Grafting**

- If contracture is severe, it is best to divide the contracture band sharply by incising perpendicular to it (Fig. 64.2). Carry the incision down to the fascia overlying the first dorsal interosseous muscle and to the leading edge of the adductor pollicis muscle.
- Cover the resultant defect, which is elliptical, with a skin graft.

**Adductor Release and Trapezial Excision**

- If the patient has sustained a deep burn, a severe adduction contracture may result. This type of contracture involves more than skin and necessitates release of deep structures.
- Release the palmar contracture and the fascia overlying the first dorsal interosseous and adductor as outlined earlier.
- If the thumb remains tightly adducted, consider releasing the insertion of the adductor pollicis muscle from the base of the proximal phalanx of the thumb. The adductor muscle in a severe burn is often fibrotic but rarely nonfunctional; therefore, it is advisable to reinsert the muscle more proximally on the neck or shaft of the thumb metacarpal through a pull-out wire or suture anchor.
- Rarely, even after the skin and adductor muscle have been released, an adduction contracture may persist. In these instances, carry the incision down over the trapeziometacarpal joint and release the joint capsule.
- If the contracture still persists, excision of the trapezium is indicated.
- It is usually necessary to pass a temporary Kirschner pin from the thumb metacarpal into the carpus to hold the thumb in its newly released position.
- After such an extensive release, coverage with a skin graft is usually inadequate. Plan on using a distant flap, such as one from the hair-free inner aspect of the contralateral forearm, to resurface and maintain breadth of the thumb–index cleft.
- If release of any adduction contracture, postoperative splitting is mandatory. Although there are several causes of a persistent contracture—including inadequate surgical release, loss of skin graft, or the inappropriate use of burned skin or flap coverage—one of the most common causes is failure to split the thumb metacarpal midway between palmar and radial abduction. A split can be fabricated from thermoglascic material and lined with silicone to maintain satisfactory breadth between the thumb and index finger. Have the patient wear the splint until the wound has matured, usually 3 to 9 months. It is often helpful to alternate splitting with use of an elastic compressive glove, which also accelerates the scar maturity.

**OPPOSITION, EXTENSION, AND FLEXION CONTRACTURES**

Less commonly, the thumb metacarpal may be drawn into a position of opposition (i.e., pronation and palmar abduction of the thumb), extension (i.e., when the index finger is drawn away from by a scar band between the distal radius and the thumb metacarpal), or flexion (i.e., when scarring over the palmar aspect of the thumb
produces flexion of the interphalangeal or metacarpophalangeal joint (26). As in adduction contractures, all of these contractures require surgical incision with or without a scar excision, followed by appropriate soft-tissue coverage and splinting.

With opposition and extension contractures, severe flexion or hyperextension contractures of the interphalangeal or metacarpophalangeal joint of the thumb often coexist, producing articular incongruity and joint subluxation or dislocation. In such cases, particularly if there is satisfactory mobility of two of the three thumb joints, an arthrodesis of the dislocated joint in a functional position is indicated.

INADEQUATE THUMB LENGTH

Severe burn injuries often result in loss of thumb length (20). Restoration of length can be accomplished by a number of surgical techniques. These include toe-to-hand transfer and osteoplastic reconstruction, consisting of a tube pedicle flap placed around a bone graft, followed by neurovascular island transfer for restoration of sensibility. Also possible are metacarpal osteotomy and progressive distraction and pollicization with movement of an adjacent digit, usually the index finger, on its neurovascular pedicle to the thumb position. If only a small amount of thumb length has been lost, use phalangization to increase thumb length. Release the thumb-web contracture, and proximally transpose the adductor muscle to the thumb metacarpal, making the thumb–index cleft deeper and giving the thumb more apparent length (29).

The burn may be so severe that thumb reconstruction is not feasible. The phalanges may have been amputated, and various lengths of metacarpals may be encased in a cocoon of burned skin. If thenar muscle contraction can be appreciated by manual palpation, a “mitten hand” can be created by excising the index finger metacarpal (leaving the base where the wrist flexor and extensor tendons attach). Thereby a cleft is created between the thumb and ulnar digits so that the patient can accomplish a pinch maneuver of a crude side-to-side type (Fig. 64.3).

The pollicization procedure involves placing a digit (usually the index finger) on top of the remains of the thumb (20,31). Pollicization is more likely to be successful if there is an intact thumb trapeziometacarpal joint, functioning thenar musculature, and relatively good sensibility of the digit to be pollicized.

Before performing the procedure, it is advisable to excise scarred tissue in the thumb–index cleft and replace it with a skin flap from the groin or abdomen, which can later be used to resurface the cleft between the pollicized thumb and the remaining ulnar digits. After flap tissue has been transferred, perform the pollicization procedure. It is preferable to transfer the index ray, particularly if it has been damaged and is already short (Fig. 64.4). If it is absent, any other digit can be transferred.

For conventional pollicization (e.g., aplasia of the thumb), design the incisions so that the pollicized digit can be transposed and rotated to provide skin flaps for a cleft between the thumb and the remainder of the hand. When pollicizing a burned index finger, make the incisions along the border of areas that have previously been scarred, exposing the index metacarpal shaft and the tip of the thumb.

POLlicization of the INDEX FINGER

- Reflect the interosseous muscles from the index metacarpal shaft. They are often fibrotic and are not useful for future motor function, as in conventional pollicizations.
- Ligate the proper digital artery to the radial side of the middle finger, and split the common digital nerve to the index and middle finger proximally as far as possible.
- Osteotomize the index finger metacarpal through its base, and remove a segment of metacarpal shaft, being careful to preserve the index metacarpophalangeal joint.
- Leave the flexor tendons to the index finger intact. If necessary, Z-lengthen the extensor tendons, which often are scarred.
- Rotate the index finger so that it can be put on top of the thumb remnant with the pulp of the pollicized digit directly facing the ulnar digits. Turn the pollicized digit so that it is 120° to 140° from the plane of the palm. It is easiest to stabilize the skeletal structure of the pollicized digit with one or two longitudinal Kirschner pins.
- Deftly tourniquet to ensure that the pollicized digit is viable and that its vascular pedicle has not been stretched or twisted.
- Close the wound, being careful to line the thumb–index cleft with soft, pliable skin.
- Maintain skeletal pin fixation for 6–8 weeks, and maintain splinting of the thumb in wide palmar abduction for 6–9 months.

Errors in positioning of the transferred digit, inadequate bony fixation, or contracture of the thumb cleft cause the most common complications of pollicization. These can usually be prevented by careful preoperative planning and attention to intraoperative technique.

Pollicization for the severely burned hand has the advantage of being a one-stage procedure that does not require microvascular techniques. It converts two relatively useless digits into a single, functional, opposable thumb, making activities requiring opposition and prehension possible.

THE PROXIMAL INTERPHALANGEAL JOINT

Burns of the proximal interphalangeal joint can produce flexion or extension contractures. If surgical intervention is necessary, take preoperative radiographs of the proximal interphalanegleal joint to confirm that a cartilaginous space is present and that the joint is not subluxed or dislocated (8).

Burn flexion contractures may arise from scarring of the palmar skin of the proximal interphalangeal joint or from dorsal burns in which the central tendon over the
The principles of successful treatment of burn syndactyly listed by Upton (27) are as follows:

- Use skin grafts.
- Use flaps to line the depth of the web space.
- Use skin grafts.

RELEASE OF CONTRACTURES

- If a contracture of only the proximal interphalangeal joint exists, incise the scar transversely across the anterior aspect of the joint, extending the incision from the radial to the ulnar midaxial line (4). It is usually unnecessary to excise the contracture band completely. Carry the incision down to the flexor tendon sheath, taking care not to sever the digital nerves. They are always deep to the burn scar and are usually covered by a thin layer of fat.
- If a proximal interphalangeal flexion contracture persists after dermal release, decide whether to perform a proximal interphalangeal capsular release. If so, the flexor tendons will be exposed, and flap coverage, using an adjacent cross-finger flap or a distant flap, will be necessary to prevent tendon desiccation (18).
- If the flap procedure is not feasible, do not perform a capsular release. Accomplish coverage with a skin graft.
- Regardless of the coverage technique, deflate the tourniquet and secure meticulous hemostasis. Assess the newly extended finger for vascular integrity, because arterial inflow may be compromised by the sudden digital extension. If the digit is pale, flex it until circulation has been restored.
- Temporary proximal interphalangeal joint immobilization with an oblique transarticular Kirschner pin is often helpful.
- Cover the defect with a full-thickness skin graft that is stented with a tie over a bolus dressing.
- After the graft has taken, extension splinting at night with a silicone-lined, static splint is recommended until the graft matures.

Flexion deformities secondary to destruction of the central tendon over the dorsum of the proximal interphalangeal joint are difficult to reconstruct, because the skin over the dorsum of the joint is scarred, the central tendon has been destroyed, and usually there is a fixed contracture of the palmar plate and collateral ligaments. Consider restitution of proximal interphalangeal extension only if the joint can be passively extended and radiographs show joint congruity. If these requirements are met, excise the scarred tendon over the proximal interphalangeal joint, and advance the more proximal, unscarred, central tendon into the dorsal base of the middle phalanx.

Occasionally, elongation of the central tendon with a free graft is necessary. After the central slip has been reconstructed, pin the proximal interphalangeal joint in extension for 3 weeks; then initiate active flexion. The results of this surgery are unpredictable and often unsatisfactory. If a fixed flexion contracture exists, arthrodesis of the joint in a functional position can provide a more reliable result.

Extension contractures resulting from intrinsic tightness often can be successfully corrected. To make the diagnosis, passively extend the metacarpophalangeal joint and then passively flex the proximal interphalangeal joint; shortened, scarred, intrinsic muscles resist passive flexion. Conversely, if the metacarpophalangeal joint is passively flexed, the intrinsic muscles, whose axis of motion is palmar to the metacarpophalangeal joint and dorsal to the proximal interphalangeal joint, are relaxed, and passive proximal interphalangeal flexion is resisted. An intrinsic release can usually be performed by excising the distal fibers of the lateral bands at the level of the neck of the proximal phalanx.

BURN SYNDACTYLY

Dorsal burns often extend into the distally sloping interdigital clefts. During the acute burn period, it may be difficult to gain access to this area, particularly if the metacarpophalangeal joints are immobilized in the “safe” position of metacarpophalangeal flexion. Syndactyly, usually of the dorsal skin, results. The degree of syndactyly varies; in severe cases, it may extend to the proximal interphalangeal joint.

Indications for correction of postburn syndactyly vary. Syndactyly of any degree restricts digital abduction and makes the grasping of large, cylindrical objects difficult. The syndactylized digits are often subjected to a sudden abduction force that can lead to traumatic breakdown of the scar contracture, bleeding, and additional fibrosis. Some patients complain that they are unable to wear gloves, and others have problems with hygiene because particles of dirt collect in a pocket formed by dorsally syndactylized skin and the normal distal edge of the palmar skin.

The principles of successful treatment of burn syndactyly listed by Upton (29) are as follows:

- Use skin grafts.
- Use flaps to line the depth of the web space.
- Make certain release is adequate with slight overcorrection.

Figure 64.5. A: A linear contracture of the index finger (left) with pliable skin on each side of the scar band. A series of multiple Z-plasties is designed (right). B: The Z-plasties are rotated into position (left), and there is full digital extension after surgery.

Figure 64.6. A: Moderately severe contracture of all digits as a result of a palmar contact burn. B: The burn scar was excised, the digits were pinned temporarily in extension, and a full-thickness autograft was applied. C: After surgery, nearly full digital extension is possible.
Avoid straight-line incisions in the depth of the palmar aspect of the commissure.

Initiate proper stent fixation of skin grafts and postoperative immobilization of the extremity.

Base your choice of technique for the release of web syndactyly on the severity of the syndactyly and the condition of the adjacent skin (3, 16, 19). Mild or moderate syndactyly can be treated by a Z-plasty or a local rotation flap. The lateral palmar rotation flap is particularly appealing, because it allows the surgeon to create a new interdigital cleft with supple, local, full-thickness skin that is unlikely to recontract (Fig. 64.7). Close the donor defect for rotation flaps, primarily if it is small, or cover it with a skin graft.

Figure 64.7. A dorsal web syndactyly exists between the index and middle fingers. A lateral volar flap (apex X') is designed to rotate 180° so that points X and X'pr can be opposed. In this example, the donor defect was closed primarily; however, if tension exists, a skin graft should be applied.

In severe cases of burn syndactyly, it is necessary to make a longitudinal incision of the burn cicatrix (Fig. 64.8). The incisions on the palmar and dorsal sides should extend to the bifurcation of the common digital artery. After the release has been accomplished, cover it with a thick split- or full-thickness autograft. Because the graft is placed on a concave surface, make sure that there is good contact between the graft and its recipient bed. Stent the graft into place. When you are certain the graft has taken, use night extension splinting with the digits abducted for 6–9 months.

Figure 64.8. A: Severe dorsal burn syndactyly (left). Scar excision (center) is followed by application of a full-thickness graft (right). B: Postoperative extension (left) and flexion (right) views.

EXTENSION CONTRACTURES OF THE WRIST AND METACARPOPHALANGEAL JOINTS

Extension contractures of the wrist and metacarpophalangeal joints occur simultaneously. These contractures usually are the result of flame burns in which the victim tightly clenches her fist or protects her face from thermal injury. Metacarpophalangeal extension contractures arise from scarred skin over the dorsum of these joints or from immobilization of the metacarpophalangeal joints in extension during the acute burn period, allowing the collateral ligaments and soft tissues around the metacarpophalangeal joints to contract (13).

Contracture severity at the level of metacarpophalangeal joints varies (13). In mild metacarpophalangeal contractures, if the wrist is dorsiflexed (i.e., the skin over the dorsum of the hand is relaxed), full, active, metacarpophalangeal flexion can be accomplished. If the wrist is passively flexed, however, metacarpophalangeal flexion is limited by tight skin over the dorsum of the wrist and hand. A dorsal transverse incision of the contracted skin at the level of the metacarpal necks is often sufficient to release the contracture. If the scar tissue of the dorsum of the metacarpophalangeal joints is thick or has been previously grafted with meshed autograft, giving the skin a corrugated appearance, it may be preferable to excise, rather than incise, the burn scar. In such instances, carry the excision down to the subcutaneous fat, taking care to preserve the dorsal veins that are nearly always deep to the burn scar.

Sometimes, metacarpophalangeal extension contractures are produced by linear bands of scar that mimic the extensor tendons. In such cases, the surgeon may make the error of not performing a deep enough release for fear of severing a tendon that is mistakenly thought to be within the burn cicatrix. This is virtually never the case. The extensor tendons lie deep to the scar in a bed of loose, areolar, connective tissue. After the release has been accomplished by incision, excision, or a combination of both, soft-tissue coverage can usually be accomplished with a skin graft.

In the case of moderate or severe metacarpophalangeal contracture, a more aggressive surgical release is necessary. The position of the metacarpophalangeal joint is fixed, regardless of wrist position, and the metacarpal heads are prominent in the palm. Metacarpophalangeal hyperextension may be so severe that the dorsal surface of the proximal phalanx may lie on top of the dorsal surface of the metacarpal. In such cases, associated flexion contractures of the proximal interphalangeal joints, caused by the flexor tenodesis effect, occur, as does destruction of the central tendon overlaying the proximal interphalangeal joint. Grasping objects of any size is difficult or impossible, and often only a crude pinch maneuver between the index finger and the thumb is possible.

Release of these fixed extension contractures requires careful preoperative planning (Fig. 64.9). Contractures of the metacarpophalangeal capsule and collateral ligaments are to be expected.

Figure 64.9. A: A dorsal burn caused combined wrist and metacarpophalangeal fixed extension contractures. B: Dorsal view (left) with outline of the proposed excision. The linear bands over the metacarpophalangeal joints contain scar, not extensor tendons. After dermal release (right), metacarpophalangeal capsulotomies, and temporary pinning in flexion, a large dorsal area requires skin grafting. C: The functional result (both hands), demonstrating excellent metacarpophalangeal flexion.
RELEASE OF EXTENSOR CONTRACTURES

- Release the metacarpophalangeal capsular contractures by splitting the extensor tendon longitudinally over the joint in its midportion and incising the dorsal capsule transversely.
- Release the collateral ligaments by sharply dividing the origin of the ligament from the metacarpal head, preserving the most inferior and proximal fibers to prevent lateral joint instability.
- After the collateral ligaments and dorsal capsule have been released, position the metacarpophalangeal joint in 70° of flexion by passing a pin from the metacarpal head into the proximal phalanx.
- Sometimes after metacarpophalangeal capsulotomies, the metacarpophalangeal joints and extensor tendons are exposed, and they must be covered with a distant flap. Plan ahead for such an eventuality to make sure that flap tissue is available.
- Initiate postoperative range-of-motion exercises after the skin graft has taken. Begin a program of active and passive metacarpophalangeal flexion exercises and night splinting with the metacarpophalangeal joints in flexion to prevent recontraction.

ELBOW CONTRACTURES

Postburn elbow contractures occur frequently, and surgical correction is often necessary because limited elbow mobility directly affects the efficiency of hand, wrist, and shoulder function (25). These contractures are often subjected to the stress of sudden elbow extension, resulting in recurrent tearing of antecubital burn scars, pain, and additional fibrosis. Occasionally, burn scarring forms deep pockets that collect debris and cause hygiene problems.

Elbow flexion contractures, particularly in children, usually can be corrected by complete division of the dermal scar in the antecubital fossa. The amount of scar varies from a longitudinal band (correctable by Z-plasty, local flap, or skin graft) to diffuse scarring (Fig. 64.10 and Fig. 64.11). Regardless of technique, take care to extend the release to subcutaneous tissue and avoid injuring anterior neurovascular structures. For severe contractures, consider division of deeper structures, which may include lengthening the biceps tendon, dividing the brachialis fascia, and anterior elbow capsulotomy. When such structures are divided, plan for flap coverage.

Figure 64.10. Y–V flap. A: Scarring of the ulnar aspect of the antecubital fossa treated with a Y–V advancement flap (a is advanced to a1). B: Flap sewn into position. (From Kurtzman LC, Stern PJ. Upper Extremity Burn Contractures. Hand Clin 1990;6:261, with permission.)

Figure 64.11. Full-thickness skin graft. A: Dotted line indicates incision for release of eschar, and the incision must extend to normal skin on the radial and ulnar sides. B: Diamond-shaped defect after release. C: Full-thickness skin graft applied for coverage. (From Kurtzman LC, Stern PJ. Upper Extremity Burn Contractures. Hand Clin 1990;6:261, with permission.)

One of the most devastating problems affecting function in the burn patient is heterotopic ossification bridging the elbow joint (Fig. 64.12) (14). The ossification forms in the acute burn period, is usually associated with a concomitant deep burn to the elbow, and is found in approximately 2% of patients with elbow burns. The first clinical signs of heterotopic ossification appear 4–6 weeks after the burn injury and are usually heralded by complaints of increasing elbow pain and a rather rapid decrease in range of motion. Initial radiographs may be unremarkable except for soft-tissue swelling, but follow-up radiographs (within 3 months) show ossification bridging the elbow joint. If heterotopic bone forms bilaterally, functional impairment is severe, and the patient will have difficulty performing even simple activities of daily living.

Figure 64.12. A: Radiographs demonstrate heterotopic ossification bridging the posteromedial surface of the elbow. The patient's elbow was rigidly fixed in extension. B: An operative photograph shows that the ulnar nerve (marked by loops) proximal and distal to the elbow joint is encased by heterotopic ossification. It was unroofed and transposed anteriorly. C: After heterotopic bone excision, elbow flexion and extension were restored.

Surgical treatment of heterotopic bone must be timed appropriately. If the bone is excised when it is immature, it may reform, making a second surgical excision even more difficult. Usually, it takes 8–16 months for the bone to mature. Diagnostic studies used to assess bone maturity such as serial technetium phosphate bone scans and measurement of serum alkaline phosphatase levels may be misleading. Despite the potential for bone reformation, we prefer early excision (8–12 months), particularly if there is ulnar nerve compromise.

The new bone usually forms posteromedially, and the ulnar nerve may be encased in it (30). Test motor and sensory function of the ulnar nerve before surgery. If function is impaired, an electromyogram and nerve conduction studies are recommended. Ulnar nerve function can be anticipated to improve following decompression.
RESECTION OF HETEROTOPIC BONE

- Perform surgical excision of the bone through a long, posteromedial elbow incision.
- Identify the ulnar nerve, proximal and distal to the new bone. If bone encases the nerve, it is helpful to unroof and transpose it anteriorly.
- Detach and reinsert the medial collateral ligament complex. After the skin has been closed, record the range of motion, and splint the elbow for 3–5 days in 90° of flexion. Then begin active and assisted passive range-of-motion exercises.

Results of surgical excision of heterotopic ossification about the elbow have shown significant improvement in range of motion in most cases (11). The worst results usually occur when there is complete ankylosis preoperatively.

Diphosphonates, which are potent inhibitors of mineralization and bone resorption, have been shown to be of some benefit in the prevention of heterotopic bone formation in patients undergoing total hip arthroplasty. There is, however, no evidence that these compounds are effective in preventing bone from reforming after excision in the burn victim. Other ancillary treatment modalities include low-dose irradiation or oral indomethacin.

AXILLARY CONTRACTURES

Axillary contractures restrict shoulder motion, particularly abduction and forward flexion (6,18). If surgical procedures are planned for more distal portions of the extremity, correct the axillary contracture first to facilitate access to these areas.

The extent of an axillary contracture varies. Most commonly, a band extends anteriorly from the chest to the upper arm, parallel to the inferior edge of the pectoralis major muscle. There may also be a posterior band from the chest to the brachium that follows the inferior and lateral edge of the latissimus dorsi. Often, the deep axillary skin in the apex of the axilla is unburned; in severe burns, however, the axillary fossa may be obliterated completely.

Surgical release of an axillary contracture involves the same principles discussed earlier in this chapter. In most cases, the treatment of choice is incision (often combined with excision) of the scar. Carry the dissection down to the axillary fat. It is often helpful to divide the fascia over the latissimus dorsi or pectoralis major muscles. After the release, obtain coverage with a thick split-thickness skin graft.

Although most axillary contractures can be successfully managed by release and skin grafting, this technique has the disadvantage of prolonged postoperative splinting, occasional graft loss, and linear contracture along the graft edges. To avoid these problems, thin regional fasciocutaneous flaps have been successfully used (2).

FREE-TISSUE TRANSFER

The majority of acute and reconstructive problems encountered in the thermally injured upper extremity can be solved with the previously described skin grafting techniques. Complex wounds, however, that have exposed joints, bone, or tendons resulting from thermal injury or extensive scar release require flap coverage. Before microsurgical free-tissue transfer, these wounds were covered with distant pedicled flaps. The groin flap was commonly used for complex hand wounds (Fig. 64.13).

Pedicle flaps remain a valuable tool but have limitations. Immobility and dependent positioning of the involved extremity required for use of a groin flap are liabilities in the rehabilitation of the acutely burned patient. In addition, in large burns, availability of pedicled skin flaps may be severely limited. Early wound coverage using free-tissue transfer techniques is a single-stage procedure that allows for earlier rehabilitation and salvage of the extremity (5). Free muscle flaps are more likely to be available even after extensive burns. They are particularly useful in reconstructive cases after patients have finished the acute phase of their burn care.

In the acute burn setting, free-tissue transfer is a valuable tool when growth plates, joints, tendons, and bone become exposed, as usually occurs in deep contact burns and high-voltage electrical injuries. Deep contact burns usually are the result of contacting mufflers, printing presses, or roller presses (Fig. 64.13). When such a burn occurs on the dorsum of the hand, the entire extensor mechanism is at risk. Early debridement and coverage with a free flap will prevent loss of the extensor mechanism. The flaps chosen for this problem depend on the size of the wound and the availability of donor sites. The lateral arm flap and temporalis fascia flap are useful choices in this situation.

Electrical injuries (high voltage) to the upper extremity are devastating. They frequently result in massive skin and muscle loss. The amputation rate for high-voltage injury approaches 50% (22). Preservation of vital structures remaining after radical debridement and limb salvage requires early coverage with large free flaps (8). Usually, latissimus dorsi or rectus abdominal muscle flaps are required to cover the entire defect. In addition, free-muscle transfer may be used to restore function in extremities severely damaged by high-voltage electrical injuries. Most commonly, a free gracilis muscle transfer is used to restore finger flexion.

Restoration of basic prehensile function in hands with established severe burn scar deformity is a formidable challenge (Fig. 64.14). To correct this mitten hand deformity, multiple problems need to be addressed: A basic thumb must be created, as well as a first web space. Additionally, established contractures in the digits and wrist must be released. Ideally, a toe transfer offers the best result in thumb reconstruction. Both the great toe and the second toe are acceptable choices in restoring prehensile ability in this deformity. We prefer the second toe in reconstructing the mitten hand and reserve the great toe for isolated thumb reconstruction.

CHAPTER 65

MANAGEMENT OF VOLKMANN'S CONTRACTURE

Richard H. Gelberman and Michael J. Botte

R. H. Gelberman: Department of Orthopaedic Surgery, Barnes Hospital, St. Louis, Missouri, 63110.
M. J. Botte: Division of Orthopaedic Surgery, Stanford Clinic, La Jolla, California, 92037.

HISTORICAL ASPECTS

Acute compartment syndrome produces high interstitial tissue fluid pressures that can reduce capillary perfusion below the level necessary for tissue viability (1, 3, 7, 8 and 9). If the compartment syndrome is sustained or untreated, ischemia results in irreversible muscle and nerve damage (12, 19, 23, 25, 28, 33, 34, 35 and 36). Muscle necrosis, fibrosis, and contracture. Concomitant nerve injury results in further muscle dysfunction, sensibility deficits, or chronic pain. The result is a dysfunctional limb with varying amounts of deformity, stiffness, or paralysis, known as Volkmann's ischemic contracture (6, 10, 13, 25, 30, 31 and 32). In severe contractures, all four digits are involved. The flexor digitorum superficialis and pronator teres are generally less severely affected. In the most severe cases, the wrist flexors, the wrist and digital extensors, and the compartments proximal to the elbow may also undergo varying degrees of fibrosis and contracture.

In 1881, Richard von Volkmann first described this condition, noting paralysis and subsequent limb contracture that followed the application of tight, constricting bandages to an injured limb (93). In 1922, Brooks described a similar condition and believed venous obstruction was a factor in the contracture formation (12). Arterial spasm of injury were subsequently indicated as causes by Lerche and Griffiths (32, 49). In an attempt to prevent the contracture described by Volkmann, Bardenheur in 1911 discussed the use of forearm fasciotomy (2). His "aponeurectomy" consisted of division of the deep antebrachial and forearm fascia. In 1922, Murphy also suggested fasciotomy as a means of prevention of paralysis and contracture when pressure was increased within a fascia-enclosed muscle space following hemorrhage or edema (65). Although the pathogenesis was not clearly understood, in 1926 Jepson objectively demonstrated the beneficial effects of early fasciotomy on the limb (44).

Since these early reports, several investigators have discussed the various aspects of ischemic contracture formation and prevention, including the need for immediate fasciotomy, the role of the median and ulnar nerve decompression and brachial artery exploration. The operative technique and appreciation of surgical anatomy evolved from reports by Benjamin (3), Echler and Lipscomb (23), Henry (39), Eaton and Green (21), Whitesides et al. (69), Newmeyer and Kilgore (66), and Gelberman (45, 52, 59, 68). The relationships between increased tissue fluid pressure and myoneural dysfunction, as well as the use of fasciotomy to prevent ischemic contracture, are now well established (1, 2, 3, 4 and 5, 7, 8, 9, 10, 11, 12 and 13). In 1929, Brooks objectively demonstrated the beneficial effects of early fasciotomy on the limb (44).

Despite the current appreciation for urgency in the management of acute compartment syndrome, delays in treatment still occur; these result in patients developing the full sequelae of Volkmann's ischemic contracture. The deficits can be devastating, and management is challenging. Treatment can require a prolonged rehabilitation program and/or operative management. A comprehensive rehabilitation program includes active and passive exercises, strengthening, splinting, desensitization, and pain management. Operative management includes nerve decompression, fasciotomy excision, contracture release, myotendinous lengthening, tendon transfers, or free tissue transfers (45, 5, 10, 13, 14, 15, 16, 17 and 18). In 1929, Brooks described a similar condition and believed venous obstruction was a factor in the contracture formation (12). Arterial spasm of injury were subsequently indicated as causes by Lerche and Griffiths (32, 49). In an attempt to prevent the contracture described by Volkmann, Bardenheur in 1911 discussed the use of forearm fasciotomy (2). His "aponeurectomy" consisted of division of the deep antebrachial and forearm fascia. In 1922, Murphy also suggested fasciotomy as a means of prevention of paralysis and contracture when pressure was increased within a fascia-enclosed muscle space following hemorrhage or edema (65). Although the pathogenesis was not clearly understood, in 1926 Jepson objectively demonstrated the beneficial effects of early fasciotomy on the limb (44).

PATHOGENESIS OF ISCHEMIC CONTRACTURE

Muscles and nerves are vulnerable to changes in oxygen tension. Muscle undergoes necrosis after 4 hours of ischemia produced experimentally by application of a tourniquet (33, 34). With prolonged ischemia, muscle necrosis leads to fibroblastic proliferation within the muscle infarct. A variable amount of longitudinal and horizontal contraction may progress over a 6- to 12-month period following the ischemic insult. The necrotic muscle adheres to surrounding structures, fixes muscle position, and reduces excursion and mobility. Limitation of muscle excursion may lead to loss of joint motion with subsequent joint contracture.

The deepest compartments, especially those adjacent to bone on the volar forearm, usually have the highest interstitial pressure during an acute compartment syndrome (7, 8, 9, 10 and 91). Subsequent injury that leads to ischemic necrosis is most marked in these deep compartments, more commonly involving the flexor digitorum profundus and flexor pollicis longus (Fig. 65-1 and Fig. 65-2). In the midline compartments, only part of the flexor digitorum profundus undergoes necrosis, usually to the ring and long fingers. In severe contractures, all four digits are involved. The flexor digitorum superficialis and pronator teres are generally less severely affected. In the most severe cases, the wrist flexors, the wrist and digital extensors, and the compartments proximal to the elbow may also undergo varying degrees of fibrosis and contracture.

Figure 65-1. The muscles affected in 16 cases of Volkmann's contracture of the forearm. (Adapted from Seddon HJ. Volkmann's Contracture: Treatment by Incision of the Infarct. J Bone Joint Surg Br 1956;38:152, with permission.)
The frequent involvement of the deep flexors of the forearm is attributed to their deep location, a factor that increases their vulnerability to ischemia (79). These deep compartments, particularly the regions adjacent to bone, usually have the highest interstitial pressures (34). With compression from within the compartment, the circulation to the deep portions of the muscle belly are compromised, whereas collateral circulation to the more superficial parts of the muscle is retained. In the forearm, the most severe muscle damage usually occurs in the middle third of the muscle belly, with more injury closer to bone, and less injury toward the proximal and distal surfaces. When a compartment syndrome remains untreated, swelling may eventually resolve, but the injured, necrotic muscle becomes fibrotic. An ellipsoid section or cord of cicatrix can develop within the muscle or group of muscles. The characteristic deformity of ischemic contracture may take weeks or months to completely develop. When the forearm, hand, and arm are significantly involved, the deformity in the upper extremity often consists of varying amounts of elbow flexion, forearm pronation, wrist flexion, thumb flexion and adduction, digital metacarpophalangeal (MP) joint extension, and interphalangeal joint flexion (69, 55, 3). The MP joint extension and proximal interphalangeal joint flexion give rise to a “claw hand” deformity. The extremity may initially be flexible, especially in milder cases. Chronic muscle imbalance and lack of joint motion may ultimately lead to fixed deformity from secondary joint capsule, ligament, and skin contracture.

The pathomechanics of the ischemic claw-hand deformity are complex. Although there may be an apparent similarity between the ischemic contracture and the intrinsic muscle contracture in some patients, the actual deformities are considerably different. Intrinsic muscle contracture results in an intrinsic-plus deformity, with flexion at the MP joints and extension at the proximal interphalangeal joints. Volkman's contracture often leads to an intrinsic-minus deformity, with hyperextension at the MP joints and flexion at the interphalangeal joints. Although the two entities are associated and may occur simultaneously, the resultant claw-hand deformity is determined by contracture of the more powerful extrinsic finger flexors. A paradoxical situation of a claw-hand deformity with intrinsic tightness can exist (82). The intrinsic contracture may not become apparent until the extrinsic flexors have been released by a muscle slide, tendon lengthening, or tenotomy. Only then does intrinsic tightness become evident.

An additional factor in the pathomechanics of upper extremity deformity is the amount of peripheral nerve injury superimposed on the muscle. Ischemic injury to the muscle usually results in muscle contracture (from fibrosis of the necrotic muscle). Nerve injury, conversely, results in muscle paralysis. Concomitant median and ulnar neuropathy in the forearm or wrist therefore contribute to intrinsic muscle weakness and, in turn, to an intrinsic-minus deformity. The final clinical outcome is dependent on the relative amount of extrinsic and intrinsic muscle contracture (from muscle ischemia) and on the amount of extrinsic and intrinsic muscle paralysis (from nerve injury) (40, 19).

CLASSIFICATION OF CONTRACTURES

Several authors have classified contractures according to severity of involvement (4, 50, 63, 80, 91, 100). The simplest classification, popularized by Seddon and Tsuge (50, 81), describes mild, moderate, and severe involvement. This classification is useful for determining treatment options.

MILD CONTRACTURES

A mild or localized contracture is limited to a portion of the deep extrinsic finger flexors, usually involving only two or three fingers. Hand sensibility and strength are normal. The intrinsic muscles are not involved, and fixed joint contractures are not present. Most mild types of ischemic contracture are caused by fractures or crush injuries to the forearm or elbow, and they usually occur in young adults (40, 81).

MODERATE CONTRACTURES

Moderate contracture, the classic type, primarily involves the flexor digitorum profundus and flexor pollicis longus muscles. Less frequently, the flexor digitorum superficialis, flexor carpi radialis, and flexor carpi ulnaris are involved. The wrist and thumb become flexed and the hand assumes a claw-hand deformity from contracture of the long finger flexors.

Secondary compression neuropathies may develop at specific locations where nerves pass beneath ligaments or fibrous arcades or through contracted muscles. The median nerve is most frequently compressed, usually at the lacertus fibrosus, pronator teres, or flexor digitorum superficialis, or within the carpal tunnel. The ulnar nerve may be compressed within the cubital tunnel or between the two heads of the flexor carpi ulnaris. The radial nerve is rarely involved, but it may be compressed at the arcade of Frohse or within the supinator muscle.

Most moderate contractures are caused by a supracondylar fracture of the humerus. These fractures occur most commonly at 5 to 10 years of age (40, 52, 63, 91).

SEVERE CONTRACTURES

The major contractures of the forearm and hand are caused by supracondylar fractures of the humerus (79, 90, 91, 100, 101). These fractures may be associated with soft tissue or other musculoskeletal injuries. The flexor and extensor tendons may be disrupted, and the median, ulnar, and radial nerves may be compressed. The flexor digitorum profundus muscle is the most commonly injured muscle, followed by the flexor pollicis longus and flexor carpi radialis muscles (79, 90, 91, 100, 101).

The management of severe contractures is complex and requires a multidisciplinary approach. The goals of treatment include improving joint motion, correcting deformity, and restoring function. Treatment options may include conservative management, surgical release, and tendon transfers. The timing of surgical intervention is dependent on the severity of the contracture and the underlying cause. Early intervention may be necessary for severe contractures to prevent permanent deformity and loss of function.
Severe contractures affect forearm extensors as well as flexors (Fig. 65.3). Complications, including loss of nerve function, malunion or nonunion of forearm fractures, and cutaneous scarring and contracture, are often encountered. The most common causes of severe contracture are prolonged ischemia secondary to brachial artery injury, and prolonged external compression secondary to drug overdose.

TREATMENT

MILD CONTRACTURES

The treatment of mild contractures depends on the severity of the deformity and the time interval between injury and initiation of treatment. Contractures of the deep forearm flexors, with normal hand sensibility and strength, may be treated conservatively. Occupational therapy, including passive and dynamic extension splinting, is designed to maintain wrist and interphalangeal joint extension, to maintain or improve thumb web-space width, and to strengthen weak thumb intrinsic muscles. Alternate the use of bivalved pancake plaster casts or custom-molded synthetic orthoses with low-profile digital extension, and thumb opposition splints. A C-bar may be incorporated into the splint to maintain thumb position. In the early stages, have the patient alternate passive and dynamic splints at 2-hour intervals during the day and, at night, wear extension splints. Splitting techniques for Volkmann's contracture have been described in detail by Goldner (26). A satisfactory outcome can be expected when mild contractures are treated soon after their development using these techniques.

Tsubo recommends operative treatment for mild contractures that are encountered late (91,92). If the contracture is limited to one or two digits and a cordlike area is palpable, simple excision of the incriminated muscle or lengthening of the involved flexor tendons is recommended.

- Perform excision of the incriminated muscle through a curved, longitudinal incision on the palmar forearm.
- Identify and protect the radial artery, median nerve, and ulnar artery and nerve.
- Retract the flexor digitorum superficialis and flexor carpi radialis radially, and the flexor carpi ulnaris ulnarly, to expose the flexor digitorum profundus.
- Isolate and excise the palpable, cordlike areas of indurated muscle. The flexor digitorum profundus of the ring and long fingers is most commonly affected.
- If the contracture is localized to the pronator teres, this muscle may be excised. If the contracture and induration involve three or four digits, flexor tendon lengthening may be required.
- Perform Z-lengthening of the involved tendons in the distal two thirds of the forearm.
- Begin the incision longitudinally, near the musculotendinous junctions, to ensure adequate tendon length for satisfactory correction. Repair the tendons using 4-0 nonabsorbable suture.
- Following the surgery, immobilize the forearm in supination, the wrist in extension, and the digits in the corrected amount of extension.

MODERATE TO SEVERE CONTRACTURES

The treatment of moderate to severe Volkmann's contracture may be divided into four phases (25):

1. Release of secondary nerve compression
2. Treatment of contractures
3. Tendon transfers for substitution and reinforcement
4. Salvage procedures for the severely contracted or neglected forearm

Phase 1: Release of Secondary Nerve Compression

Following muscle infarct, nerves may become compressed within a constricting cicatrix, or at specific anatomic locations where space is minimal. Secondary compressive neuropathies require attention in the earliest stages of treatment. Improvement of nerve function is related to the severity and duration of compression, as nerves may sustain compression for longer periods than muscle and still show some reversibility, particularly in sensory function (11,73). When continuity is maintained, nerves may show signs of gradual recovery over a 12-month period (80,85). If both fibrosis and contracture are severe, all three major forearm nerves may become constricted. Careful clinical assessment is essential before the first phase of treatment.

Median Nerve Decompression Return of median nerve function is essential for restoring a useful functional extremity. This nerve lies in the center of the constricting cicatrix and may become compressed in four anatomic regions: the lacertus fibrosus, the pronator teres, the proximal arch of the flexor digitorum superficialis, and the carpal tunnel. Sensory and motor loss consistent with median neuropathy warrant aggressive management for decompression.

- Use an incision similar to that used for decompression of an acute forearm compartment syndrome (24) (Fig. 65.4). Begin the incision on the palmar aspect of the medial arm, about 2 cm proximal to the medial epicondyle. Extend it obliquely across the antecubital fossa to the mobile wad. Continue the incision longitudinally, curving slightly ulnarily to reach the palmar distal forearm. Extend the incision into the palm for carpal tunnel release. Locate the distal portion of the incision ulnar to the palmaris longus to avoid injury to the palmar cutaneous branch of the median nerve.

![Figure 65.4](image)

- Identify the median nerve in the proximal portion of the incision and trace it distally to the lacertus fibrosus. The lacertus fibrosus is a fascial extension of the biceps tendon and lies anterior to the median nerve at the elbow. Nerve compression occurs frequently in this area in the acute stages of a forearm compartment syndrome, and it may also occur in the later stages of contracture.
- If signs of proximal median nerve compression are present, release the lacertus fibrosus. Incise the fascia of the lacertus fibrosus in a longitudinal fashion along the course of the median nerve to allow complete decompression and exposure of the nerve.
- Continuing distally, the median nerve will pass between the two heads of the pronator teres muscle. Nerve compression can occur between these two heads. The ulnar head lies deep to the nerve, and the humeral head is superficial to the nerve. A tendinous band, which often lies along the deep head, may contribute to compression.
- Completely release the nerve throughout the entire length of its passage through the pronator teres. This often requires division of the humeral head of the pronator teres and division of any tendinous bands, deep or superficial, that may impinge on the nerve.
- Distal to the pronator teres, the median nerve continues beneath and within the fascia of the flexor digitorum superficialis muscle, passing deep to the arch formed by the ulnar and radial origins. The nerve is most frequently compressed beneath the fibrous origin of this muscle (72).
- Decompress the nerve by either incising the investing fascia or by dissecting the flexor digitorum superficialis from the underlying flexor digitorum profundus. Completely release the nerve from the investing fascia (72).
- Despite the proximal location of muscle necrosis in Volkmann's contracture, the incidence of median nerve compression in the carpal tunnel is high. Extend the incision for forearm decompression and expose the palmar fascia and transverse carpal ligament (24,87).
- Incise these structures to decompress the median nerve decompression from the distal arm to the midpalm.

Ulnar Nerve Decompression The incidence of ulnar nerve compression is much lower than that of median nerve compression. It is often compressed at the elbow as it passes between the ulnar and humeral heads of the flexor carpi ulnaris. Decompress if there are signs of ulnar neuropathy.

Radial Nerve Decompression The radial nerve is rarely involved in compression neuropathies following Volkmann's contracture. Occasionally, however, it may require decompression as it passes under the tendinous origin of the supinator muscle (arcade of Frohse) or within the muscle itself. Nerve compression is manifested...
by motor loss of the digital and thumb extensors and the ulnar wrist extensors. Radial wrist extensor strength and radial nerve sensibility remain intact, as these neural branches arise proximal to the area of compression (10).

- To decompress the radial nerve, make a straight, longitudinal incision on the proximal half of the posterior forearm along an imaginary line extending between the lateral epicondyle and the radial styloid.
- Develop the interval between the extensor carpi radialis brevis and the extensor digitorum communis. This interval is most easily defined in the distal portion of the incision and should be developed here first and traced proximally.
- Retract the extensor carpi radialis brevis radially and the extensor digitorum communis ulnarily.
- Identify the supinator.
- Identify the radial nerve proximally where it enters the supinator. The nerve may be found to be compressed by the tendinous bands of the arcade of Frohse, by a vascular leash that crosses the nerve transversely in this region, or by the supinator muscle itself. Carefully divide the appropriate structures to decompress the nerve (19).

Forearm nerve decompression should be undertaken as soon as the patient's condition permits. A nerve stimulator may be helpful for verification of conductivity, especially in heavily scarred areas. Early return of sensibility and a decrease in pain may be expected when decompression is undertaken in a timely manner. Motor function return, although variable, can progress over several days or weeks, depending on whether neuropaxia or axontemesis is present. If nerves are irreparably damaged or have lost continuity (neurotemesis), secondary excision of damaged segments and microsurgical repair or reconstruction may offer some return of nerve function. Alternatively, reconstruction may be accomplished with appropriate tendon transfers.

**Phase 2: Treatment of Contractures**

Elbow flexion, forearm pronation, wrist flexion, digital clawing, and thumb adduction are fixed deformities that develop over time. Procedures used to help correct established forearm contractures include incision, flexor tendon lengthening or excision, and flexor pronator slide. These procedures should be performed at the time of, or subsequent to, nerve decompression.

**Infarct Excision** Perform infarct excision 1 to 6 months after injury (Fig. 65.5) (62,80,91-92). Seddon recommends at least 6 months of preliminary splinting before contracture release (86).

**Figure 65.5.** Excision of an infarct in the forearm, with preservation of the flexor carpi ulnaris and ulnar neurovascular bundle. (Adapted from Seddon HJ. Rev Chir Orthop Reparatrice Appar Mot 1960;46:149, with permission.)

- Excise the frequently encountered ellipsoid infarct through a long palmar forearm incision (80).
- Excise fibrotic muscle and contracted scar tissue. The deep digital flexors and thumb flexor are usually most extensively involved. The pronator teres and pronator quadratus may be released or, if they are fibrotic, excised.
- Gently manipulate the forearm and wrist into supination and extension, respectively, and immobilize in this corrected position following surgery.

**Flexor Tendon Lengthening** Goldner has noted that infarct excision may not be necessary and advocates Z-lengthening of the forearm flexors proximal to the wrist (30). The flexor digitorum profundus, flexor digitorum superficialis, flexor pollicis longus, and pronator teres may be lengthened to accomplish digital and thumb extension, and forearm supination (6,30). If severe forearm fibrosis is encountered and digital contracture is severe, excise the flexor digitorum superficialis.

The chief disadvantage of flexor tendon lengthening in the forearm is further weakening of an already weakened muscle. However, contracture release is usually functionally advantageous to the maintenance of maximal strength. Tendon transfers, if needed, may be performed at a later date.

**Flexor Pronator Slide** The flexor pronator slide, first described by Page in 1923 (69), has gained wide acceptance (22,50,91,92). It has been shown to be more effective than infarct excision alone in obtaining a lasting correction (22).

- Make a skin incision on the medial side of the elbow, 6 cm proximal to the medial humeral condyle and extending to the junction of the middle and distal thirds of the forearm. Separate the subcutaneous tissue from the deep fascia on the ulnar and radial sides of the incision.
- Isolate the ulnar nerve at the level of the elbow and transpose it anteriorly.
- Proceed with systematic, complete operative detachment of the origins of the flexor muscles of the forearm. Dissect the muscles subperiosteally using a scalpel.
- Release the origins of the pronator teres, flexor carpi radialis, palmaris longus, and the humeral head of the flexor carpi ulnaris, and then detach the flexor digitorum superficialis.
- Detach the ulnar head of the flexor carpi ulnaris and the broad origin of the flexor digitorum profundus from the anterior aspect of the ulna.
- Carry the dissection across the interosseous membrane and release the origin of the flexor pollicis longus from the anterior aspect of the radius.
- Take care to avoid injury to the interosseous artery, vein, and nerves when detaching the flexors from the interosseous membrane.
- Allow the muscles to slide distally 2–3 cm.
- The incision may be extended distally and the palmar wrist capsule and pronator quadratus released. Although excision of the infarct and neural releases may be performed at the time of the flexor pronator slide, tendon transfers are performed secondarily (91-92).
- Postoperatively, immobilize the extremity for 2–3 weeks with the elbow at 90° flexion, the forearm supinated, and the wrist and digits extended.

The flexor pronator slide has been criticized for the unpredictability of correction achieved, the risk of recurrence of deformity with growth, and the resultant decrease in grip strength, particularly at the distal interphalangeal joint (62,91-92). Despite these criticisms, the procedure has gained popularity and has been shown to be effective in achieving satisfactory to excellent results in a large group of patients with moderate to severe contractures (91-92).

**Phase 3: Tendon Transfers for Substitution and Reinforcement**

Among the most desirable functions to restore in patients with Volkmann's contracture are finger and thumb flexion and thumb opposition. Tendon transfers are usually effective than infarct excision alone in obtaining a lasting correction (22). It has been shown to be more effective than infarct excision alone in obtaining a lasting correction (22).

**Tendon Transfers**

- Transfer the extensor carpi radialis longus to the flexor digitorum profundus, and transfer the extensor carpi ulnaris, lengthened by tendon graft, to the thumb for opposition (71,73).
- Excise the tendons of the flexor digitorum superficialis if they are nonfunctional. The extensor pollicis brevis may be used to reinforce the extensor carpi ulnaris–opponens transfer.
- Alternative transfers to augment thumb opposition include the abductor digiti quinti opponensplasty described by Huber (42,52) and the extensor indicis proprius opponensplasty described by Zancoli (100) and Burkhalter et al. (14).
- Flexor tenodesis has been weakened severely by previous Z-lengthening, reinforcement by transfer of the extensor carpi radialis longus to the flexor
digitorum profundus, and transfer of the extensor carpi ulnaris to the flexor pollicis longus, can be performed (30).

**Phase 4: Salvage of the Severely Contracted or Neglected Forearm**

The procedures of Phases 2 and 3 usually provide satisfactory results, and further procedures are seldom necessary. Occasionally, however, additional measures may be required for satisfactory correction of the severely contracted or neglected forearm. Operations that have proved useful include proximal or distal row carpectomy, radial and ulnar shortening, wrist fusion, and digital joint fusion.

Proximal or distal row carpectomy results in limb shortening that allows wrist extension while maintaining flexibility. In severe deformities, carpectomy may be performed before tendon transfer. If adequate donor muscles are not available for transfer, interphalangeal joint fusion can be performed. The stabilized limb can then function as a hook, which is generally superior to a prosthesis, especially if some sensibility is retained (30). Radial and ulnar shortening and wrist fusion are rarely indicated for the treatment or salvage of Volkmann's contracture.

**RECONSTRUCTION OF HAND DEFORMITIES**

The hand deformity associated with Volkmann's contracture is complex, requiring a systematic approach. Intrinsic contractures should be addressed only after extrinsic finger flexors have been released. Fixed extrinsic contractures create a claw-hand deformity (hyperextension of the MP joints and flexion of the interphalangeal joints). Following extrinsic muscle release, intrinsic tightness may become apparent. Complete release of intrinsic contractures may not be desirable, since preservation of some MP joint flexion will prevent recurrence of the claw-hand deformity. If the intrinsic contracture is severe, the oblique fibers of the extensor hood may be released to permit flexion of the interphalangeal joints (62).

Thumb-in-palm deformity often accompanies the claw hand in Volkmann's contracture. The deformity may be caused by both intrinsic and extrinsic contractures. Flexion contracture at the interphalangeal joint may be corrected with flexor pollicis longus lengthening. Residual deformity following tendon lengthening is attributable to intrinsic muscle contracture, joint contracture, or skin contracture of the first web. Recommended procedures for correction of a severe thumb-in-palm deformity include release of the adductor pollicis, deepening of the thumb web space, fusion of the MP joint or interphalangeal joint, or excision of the trapezius (6,36). Thener origin release (recession) and release of the first dorsal interosseous muscle may also be necessary for additional correction (6,57).

The most significant hand disabilities may not be caused by intrinsic contractures but rather by secondary problems from sequelae of extrinsic muscle contractures in the forearm or by associated neuropathy. Loss of median and ulnar nerve sensitivities, intrinsic paralysis secondary to median and ulnar motor nerve paralysis, and interphalangeal joint flexion deformity secondary to contracture of the extensor fl exors cause severe functional deficits. Proper management of these problems, as described in **Phase 1** and **Phase 2,** should significantly improve hand function.

**FREE VASCULARIZED TISSUE TRANSFERS**

The deformity of established Volkmann's ischemic contracture remains a challenging problem despite the available methods of management. Advances in the free transfer of vascularized muscle, nerve, and skin have offered potential additional methods of reconstruction (5,16,17 and 18,43,88). One of the early uses of these techniques for reconstruction of Volkmann's contracture was the transfer of the lateral head of the pectoralis major to the flexor forearm, reported by Chien et al. in 1977 (15). Subsequently, Taylor and Daniel achieved satisfactory results with a free vas Quentinlary and radial nerve graft transfer to an irreparably damaged median nerve (69). Chuang et al. have obtained an 80% success rate in free muscle transfer in nine patients undergoing 10 transfers for Volkmann's contracture (16,17 and 18). As free tissue transfer has become more popular, reconstruction of forearm muscles has now included the use of the gracilis, rectus femoris, latissimus dorsi, or pectoralis muscles (15,16,17,18,43,53,54 and 55,56). The early results of these procedures are promising, especially in their role in the reconstruction of severe or neglected Volkmann's contracture in which few adequate donor muscles are available for tenden transfer.

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Surgical success depends greatly on sensibility. Tachdjian and Minear report sensory defects in about 50% of patients with average intelligence (24). Sensation mediated by thalamic activity, such as light touch and temperature, is usually normal in the patient with spastic hemiparesis. Sensory defects most often affect the cortical functions of stereognosis, position sense, and two-point discrimination (24). These deficits stem from parietal lobe lesions.

Sensory examination is very difficult in children under age 3 or 4 years. Information may be gathered by observing the child at play. Stereognosis is assessed by having the child close his eyes and raise his hands over his head while identifying and describing the characteristics of objects placed in each hand (6). If appropriate, two-point discrimination and proprioception may be determined.

Hofer considers sensibility to be normal when five of five objects are identified correctly, graphesthesia is accurate, or two-point discrimination is less than 5 mm (8). Sensory is graded as mildly impaired when only three of five objects are identified, or two-point discrimination is 5–10 mm. Moderate to severe impairment applies to hands with greater limitations. Patients with abnormal sensibility usually gain little from surgery. Prehension requires good proprioception and stereognosis, and it may not be an appropriate goal for the hand with poor sensibility. Green and Banks have shown that the results of surgery correlate with stereognosis (6). The patient who exhibits poor stereognosis may exclude the abnormal extremity from use. Such children often have a distorted body image. These patients generally do not benefit from reconstructive surgery.

Motor Examination

Examine the child on several occasions and in different settings to evaluate her abilities to grasp and release and to reach for and transfer objects. Observe her at play, at specific tasks, while performing activities of daily living, and after periods of stretching (29). Study functional tasks, including dressing, toileting, feeding, and key pinch. Activity should be assessed in different settings and at varied table levels because the position of the shoulder and trunk may greatly affect hand function (29). Hofer has emphasized the importance of hand placement in planning treatment (6). Ask her to touch her head and then the opposite knee. Performing this exercise...
within 5 seconds demonstrates good function and according to Hoffer is a favorable prognostic sign.

If the patient can cooperate, perform voluntary muscle testing and grade the individual muscles. Judge whether a deficit in muscle function is due to paresis or to overactivity of antagonist muscles. Observe the patient's use of the more normal hand to position and open the fingers of the other hand for grasp. Spasticity and increased tone are determined by passive testing. Contracture of the flexor digitorum superficialis, for example, may explain the patient's need to flex the wrist before release (4). Excess force flexor tone can be distinguished from wrist flexor tone by testing wrist extension with the fingers passively flexed.

Nerve and neuromuscular blocks may aid in distinguishing tone from contracture. For example, it may be difficult to assess the strength of wrist and finger extensors with the wrist held in flexion. Blocking the median and ulnar nerves at the elbow will identify joint contractures, permit evaluation of extenders, and determine if deformity is secondary to increased tone or fixed muscle/tendon contractures (3). Measuring the range of motion before and after nerve block determines the need for release of soft tissue and contracture.

Preferred motors for tendon transfer are those strong muscles under good voluntary control that are phasic with the activity for which transfer is planned (2). Goldner suggests that repeated observation of the patient's hand in grasp and release permits determination of phasic activity (4). Hoffer and others have advocated dynamic electromyography for this purpose (8,11). Hoffer contends that a muscle will not change in phasic activity following transfer (9). Muscles in phase for specific activities will be functional. Muscles active only in release and not in grasp, for example, will be effective if transferred to finger extensors. Those muscles active only during grasp are good transfers for wrist extension. Muscles that fire continuously are not candidates for transfer, according to Hoffer (6). Other authors have observed such muscles becoming phasic after transfer (28). This issue is not yet resolved, and the role of dynamic electromyography remains controversial. Although acknowledging its potential, we do not rely on this technique in planning treatment.

OVERALL ASSESSMENT

Assess cognitive, sensory, motor, and psychosocial elements in planning management, and recognize the overall severity of involvement. Green and Banks (8) have devised a grading system for evaluating patients, and this has been modified by Samilson and Morris (29).

- Excellent: good function in activities of daily living, effective grasp and release, excellent control, wrist extension of 45° or more, full active finger extension, active supination of 50° or more
- Good: hands used as helpers in activities of daily living, effective grasp and release with good control, wrist extension of 15° to 45°, can actively extend the fingers with wrist extended
- Fair: hands used as helpers but not effective in dressing, moderate grasp and release, fair control
- Poor: hands used only as weights, poor or absent grasp and release, poor control, no finger extension unless the wrist is in maximum flexion

It is very important to assess the patient's and the family's motivation. Surgery is of value only when the patient and parents are committed to attaining realistic goals. Make clear to the parents that a normal extremity will not be the outcome, but that worthwhile improvements in function and cosmesis may result (29).

AIMS OF TREATMENT

Cerebral palsy patients have deficits in function, cosmesis, and hygiene. The spastic hemiparetic patient with reasonable intelligence, good sensibility, motivation, and appropriate parental support should have a good functional extremity as the goal. Planned procedures in such patients have predictable results (3). Mentally retarded patients with poor sensibility should instead undergo procedures directed toward improvement of hygiene and prevention of skin maceration (24). Improvement of cosmesis and hygiene are goals for patients with reasonable intelligence but other limiting factors. Diminished sensibility and voluntary control are not contraindications to surgical treatment, although expectations are lower in such patients (3).

PATIENT AGE AND TIMING OF SURGERY

Patterns of deformity may change during the first several years of life. While the patient's age is only one of the factors to be considered, surgery generally should not be performed before the motor pattern becomes established, and not until central nervous system maturation permits compliance with the postoperative regimen (33). To prevent deformity and rejection of the extremity, however, surgery should not be overly delayed.

During the first few years, thumb abduction, wrist and digital extension, and forearm supination should be preserved through use of resting and/or night splints. By age 4, the pattern of persistent deformity becomes evident, and children may become candidates for operative treatment. The optimal time for tendon transfers is between ages 5 and 12 years (2).

SURGICAL TECHNIQUES

The most common deformities of the upper extremity are listed in Table 66.1. Treatment of the proximal part of the extremity should be done before treatment of the hand. In general, begin with capsulotomies (rarely needed in children), tenotomies, and tendon lengthenings to correct deformities; proceed to tendon transfers; and conclude with arthrodesis of joints where necessary.

![Table 66.1. Common Deformities of the Upper Extremity](https://example.com/table661)

**SHOULDER**

**Adduction–Internal Rotation**

Adduction–internal rotation is the most common shoulder deformation. It results from spasticity and contracture of the subscapularis and pectoralis major. Internal rotation contracture limits the positioning of the upper extremity and may be managed by passive stretching exercises. For resistant deformity, subscapularis and pectoralis major lengthening or release is recommended (4). If the deformity persists, humeral osteotomy may be necessary.

**Subscapularis and Pectoralis Major Lengthening Technique**

- We prefer a deltopectoral approach, although the procedure may be performed through an axillary incision. Make a longitudinal incision from the coracoid to the border of the pectoralis major insertion (Fig. 66.1A).
tenotomy, and rerouting of the pronator to function as a supinator (may so limit use of the hand as to warrant such treatment. Two surgical measures have been suggested for correction of severe pronation deformity: pronator

**Pronation**

**FOREARM**

**Elbow Flexor Release Technique**

This release tends to weaken the muscle excessively (contracture is treated by biceps tendon lengthening, brachialis tenotomy, recession of the origins of the wrist flexors (excluding flexor digitorum profundus and sufficiently severe to compromise hygiene, limit reach, interfere with crutch use, and present other functional limitations. Flexion deformity caused by spasticity or

**Flexion Deformity**

Elbow flexion deformity is common, but it is often mild and can be managed by passive stretching exercises. Occasionally, flexion tone and/or contracture become sufficiently severe to compromise hygiene, limit reach, interfere with crutch use, and present other functional limitations. Flexion deformity caused by spasticity or contracture is treated by biceps tendon lengthening, brachialis tenotomy, recession of the origins of the wrist flexors (excluding flexor digitorum profundus and superficialis), and, if necessary, anterior elbow joint capsulotomy. Preoperative musculocutaneous nerve block may be useful in distinguishing increased tone from contracture (9). Resist the temptation to release flexor muscle origins at the elbow to correct an ipsilateral flexed wrist, flexed fingers, or thumb-in-palm deformity, as this release tends to weaken the muscle excessively (9). Elbow flexion recovers postoperatively provided the biceps and brachialis were functioning before the procedure.

**Elbow Flexor Release Technique**

Make an S-shaped incision in the antecubital fossa (Fig. 66.2A). Excise the lacertus fibrosus.

**Abduction–External Rotation**

Abduction–external rotation is uncommon (9).

- Perform surgical release, when it is indicated, through a “strap” incision, permitting access to the deltoitd and the spine of the scapula.
- Detach the fibers of the anterior two thirds of the deltoitd from their insertion into the humerus and recess the deltoitd muscle. Do not disturb the insertion of the scapular portion of the deltoitd.
- Perform a Z-lengthening of the tendons of the teres minor and the infraspinatus.
- Immobilize the shoulder in a Velpeau bandage (reinforced with plaster) for 2 weeks. Begin active assisted and passive shoulder exercises while maintaining the limb in a protective Velpeau dressing between exercise periods.

**Elbow Flexor Release Technique**

- Identify the deltoitdopelvic groove and develop the interval between the deltoitd and the pectoralis major (Fig. 66.1B). Protect the cephalic vein.
- The scapularis, bordered inferiorly by the anterior humeral circumflex veins, is lengthened medially to the glenohumeral joint (Fig. 66.1C). For persistent deformity, release the subscapularis at its insertion into the humerus.
- If the tendon of the pectoralis major is tight, lengthen it by a stepcut incision.
- Postoperatively, immobilize the limb in 25° to 30° of abduction and 20° of external rotation for 4 to 6 weeks. Begin active assisted exercises to retain shoulder range of motion at 2 weeks.
- More resistant deformities may require an external rotational osteotomy of the proximal humerus. The osteotomy is performed via an anterior approach and is held with crossed pins or with plate fixation.

**Abduction–External Rotation**

Abduction–external rotation is uncommon (9).

- Perform surgical release, when it is indicated, through a “strap” incision, permitting access to the deltoitd and the spine of the scapula.
- Detach the fibers of the anterior two thirds of the deltoitd from their insertion into the humerus and recess the deltoitd muscle. Do not disturb the insertion of the scapular portion of the deltoitd.
- Perform a Z-lengthening of the tendons of the teres minor and the infraspinatus.
- Immobilize the shoulder in a Velpeau bandage (reinforced with plaster) for 2 weeks. Begin active assisted and passive shoulder exercises while maintaining the limb in a protective Velpeau dressing between exercise periods.

**Elbow Flexor Release Technique**

- Identify the deltoitdopelvic groove and develop the interval between the deltoitd and the pectoralis major (Fig. 66.1B). Protect the cephalic vein.
- The scapularis, bordered inferiorly by the anterior humeral circumflex veins, is lengthened medially to the glenohumeral joint (Fig. 66.1C). For persistent deformity, release the subscapularis at its insertion into the humerus.
- If the tendon of the pectoralis major is tight, lengthen it by a stepcut incision.
- Postoperatively, immobilize the limb in 25° to 30° of abduction and 20° of external rotation for 4 to 6 weeks. Begin active assisted exercises to retain shoulder range of motion at 2 weeks.
- More resistant deformities may require an external rotational osteotomy of the proximal humerus. The osteotomy is performed via an anterior approach and is held with crossed pins or with plate fixation.

**Abduction–External Rotation**

Abduction–external rotation is uncommon (9).

- Perform surgical release, when it is indicated, through a “strap” incision, permitting access to the deltoitd and the spine of the scapula.
- Detach the fibers of the anterior two thirds of the deltoitd from their insertion into the humerus and recess the deltoitd muscle. Do not disturb the insertion of the scapular portion of the deltoitd.
- Perform a Z-lengthening of the tendons of the teres minor and the infraspinatus.
- Immobilize the shoulder in a Velpeau bandage (reinforced with plaster) for 2 weeks. Begin active assisted and passive shoulder exercises while maintaining the limb in a protective Velpeau dressing between exercise periods.

**Elbow Flexor Release Technique**

- Identify the deltoitdopelvic groove and develop the interval between the deltoitd and the pectoralis major (Fig. 66.1B). Protect the cephalic vein.
- The scapularis, bordered inferiorly by the anterior humeral circumflex veins, is lengthened medially to the glenohumeral joint (Fig. 66.1C). For persistent deformity, release the subscapularis at its insertion into the humerus.
- If the tendon of the pectoralis major is tight, lengthen it by a stepcut incision.
- Postoperatively, immobilize the limb in 25° to 30° of abduction and 20° of external rotation for 4 to 6 weeks. Begin active assisted exercises to retain shoulder range of motion at 2 weeks.

Tenotomy is indicated when the forearm cannot be supinated to more than 45° to 30° from neutral (33). Rerouting offers the advantage of strengthening supinator power. While some authors have reported consistently good results following pronator teres rerouting, others have found the procedure somewhat unpredictable and capable of producing supination deformity (27,31). A fixed supination deformity is more disabling than a pronation contracture. Hence, approach this procedure with some caution.

Coexisting contractures of the forearm in pronation and of the wrist in flexion are common in cerebral palsy. The inability to extend the wrist and supinate the forearm compromises digital motion, power pinch, and grip. Prolonged pronation contracture may produce radial head dislocation (24). Release of the flexor pronator origin can provide considerable lengthening and improve appearance and function of an extremity with fixed deformities (14). In passively correctable deformities that assume a flexed position during grasp, transfer of flexor carpi ulnaris (FCU) to extensor carpi radialis brevis (ECRB) is recommended (8). A surgical technique is described in the following section on wrist flexion deformity. Supination may be improved after this transfer by suturing the FCU while the forearm is moderately supinated (2).

Pronator Teres Tenotomy Technique

- Make a 4 cm longitudinal incision on the anterolateral mid forearm over the pronator teres insertion.
- Develop the interval between the brachioradialis (BR) and the extensor carpi radialis longus (ECRL) to expose the pronator teres. Transect the insertion of pronator teres onto the radius.
- Close the wound and apply a long-arm cast with the forearm in 60° of supination. At 4 weeks, replace the cast with a posterior splint and begin active range of motion of the elbow. Discontinue the splint at 8 weeks (31).

Wrist Arthrodesis

Wrist arthrodesis is indicated only when there is no potential for active finger flexion and extension (12). In passively correctable deformities that assume a flexed position during grasp, transfer of flexor carpi ulnaris (FCU) to extensor carpi radialis brevis (ECRB) is recommended (8). A surgical technique is described in the following section on wrist flexion deformity. Supination may be improved after this transfer by suturing the FCU while the forearm is moderately supinated (2).

Flexor–Pronator Slide Technique

- Start the incision 5 cm proximal to the medial epicondyle and continue it distally across the antecubital in a zigzag fashion to the midportion of the proximal forearm. Take care not to damage the medial antebrachial cutaneous nerve in the distal part of the incision and the medial brachial cutaneous nerve posterior to the medial part of the epicondyle.
- Identify the ulnar nerve and dissect it from its groove (Fig. 66.3A). Divide the medial intermuscular septum. Protect the ulnar nerve branches to the FCU and the two ulnar heads of the flexor digitorum profundus (FDP). Retract the ulnar nerve by vessel loops.
- Incise the lacertus fibrosus fascia. Identify and gently retract the median nerve and brachial artery. Take care to preserve the motor branches of the median nerve to the flexor–pronator muscles. This is an exacting dissection and must be performed with patience. Start distally, elevate the FCU and FDP origins from the ulna and the interosseous membrane (Fig. 66.3B). Continue this dissection proximally along the ulna as far as the ulnar groove. The flexor digitorum superficialis (FDS) usually must be released from the radius and the interosseous membrane.
- Separate the flexor–pronator muscle mass from the underlying anterior capsule of the elbow, divide it at its origin on the medial part of the epicondyle, and advance it distally about 4 cm. The flexor–pronator muscle mass may be sutured to the underlying tissue at the desired retatchment point. If pronation deformity of the forearm is not a problem, bring the pronator teres origin over the periosteum of the ulna at the proper tension so that pronation of the forearm is not compromised.
- If a flexion contracture of the elbow persists, release the brachialis.
- Deftt the tourniquet and obtain hemostasis. Place drains in the forearm and the antecubitum; these should be removed at the first dressing change.
- By the close of the procedure, the wrist should dorsiflex 45° to 60° with the fingers in maximum extension. Use plaster splints to hold the forearm in supination, the wrist in 30° of extension, the metacarpophalangeal (MCP) joints in 25° of flexion, and the elbow flexed 45° to 90°.
- At the first dressing change, replace the splint with a cast, which is worn for 3 weeks. Active assisted motion is started after cast removal. Custom-molded anteroposterior splints that maintain the wrist in extension are worn between treatments for 6 weeks, and then only at night for an additional 6 months.

Inadequate Extension

Function in patients with wrist flexion contractures may be improved by Z-lengthening of the wrist flexors: FCU, flexor carpi radialis, and palmaris longus. This procedure works best if the patient has active wrist extensor power. Wrist flexor lengthening is not needed if the wrist can be voluntarily extended to at least 10° past neutral, and if it can be actively flexed and assists in finger extension (5).

Wrist arthrodesis is indicated only when there is no potential for active finger flexion and extension (24). Fusion lessens severe flexion deformities and is particularly helpful for athetoid patients (12). Perform arthrodesis only after testing hand function in a cast, with the wrist in the position chosen for the procedure. It is contraindicated if the patient depends on wrist flexion for release or wrist extension for grasp, or if other planned tendon transfers might be compromised by the arthrodesis. The fusion includes the radiocarpal, midcarpal, and carpometacarpal joints. The epiphyses and the distal radio-ulnar joint are preserved.

When grasp is compromised by inadequate wrist extension from weak extensors, but finger extension can be performed actively with the wrist passively extended, transfer of the FCU is recommended (8). The tendon of the FCU is passed subcutaneously around the ulnar border of the forearm and is transferred to the tendon of the ECRB. The transfer eliminates a deforming force pulling the hand into ulnar deviation and flexion.

Several prerequisites exist for this transfer. First, there must be satisfactory passive forearm supination and wrist and finger extension. Second, any fixed deformity should be corrected by successive stretching casts and exercises. Finally, there must be adequate digital motor control. The procedure has been widely used for many years with good results (6,18,24,25,29,33). However, some long-term studies report extension contractures and difficulty with grasp and release following this transfer.

Figure 66.3. A: The ulnar nerve is identified and the median intermuscular septum divided. B: The flexor–pronator origins are elevated from the ulna and advanced distally.
In an effort to define the indications for this transfer, the spastic hand has been classified into three groups based on the ability to grasp and release through wrist position (37):

- **Type I**: Fingers can actively extend with the wrist in less than 20° of flexion.
- **Type II**: Fingers can actively extend with the wrist in less than 50° of flexion.
- **Type III**: Fingers cannot extend with the wrist in any position.

Type I patients exhibit mild spasticity of the FCU and finger flexors. If indicated, tenotomy of the FCU may be of value in this group.

Children who can actively extend their fingers to near neutral with the wrist passively extended but cannot extend the wrist to neutral are most likely to benefit from an FCU-to-ECRB transfer (35,36). Children who cannot actively extend the fingers with the wrist passively extended but who can with the wrist flexed at 45° may also benefit.

Patients with type III deformity lack voluntary grasp and release patterns. The FCU-to-ECRB transfer is not indicated in this group (36). These patients may benefit from multiple tendon fractional lengthenings in the forearm, allowing the fingers to remain out of the palm for improved cosmesis and hygiene.

**FCU-to-ECRB Transfer Technique**

- Make a 3 cm longitudinal incision radial to the insertion of the FCU. Make a second 6 cm longitudinal incision along the palmar-ulnar aspect of the forearm. The two incisions extend over the muscle belly of the FCU from the wrist flexor crease to the junction of the middle and proximal thirds of the forearm.
- Expose the FCU, isolate the ulnar nerve, and tag it with a vessel loop posterior to the tendon (Fig. 66.4A). Split the muscle sheath of the FCU and transect the tendon just proximal to its insertion on the pisiform. Strip the muscle fibers of the FCU extraperiosteally from the ulna. Free the muscle proximally, without disturbing its nerve supply from the ulnar nerve. Continue the dissection throughout the length of the wound, allowing mobilization of the muscle sufficient to permit its passage in a straight line from its origin to the dorsum of the wrist.

![Figure 66.4. A: The flexor carpi ulnaris is exposed, released distally, and freed proximally. B: The flexor carpi ulnaris (FCU) tendon is passed around the ulna through the subcutaneous tunnel and transferred to extensor carpi radialis brevis (ECRB). *extensor carpi radialis longos](image)

- Make a third longitudinal incision over the wrist in line with the long metacarpal, beginning at the distal end of the radius and extending for 5 cm proximally. Incise the extensor retinaculum over the second compartment and identify the ECRB. By blunt dissection, prepare a tunnel extending from the proximal FCU incision to the dorsal radial incision. Construction of this tunnel is facilitated by use of a tendon passer. Depending on the amount of lengthening required, the FCU tendon may be transected, and the wound closed in a straight line through a large skin incision.
- Pass the FCU tendon around the ulna through the subcutaneous tunnel (Fig. 66.4B). Make a slit in the tendon of ECRB with a #11 blade.
- Place the wrist in 40° of extension and the forearm in supination, pass the tendon of the FCU through the slit in the ECRB. For the intratendinous suturing, use 3-0 nonresorbable suture. Secure the attachment of the FCU to the ECRB with additional interrupted sutures. The tension must be sufficient to maintain the wrist in neutral against gravity, but it should permit passive flexion to 15°. Close the wound and apply a long-arm cast with the forearm in supination and the wrist in 15° of extension.
- The cast is worn for 4 weeks; then active exercises for ulnar deviation and wrist extension are begun. A bivalved cast or a plastic splint is worn between exercise periods for 2 to 3 months. This program is discontinued when the wrist can be maintained actively in extension. A night brace is worn throughout this time and for an additional 4 months or until there is no tendency toward recurrence (8,24,26,33).

**HAND**

**Digital Flexion Deformity**

Proximal interphalangeal (PIP) flexion deformity may be caused by spasticity and myostatic contracture of the FDS and FDP muscles or by paresis of the extensor digitorum communis (EDC). Flexion deformity is increased on wrist extension and diminished on wrist flexion. Serial plaster casts with progressive wrist extension may lessen flexion deformity of the digits. If conservative treatment is ineffective, surgical lengthening of the spastic or contracted finger flexors is indicated (5). Do not perform lengthening if the wrist can be voluntarily brought to neutral without excessive digital flexion, or if the wrist flexors are weak. With this deformity, lengthening is indicated to lessen flexion deformity of the digits. If conservative treatment is ineffective, surgical lengthening of the spastic or contracted finger flexors is indicated (5). Do not perform lengthening if the wrist can be voluntarily brought to neutral without excessive digital flexion, or if the wrist flexors are weak.

To assess the amount of tendon lengthening required, hold the wrist in maximum extension, placing the MCP joints of the fingers in extension, and then observe the position of the digits. If the digits can be passively extended to near neutral, then an additional 4 months or until there is no tendency toward recurrence (5).

**Fractional Flexor Lengthening Technique**

- Expose the flexor tendons through a midline incision on the palmar surface of the distal forearm (Fig. 66.5A). Divide the deep fascia.

![Figure 66.5. A: Exposure of flexor tendons. B: Lengthening of flexor tendons by stepcut incisions. C: Goldner (4) suggests bisecting the tendon for a distance of twice that of the proposed lengthening. One slip of the tendon is divided and sutured halfway from the cut end to the intact tendon. The remaining portion is then cut distally.](image)

- Identify and protect the ulnar nerve and artery on the radial side of the FCU tendon. Isolate the radial artery on the radial side of the flexor carpi radialis (FCR). Lengthen the FDS tendons by stepcut incisions at the musculotendinous junction (Fig. 66.5B). Goldner suggests bisecting the tendon for a distance twice that of the proposed lengthening (Fig. 66.5C) (5).
- Divide one slip of the tendon and suture it halfway from the cut end to the intact tendon, after passively extending the finger. Then cut the remaining portion of the tendon distally, without disturbing the underlying muscle tissue. This results in a controlled lengthening.
- With the wrist extended 50°, the PIP joints should be flexed 45°. Repair the incisions with 4-0 resorbable suture.
- Release of the FDP at the same operation may not be advisable because grasp is weakened if both extrinsic digital flexors are lengthened. See how the patient adjusts to lengthening of the superficialis tendons before considering surgery of the FDP.
Expose the muscle tendon units of the FDP by retracting the FCR and the FDS and protecting and retracting the median nerve.

Lengthen the FDP in a manner similar to that used for the FDS, but at a different level. Lengthen the flexor pollicis longus (FPL) if the thumb is held in a flexed position and interferes with pinch and grip.

Patients with a rigid flexion contracture may require FCR and FCU lengthening. Lengthening is not required if the fingers can be flexed easily while maintaining the wrist in active extension. If the procedure proves necessary, lengthen the FCU first. Lengthen the tendon of the FCU only if the FCR procedure provides insufficient correction.

Release the trapeziun and achieve meticulous hemostasis at the end of the procedure. Do not close the deep fascia.

Apply long-arm anteroposterior splints to the fingertips, including the thumb, with the elbow at 90°, the forearm supinated, the wrist in 40° of extension, and the fingers and thumb in neutral.

Physical therapy for patients undergoing flexor tendon lengthening includes active exercises at 4 weeks after surgery. Bivalved plastic splints are worn between exercise periods. Night splinting continues for 6 months (5,33).

Inadequate MCP Extension

If digital extension is unsatisfactory, a motor should be transferred to the EDC. The procedure is indicated when there is no significant contracture and a muscle is available for transfer that is synchronous with finger extension (8). The FCU, BR, and ECRB have been recommended for the transfer (5,22,29,33). We prefer transfer of the FCU into the EDC because the muscles are synchronous and the transfer produces a tenodesis effect (10,39).

FCU-to-EDC Transfer Technique

The exposure is similar to that described for the FCU-to-wrist extensor transfer. Make a longitudinal incision that extends along the ulnar-palmar aspect of the forearm, from the palmar wrist crease to the junction of the proximal and middle thirds of the forearm.

Expose the FCU and identify and protect the ulnar artery and nerve. Divide the FCU tendon at its insertion into the pisiform and free it proximally, while carefully preserving the proximal innervation of the tendon.

Make a second longitudinal incision over the fourth dorsal compartment. Divide the extensor retinaculum and expose the EDC.

Pass the tendon of the FCU through a subcutaneous tunnel to the dorsal incision. Hold the wrist and MCP joints in neutral. Split the FCU tendon into two segments and suture these into each of the tendons of EDC. Adjust the tension so that each finger's MCP joint hyperextends slightly when the wrist is flexed.

Apply a long-arm cast with the wrist in 30° of extension and the MCP joints in neutral. This position is maintained for 4 weeks, at which point active exercises are started. Prescribe a splint that limits finger and wrist flexion, to be worn for 2 months, followed by a night splint for 6 months (28,33).

Swan-Neck Deformity

Swan-neck deformity is characterized by hyperextension of thePIP joints with flexion at the distal interphalangeal (DIP) joints (Fig. 66.6A). In cerebral palsy, it usually results from muscle imbalance caused by the spastic intrinsics exerting excessive pull on the extensor mechanism. Contraction of the tight or spastic intrinsics results in PIP hyperextension. The tenodesis effect of the EDC while the wrist is flexed also contributes to the deformity. The palmar plate stretches and the lateral bands sublux dorsally, increasing the hyperextension of the PIP joint. The deformity impairs grasp and pinch. Treatment consists of superficialis tenodesis with or without capsulorrhaphy of the PIP joint, as described by Swanson (32).

Superficialis Tenodesis Technique

Make a mid-lateral incision from the midpoint of the middle phalanx to the base of the proximal phalanx. For the index finger, the incision should be on the ulnar side; for the little finger, it should be on the radial side.

Incise the retinacular ligament longitudinally. Gently retract the neurovascular bundle on the side of the incision to the other side.

Make an incision in the flexor sheath between the A1 and A2 pulleys; identify each flexor tendon by a vessel loop and retract it.

Expose the palmar aspect of the proximal phalanx by subperiosteal dissection, and drill two small holes 1 cm apart in the palmar cortex of the proximal phalanx in a palmar-to-dorsal direction (Fig. 66.6B). Connect the two holes on the palmar aspect using a curet. Roughen the bone for attachment of the tendon.

Draw the superficialis tendon into the medially cavity by a nonresorbable 4-0 suture. Then pass the suture through the palmar cortex defect and out a hole in the dorsal cortex, to the dorsal aspect of the finger, and secure it over a button. Anchor the tendon to the bone with the PIP joint in 30° of flexion. Drill a 0.045 Kirschner wire (K-wire) across the joint from the proximal portion of the middle phalanx through the neck of the distal end of the proximal phalanx.

Close the flexor sheath with fine resorbable suture. Repair the retinacular ligament and suture the skin.

Capsulorrhaphy is required in some cases. Incise the capsule at right angles to the finger. With the joints in 30° of flexion, place 4-0 nonresorbable sutures in the distal end of the proximal flap and the proximal end of the distal flap (32,33).

Thumb-in-Palm Deformity

Thumb-in-palm deformity is extremely disabling, as it prevents lateral pinch and grasp. The deformity consists of flexion, adduction, and external rotation of the first ray with flexion of the distal phalanx. The deformity may be due to adductor spasticity or to spasticity and contracture of the FPL. Stretching of the MCP joint capsule may produce instability of the joint. Secondary tenar space narrowing may develop. If severe, this can eventually lead to subluxation of the carpometacarpal joint (33).

Many procedures have been proposed for correction, including MCP and interphalangeal (IP) arthrodesis, webspace release, tendon transfer, tendon lengthening, and MCP capsulodesis (2,13,15,16 and 17,21,30). For planning correction, the classification scheme of Mital and Sakellarides is helpful (24).

Type I deformity results from paresis of the extensor pollicis longus, with or without instability of the MCP joint. Procedures suggested to correct this include tendon transfer of the BR into the abductor pollicis longus (APL) and the extensor pollicis brevis (EPB), and rerouting of the extensor pollicis longus (EPL) (13,20,21). We recommend the BR transfer. If the joint is unstable, stabilize the MCP joint by capsulodesis or arthrodesis (1,7). Gelberman suggests arthrodesis if the MCP joint shows hyperextension deformity greater than 20° (2). If performed in a child, the procedure should not interfere with growth of the thumb (2). Reserve arthrodesis for cases in which soft-tissue procedures prove unsatisfactory. A different opinion is voiced by Goldner et al., who recommend simultaneous correction of the soft-tissue deformity and MCP joint arthrodesis (7).

Type II deformity is caused by spasticity or contracture of the adductor pollicis. Treat adductor pollicis contracture by release of the transverse and oblique heads of the muscle. Myotomy is preferred to tenotomy, because it avoids hyperextension of the MCP joint while permitting release of the first metacarpal. If severe spasticity is present, simultaneously perform neuroectomy of the motor branch to the adductor. Should the first dorsal interosseous contribute to the deformity, release it from the first or second metacarpal, or both.

In type III deformity, there is paresis of the APL. We suggest tendon transfer of the BR to the APL. Full passive abduction of the first metacarpal and passive thumb extension are prerequisites for tendon transfer.

Type IV deformity is caused by overactivity of the FPL. Perform Z-lengthening of the flexor digitorum longus in the distal forearm to overcome flexion deformity. Alternatively, some authors suggest the subcutaneous transfer of the flexor digitorum longus to the radial side of the proximal phalanx of the thumb, with tenodesis...
Technique for BR-to-APL Transfer

- Make a palmar zigzag incision over the MCP joint. Retract the neurovascular bundles.
- Incise the A1 pulley and mobilize and retract the FPL.
- Incise the palmate plate, leaving its distal attachment intact. Release the insertions of intrinsic onto the plate.
- Retract a 4-0 double-arm wire suture with pullout wire in Bunnell fashion into the palmate plate.
- Prepare a small groove on the neck of the metacarpal to accommodate the plate. Drill two holes to the dorsum of the metacarpal. Drill a 0.045 K-wire through the proximal phalanx, so that it may later be brought across the joint in retrograde fashion.
- Holding the joint in 30° of flexion, pass the suture through the apertures and tie it over a button on the dorsum of the thumb. Pass the K-wire across the MCP joint.
- Hold the thumb in abduction in a plaster cast. Remove the pullout wire at 6 weeks and the K-wire at 8 weeks.

Technique for Arthrodesis of the MCP Joint

- Make a radial mid-lateral incision. Incise the collateral ligament and capsule along the metacarpal head and dislocate the joint.
- Carefully remove the articular cartilage from the metacarpal head using a small rongeur. Remove the articular surface of the proximal phalanx without disrupting the physes. Drill two 0.045 K-wires through the subchondral bone of the proximal phalanx so that they may be passed retrograde across the MCP joint.
- Hold the joint in 10° of flexion and 10° of lateral rotation and pass the wires. Repair the capsule and collateral ligament with 4-0 resorbable suture. A thumb spica cast is worn for 4 weeks or until there is firm union. The pins, which have been cut subcutaneously, are left in place for about 1 year.

Technique for Capsulodesis of the MCP Joint

- Identify and retract the common digital nerve ulnarily.
- After the skin flaps are raised, incise the palmar fascia. Retract the flexor tendons to the index finger radially and those to the long finger ulnarily.
- Incise the fascia over the adductor pollicis and first dorsal interosseous (Fig. 66.7B). Retract the first dorsal interosseous radially.
- Identify the tendon of the adductor pollicis. The transverse head of the adductor pollicis arises from the distal two thirds of the long finger metacarpal. The oblique head originates from the capitate and from the bases of the index and long metacarpals. Release the adductor from its origin.
- It is generally necessary to release the flexor pollicis brevis, the opponens pollicis, and the abductor pollicis brevis muscles as well. This may be accomplished by elevating their origins from the transverse carpal ligament.
- Preserve the deep branch of the ulnar nerve and perforating branches of the radial artery. It is rarely necessary to perform neurectomy of the innervation of the adductor pollicis. However, extreme spasticity may require careful dissection and neurectomy of the deep palmar branch of the ulnar nerve, which is the motor branch to the adductor.
- Release the tourniquet and obtain hemostasis.
- A cast holds the MCP joint in neutral and the IP joint in slight flexion. Apply a plastic splint at 4 weeks to maintain the position of abduction and opposition. Active and passive exercises are begun at 4 weeks to rehabilitate thumb function. The cast should be worn for 6 weeks if simultaneous tendon transfers have been performed. Night splints are worn for 6 months to prevent recurrence of the deformity (29-33).

Technique for BR-to-APL Transfer

- Make a radial longitudinal incision from the radial styloid process to a point 3 cm distal to the lateral epicondyle.
- Free the insertion of the BR from the radial styloid (Fig. 66.8A).
- Protect the branches of the superficial radial nerve. The nerve travels along the forearm deep to the BR and can be found adjacent to the radial artery in the proximal forearm. In the distal forearm, the superficial radial nerve emerges from beneath the BR and penetrates the deep fascia.
- Dissect the tendon and muscle of the BR free from the antecubital fascia and adjacent muscles to which they are adherent. The muscle must be mobilized proximally as far as possible to gain maximal excursion.
- Transect the APL at its musculotendinous junction proximal to the dorsal retinaculum. Hold the first metacarpal in abduction, weave the distal cut end of the APL through the BR, and suture it with 3-0 nonresorbable suture (Fig. 66.8G).
- Tension should allow the first metacarpal to be adducted passively to within 2 cm of the palm, with the wrist in neutral. Tip pinch between the thumb and index must be preserved; check this after performing the transfer.
- Correct persistent extreme flexion of the MCP by transferring the proximal end of the APL to the EPB tendon.
- Apply an above-elbow cast with the wrist in neutral, the thumb in neutral, and the first metacarpal in maximal abduction. The cast is removed at 4 weeks, and a short-arm plastic thumb spica splint is worn to maintain the thumb in maximal abduction. Begin active exercises at 4 weeks to restore thumb function. Prescribe night splints for an additional 6 months (29-33).

Technique for Adductor Release

- Make an incision in the thenar flexion crease, from the second metacarpal neck to just proximal to the wrist flexion crease (Fig. 66.7A). If deepening of the web is indicated, use a standard or four-quadrant Z-plasty incision. Make a transverse incision in the web, from the ulnar border of the proximal flexion crease of the thumb to the radial border of the proximal transverse palmar crease; then make two oblique cuts at a 60° angle.

Figure 66.7. A: Skin incision. B: The first dorsal interosseous is retracted radially and the adductor pollicis is identified.

Figure 66.8. A: The insertion of the brachioradialis is freed from the radial styloid. B: The distal cut end of adductor pollicis longus is woven through the brachioradialis.
**Technique for FPL Abductorplasty**

- Make a radial mid-axial incision from the middle of the distal phalanx to the neck of the first metacarpal. Develop the palmar skin flap, exposing the FPL.
- Transect the tendon opposite the proximal phalanx.
- Perform arthrodesis or tenodesis of the IP joint in 15° of flexion.
- Make a longitudinal incision in the forearm just radial to the FPL tendon. Curve the incision in an ulnar direction at its distal end just proximal to the wrist crease.
- Bring the distal end of the FPL to this wound. Prepare a subcutaneous tunnel from the lateral side of the MCP joint to the apex of the wrist incision. Pass the distal end of the FPL through this tunnel. With the thumb abducted 50° and the wrist in neutral, suture the transferred FPL to the dorsoradial proximal phalanx base without tension.
- Apply a plaster splint holding the thumb abducted and the wrist flexed 30° for 6 weeks. A plastic static thumb abduction splint is worn for an additional 6 weeks (30).

**Technique for EPL Rerouting**

Extensor pollicis longus rerouting is a thumb abduction augmentation transfer performed only in conjunction with adductor–flexor intrinsic release (20). Despite acting as an IP extensor, the EPL also adds the thumb. EPL rerouting eliminates a deforming force and converts this tendon to a more functional position.

- Identify the EPL through a dorsal distal forearm incision just proximal to Lister's tubercle.
- Make a second dorsal incision over the MCP joint and the proximal phalanx in the hand, again exposing the tendon.
- Dissect a narrow longitudinal strip of the EPL insertion in the midline of the dorsal thumb incision, leaving sufficient tissue for closure of the areolar tissue.
- Withdraw the tendon into the distal forearm.
- Release the forearm fascia allowing the EPL tendon to pass in a straight line to the thumb base.
- Place a tendon passer from the dorsal thumb incision along the path followed by the EPB and APL tendons through the first dorsal retinacular compartment.
- Direct the tip proximally into the dorsal forearm incision. Grasp and pull the EPL tendon distally through the first dorsal compartment into the dorsal incision. Pass the tendon around the APL insertion, placing the direction of tendon pull radially. Suture the tendon into the MCP capsule. A tendon advancement incision. Despite acting as an IP extensor, the EPL also adds the thumb. EPL rerouting eliminates a deforming force and converts this tendon to a more functional position.
- If the MCP joint hyperextends passively, take care to insert the tendon into the metacarpal and not the proximal phalanx base. In this instance, a temporary K-wire should be placed across the MCP joint. Apply a short-arm thumb spica cast with the thumb in extension and maximal palmar abduction.
- Remove the case (and K-wire if needed) at 4 weeks. Apply a removable splint and begin range-of-motion exercises. Continue splinting for 6 weeks.

CHAPTER 67

MANAGEMENT OF UPPER EXTREMITY DYSFUNCTION FOLLOWING STROKE OR BRAIN INJURY

Mary Ann E. Keenan and Patrick J. McDaid

INTRODUCTION

Cerebrovascular accident (CVA) and traumatic brain injury (TBI) are distinct syndromes. However, the stroke and brain-injured patient share many features (see, e.g., 3, 42, 46, 52, 55, 56, 64, 85, 89, 92, 109, 128, 135, 148, 174, 178, 186, 190, 205, 206, 217, 236, 239). Both patient groups exhibit upper motoneuron (UMN) syndromes with impairment of motor control, spasticity, and stereotypical patterns of movement (synergy). Cognitive, memory, and sensory deficits are also commonly seen in these patients. Because of the similarities between stroke and TBI, there is a great deal of overlap in terms of specific surgical and nonsurgical techniques for treating the upper extremity problems caused by these conditions.

Lesions of the central nervous system (CNS), the peripheral nervous system, and the musculoskeletal system, and lesions causing pain may lead directly or indirectly to syndromes of restricted or excessive motion of the limbs. Syndromes of restricted limb motion are the most common type of movement impairment. Syndromes of excessive motion are less common. A distinction between restricted versus excessive motion is made. This is because the functional implications of each and the treatment of the problems they generate are very different. Syndromes of restricted limb motion are manifested by impaired access of the limbs to targets in the environment during voluntary movement. Limbs are unable or are poorly able to move toward objects or places because movement across joints is restricted. An example is a patient with spastic finger flexors who attempts to open the hand to grasp an object. Another example seen after head injury is heterotopic bone formation about the elbow, which restricts joint motion and impairs use of the upper extremity even in the presence of voluntary muscle action. Limbs with restricted motion lose their operating range and are unable to be positioned adequately for function. The general treatment strategy for limbs with restricted motion is to identify and reduce sources of limb restriction.

Syndromes of excessive limb motion are manifested by impaired tolerances in the production of voluntary movement parameters such as movement amplitude, accuracy, timing, and force. Clinical conditions associated with excessive motion seen after head injury include such movement disorders such as hemiballismus, athetosis, tremors, and cerebellar ataxia. Biomechanical laxity in the musculoskeletal system may also be associated with excessive motion. For example, inferior subluxation of the shoulder may lead to excessive motion.

Orthopaedic Surgery as a Rehabilitation Tool

The effects of injury to the brain extend beyond the confines of the skull and the subsequent cognitive function of the brain. The musculoskeletal system is profoundly affected by brain dysfunction. Hypertonicity, the unmasking of primitive reflexes, and impaired motor control contribute to the abnormal limb positions, contractures, and impaired mobility so frequently encountered in persons with brain injury.

The converse is also true. The brain is strongly affected by dysfunction of the musculoskeletal system. Just as the shoulder and elbow position the hand for grasping and manipulating objects, the musculoskeletal system gives mobility to the brain and positions it to interact with the world. Mobility of the individual is a key element of human life and of fundamental importance to our well-being.

Professionals working in the field of brain injury and stroke rehabilitation are knowledgeable about the cognitive and behavioral deficits that accompany brain injury. It has been our experience that less importance has been given to the musculoskeletal impairment that results from brain trauma or stroke. The penalties of musculoskeletal limitations for the individual can be devastating. Improving an individual's physical mobility is often therapeutic, leading to increases in their cognitive, behavioral, and emotional capacities.

Wellness promotion has become an objective of medical care. Which in the physically disabled population, means maximizing function and mobility in order to avoid the complications of chronic incapacity. Potential complications of physical immobility include decubiti, infection, pain, social isolation, and physical and emotional dependence. For society, this results in a costly loss of productivity for the patient and often family members as well.

Expectations and Timing of Orthopaedic Surgery

When evaluating patients with CNS dysfunction, questions commonly arise regarding the indications for surgery, the cost, what outcome to expect, and the practicality of this approach. Consider these issues on an individual basis for each patient. General principles have been delineated that can serve as guidelines for decision making:

1. Operate early—before deformities are severe and fixed. Orthopaedic surgery is a powerful rehabilitation tool. It is often the only treatment that will correct a limb deformity or improve function. Surgery should not be considered a treatment of last resort when conservative measures have failed. Physical and occupational therapy cannot affect a permanent change in motor control. Drug therapy for increased muscle tone has generalized effects and cannot be targeted to specific offending muscles. Phenol blocks and botulinum toxin injections provide only temporary modulation of muscle tone. When a permanent treatment is needed to decrease muscle tone or redirect muscle force, consider surgery. The results of surgical intervention are improved when deformities are corrected early. Loss muscle lengthening is needed when deformities are mild and there is little or no fixed contracture to overcome. Early surgery preserves maximum muscle

strength, joint capsule and ligament flexibility, and articular cartilage integrity. In general, the patient will also be in better physiologic condition to undergo surgery if there has not been a period of several years of immobility.

2. Better underlying motor control means better function for the extremity. Orthopaedic surgery cannot impart control to a muscle. Lengthening a spastic muscle can improve function by diminishing the overactive stretch reflex and uncovering any control that was present. Successful surgery depends on a careful evaluation preoperatively to determine the amount of volitional control present in each individual muscle that is affecting limb posture and movement.

Motor performance occurs on a continuous scale, with the disabled at the lower end and the elite athlete at the upper end. Infinitiesmall improvements in the performance of elite athletes distinguish between the winner and loser. Incremental changes in limb function also result in performance improvements for the disabled individual. Surgery should not be reserved for patients with severe impairment and disability. Individuals with milder degrees of impairment can benefit greatly from relatively simple procedures such as lengthening of the extrinsic finger flexors to regain sufficient fine motor control to perform more intricate hand functions. The amount of improvement correlates best with the degree of underlying motor control and not with the severity of the deformity.

3. Distinguish between the function of the extremity and the function of the individual. We commonly speak of “functional” and “nonfunctional” surgical procedures. These terms refer to the expected outcomes for a limb but do not indicate the outcome for the person as a whole. Surgical releases of an arm contracted in a flexed and internally rotated position in a hemiplegic patient allows the person to become independent in dressing, even though the arm itself remains nonfunctional.

4. Consider the cost of not correcting limb deformities. The cost of motor control evaluation using dynamic electromyography (EMG) is relatively modest for the benefits it provides. Dynamic EMG is a one time expense. The cost of performing an incorrect surgical procedure that fails to correct or worsens a limb deformity is much greater. The cost of performing a surgical procedure is likewise more cost effective when compared with a lifetime of attendant care, spasticity medications, repeated blocks, orthotics to control limb position, complications such as skin ulceration and infection, and lost productivity for the patient and caretakers.

STROKE

Stroke is the leading cause of acquired hemiplegia and long-term disability in the United States (26,77,119,137,140,181,223,224). It is also the third leading cause of death. Roughly 600,000 people suffer a new or recurrent stroke each year. Management of the stroke patient has become a major priority for physicians treating the elderly. There are 4,000,000 stroke survivors alive today. The average patient who survives beyond the first few months has a life expectancy of greater than 6 years (10,79,80). Stroke victims survive long enough and achieve adequate function to justify aggressive rehabilitation.

Pathophysiology of Stroke

Cerebral function depends on a continuous supply of oxygen. Any significant interruption of oxygen by thrombosis, emboli, or hemorrhage results in neuron death and dysfunction. Lesions in the cerebral cortex affect cognitive, sensory, and motor function. Thrombosis is the most common cause of infarction and accounts for nearly three fourths of all CVAs (79,80).

Arteriosclerosis is the most significant predisposing factor.

Craniatal hemorrhage accounts for approximately one sixth of all CVAs, and includes spontaneous intracranial hemorrhage and subarachnoid hemorrhage. Hypertension is commonly present in these patients. Isolated cerebral emboloid account for less than 10% of CVAs.

Predisposing factors to CVAs include arteriosclerosis, increasing age, genetic predisposition, hypertension, hyperlipidemia, hypercholesterolemia, obesity, cardiac anomalies (atrioventricular septal defect, patent ductus arteriosus, myxomatous mitral valve), diabetes mellitus, collagen vascular disease (vasculitis, polyarteritis), hyperviscosity states (polycythemia, sickle cell anemia), oral contraceptive use, tobacco smoking, severe cerebrovascular spasm secondary to migraine headaches, and septic vasculitis (tuberculosis, syphilis, and mucormycosis).

Neurologic Impairment Following Stroke

Distinct clinical syndromes arise from insults to specific areas of the cerebral cortex. CVAs involving the middle cerebral artery are the most common, and produce the typical hemiplegic picture of greater impairment in the upper extremity, face, and speech compared with lower extremity involvement. The middle cerebral artery supplies the largest area of the cerebral cortex. This area controls sensory and motor function of the trunk, upper extremity, and face, as well as the functions of speech.

The anterior cerebral artery supplies the mid-cortex in the sagittal plane. This area of cerebral cortex controls sensory and motor function predominantly in the lower extremity. CVAs involving the anterior cerebral artery result in a hemiplegic picture of sensory and motor deficits chiefly involving the lower extremity.

The posterior cerebral artery supplies the visual cortex in the occipital region. Impairment of this artery typically results in visual impairment. Bilateral cortical involvement may lead to severe mental impairment, frontal release signs, loss of short-term memory, and inability to learn.

CVAs in the vertebral basilar system are rare. Deficits in balance and coordination arise from interruption of afferent and efferent pathways between the brain and spinal cord. Balance reactions are also dependent on limb control and proprioception (86,119,141,261).

Cognitive Impairment

Cognitive deficits commonly follow CVAs. Impairment of mentation, decreased learning ability, and loss of short-term memory may occur (10,14,17,25,26,33,34,41,51,77,79,80,91,104,121,141,149,164,166,168,181,223,230,245). The patient's ability to cooperate with treatment affects rehabilitation potential. In patients with extensive frontal lobe deficits, these deficiencies may be severe. Patients with extensive frontal lobe pathology exhibit clinical features similar to senility, with lack of attention span and little motivation for recovery. Their prognosis for rehabilitation is poor.

Aphasia is a loss of ability to communicate. It may be receptive or expressive in nature. It usually involves both components. Aphasia occurs with lesions of the left hemisphere, usually without regard to hand dominance. A receptive aphasia hinders rehabilitation most strongly because the patient cannot understand instructions. Persistent receptive loss has a poor prognosis.

Expressive aphasia may be compatible with rehabilitation, allowing a patient to comprehend and follow instructions. Expressive aphasia may resolve significantly.

Apraxia, or impairment of execution (motor planning), is characterized by a loss of ability to perform a previously learned action, such as tying shoe laces or waving good-bye. Apraxia is not the result of motor or sensory loss. It occurs more commonly with right hemispheric involvement (left hemiparesis). The apraxia, however, occurs on both sides of the body. The prognosis with severe apraxia is generally poor. Some improvement with practice and repetition may occur. If impairment persists after 3 months, further improvement is unlikely (13).

Sensory Impairment

A wide span of sensory loss can occur following stroke. Sensory perception occurs in the cerebral cortex and is most often affected by lesions of the middle cerebral artery. Sensory loss may be manifest by impairment of touch, pinprick, two-point discrimination, proprioception, discrimination of size, shape, texture, or point localization, or the presence of astereognosis. Impairment of sensory function in the upper extremity is a poor prognostic sign, even though motor function may be intact or only minimally impaired (14,20,25,28,27,33,34,41,53,73,77,83,97,104,121,128,137,138,141,154,164,165,167,168,173,191,198,221,223,230,234,241,244).

Lesions of the parietal lobe of the nondominant hemisphere may result in a lack of awareness of the involved side of the body (neglect). A failure to recognize and use the involved side may occur despite minimal motor involvement.

Disturbances of vision may occur. These include hemianopia (blindness in one eye), disturbance of perception, poor perceptual organization, loss of geometric sense, inability to copy figures, and failure of tasks involving spatial analysis. Hemianopia is likely to be permanent but it usually has little impact on rehabilitation potential. Disturbances in visual perception are more significant and may result in failure in activities of daily living (216).

Motor Impairment

Motor impairment is commonly the most obvious sequela of stroke. Recovery follows a fairly typical pattern. A period of flaccid paralysis occurs, lasting from 24 hours to several weeks. This is followed by a period of increasing muscle tone. In general, the longer the period of flaccidity, the poorer the prognosis for functional recovery. In the arm, the shoulder adductor and internal rotator muscles become tight. The elbow, wrist, and finger flexors also develop marked tone.

These changes are usually evident within 48 hours after the stroke. Any paralysis remaining after 3 months usually persists, although some slight improvement may occur over 6 months (10,14,17,20,24,25,26,27,28,33,34,41,53,54,67,77,79,80,96,98,113,114,119,121,124,126,128,137,138,141,149,154,164,165,166,167,168,173,181,185,191,198,201,205,221,222,223,225,230,231,232,233,234,241,243,244,249,250). Functional improvement may continue as a result of further
sensorimotor reeducation. Increasing muscle tone usually leads to muscle spasticity. Hyperactive deep tendon reflexes and clonus may appear.

Voluntary movement returns first in the most proximal muscle groups of the limbs and follows in a proximal-to-distal direction or pattern of recovery. Voluntary movement should be sought and examined during the early recovery phase, when flaccidity is present.

Motor control is graded in the extremity using a clinical scale (Table 62.1) \(116,145,146\). The extremity may be hypotonic or flaccid and without any volitional movement. A spastic extremity may be held rigidly without any volitional or reflexive movement. Patterned or synergistic motor control is defined as a mass flexion or extension response involving the entire extremity. Mass flexion in the upper extremity consists of extension of the hip and knee with equinovarus of the foot and ankle. Synergistic movement may be reflexive, in response to a stimulus, but without volitional control. Some patients can also volitionally initiate the synergistic movement. Selective motor control with pattern overlay is defined as the ability to move a single joint or digit with minimal movement in the adjacent joints when performing an activity slowly. Rapid movements or physiologic stress make the mass pattern more pronounced. Selective motor control is the ability to volitionally move a single joint or digit independently of the adjacent joints. Spasticity can mask underlying motor control (Fig. 67.1).

Figure 67.1. This series of tracings records by electrogoniometer the maximum arc and frequency of elbow flexion—extension movement in a patient with traumatic brain injury. The first tracing is maximal effort before placement of a block. The second tracing shows improvement after a bupivacaine motor point block of the brachioradialis. Further improvement is noted immediately after bupivacaine block of the biceps and 30 minutes after block of the brachioradialis. After the biceps block has been allowed to set up, further improvement is noted. The blocks were used to demonstrate that there was volitional motor control in the elbow flexors that was previously masked by the spastic response of the muscles to movement. The blocks also preview the improvement to be gained by fractional lengthening of the elbow flexors. (With permission from Hisey MS, Keenan MAE. Orthopaedic Management of Upper Extremity Dysfunction Following Stroke or Brain Injury. In Green DP, Hotchkiss RN, Pederson WC, eds. Operative Hand Surgery, 4th ed. New York: Churchill Livingstone, 1998:287.)

Patterned movement, even when initiated volitionally, is a primitive form of motor control and of no functional use in the upper extremity. The hand requires some selective control for functional use. The lower extremity can more successfully use synergistic motions for functional activities, such as transfers or walking. For example, the patient can be taught to use the flexion movement to advance the limb and the extension pattern to provide limb stability during stance.

The final processes in sensory perception occur in the cerebral cortex, where basic sensory information is integrated to complex sensory phenomena such as proprioception, spatial relationships, shape, sight, and texture. Patients with severe parietal dysfunction and sensory loss may lack sufficient perception of space and awareness of the involved segment of their body to ambulate. Patients with severe perceptual loss may lack balance to sit, stand, or walk.

Orthopaedic Management of Stroke

The Period of Acute Injury Efforts at this time are directed toward the medical stabilization of the patient. The orthopaedic surgeon is rarely involved in the acute care of the stroke patient. In some situations, the orthopaedic surgeon may be asked to assist with splinting extremities to prevent limb deformities.

The Period of Physiologic Recovery Spontaneous neurologic recovery occurs primarily during the first 6 months following a stroke. This is particularly true for recovery of muscle function. During the subacute phase, limb flaccidity changes to spasticity. The patient is commonly in a rehabilitation facility for a portion of this time. Muscle weakness can result in joint subluxation or ligamentous laxity if the limb is not protected using a sling to support the shoulder or splints to support the wrist. When spasticity becomes pronounced, temporary measures are used to prevent contracture formation until spontaneous neurologic recovery has ceased.

The Period of Functional Adaptation to Residual Deficits Generally the patient is neurologically stable after 6 months. Decisions can then be made regarding surgery to correct limb deformities and rebalance the muscle forces. This is the time of greatest contribution by the orthopaedic surgeon.

TRAUMATIC BRAIN INJURY

Injury to the brain is a leading cause of disability and death in the United States (\(85,100,139,169,214,216,225,228,251\)). An epidemiologic study of physician-documented cases of TBIs occurring in San Diego County, California, in 1981 determined an annual incidence of 180 per 100,000 population (\(139\)).

Applying this rate to the United States population provides an estimate of 410,000 new cases of TBI cases each year. Eleven percent of these patients die shortly after the injury. Approximately 80% of the survivors have a good or moderate neurologic recovery. Most traumatic injuries to the brain are in individuals who are younger than 45 years old, and those who survive have a normal life span despite the injury.

Prognosis

Prognosis following TBI has traditionally been predicted relative to the Glasgow Coma Scale (GCS) (Table 67.2) \(89,100,225\). The GCS evaluates a patient's responses to eye opening, motor responses, and verbal responses. The Glasgow Outcome Scale is frequently used to determine outcome following brain injury (Table 67.3). Using the GCS score obtained within 24 hours of the patient’s admission to the hospital, a coma score of 11 or greater is associated with an 82% probability of moderate or good neurologic recovery. Lower scores have a significantly higher incidence of severe sequelae.

Table 67.2. Glasgow Coma Scale*
Early surgical intervention is appropriate. The orthopaedic surgeon must consider the rate of continued improvement in motor control when deciding at what point to intervene surgically. If the additional procedures are avoided during the transitional stage, there is not an exact time that must elapse before considering surgery to improve musculoskeletal function (prolonged period of time, often years). The period of physiologic recovery occurs within the first 6 months following injury.

The first priority is to diagnose all injuries accurately. Although it has been demonstrated to predict mortality accurately, recent studies have suggested the GCS as a single variable may have limited value as a predictor of functional outcome and many trauma centers are now using the Revised Trauma Score (RTS) to assist with triage of multitrauma patients. The RTS combines the GCS as well as the systolic blood pressure and respiratory rate, and is used to predict both mortality and disability.

The orthopaedic management of TBI can be divided into three distinct time periods. The initial phase of management occurs immediately following the injury in the acute care hospital. The majority of TBIs are the result of a motor vehicle accident. Multiple trauma is common. The orthopaedic surgeon is a consultant with a critical role. Aggressive treatment of orthopaedic injuries at an early stage is important to functional outcome.

Age is an important factor determining neurologic outcome following brain injury regardless of the severity of injury. Patients younger than the age of 20 years at the time of brain injury experience as a group a 62% moderate or good neurologic recovery. Patients between the ages of 20 and 30 can expect a 46% chance of moderate or good neurologic recovery. In a series of pediatric patients with brain injury, overall 90% achieved a moderate or good neurologic recovery and only 8% expired or remained in a persistent vegetative state (84,85). Young children with a GCS score of 5 or better have a good prognosis for recovery. In addition to having a poorer prognosis for recovery, the cost and time required for rehabilitation of older patients is higher than that for younger patients (39).

Although it has been demonstrated to predict mortality accurately, recent studies have suggested the GCS as a single variable may have limited value as a predictor of functional outcome and many trauma centers are now using the Revised Trauma Score (RTS) to assist with triage of multitrauma patients. The RTS combines the GCS as well as the systolic blood pressure and respiratory rate, and is used to predict both mortality and disability.

The duration of coma is another prognostic indicator. If remission from coma occurs within the first 2 weeks of brain injury, 70% of patients can be expected to achieve a good recovery. If the coma persists beyond 4 weeks, the chance of good recovery is much diminished. Brain stem involvement, as indicated by the presence of decerebrate or decorticate posturing, has a poor prognosis for outcome. If decerebrate posturing occurs and resolves within the first week after injury, 40% of patients will have a good neurologic recovery. If decerebrate posturing persists beyond the first week, only 9% of patients will achieve a good neurologic recovery. In a similar manner, the duration of posttraumatic confusion can also be an indicator of prognosis. If the period of posttraumatic confusion persists for more than 4 weeks, then one third of these patients will have a poor neurologic outcome. It should be remembered, however, that prognosis is a probability statement, and although various factors can be used as guidelines, none is an absolute indicator in the individual patient.

Orthopaedic management of brain injury

The period of acute injury

The orthopaedic management of TBI can be divided into three distinct time periods (70,75,108). The initial phase of management occurs immediately following the injury in the acute care hospital. The majority of TBIs are the result of a motor vehicle accident. Multiple trauma is common. The orthopaedic surgeon is a consultant with a critical role. Aggressive treatment of orthopaedic injuries at an early stage is important to functional outcome.

The first priority is to diagnosis all injuries accurately (6,38,40,45,57,59,61,65,66,70,73,76,78). It is common for injuries such as fractures or major peripheral nerve injuries to go undetected. Garland reported an 11% incidence of delayed diagnosis of fractures, with an average time to diagnosis of 57 days (65,214). In the comatose patient, obtain radiographs of all major joints and any other areas of suspicion for injury. It is important not to assume that all neurologic deficits present are from the CNS injury. Stone and Keenan reported that 34% of brain-injured patients have missed peripheral nerve injuries (214). Especially in the presence of a limb fracture, look for a peripheral nerve injury (65,214).

After head injury, pain is often caused by reflex sympathetic dystrophy (RSD), deep vein thrombophlebitis, spasticity, occult fracture, and the formation of heterotopic ossification (HO) (36,61,62,61,62,170,209,214,215,228). If pain is treated promptly (and this depends on an accurate and early diagnosis), prolonged restriction of motion may be avoided. HO, fracture and fracture malunion restrict motion on the basis of lost structural integrity. Many brain-injured patients who recover cognitively have residual spasticity and impaired balance and consequently, are less able to compensate for such structural impediments (61,138). Peripheral nerve injury produces weakness and pain, both potential causes of restricted motion.

Brachial plexus injuries are problematic. Plexopathies have been reported in up to 10% of patients with TBI (65,214). They are particularly prevalent in blunt trauma, especially motorcycle accidents and ejections from a motor vehicle. They are often associated with fracture or dislocation, particularly clavicle fractures. If the plexopathy results in a flail arm in a patient with ipsilateral humerus fracture, there is a predisposition for delayed union.

The second rule of orthopaedic care is to assume that the patient will make a good neurologic recovery. All orthopaedic injuries should be treated promptly and appropriately. When possible, internal fixation is best. Spasticity develops, and casting a spastic joint in a flexed position may result in a joint contracture or an unsatisfactory reduction. Fracture healing is accelerated, presumably by the same humoral factors that contribute to heterotopic bone formation (8,111,194,228). Fracture malunion is a common and potentially avoidable complication (Fig. 67.2).

The third principle is to expect lack of patient cooperation. As the patient emerges from coma, they may be anticipated to go through a period of agitation and confusion. Fracture care should be made as foolproof as possible because patient cooperation cannot be expected. Anticipating a possible period of agitation, traction and external fixators for treatment of extremity fractures should be avoided when possible (61,68,70,73,76,78,158,228,237,415).

The period of physiologic recovery

Following TBI, neurologic recovery can proceed for prolonged period of time. The majority of improvement in motor control occurs within the first 6 months following injury (42). Cognitive changes are made most rapidly in the early phases following brain injury but can continue for a very prolonged period of time, often years (Table 67.4) (88). Because the period of potential neurologic recovery following head injury is prolonged, definitive surgical procedures are avoided during the transitional stage. There is not an exact time that must elapse before considering surgery to improve musculoskeletal function (109).

The orthopaedic surgeon must consider the rate of continued improvement in motor control when deciding at what point to intervene surgically. If the additional improvement in motor control will be overridden by the complications of contracture formation, osteopenia, peripheral nerve compression, and muscle atrophy, then early surgical intervention is appropriate.

HETEROTOPIC OSSIFICATION

During the period of physiologic recovery, the patient is commonly in a rehabilitation facility. Serious head injury is usually complicated by UMN syndrome (7,19,71,104,105,112,120,136,145). Spasticity is commonly severe and prevents adequate joint range of motion. Spasticity also interferes with the maintenance of limb position despite the most conscientious, contrac-ted, and aggressive treatment. Even in those situations in which joint motion can be maintained by a knowledgeable therapist, it commonly requires much force, which is painful for the patient, potentially harmful, and very time consuming. Lesser degrees of spasticity can also impede a patient's function or require the use of positioning devices that interfere with the use of an extremity.

Multiple complications can occur in the presence of spasticity (Table 67.5). Contractures are common. Limited positioning and myostatic contractures combined with the patient's diminished nutritional status can result in pressure sores or hygiene problems. When fractures are present, malunions can occur in the face of uncontrolled muscle tone and accelerated fracture healing. Joint subluxation can also occur from prolonged spasticity or the attempts to range a joint in the face of severe spasticity. If a ligamentous injury occurred at the time of injury, frank dislocation of a joint can be caused by hypertonicity. Spasticity also appears to be one of several etiologic factors in the formation of HO in a periar-ticular location (Fig. 67.3). (12,18,40,43,60,64,68,69,70,83,86,88,111,113,127,132,147,153,157,163,171,192,194,226,227,238). Another common complication of spasticity is acquired peripheral neuropathy (36,45,49,65,170,214). The most common peripheral neuropathies acquired with severe spasticity and contracture formation are ulnar neuropathy at the elbow, resulting from severe flexion and continuous pressure on the ulnar nerve, and carpal tunnel syndrome, secondary to severe wrist flexion and pressure of the median nerve against the leading edge of the transverse carpal ligament (Fig. 67.4) (170,214). During the period of physiologic recovery, the temporary control of spasticity is the major focus of treatment. Prevention of additional complications such as disuse muscle atrophy, joint contractures, HO, and peripheral neuropathies is critical to a good functional outcome (6,8,11,17,18,22,23,27,32,35,36,38,40,43,59,60,61,65,66,68,70,73,76,78,81,82,83,86,88,103,104,107,108,111,113,126,132,133,147,153,155,157,158,164,171,172,176,179,182,189,192,196,197,202,209,210,211,214,215,216,219,226,230,245). Early joint contractures are also best corrected during this phase of treatment. This is accomplished by first reducing spasticity and then correcting contractures by splinting, casting, and range-of-motion therapy.

Table 67.5. Complications of Spasticity

Figure 67.3. Lateral radiograph of the elbow in a patient with traumatic brain injury showing heterotopic ossification anteriorly causing ankylosis in 90° of flexion. There was no concomitant injury to the elbow and the radio-capitellar joint is not involved.

Figure 67.4. Clinical photograph (A) and radiograph (B) of a patient with severe wrist flexion deformity and subsequent carpal tunnel syndrome from compression of the median nerve against the proximal edge of the transverse carpal ligament.

The Period of Functional Adaptation to Residual Deficits When physiologic neurologic recovery has ceased, the brain-injured patient is commonly left with residual limb deformities from spastic contractions, contracture, and muscle imbalance. It is at this time that definitive orthopaedic surgical procedures are performed to rebalance the muscle forces and correct the residual deformities (206).
HO presents clinically with an intense inflammatory reaction about the joint seen as redness, warmth, severe pain, and rapidly decreasing range of motion (4, 12, 18, 35, 38, 40, 43, 47, 54, 59, 60, 61, 62, 63, 64, 65, 66, 67, 70, 74, 83, 88, 97, 113, 127, 132, 147, 163, 175, 193, 194, 195, 196, 202, 209, 210, 211, 218). Although the time of initial occurrence is variable, HO is usually detected 2 months following the onset of TBI. Generally, radiographs show evidence of the heterotopic bone in the form of spotty periarticular calcification.

The incidence of periarticular HO following TBI is 11%, with hips most commonly involved, followed by shoulders and elbows (68, 111, 132, 226). Although the exact etiology is not known, and likely multifactorial, it clearly has a predilection for joints surrounded by spastic or paretic muscle (69, 222, 236). A dramatic increase in incidence to 85% is seen in patients who have concomitant musculoskeletal injuries. Because of this increased incidence, consideration should be used to prophylaxis. Several modalities have been used with varying success. High-dose diphosphonates (Didronel) and nonsteroidal anti-inflammatory drugs, particularly indomethacin have been used in the early postinjury period (4, 63, 65, 134, 197, 212, 218, 237). Radiation (800 CGY limited field) can be used within several days following the injury (4, 47, 62, 63, 147, 153, 202). Joint manipulation is also used, but the benefit of this procedure is unclear if the heterotopic bone has already begun to form (73, 218). Formation of HO can be followed radiographically and by following serial alkaline phosphatase measurements. The HO is mature when the alkaline phosphatase levels returned to a normal value, and the radiographs show a well-defined, bone mass with a cortex. Technetium bone scans show increased uptake for many years and are of little value in this situation. Serum osteocalcin levels to diagnose HO or determine its maturation are unreliable (163). Surgical excision is thought to carry a higher risk of recurrence if it is attempted before maturation. This comes from work with HO in spinal cord injury patients and has not been shown to be applicable to TBI patients (55, 36, 62, 63, 69, 86, 132, 157, 195, 218). Early excision should be considered in cases in which the HO is causing progressive nerve or vascular compromise, or is threatening joint ankylosis.

REFLEX SYMPATHETIC DYSTROPHY

RSD is characterized by constant, spontaneous, severe, burning pain and is usually associated with hypo- and hyperesthesia, hyperthermia, and alldynia, along with vasomotor and sudomotor disturbances that, if persistent, result in trophic changes (65). It commonly develops following CVA (posthemiplegic dysphoria), TBI, and surgery. It may be associated with trauma, which occurred concurrently with TBI, although the severity of the initial injury is unrelated to the ensuing symptoms.

Onset following trauma is usually within the first several weeks; however, with stroke and brain injury, the onset may be delayed and atypical. Because of this, RSD may remain undiagnosed in the stroke or brain-injured population until it becomes irreversible.

Radiographs that show patchy demineralization of involved epiphyses even during the first phase aid diagnosis. Subperiosteal resorption, tunneling of the cortex, and striaion may be evident on good quality films. Unfortunately, none of these changes are specific for RSD. Triple phase bone scan may help with diagnosis. The pattern seen varies with the phase of the disease. In the acute phase, the flow (immediate), blood pool (early), and delayed (static) scan patterns all show increased uptake, usually in a periarticular distribution. False-negative results are frequent in the dystrophic phase, in which the flow and blood pool scans are normal, and the delayed phase scan shows a somewhat less prominent periarticular increase in uptake. In the atrophic phase, both the flow and early scans show decreased uptake, whereas the delayed phase is normal.

Treatment includes several modalities. Physical therapy, particularly active and active assisted range of motion, gentle muscle strengthening and conditioning, massage, and heat therapy have been effective. Tricyclic antidepressants (amitriptyline) may have their effect because of their inhibition of serotonin uptake at pain-suppressing neurons, prolonging the serotonin effect at the receptor. Narcotics have a role in low-dose epidural infusions in combination with local anesthetics. Systemic corticosteroids and adrenergic blocking agents have both been advocated. Nerve blocks, including stellate ganglion blocks, Bier blocks, surgical sympathectomy, and chemical sympathectomy have been reported with high percentages of patients improved. At present, we use a regimen of amitriptyline, physical therapy, and percutaneous sympathetic blockade.

GENERAL CONSIDERATIONS FOR DECISION MAKING

DEGREE OF SPASTICITY

The majority of stroke patients have a period of limb flaccidity before the gradual onset of increasing muscle tone or spasticity (resistance to quick stretch). Because of the mean older age of these patients compared with brain-injured patients, their muscles are also weaker. This, combined with the shorter period of spontaneous recovery, makes the neurologist more likely to have quadriplegic involvement, concomitant peripheral nerve injuries, residual deformities from fractures, and joint limitation from HO but better return of motor control. Functional surgical procedures are more common in this patient population.

The major cause of HO is not known, and likely multifactorial, it clearly has a predilection for joints surrounded by spastic or paretic muscle (69, 226, 238). A dramatic increase in incidence to 85% is seen in patients who have concomitant musculoskeletal injuries. Because of this increased incidence, consideration should be used to prophylaxis. Several modalities have been used with varying success. High-dose diphosphonates (Didronel) and nonsteroidal anti-inflammatory drugs, particularly indomethacin have been used in the early postinjury period (4, 63, 65, 134, 197, 212, 218, 237). Radiation (800 CGY limited field) can be used within several days following the injury (4, 47, 62, 63, 147, 153, 202). Joint manipulation is also used, but the benefit of this procedure is unclear if the heterotopic bone has already begun to form (73, 218). Formation of HO can be followed radiographically and by following serial alkaline phosphatase measurements. The HO is mature when the alkaline phosphatase levels returned to a normal value, and the radiographs show a well-defined, bone mass with a cortex. Technetium bone scans show increased uptake for many years and are of little value in this situation. Serum osteocalcin levels to diagnose HO or determine its maturation are unreliable (163). Surgical excision is thought to carry a higher risk of recurrence if it is attempted before maturation. This comes from work with HO in spinal cord injury patients and has not been shown to be applicable to TBI patients (55, 36, 62, 63, 69, 86, 132, 157, 195, 218). Early excision should be considered in cases in which the HO is causing progressive nerve or vascular compromise, or is threatening joint ankylosis.
during the period of physiologic recovery.

**Phenol Blocks**

Pinen, a derivative of benzene, denatures the protein membrane of peripheral nerves in aqueous concentrations of 5% or more. When pinen is injected in or near a nerve bundle, pinen's neurolytic action on the myelin sheath or the cell membrane of axons with which it makes contact serves to reduce neural traffic along the nerve. The onset of the destructive process with higher concentrations of pinen may begin to show effects several days after injection. The denaturing process induced by pinen extends biologically on the order of weeks, but eventually regeneration occurs. A pinen block is used as a temporizing measure rather than a permanent intervention. In our clinical experience and the experience of others, the effect of a pinen block typically lasts 3 to 5 months.

Histologically, it has been shown that pinen destroys axons of all sizes in a patchy distribution but more so on the outer aspect of the nerve bundle, onto which pinen is dripped. When pinen is percutaneously injected, it is likely that the nerve block will be incomplete. This is especially useful in situations in which a spastic muscle also has volitional capacity because under these circumstances, it is desirable to reduce spasticity while still preserving volitional capacity of a given muscle or muscle group.

The technique of pinen injection is based on electrical stimulation. Motor branches are injected close to the offending muscle or muscle group. These are referred to as motor points. A surface stimulator is briefly used to approximate the percutaneous stimulation site in advance. A 25 gauge Teflon-coated hypodermic needle is advanced toward the motor nerve. Electrical stimulation is adjusted by noting whether muscle contraction of the index muscle takes place. As the electrode gets closer to the motor nerve, less current intensity is required to produce a contractile response. The motor nerve is injected when minimal current produces a visible or palpable contraction of the muscle. Generally, 4 to 7 ml of 5% to 7% aqueous pinen is injected at each site. As with any injection, care needs to be taken not to inject into a blood vessel and this is done by aspirating before the injection (13,16,29,44,70,71,72,101,102,104,167,122,123,125,130,131,145,146,156,159,229).

**Botulinum Toxin Blocks**

Botulinum toxin is a newer agent used in the localized treatment of spasticity. Ordinarily, an action potential propagating along a motor nerve to the neuromuscular junction triggers the release of acetylcholine (ACh) into the synaptic space. The released ACh causes depolarization of the muscle membrane, activating a biochemical sequence that leads to muscle contraction. Botulinum toxin type A is a protein produced by Clostridium botulinum that inhibits this calcium-mediated release of ACh at the neuromuscular junction. Botulinum toxin A attaches to the presynaptic nerve terminal and divides into a light and a heavy component. The light component invades the nerve cell and interferes with fusion proteins affiliated with vesicles of ACh, thereby preventing the release of ACh from their storage vesicles.

Botulinum toxin injection has been used to treat a variety of dystonias and is currently approved by the Food and Drug Administration (FDA) for the treatment of blepharospasm, facial spasm, and strabismus. A number of studies have reported its use in treating spasticity in individuals with cerebral palsy, stroke, head trauma, and multiple sclerosis (37,50,58,145,146,200,205,240). Clinical benefit lasts 3 to 5 months but may be more variable. Botulinum toxin is injected directly into an offending muscle, and depending on the size of the muscle being injected, dosing has ranged between 10 and 200 units (U). Current practice is to wait at least 12 weeks before re-injection and not to administer a total of more than 400 U in a single treatment session. Because this upper limit of 400 U may be reached relatively quickly, a different strategy is needed for the limb requiring many proximal and distal injections. Botulinum toxin A and phenol may be combined, the former being injected into smaller distal muscles and the latter aimed at larger proximal ones. A 3- to 7-day delay between injection of botulinum toxin A and the onset of clinical effect is typical. Effects will not be seen by the patient immediately and usually a follow-up visit is arranged to check the result. The amount of toxin given for a particular muscle is variable.

The technique of botulinum toxin injection varies. Some physicians inject through a syringe attached to a hypodermic needle that doubles as a monopolar EMG recording electrode. Patients may be asked to make an effort to contract the targeted muscle or the muscle may be contracting involuntarily as in dystonia. After inserting the needle electrode, injection is made when EMG activity is recorded. For deep or small spastic muscles (e.g., finger flexors), electrical stimulation is preferred as a means of localizing the muscle before injection.

Botulinum toxin injections have gained much popularity in the past several years. The advantages of botulinum toxin are (a) ease of injection and (b) the lack of residual scaring after injection. The disadvantages of botulinum toxin are (a) high cost and (b) stimulation of antibody formation that requires higher doses for repeated injections. Phenol, in contrast, requires more technical expertise to localize the nerve or motor points for injection. Phenol is caustic and causes localized scarring of the nerve and muscle. Phenol, however, is inexpensive and readily available.

**Common Techniques of Nerve and Motor Point Blocks**

**Shoulder Adduction Spasticity**

Shoulder adduction and internal rotation spasticity are common in the upper extremity of both stroke and brain-injured patients. This deformity interferes with hygiene and upper body dressing. Phenol motor point blocks or botulinum toxin injections of the pectoralis major muscle are effective in reducing tone and improving shoulder adduction during the physiologic recovery phase (16,37,49,104,145,146,200,205,240).

- Inject botulinum toxin directly into the muscle.
- The effects of the botulinum toxin injection appear slowly over the ensuing 48 hours. Start physical therapy as the muscle relaxes.
- For phenol injections, localize the motor points using a surface stimulator over the pectoralis major muscle. Then use an insulated, Teflon-coated needle in conjunction with a nerve stimulator to localize more accurately the points where the motor nerves enter the muscle.
- Inject approximately 1 ml of a 5% aqueous solution of phenol at each point. A decrease in tone can be expected to last approximately 2 months, during which time an active therapy program can continue.
- There is an initial reduction in muscle tone immediately after the block. The muscle will continue to relax gradually over the next 24 hours.
- Begin physical therapy immediately using both active and passive techniques to increase shoulder range of motion. The duration of the block is approximately 2 months.
- Repeat blocks as needed during the period of time in which neurologic recovery can be expected to continue. In addition, blocks of the thoracodorsal nerve can also be performed.

**Elbow Flexor Spasticity**

During the physiologic recovery phase, control of elbow flexor spasticity requires the elimination or decrease of excessive tone in each of the three flexor muscles. The brachioradialis muscle has been shown by dynamic EMG studies to be the most spastic of the elbow flexor muscles (112). Because the radial nerve innervates this muscle, it is necessary to perform a motor point block of the brachioradialis muscle (F1g. 67.5).

- Localize the motor points on the surface of the brachioradialis muscle using a surface stimulator. Then use an insulated Teflon-coated needle in conjunction with a nerve stimulator to localize more accurately to the motor points.
- Inject approximately 1 ml of a 5% solution of phenol in saline at each point. The ensuing block of the brachioradialis muscle takes effect over the following 24 hours.

Spasticity of the biceps and brachialis muscles also interfere with elbow extension. Botulinum toxin can be injected into the individual elbow flexor muscles. Alternately,
a phenol block of the musculocutaneous nerve will provide temporary relief (Fig. 67.6) (112). The block is commonly performed percutaneously. The musculocutaneous nerve has minimal corticosensory representation. Percutaneous phenol injection of the musculocutaneous nerve therefore does not interfere with sensation in the upper extremity. The advantages of performing the musculocutaneous nerve block percutaneously are (a) it does not require general anesthesia; (b) because no surgery is required, it is more readily done; and (c) it provides only a partial blockade of the action of the biceps and brachialis muscle. The partial block preserves the potential for upper extremity functional training.

**Figure 67.6.** A percutaneous injection of the musculocutaneous nerve can be used to diminish temporarily spasticity of the biceps and brachialis muscles.

- Perform phenol injection of the musculocutaneous nerve using a Teflon-coated needle and a nerve stimulator.
- Introduce the needle from the medial aspect of the arm and pass between the lower edge of the short head of the biceps and the brachialis. In a spastic patient, this interval is easily identified.
- Move the needle while applying stimulation until the point of maximal response is noted.
- Inject 3 ml of an aqueous solution of 5% phenol at this location. Use an aqueous solution for percutaneous injections to provide better diffusion of the phenol.

**Wrist and Finger Flexor Spasticity**

- Treat spastic forearm flexor muscles causing wrist and finger flexion deformities during the physiologic recovery phase with botulinum toxin injection of the muscles or with phenol motor point blocks (37,70,71,72,200,205,240). Because of the large sensory components of both the median and ulnar nerves, direct injection of the nerves with phenol is undesirable.
- To localize the point of entry of the motor branches into the muscles, use surface electrical stimulation. Mark the points of maximal response on the skin.
- For insulation, insert at these points a needle coated with Teflon. Use additional stimulation to define the motor points of the muscles further.
- When the motor point has been localized, inject an aqueous solution of phenol at each site. Do not inject more than 5 points in a forearm in 1 day to avoid excessive swelling and inflammation.
- Residual spasticity and mild contracture are commonly present despite motor point blocks or botulinum toxin. The blocks can be supplemented with functional electrical stimulation of the wrist and finger extensor muscles and by casting or splinting techniques.
- Perform gentle passive range of motion of the wrist and fingers. When motor control is present, include a program of active exercise and functional training.

**Intrinsic Spasticity in the Hand**

Spasticity involving the intrinsic muscles of the hand is common but is usually masked by spasticity in the extrinsic finger flexors. An adducted thumb, limited extension of the metacarpophalangeal joints, or swan-neck positioning of the fingers should alert the physician to the possibility of underlying intrinsic spasticity. Botulinum toxin can be injected into the offending muscles. Alternately, a phenol block of the motor branches of the ulnar nerve in Guyon’s canal can be administered after surgical exposure (Fig. 67.7) (103, 104,115,122,131). The close proximity of the sensory branch of the nerve makes percutaneous injection undesirable because loss of sensation in the hand or painful dysesthesia could develop with phenol injection of the sensory nerve.

**Figure 67.7.** Isolation of the motor branches of the ulnar nerve distal to Guyon’s Canal. (Reprinted with permission from Keenan MA, Kozin SH, Berlet AC. Manual of Orthopaedic Surgery for Spasticity. New York: Raven Press, 1993.)

- Make an incision on the palmar surface of the hand radial to the pisiform bone and extend distally for 1 inch. Take care to prevent harm to the ulnar artery.
- Expose the ulnar nerve and identify the motor branches using a nerve stimulator. Generally, two motor branches are seen; the main branch lies beneath the sensory branch and a smaller motor branch can be seen entering the hypothenar muscles.
- Place a moistened gauze sponge under the nerves to be injected to protect the surrounding soft tissues.
- Inject the motor branch with 5% phenol in glycerin. Use phenol for surgical blocks when the nerve is being injected under direct vision. The glycerin allows the phenol to be released more slowly into the nerve, thereby prolonging its effect. The duration of the block lasts approximately 6 months.
- Unless combined with other surgery no splinting or casting is used postoperatively. Apply a soft dressing to the hand and begin active and passive exercises on the first postoperative day.

**Thumb-in-Palm Deformity**

The thumb-in-palm deformity is heterogeneous in appearance and may be secondary to spasticity of multiple muscles (19,48,104,143,144,186,193,199,204,220). If flexion of the interphalangeal joint of the thumb is present, then perform a botulinum toxin injection or a motor point block of the flexor pollicis longus (171). When the thumb is in a severely adducted position, use phenol for a surgical block of the motor branches of the ulnar nerve (122).

- When the adduction deformity of the thumb is also secondary to spasticity of the median innervated muscles of the thenar eminence, a phenol block of the recurrent motor branch of the median nerve can be performed (107). Perform the block percutaneously using a Teflon-coated needle and nerve stimulator.
- The recurrent motor branch of the median nerve enters the thenar mass at the junction of a line drawn along the radial border of the long finger and Kaplan’s cardinal line. Kaplan’s cardinal line is drawn parallel to the proximal palmar crease beginning at the apex of the first web space (Fig. 67.8).
Use a nerve stimulator and insulated needle to localize the nerve during the percutaneous injection. Then inject approximately 2 ml of aqueous phenol at the point of maximum response to stimulation.

Casting or splitting may be needed after the block if a contracture is present. Employ active and passive range of motion exercises. Perform functional training when any motor control is present in the upper extremity.

EVALUATION OF RESIDUAL LIMB DEFORMITIES

ASSESSMENT OF COGNITION AND COMMUNICATION

Upper extremity function requires complex and highly sophisticated mechanisms working together in unison. Improving upper extremity function requires careful systematic evaluation before surgery. The goals of surgery must be practical and clearly understood by the patient and the family. Assessment includes an evaluation of cognition and communication skills (15, 104, 117, 127, 133, 136, 231). The patient must be capable of following simple commands and should also be able to cooperate with a postoperative therapy program.

SENSORY EVALUATION

Intact sensation is essential to functional use of the hand (2, 14, 15, 17, 20, 25, 33, 48, 53, 65, 75, 77, 104, 105, 106, 107, 108, 126, 145, 146, 150, 158, 160, 164, 165, 183, 188, 199, 230, 231, 235). The basic modalities of pain, light touch, and temperature must be present. Two-point discrimination is a valuable predictive test. A patient rarely uses the hand for functional activities if the discrimination is greater than 10 mm. Proprioception and kinesiesthetic awareness of the limb in space are also important. Kinesiesthetic awareness is tested in a hemiplegic individual by placing the spastic limb in a position and asking the patient to duplicate this position with the sound limb while keeping the eyes closed. Stereognosis is not a practical test in spastic patients. They lack the fine motor control necessary to manipulate an object in the hand. It is helpful to observe the patient's spontaneous use of the hand. Visual perceptual deficits add increased problems involving motion of the limb and even awareness of the limb itself.

EVALUATION OF LIMB DEFORMITY AND FUNCTIONAL CAPABILITY

Diffuse axonal injury, multifocal vascular pathology, and diffuse hypoxic encephalopathy lead to a large variety of posttraumatic motor phenomena, many of which are functionally significant (Table 67.6). Lesions affecting the corticospinal system, the cerebellum and its pathways, and the extrapyramidal system are common. Hemiparesis is the most common long-term residual problem of head injury. Many patients, however, have a brain stem syndrome consisting of ipsilateral ataxia and contralateral spastic hemiparesis. A small percentage have a pseudobulbar athetoid type of picture. The literature also identifies patients with residuals of bilateral hemiparesis, ataxia involving both sides of the body, and severe dystonic decerebrate posturing or rigidity. Many patients, especially during the early recovery stage from head injury reveal mixed signs such as spasticity combined with tremor and ataxia. Peripheral neuropathy is common after head injury, and focal dystonias, although unusual, is also seen. Because so many different aspects of the motor control system may be affected by a head injury, we present a way of organizing the unyielding array of symptoms that emerge from a damaged nervous system. Our perspective is a practical one, namely taking into account the impact of movement disorders on the patient's ability to function in real life.

Table 67.7. Common Clinical Patterns of Motor Dysfunction in the Upper Extremity*
• Does the patient have voluntary control over a given muscle?
• Is the muscle spastic to passive stretch?
• Is the muscle, as an antagonist, activated during active movement generated by an agonist?
• Does the muscle have increased stiffness when stretched?
• Does the muscle have fixed shortening (contracture)?

When many muscles cross a joint, the characteristics of each muscle may vary. Because each muscle may contribute to motion and movement of the joint, information about each muscle's contribution is useful to the assessment as a whole. Treatment depends on such information (18, 145, 146).

Spasticity often masks underlying motor control. In the upper extremity, the most common pattern of spasticity is one of flexion. Passive range of motion of each joint should be established first. This is tested by slow extension of the joint to avoid the velocity sensitive response of the muscle spindle. When spasticity is significant and passive joint motion is incomplete, perform an anesthetic nerve block to assess whether a myostatic contracture is present (104, 105, 117, 118, 120). In order to evaluate passive joint motion in the entire upper extremity, perform a brachial plexus block using a local anesthetic.

Unmasking of primitive patterning reflexes further contributes to the motor impairment. Spasticity (hyperactive response to quick stretch), rigidity (resistance to slow movement), or movement dystonias may be present. The degree of spasticity within selected muscles can be graded clinically in response to a quick stretch as mild, moderate, or severe. There is surprising consistency between observers using this simple grading system. Another method of quantifying muscle tone, which is readily accessible and easily performed at the bedside, is to measure the amount of intramuscular pressure generated by a passive quick stretch or during functional use of the limb. Intramuscular pressure can be measured using a wick or slit catheter technique. The pressure generated within the muscle is proportional to the force of contraction (5, 182).

Motor control can be graded in the extremity using a clinical scale (Table 67.1) (112). The patient should be observed clinically in a variety of functional tasks.

### Laboratory-Assisted Assessment of Motor Control

Clinical examination supported by laboratory studies is the mainstay of evaluation. The clinical questions of interest regarding a given problem include the following:

• Does the patient have selective voluntary control over the given muscle?
• Is the muscle activated dysynergically (i.e., in antagonism to movement) when the patient attempts to move the relevant joint?
• Is the muscle resistive to passive stretch (i.e., spastic?)
• Does the muscle have fixed shortening (i.e., contracture)?

Given the degree of clinical effort, patient morbidity and procedural costs involved in treating complicated movement dysfunction in patients with CVA and TBI, clinical examination alone may not be sufficient to answer these questions with a high degree of confidence. Technology-driven laboratory assessments that may include formal gait and motion analysis, dynamic EMG studies, and nerve blocks may be helpful (105, 112, 117, 118, 120). Dynamic multichannel EMG is acquired with simultaneous measurements of joint motion (kinematics) in the upper extremity. Kinetic, kinematic, and dynamic EMG data assist the clinician in interpreting whether voluntary function (effort-related initiation, modulation, and termination of activity) is present in a given muscle and whether that muscle's behavior is also dysynergic (sometimes referred to as "out of phase" behavior). In addition, responses to different rates of passive stretch of muscle before and after local anesthetic nerve block can help the clinician distinguish between the dynamic, velocity-sensitive reflex resistance of spasticity versus passive muscle tissue stiffness and contracture. Somatosensory evoked potentials (SEPs) and motor evoked potentials (MEPs) provide information on the integrity of the sensory and motor pathways and may be helpful in predicting recovery of motor function after stroke (93). Combined with clinical information, laboratory measurements of muscle function often provide the degree of detail and confidence necessary for making conservative and surgical treatment decisions.

Combining the findings in several previous studies of spastic patients from our institution the following classification of EMG activity was devised to standardize terminology and may be used for either the upper or lower extremity (Table 67.8) (105, 112, 117, 118, 120).
ORTHOPAEDIC MANAGEMENT OF COMMON UPPER EXTREMITY DEFORMITIES

GENERAL CONSIDERATIONS

The patterns of limb spasticity seen following stroke and TBI are very similar. The same orthopaedic procedures can be used in both patient populations. The orthopaedic treatment interventions will be described together. These procedures, however, are not applied equally to both patient groups. The degree of spasticity, the timing of neurologic recovery, and the pattern of spontaneous neurologic recovery are different between stroke and brain-injured patients. These differences account for the variation in the need for specific treatments between the two groups.

Patients who have had TBI or stroke present unique challenges to the surgical team. The patients may have behavioral deficits or cognitive limitations that would make them difficult to manage with regional anesthesia and sedation. Therefore, general anesthesia is preferred (67,215). The patients often have previously had a tracheostomy performed; therefore, an anesthesia team familiar with airway difficulties caused by this procedure is important. Great care must be taken when positioning these patients for long procedures because contractures of other portions of their bodies may increase the risk of pressure ulcer formation.

![Fig. 67.3](image)

Anterior HO occurs spontaneously after TBI in 4% of patients. In these cases, the HO does not involve the collateral ligaments or the radio-capitellar joint (66). Releasing the pectoralis major may produce a cosmetic defect, but its release is necessary when there is anterior HO (65). Most do not require surgery. Awaiting normal development of the face and hand before surgery is favored (66). However, surgical correction is recommended if the deformity is severe or if there is a functional limitation. The surgical correction may involve an osteotomy of the humerus or a tendon transfer (66).

Fig. 67.3

Heterotopic Ossification

Results of HO resection are better with higher cognitive function and when volitional movement of the involved joint is present (68). In addition, surgical excision of functionally significant periarticular HO often results in significant improvements in range of motion, independence, and quality of life (62,63,69,132). Radiographically immature lesions also have a higher rate of recurrence (18,47,60,62,63,69,111,127,132,147,157,199). It may not be feasible or desirable to allow the HO to reach maturity before resection, because although the risk of recurrence is higher, ankylosis of the joint and subsequent contracture worsen the overall functional result.

Shoulder Incidence of shoulder and elbow HO is similar in some reports (69), whereas elbow HO predominates in others (69,132,157). Shoulder HO radiographically appears to form intramedial to the joint. This can be deceiving and computed tomography may be needed to localize the abnormal bone. When the bone is located anterior to the joint, use a deltopectoral incision. When it is necessary to resect a shoulder HO, it may also be necessary to release or lengthen internal rotators simultaneously without entering the joint capsule (63,127,132). Releasing the pectoralis major may produce a cosmetic defect, but its release is necessary when there is a severe internal rotation and adduction deformity. Close the wound in layers over a drain. When the HO is located posterior to the shoulder, it commonly follows the teres major from the scapula to the posterior humerus; therefore, use a posterior approach. Great care must be taken to identify the axillary nerve in normal tissue because it is commonly encased within the mass of heterotopic bone and is easily transected. Following HO resection begin range-of-motion exercises immediately. Following HO resection begin range-of-motion exercises immediately.

Elbow HO occurs spontaneously after TBI in 4% of patients. In these cases, the HO does not involve the collateral ligaments or the radio-capitellar joint (Fig. 67.3). Even when joint ankylosis occurs, forearm rotation is maintained (63,127,132). HO forms in 90% of fractured or dislocated elbows in head injured adults (73). When HO follows trauma, it commonly forms in the collateral ligaments and may involve the radio-capitellar joint. Consider prophylactic treatment with either anti-inflammatory agents, diphosphonates, or radiation in patients with concurrent head injury and elbow trauma. When elbow HO does form, tardy ulnar nerve palsy should be suspected, particularly when the bone is located medial or posteromedial (113). Elbow HO occurs in 20% of patients with TBI and forearm fractures (69). Anterior HO

| Class I | Normal EMG Activity |
| Class II | Presence of Phasic Activity |
| Class III | Maximal Phasic Activity |
| Class IV | Continuous Activity |

**Table 67.8. Classification of Electromyographic Activity**

- Class I constitutes a normal phasic pattern with appropriate on and off EMG activity.
- Class II consists of EMG activity that, although phasic, begins prematurely and continues for a short period beyond the normal duration of activity for that muscle. This is more commonly seen in the lower extremity.
- Class III consists of phasic activity with prolongation beyond the normal timing of the muscle. Class III activity can be further subdivided into three patterns, depending on the degree of prolongation.
- Class III A consists of phasic activity with a short period of low-intensity EMG activity extending into the next phase of the flexion-extension cycle secondary to mild spasticity.
- Class III B consists of phasic activity with prolongation extending for at least half of the next phase of motion. This is indicative of a moderate amount of spasticity.
- Class III C represents a severely spastic muscle and consists of phasic activity with severe prolongation in which EMG activity is continued throughout the next phase of motion at a high intensity but the underlying phasic nature of the muscle activity is still distinguishable.
- Class IV consists of continuous EMG activity without phasic variations.
- Class V consists of EMG activity seen only in response to a quick stretch by the antagonist muscles. There is no volitional activation of the muscle. This pattern is common in the finger extensors.
- Class VI consists of absent EMG activity.
occurs roughly one third as often as posterior HO, with a posterolateral location the most frequent. Surgical approaches for elbow HO are posterolateral, medial, and anterolateral. Base the decision on which approach to use on plain radiographs, computed tomography with or without three-dimensional reconstructions, and the need to decompress any nerves. Unfortunately, delaying surgical excision for the suggested 12 to 18 months often results in severe elbow impairment. Even with this delay, however, recurrence is common.

Posterior HO is palpable subcutaneously. It extends between the lateral humeral condyle and the lateral olecranon. The elbow is commonly ankylosed in mild flexion. When excising the HO, it is helpful to resect the central bridge first, allowing some motion of the elbow and exposure of the posterior fat pad. Once motion is obtained, the landmarks can be identified more easily and the remainder of the HO can be resected from the humerus and olecranon. Preserve the fat pad to prevent recurrent contracture.

A medial approach is indicated when ulnar nerve transposition is necessary, when posterior HO extends medially, or when HO of the medial collateral ligament limits motion in this approach. The ulnar nerve is identified proximally and protected. Occasionally, as the nerve is followed distally, it will dive through a gap between posterior and medial HO. If it is thus encircled, it must be freed and transposed anteriorly before HO resection.

Anterior HO generally forms in the midline and follows the brachialis to the coronoid. If the biceps is involved, proximal forearm synostosis may occur. With anterior HO the elbow is most often fixed in 90° of flexion. The anterolateral approach allows exposure of the HO, identification of the radial and median nerves, and the brachial artery. Should lengthening of the brachialis and biceps be necessary, this is also facilitated by this approach. First, resect the central bridge, establishing motion, then extend the elbow and resect the remnants. Anterior capsular release may be performed if necessary. Close wounds over drains in layers. Following resection of elbow HO, arc of motion averages 65°. Complications of resections include wound breakdown, posterior interosseous nerve palsy, and re-ankylosis.

Forearm Radioulnar synostosis can result in a profound decrease in upper extremity function. Often occurring following trauma, radioulnar HO can be particularly troublesome. When it is present, the posterolateral incision can be extended along the posterolateral border of the proximal ulna to gain access for removal. Remember that less extensive dissection minimizes the chances of a recurrence.

SHOULDER

The paretic shoulder deserves special attention because it is a common source of pain. A variety of different factors contribute to the painful, immobile shoulder: RSD; brachial plexitis; inferior subluxation; spasticity with adduction, internal rotation contracture; adhesive capsulitis; spastic abduction; HO; and traumatic lesions, such as rotator cuff tears or fractures and dislocations.

Adhesive Capsulitis

Adhesive capsulitis is commonly seen in patients following stroke and in those with RSD. They have a characteristically painful shoulder with limited glenohumeral motion. Three clinical and four arthroscopic stages have been identified. Brachial plexopathy must be ruled out by using diagnostic EMG.

Inferior subluxation of the shoulder is a common occurrence in patients with flaccid paralysis of the shoulder girdle. This is most commonly seen in stroke patients or in brain-injured patients with concomitant brachial plexus trauma. The subluxation is usually self-limiting, but occasionally, the shoulder will be chronically subluxated, causing pain. The patients typically have no functional use of the extremity. Patients complain of increased pain when upright. The pain may be due to chronic stretch on the shoulder capsule or from traction on the brachial plexus. Physical examination shows a positive sulcus sign, with little to no active motion of the involved shoulder. There is a prominence of the acromion and atrophy of the deltoid. There may be contracture of the shoulder in adduction and internal rotation. Subacromial or intra-articular injections of local anesthetics do not relieve the symptoms. Radiographs show inferior subluxation of the humerus on the glenoid.

Conservative treatment may include electrical stimulation to the deltoid and supraspinatus muscles use of a sling. This relieves the symptoms by elevating the humeral head in the glenoid. Although this technique is usually successful in the short run, it is frequently unacceptable to the patient as a permanent solution. A surgical approach was developed by Halsey and Keenan. This consists of the following steps:

- Arthroscopic capsular release may be performed for adhesive capsulitis. Perform capsular release via a three-portal technique, with a standard anterior port and two posterior ports, one just above and one just below the posterior soft spot.
- Release the posterior superior capsule using the posterior superior port for a straight punch, with the arthroscope in the anterior port.
- Establish the posterior inferior port and with the arthroscope in the superior port, use a straight punch through the inferior port to release the inferior capsule. Take care to dissect the inferior capsule away bluntly from the underlying tissue to avoid injuring the axillary nerve.
- Begin range-of-motion exercises immediately. These exercises may be facilitated by a long-acting interscalene block. Botulinum toxin injections or phenol blocks of spastic shoulder muscles also facilitate the postoperative rehabilitation.

![Figure 67.10. AP radiographs of the shoulder in a patient with painful inferior subluxation before and after biceps suspension. Note inferior subluxation of the humerus preoperatively (A) with reduction after surgery (B). (With permission from Halsey MS, Keenan MAE. Orthopaedic Management of Upper Extremity Dysfunction Following Stroke or Brain Injury. In Green DP, Hotchkiss RN, Pederson WC, eds. Operative Hand Surgery, 4th ed. New York: Churchill Livingstone, 1998:287.)](image)
solution to this problem of excessive laxity is the biceps suspension procedure (Fig. 67.11).

Figure 67.11. The biceps suspension procedure.

Several procedures have been described to treat paralytic inferior subluxation of the shoulder, but none has gained widespread acceptance. Braun (31) has advocated using the coracoacromial ligament to suspend the humeral head. The lateral portion of the coracoid process together with the coracoacromial ligament is detached and transferred to the humeral head, where it is fixed using a cancellous lag screw. Garland has advocated detaching the proximal end of the long head biceps tendon, looping the tendon over the clavicle and securing it back on itself. With time, the paretic biceps muscle tends to stretch and the humerus once again subluxates inferiorly. Shoulder arthrodesis has also been performed but is not well accepted by the patient because it produces a rigid joint, which interferes with passive positioning, hygiene, and nursing care.

The Biceps Suspension Procedure

- Place the patient in the beach chair position with a small bolster under the scapula.
- Use a standard deltopectoral approach. If the pectoralis major is causing an adduction or internal rotation deformity, release it at its insertion.
- Identify the musculotendinous region, where the tendon of the long head of the biceps joins the muscle belly. Take care to preserve the musculocutaneous nerve, which enters the medial aspect of the muscle.
- Detach the long head of the biceps. To obtain the greatest length of tendon, attach the distal, muscular portion of the long head of the biceps to the conjoined tendon medially to preserve elbow flexion and supination strength. Then dissect the proximal portion of the long head of biceps tendon in the biceps groove and rotator interval. It is important to direct the biceps tendon in the groove in order to pull the humeral head proximally and medially during final tensioning of the graft and reduction of the glenohumeral joint (Fig. 67.11).
- Use a burr to drill a hole in the humeral neck in an anterior to posterior direction, just distal to the biceps groove. Burr a second hole in the proximal portion of the biceps groove, between the greater and lesser tuberosities. Use an angled curet to connect the two holes, forming a bony tunnel in the proximal humerus. Place a braided, nonabsorbable traction suture in the distal portion of the biceps tendon. Use a wire loop to pass the tendon from proximal to distal through the tunnel.
- Position the arm with the humeral head reduced in the glenoid and the arm in 30° of internal rotation. Using the suture, attach the distal tendon back to the proximal tendon, thus creating a suspensory loop of biceps tendon. Protect the repair in a sling for three months to allow bone-to-tendon healing.

Spastic Abduction

Overactivity of the supraspinatus muscle can cause spastic abduction posturing. The deformity is usually dynamic, becoming more prominent with ambulation, transfers, or other attempted activities (Fig. 67.12). The affected arm is held in an abducted posture, making balance while ambulating difficult. Patients complain that their balance is thrown off because of bumping into furniture, doorways, and people in crowds. Diagnosis requires examination of the patient at rest and during a variety of activities. It is also helpful to elicit from care takers or family members any history of activities that trigger this posture. Use dynamic EMG to confirm that spasticity of the supraspinatus muscle is causing the deformity.

Figure 67.12. Dynamic EMG of shoulder muscles in a patient with spastic abduction of the shoulder. Although standing causes a mild increase in activity of the deltoid muscle, the supraspinatus exhibits severe spasticity and is the cause of the dynamic abduction deformity.

The Supraspinatus Slide

It is possible to lengthen the supraspinatus effectively by means of a slide procedure. This procedure has been used successfully to correct spastic abduction deformity.

- Place the patient in the lateral decubitus position, with the affected extremity uppermost. To protect the brachial plexus, place an axillary roll in the unaffected axilla and ensure that all bony prominences are well padded.
- Make a 10 to 15 cm incision parallel to the scapular spine.
- Detach the trapezius insertion from the spine of the scapula, leaving a cuff of fascia for later reattachment (Fig. 67.13).

Figure 67.13. The supraspinatus slide procedure for spastic abduction of the shoulder.
Retract the deltoid laterally. Using a small periosteal elevator, elevate the origin of the supraspinatus subperiosteally from the medial border of the scapula. Continue the dissection laterally, taking care to avoid injury to the neurovascular pedicle at the suprascapular notch. Allow the muscle to slide laterally.

Reattach the trapezius to the scapular spine. The remainder of the closure is performed in routine fashion. Allow the patient full, unrestricted postoperative motion.

The Adducted and Internally Rotated Shoulder

The arm is adducted tightly against the lateral chest wall, and shoulder internal rotation causes the forearm to lie against the middle of the chest. The tendon of pectoralis major is often prominent when the examiner attempts to abduct and externally rotate the shoulder but other muscles contribute to the deformity. The glenohumeral joint normally functions as a universal joint, enabling the hand to reach an almost spherical volume of locations in three-dimensional space. When patients attempt to reach forward, spastic adductors and internal rotators can severely restrict acquisition of targets in the environment and on the body. The patient's ability to stabilize, push, or apply force to an object is also compromised. From the perspective of passive function goals such as skin care and axillary hygiene, spastic adductors and internal rotators hinder efforts of caregivers to gain access to the axilla to provide needed care. Restricted motion may impair dressing, washing, and bathing, and promote skin irritation and maceration. Passive manipulation of the shoulder during personal care may cause pain and trigger spastic resistance in reactive muscles.

Muscles that contribute to spastic adduction and internal rotation dysfunction of the shoulder include latissimus dorsi, teres major, the clavicular and sternal heads of pectoralis major, and subscapularis. Involvement of latissimus dorsi and teres major should be considered when hyperextension posturing of the shoulder is observed. Antagonistic activity in these muscles may be masking a patient's potential for active flexion. Diagnostic lidocaine block to the thoracodorsal nerve or the lower subscapular nerve may unmask that voluntary potential. When the pectoralis major is chronically spastic, the musculotendinous insertion of pectoralis major is prominent and tight. However, the two heads of this muscle may be differentially spastic, and EMG recordings from each or diagnostic lidocaine blocks to medial and lateral pectoral nerves may help to distinguish whether one or both heads are pathophysiologically active. Release of all four muscles may be required to relieve the deformity in a nonfunctional extremity. In patients who have evidence of underlying control of muscle function despite the presence of dyssynergy, the pectoralis major, latissimus dorsi, and teres major muscles can be fractionally lengthened at their muscle tendon junctions. Alternately, the teres major muscle can be partially released from its origin on the scapula and allowed to slide distally in the same manner as the supraspinatus slide.

Anterior Shoulder Release

- Place the patient in a slight beach chair position with a small bolster under the scapula. Prep and drape the arm so that the entire arm and shoulder are accessible.
- Make an incision on the anterior shoulder beginning at the coracoid process and extending distally for approximately 7 cm.
- Identify the tendinous insertion of the pectoralis major tendon and use electrocautery to release it near its insertion (Fig. 67.14).

- Expose the subscapularis and isolate it from the shoulder capsule near its insertion on the humerus. Release the subscapularis muscle without violating the glenohumeral joint capsule (Fig. 67.15).

Figure 67.15. Anterior shoulder release for internal rotation and adduction deformity. Isolation and release of subscapularis muscle. (Reprinted with permission from Keenan MA, Kozin SH, Berlet AC. Manual of Orthopaedic Surgery for Spasticity. New York: Raven Press, 1993.)

- Do not open the joint capsule or instability, or intra-articular adhesions may result.
- After identifying the latissimus dorsi and teres major muscles through the interval between the short head of the biceps and deltoid musculature, release these deforming muscles (Fig. 67.15).
- Place a drain deep into the wound prior to closure.
- Postoperatively, institute an aggressive mobilization program following skin healing and employ gentle range-of-motion exercises to correct any remaining contracture. Careful positioning of the limb in abduction and external rotation is necessary for several months to prevent recurrence.

Fractional Lengthening of the Shoulder Muscles

- Place the patient in a 45° lateral position. Prep and drape the arm so that the entire arm and shoulder are accessible.
- Make an incision on the anterior shoulder directly over the palpable insertion of the pectoralis on the humerus. Retract the pectoralis major muscle upwards to visualize the muscle tendon junction on its undersurface near its insertion on the humerus. Sharply transect the tendinous fibers as they overlie the muscle belly. This allows the tendon to slide distally on the muscle belly while maintaining the integrity of the muscle tendon unit.
- Make a second incision over the posterior axillary fold and identify the latissimus dorsi and teres major muscles at their insertion's on the humerus. Again, sharply transect the fibers of the tendons overlaying the muscle bellies.
- Close the wounds in a routine fashion.
- Postoperatively, employ a sling for comfort for 2 to 3 weeks, and begin gentle active assisted range-of-motion exercises on the first postoperative day. Further lengthening of the muscles will occur with functional use of the arm during the next several weeks.

ELBOW

Spastic Flexion

Upright posture favors hypertonia in the “antigravity” elbow flexors of the upper limb. In the patient without motor control, severe flexion posturing can lead to skin maceration in the antecubital fossa, malodor, and skin breakdown. In reality, a continuum of volitional control is seen. Many patients complain that their elbows persistently “ride up” when they stand up and walk. They also complain that their flexed elbow hooks door frames and other people, and that putting on a shirt or jacket is a struggle. Kinesiologically, the elbow lengthens and shortens the upper extremity. Consequently, active dysfunction is characterized by impaired reaching for objects in the environment, placing them elsewhere or bringing them to the body.
Functional Elbow Lengthening: Control of limb placement depends on both shoulder and elbow control. Smooth control of elbow flexion and extension is frequently impaired. The usual clinical picture is one of cogwheel motion on attempted extension of the elbow. Elbow extension range is often limited with a very prolonged period of extension. Elbow flexion is relatively normal. Laboratory examination using dynamic EMG helps to confirm the presence of volitional capacity as well as dysynkinesia during movement for each of the elbow flexors. Obtain dynamic recordings from biceps, brachialis, brachioradialis, lateral, medial, and long head of the triceps. Dynamic EMG combined with electromyographic measurement of elbow motion of stroke and TBI patients has revealed a consistent pattern of muscle activity responsible for this clinical picture (112,116). The pattern most commonly seen is that all three heads of the triceps muscle are operating in a normal phasic pattern. The brachioradialis muscle most frequently shows continuous spastic activity. One or both heads of the biceps muscle are also spastic. Less spasticity is observed in the brachialis muscle. This pattern of muscle activity is also common in patients with cerebral palsy. Armed with this information, a rational surgical plan can be devised to improve elbow control.

Fractional (myotendinous) lengthening is preferred whenever possible in spastic muscles. This allows the underlying tone and strength of the muscle to determine the amount of lengthening rather than having the surgeon estimate this elusive quantity. Lengthening over the muscle belly eliminates the need for suturing, and this diminishes the amount of scarring that occurs. A new tendon reforms and fills in the gap within several months. The fractional lengthening technique allows the patient to begin gentle active motion immediately after surgery because the muscle tendon unit remains intact. In contrast, a Z-lengthening technique requires immobilization for a minimum of 4 weeks to allow healing of the relatively avascular tendon and prevent inadvertent rupture.

Three methods are available to decrease tone in a spastic brachioradialis. Surgical lengthening of the brachioradialis can be used if volitional control is demonstrated on EMG. If little or no control is demonstrated, release of the severely spastic brachioradialis muscle at the level of the elbow may be performed. Lengthening of the spastic biceps and brachialis muscles as indicated by dynamic EMG is also performed to improve elbow motion and hand placement. Meals has advocated neuroectomy of the radial nerve branches to the brachioradialis (151). This technique would not correct an established contracture of the brachioradialis.

**Technique of Functional Elbow Lengthening**

- **Beginning with the biceps**, make a longitudinal incision over the anterior arm starting just distal to the lower edge of the pectoralis major tendon and extending distally 5 cm.
- **Expose the muscle tendon junction of both the long and short heads of the biceps**. Then sharply transect the tendons directly overlying the muscle belly.
- **Close the incision in a routine fashion**.
- **Apply a sterile tourniquet to the upper arm and inflate after exsanguination of the limb**.
- **Make a curved incision on the volar aspect of the elbow in the antecubital space**. Begin the incision over the lateral border of the biceps muscle, pass medially across the antecubital crease and gently curve distally onto the anteromedial aspect of the forearm.
- **Divide the lacertus fibrosis and expose the biceps tendon**. Retract the biceps tendon to expose the underlying brachialis muscle. Sharply transect the broad band of tendinous fibers on the anterior surface of the brachialis muscle, leaving the underlying muscle tissue intact. Then extend the elbow, fractionally lengthening the brachialis by approximately 1 cm (Fig. 67.16).

**Figure 67.16.** Fractional lengthening of the long and short heads of the biceps at their proximal musculotendinous junction.

- In the presence of a severe rigid contracture, it may be necessary to perform a Z-lengthening of the biceps tendon. Make a Z-step cut for the entire length of the biceps tendon. Then suture the ends of the biceps tendon in a lengthened position using a nonabsorbable suture.
- **Close the subcutaneous tissues and skin edges over a drain**.
- **In patients who have volitional function in the brachioradialis, fractionally lengthen the muscle at the myotendinous junction**.
- **Make a separate 3 cm longitudinal incision on the radial aspect of the forearm to identify the myotendinous junction of the brachioradialis**. Roll the muscle, exposing its deep surface. Here the tendon extends more proximally. Sharply transect the tendinous fibers, allowing the brachioradialis to lengthen.
- **If preoperative nerve conduction studies have shown an ulnar neuropathy at the level of the elbow, perform anterior transposition of the ulnar nerve**.
- **Close the incision over a drain in a routine manner**.
- **When the biceps has been lengthened proximally, no immobilization is needed**. Remove the drain within the first 24 hours following surgery and begin active range-of-motion exercises. Allow no resistive exercises for 3 weeks to prevent overlengthening of the muscles with resulting weakness. If a Z-lengthening of the biceps tendon was done distally, place the patient in a posterior splint with the elbow in 90° of flexion for 4 weeks to protect the biceps tendon repair. Functional elbow flexor lengthening has significantly enhanced the fluid control of elbow motion and improved hand placement in properly selected patients.

**Nonfunctional Elbow Release** Persistent spasticity of the elbow flexors causes a myostatic contracture and flexion deformity of the elbow. This results in skin maceration and breakdown of the antecubital space (115,116,129). This position of severe elbow flexion also predisposes the ulnar nerve to an acquired compression neuropathy by increasing the vulnerability to direct pressure and decreasing the cross sectional area of the cubital tunnel (113,214). Perform surgical release of the biceps tendon and brachioradialis muscle combined with lengthening or release of the brachialis, depending on the severity of the contracture. The joint capsule is generally not released. Gradual extension of the elbow with serial casting or physical therapy corrects the preoperative deformity and decreases the ulnar nerve compression. Anterior transposition of the ulnar nerve may be necessary to improve ulnar nerve function further.

- **Make a curved incision on the volar aspect of the elbow in the antecubital space**. Begin the incision over the lateral border of the biceps muscle, pass medially across the antecubital crease, and gently curve distally onto the anteromedial aspect of the forearm. When the contracture is severe and long standing, use a straight longitudinal incision to facilitate wound closure.
- **Dissection develops the interval between the brachioradialis and the biceps musculature**. Identify and protect the radial nerve.
- **Using electrocautery, transect the brachioradialis through its muscle belly proximally** (Fig. 67.17). Transect the biceps tendon and lacertus fibrosis at the level of the elbow.

**Figure 67.17.** Release of a nonfunctional elbow flexion contracture. The biceps tendon is transected. The brachioradialis muscle belly is divided proximally using electrocautery. The brachialis muscle is fractionally lengthened. (With permission from from Keenan MA, Koizin SH, Berlet, AC. Manual of Orthopaedic Surgery for Spasticity. New York: Raven Press, 1993.)

- **When the deformity is not severe, lengthen the brachialis muscle at its myotendinous junction by transecting the tendinous fibers on the anterior surface of the muscle, leaving the underlying muscle intact**. Leave the remainder to counterbalance any pull by the triceps muscles.
When the elbow flexion contracture is severe and has been present for many years, it may be necessary to completely transect the brachialis muscle.

Avoid an anterior capsulodesy because of the associated increased stiffness and intra-articular adhesions postoperatively.

If preoperative nerve conduction studies have shown an ulnar neuropathy at the level of the elbow, perform an anterior transposition of the ulnar nerve.

Close the skin incision over a drain in routine manner. Approximately 50% correction of the deformity can be expected at surgery without causing excessive tension on the contracted neurovascular structures. Serial casting or drop out casts can be used to obtain further correction over the ensuing weeks (117,103,108,133).

**Spastic Extension**

Spastic extension of the elbow is much less common than spastic flexion. These patients have frequently had a brain stem infarct or injury. They complain of difficulty reaching their face for activities of daily living.

**Triceps Lengthening**

Experience with triceps lengthening for spasticity is limited because it is an uncommon problem. When needed, however, good results have been reported with surgical lengthening (157). A V-Y triceps plasty allows improved flexion range of motion, at the cost of decreased extension power and extensor lag. Use this procedure with caution in patients who rely on their arms to assist with ambulation or transfers because strength is lost with any lengthening procedure.

**Ulnar Neuropathy**

Ulnar neuropathy occurs in stroke and brain-injured patients for a number of reasons. Prolonged elbow flexion with traction on the nerve can lead to decreased volume of the cubital tunnel, resulting in nerve compression. Support of the torso by leaning on a chronically flexed elbow may result in direct compression of the nerve. HO, particularly when it is in a posterior location, may involve the ulnar nerve causing a neuropathy. The patients are often limited in their ability to complain about ulnar nerve symptoms because of limited cognitive and communicative abilities. The diagnosis is usually suspected because of intrinsic atrophy, and it is confirmed using nerve conduction studies. A 2.5% incidence has been shown in patients with TBI at a large brain injury referral center (113,214).

Treatment is ulnar nerve transposition, often at the same time as elbow flexor lengthenings, flexor releases, or resection of HO. Subcutaneous transposition is preferred to avoid stimulation of HO formation.

**FOREARM**

Pronation and pronation deformities are commonly associated with elbow spasticity, wrist spasticity, or both. Pronation deformities are much more common. These deformities are most often treated together with the associated deformities. They seldom require treatment individually.

**Spastic Pronation**

Pronation deformity of the forearm in an UMN lesion is more common than supination deformity. Pronation bias makes it difficult for a person to reach for a target underhand, whereas supination deformity impairs reaching for targets that require overhand reach. Many activities of daily living depend on active supination. The use of feeding and grooming utensils and clothes fasteners becomes problematic when spastic or contracted pronators restrict supination. Physical examination reveals a fully pronated resting position of the forearm. When passive supination range of motion exceeds active supination range, the possibility of pronator muscle dyssynergy during active supination should be suspected. Muscles that potentially contribute include pronator teres and pronator quadratus. Dynamic EMG studies of pronator teres, pronator quadratus, and biceps greatly augment clinical examination. Clinical examination does not easily predict which of the pronators might be retaining volitional capacity and which might be spastic. Both pronator muscles may show varying degrees of volition and spasticity. Interestingly, flexor spasticity of the powerful biceps often coexists with a pronated forearm deformity.

During the period of functional recovery, phenol or botulinum toxin may be injected into either or both pronators, depending on clinical and laboratory analyses. In the period of residual deficits, surgical lengthening of pronator teres and pronator quadratus may be performed depending on their individual voluntary capacities and the clinical goal is to improve active supination function by reducing pronator dyssynergy. The possibility of lengthening the pronator teres has long been recognized, but fractional lengthening of the pronator quadratus is of recent vintage. Release of the flexor-pronator origin was previously a common operation. We do not advocate this procedure because it does not target the individual muscles responsible for deformities. When an excessive amount of the pronator teres origin was released or when there was no function in the pronator quadratus muscle, an iatrogenic supination deformity occurred. The supination deformity was much less functional than a pronated forearm. When the pronators are contracted and not active volitionally, muscle releases may be considered, although passive functional advantages, other than cosmesis, may be difficult to come by.

**Fractional Lengthening of the Forearm Pronators**

Approach the pronator teres in the interval between the mobile wad and the flexor carpi radialis in the midforearm. Take care to preserve the superficial radial nerve and radial artery that occupy this interval.

Identify the pronator teres as it inserts on the radius. Perform myotendinous lengthening by cutting the tendinous fibers of the musculotendinous junction and allowing the tendon fibers to slide on the muscle belly, thereby lengthening the muscle tendon unit.

When dynamic EMG has demonstrated that the pronator is spastic but does not have any volitional activity, release the pronator from its insertion on the radius. In either case, take care not to extend the dissection proximally into the supinator to avoid injury to the posterior interosseus nerve.

Approach the pronator quadratus via an incision over the volar aspect of the forearm just proximal to the wrist crease.

Retract the finger flexor tendons radially to expose the broad myotendinous junction of the pronator quadratus. Transect the tendon fibers, leaving the underlying muscle fibers intact. Then supinate the arm, separating the ends of the tendon fibers and lengthening the pronator quadratus (Fig. 67.18). When the pronator quadratus is contracted and does not have any functional capacity, transect to eliminate it as a deforming force.

**Spastic Supination**

Spastic supination is a far less common deformity but is also associated with elbow flexion deformities. Most often, this deformity is seen as a complication of the surgical flexor-pronator origin release. The biceps, supinator, or both may cause supination deformity. Physical examination supplemented by dynamic EMG may be used to determine the relative contribution of each.

Perform correction of the supination deformity in conjunction with correction of the elbow flexion deformity. As described previously, in the functional extremity, perform a biceps Z-lengthening. In a nonfunctional extremity, perform a distal biceps release. Often, at the conclusion of this procedure, the arm is able to achieve a functional range of pronation. If not, attention must be turned to the supinator.

- Lengthen the supinator by elevating the insertion from its radial insertion. Use a standard anterior approach to the elbow and proximal radius. An extension of the approach, as noted for the elbow release, is generally used.
- Approach the supinator in the plane between the brachialis and the brachioradialis.
Wrist Flexor Release and Wrist Fusion

Extrinsic finger flexors after dynamic EMG reveals whether the FDS or FDP is generating antagonistic activity acting to restrain wrist extension. Motor point block of the

EMG activity in FCR is often present during attempts at wrist extension, and activity in FDS or FDP may be present. In patients with ulnar deviation, EMG activity is typically seen in FCU on reaching effort, but "isolated" testing also suggests that patients can often activate FCU voluntarily. Because EMG activity is not correlated with force production, diagnostic nerve blocks are often helpful in unmasking movement. Temporary chemical "weakening" of a dyssynergic wrist flexor may unmask strength in the wrist extensors sufficient to improve active wrist motion. A similar hypothesis can be used for the extrinsic finger flexors after dynamic EMG reveals whether the FDS or FDP is generating antagonistic activity acting to restrain wrist extension. Motor point block of the

To eliminate the need for a wrist orthosis after surgery. Splints tend to be lost by these patients and their caretakers. Gravity alone can cause a recurrence of the flexion

When a patient has underlying voluntary control, surgical treatment for flexed and hyperextended wrists are myotendinous lengthenings. Selective muscle releases, wrist fusion, and proximal row carpectomy can be considered in the presence of severe deformities. Subtotal carpectomy combined with radio-carpal or radio-metacarpal fusion has been suggested for the treatment of severe flexion contracture either not amenable to, or refractory to, soft-tissue releases alone (185, 186).

In patients with a severely contracted hand, a single-stage procedure consisting of superficialis-to-profundus transfer, wrist flexor release, FPL lengthening, wrist arthrodesis, carpal tunnel release, and ulnar motor branch neuroectomy or intrinsic release can provide comprehensive correction. Such a definitive approach to severe deformities is associated with acceptable morbidity and eliminates the possibility of recurrence or undercorrection from untreated intrinsic pathology (189).

Spastic forearm muscle fibers causing wrist and finger flexion deformities are treated during the physiologic recovery phase by phenol motor point blocks (70, 71 and 72). Because of the large sensory components of both the median and ulnar nerves, perform motor point injections of the wrist and finger flexors using surface stimulation to localize the motor points. The blocks can be supplemented with functional electrical stimulation of the wrist and finger extensor muscles, and by casting or splinting techniques. Perform gentle passive range of motion of the wrist and fingers. When motor control is present, a program of active exercise and functional training is also employed. Electrical orthoses, which rely on functional electrical stimulation (FES), are available and have been shown to provide improvement in hand function in people with spinal cord injury or stroke. These devices are still in their early stages of development; however, technical advances in the field of FES provide hope for more widespread applicability in the future.

Fractional Wrist Flexor Lengthening

In an extremity with documented volitional control, perform fractional lengthening of the appropriate wrist flexors. This is done in conjunction with lengthening of the extrinsic finger flexors, when indicated.

- Make a longitudinal incision on the volar surface of the forearm. Extend this incision distally if a carpal tunnel release is necessary. Divide the palmaris longus tendon if it is tight.
- Perform myotendinous lengthening by transecting the tenosynovial portion overlying the myotendinous junction (Fig. 67.19).

- Do not use immobilization after surgery. Begin a program of active exercise immediately. Don't allow passive stretching of the wrist for 3 weeks. Resistive exercises can be started 6 weeks after surgery.

Wrist Flexor Release and Wrist Fusion

When wrist flexion deformities are severe and there is little or no function seen in the hand, perform a release of the wrist flexors. A proximal row carpectomy may be useful in patients with severe, long-standing contracture to correct the deformity. Then stabilize the wrist with a wrist fusion to eliminate the need for a wrist orthosis after surgery. Splints tend to be lost by these patients and their caretakers. Gravity alone can cause a recurrence of the flexion deformity. Unopposed wrist or finger extensor tone can result in a hyperextension deformity. Because the median nerve is compressed against the proximal transverse carpal ligament causing a painful neuropathy, perform a carpal tunnel release as well.

- Position the patient supine and apply an arm tourniquet.
- Make a volar incision extending to the transverse carpal ligament.
- Identify and transect the tendons of the palmaris longus, flexor carpi radialis, and flexor carpi ulnaris. Take care to protect the radial and ulnar artery as well as the median, radial, and ulnar nerves.
- Perform carpal tunnel release.

- Identify and transect the tendons of the palmaris longus, flexor carpi radialis, and flexor carpi ulnaris. Take care to protect the radial and ulnar artery as well as the median, radial, and ulnar nerves.
- Perform carpal tunnel release.

- Make a volar incision extending to the transverse carpal ligament.
- Identify and transect the tendons of the palmaris longus, flexor carpi radialis, and flexor carpi ulnaris. Take care to protect the radial and ulnar artery as well as the median, radial, and ulnar nerves.
- Perform carpal tunnel release.

- Position the patient supine and apply an arm tourniquet.
- Make a volar incision extending to the transverse carpal ligament.
- Identify and transect the tendons of the palmaris longus, flexor carpi radialis, and flexor carpi ulnaris. Take care to protect the radial and ulnar artery as well as the median, radial, and ulnar nerves.
generally seen in the extensor indicis proprius muscle first. With the flexor muscles relaxed, the activity of the extensor muscles can be more accurately evaluated. When extensor control returns, it is important to assess whether there appears to be active control of finger flexion. In the continuum of neurologic impairment and recovery, control of wrist and finger flexion is seen before active control of finger extension. Place a finger in the patient's palm and ask the patient to grasp. Often, an increase in the pressure of grasp can be felt indicating underlying muscle control.

The degree of motor control may be masked by the severe amount of tone present in the finger flexors. First, establish passive range of motion. Following this, ask the patient to open and close the fingers and to flex and extend the wrist. If no active wrist or finger extension is seen, it is still important to assess whether there appears to be active control of finger flexion. In the continuum of neurologic impairment and recovery, control of wrist and finger flexion is seen before active control of extension. Place a finger in the patient's palm and ask the patient to grasp. Often, an increase in the pressure of grasp can be felt indicating underlying muscle control.

Next, perform an anesthetic block of the median nerve in the antecubital space to eliminate flexor tone temporarily. A block of the ulnar nerve in the cubital canal can be used to help assess extension deformities. The fingers are typically clasped into the palm. Fingernails may dig into palmar skin, and access to the palm for washing may be compromised. When access is needed, insert a finger into the palm of the hand. Some relaxation of finger tightness may occur if the wrist is positioned in extreme flexion. The deformity, however, is often accompanied by wrist flexion as well.

Spastic Clenched Fist

The spastic clenched fist deformity is common in brain injury or stroke involving the upper extremity. This pattern results from unmasking of the primitive grasp reflex. The fingers are typically clasped into the palm. Fingernails may dig into palmar skin, and access to the palm for washing may be compromised. When access is chronically restricted, skin maceration, breakdown, and malodor occurs. Patients may complain of pain when they or their caregivers attempt to pry the fingers open in order to gain palmar access. The spastic clenched fist deformity is common in brain injury or stroke involving the upper extremity. This pattern results from unmasking of the primitive grasp reflex. The fingers are typically clasped into the palm. Fingernails may dig into palmar skin, and access to the palm for washing may be compromised. When access is chronically restricted, skin maceration, breakdown, and malodor occurs. Patients may complain of pain when they or their caregivers attempt to pry the fingers open in order to gain palmar access. Some relaxation of finger tightness may occur if the wrist is positioned in extreme flexion. The deformity, however, is often accompanied by wrist flexion as well.

The degree of motor control may be masked by the severe amount of tone present in the finger flexors. First, establish passive range of motion. Following this, ask the patient to open and close the fingers and to flex and extend the wrist. If no active wrist or finger extension is seen, it is still important to assess whether there appears to be active control of finger flexion. In the continuum of neurologic impairment and recovery, control of wrist and finger flexion is seen before active control of extension. Place a finger in the patient's palm and ask the patient to grasp. Often, an increase in the pressure of grasp can be felt indicating underlying muscle control.

Next, perform an anesthetic block of the median nerve in the antecubital space to eliminate flexor tone temporarily. A block of the ulnar nerve in the cubital canal can supplement relaxation. With the flexor muscles relaxed, the activity of the extensor muscles can be more accurately evaluated. When extensor control returns, it is generally seen in the extensor indicis proprius muscle first.

Functional Procedures versus Procedures for Hygiene

Preoperative evaluation is performed to determine which extremities have sufficient volitional control of the muscles to allow surgical procedures aimed at restoring function to the hand. Often, severe deformities are present, but there is insufficient or no volitional activity in the muscles. In these cases, perform contracture releases to decrease pain, improve position and cosmesis of the hand, and to ease basic skin care and hygiene. The criterion for determining which procedures are most appropriate are summarized in Table 67.10.
Muscles that contribute to the clenched fist deformity include the FDS and FDP. If the PIP joints flex while the DIP joints remain extended, spasticity of FDP rather than FDP may be suspected. Dynamic EMG studies have shown that the flexor digitorum superficialis muscles exhibit a marked degree of spasticity, whereas the flexor digitorum profundus muscles are often normal or minimally spastic (105,117,118,120). Despite the marked increase in tone, it often has some underlying volitional control. The flexor profundus has less spasticity and better volitional control. Volitional control of the finger extensors is present in 50% of patients with spastic flexion deformities.

The intrinsic may also be spastic along with the extrinsics, but an intrinsic plus posture (i.e., combined MCP flexion and PIP extension) is not seen because spastic extrinsic flexors dominate by flexing the PIP joints. Some degree of contracture of the extrinsics is typical of the chronically clenched fist. From the perspective of active functional potential, some degree of volitional control may also be present in either or both sets of extrinsic finger flexors. Spastic finger flexors may override and mask the patient’s potential to extend the fingers. Sometimes, a patient presents with spasticity in just one or two muscle slips of either FDP or FDS. For example, we have seen a number of cases of index finger flexion traced to a spastic FDP muscle slip for that finger alone.

During the period of residual deficits and remediable function, a variety of orthopaedic options are available. When volitional control is demonstrated in the extrinsic flexor muscles by dynamic EMG, the fractional lengthening is indicated. In a hand with skin maceration and malodor from a clenched fist deformity in which no volitional movement is detected, more significant lengthening of the flexor tendons is required. In this situation, perform a superficialis-to-profundus (STP) tendon transfer.

Fractional Lengthening of Extrinsic Finger Flexors in the Functional Hand

- Make a longitudinal incision on the volar surface of the forearm, commonly at the same sitting with wrist flexor lengthenings (Fig. 67.19).
- Divide the palmaris longus tendon if it is tight. Perform the lengthening of the individual FDS and FDP tendons by sharply incising the tendon fibers as they overlie the muscle belly at the musculotendinous junction, allowing the tendon to slide distally.
- Lengthen the flexor pollicis longus tendon in an identical manner. This technique allows the tendons to lengthen with minimal scarring. By transecting the tendon over the muscle belly, no sutures are needed. This eliminates scarring from foreign body reaction to suture material. The underlying support and vascularity of the muscle provides an optimal environment for the tendons to heal and reconstitute themselves.
- Do not immobilize postoperatively. Begin the patient on a program of active and active assisted exercises on the first postoperative day. If the patient has significant pain or spasticity, a short volar splint can be used for comfort. Remove the splint for exercise. In patients with limited motor control, it is often useful to use the splint to position the wrist while the patient exercises the fingers. This immediate active motion allows the flexor tendons to continue to lengthen in the postoperative period as necessary.
- Ultimately, the amount of flexor lengthening is determined for each individual muscle by its underlying tone and control rather than by the surgeon’s “educated guess” of tone while the patient is under anesthesia. By using this technique, we have had marked improvement in functional results when compared with our previous regimen of postoperative immobilization. In cases in which the motor control is very limited, extrinsic finger flexor lengthening can be combined with wrist fusion.

Superficialis-to-profundus Tendon Transfer in the Nonfunctional Hand

In a hand with skin maceration and malodor from a clenched fist deformity in which no volitional movement is detected, more significant lengthening of the flexor tendons is required. In this situation, an STP tendon transfer is performed (21,114,115,118,119). This provides a more cosmetically pleasing hand position, aids in hygiene by getting the fingers out of the palms, and provides, at best, a mass action grasp pattern and at least a passive restraint to extension.

Figure 67.21. Superficialis-to-profundus tendon transfer: The four superficialis tendons are sutured together distally and then transected for transfer. The profundus tendons are sutured together proximally and then cut. The fingers are extended, and the distal end of the superficialis tendons are then sutured en masse to the proximal end of the profundus tendons. (Reprinted with permission from Keenan MA, Kozin SH, Berlet, AC. Manual of Orthopaedic Surgery for Spasticity. New York: Raven Press, 1993.)

- Perform the STP tendon transfer through a longitudinal palmar incision that may be extended distally to allow release of the carpal tunnel and access to Guyon's canal.
- Identify and transect the palmaris longus tendon. Suture together the four superficialis tendons distally and then transect for the en masse transfer (21,114,115,119).
- Suture together the profundus tendons proximally and then cut. Extend the fingers and suture the distal end of the superficialis tendons en masse to the proximal end of the profundus tendons.

Several other surgical procedures are routinely performed in combination with the STP tendon transfer to treat the concurrent deformities. A neurectomy of the motor branch of the ulnar nerve is needed to prevent an intrinsic plus deformity from developing (21,114,115,122,189). If an intrinsic contracture is seen at the time of surgery following the STP lengthening, perform a release of the intrinsics.

- Use a carpal tunnel release to decompress the median nerve.
- To prevent a recurrent wrist flexion deformity from occurring secondary to passive wrist flexion, stabilize the wrist. Wrist extensor tenodesis has been attempted but often will stretch out with time.
- A cock-up wrist splint can be worn, but patient compliance is poor.
- A fusion of the wrist in 15° of extension provides the most reliable means of maintaining hand position and is now routinely performed. The surgical technique has been described earlier. A proximal release of the thenar muscles is often needed to correct a thumb-in-palm deformity (19,48,104,143,144,189,193,195,204,220).
- Because the STP transfer and wrist fusion are extensive surgery, we prefer to perform the thenar slide procedure at a later time, if it is indicated.
- Postoperatively, immobilize the wrist for three weeks in a short arm splint that includes the fingers and thumb. Hold the wrist in 15° of extension and immobilize the fingers with the metacarpophalangeal joints in 60° of flexion and the interphalangeal joints extended. Begin gentle range of motion of the metacarpophalangeal joints after cast removal. Use a volar wrist splint until the wrist fusion is healed.

Spastic Thumb-in-palm Deformity

The thumb-in-palm deformity is heterogeneous in appearance and may be secondary to spasticity of multiple muscles including the flexor pollicis longus muscle and the median and ulnar innervated thenar muscles (19,48,104,143,144,189,193,195,204,220). The thumb is held within the palm, the DIP joint of the thumb is commonlyflexed, and the thumb is unable to function during key grasp or in three-jaw chuck grasp (i.e., in opposition to the pads of the index and third fingers). In addition, skin maceration and breakdown can occur if proper hygiene is prevented.

Clinically, spasticity of the flexor pollicis longus is indicated by flexion of the interphalangeal joint. Some patients may be able to extend the thumb if the wrist is flexed, suggesting that a spastic flexor pollicis longus (FPL) may be impeding active thumb extension when the wrist is more extended and FPL is tighter. The thumb-in-palm deformity may result from spastic activity in FPL, adductor pollicis (AP), or the thenar muscles, particularly flexor pollicis brevis. Adduction of the thumb metacarpal indicates spasticity of the AP muscle and possibly the first dorsal interosseous muscle. A quick stretch of the thumb into abduction often elicits a clonic response. An anesthetic block of the ulnar nerve in Guyon’s canal at the wrist temporarily eliminates intrinsic tone. This will demonstrate the presence of any myostatic contractures and will also confirm that the AP was an offending muscle in the deformity. Contracture of the skin of the web space and interphalangeal joint contracture of the thumb may also develop over time. If some volitional potential in thumb extenders or thumb abductors is present, lengthening of the spastic FPL and AP will facilitate key
because if not caused by spasticity the deformity will not improve with treatment for spasticity. With treatment and deformities resulting from the more usual mechanisms such as traumatic central slip injury with lateral band subluxation or traumatic mallet finger, exerted by the intrinsics and long extensor. In both of these cases, take care to distinguish between deformities caused by the intrinsic spasticity that should improve with distal releases and inappropriate treatment for extrinsic spasticity or contracture. Boutonnière deformities are commonly associated with intrinsic spasticity. They result from a combination of intrinsic spasticity combined with FDS tone. Swan-neck deformities from intrinsic spasticity and contracture are frequently masked by extrinsic spasticity and contracture. In the period of residual deficits and remediable function, orthopaedic treatment consists of fractional lengthening of the FPL at the myotendinous junction combined with a thenar muscle slide, in which the origins of the thenar muscles are detached from the transverse palmar ligament while preserving the neurovascular pedicle. Fractional lengthening of the FPL at the myotendinous junction will improve thumb extension. This is generally performed in conjunction with wrist or digital flexor lengthening. In order to provide a functional lateral pinch, it is desirable to stabilize the interphalangeal joint of the thumb. This may be done using a Mobberg screw or a Herbert screw (Fig. 67.22).

**Deformities from Intrinsic Spasticity**

- Make a stab incision on the tip of the thumb pulp, and under fluoroscopic guidance, pass the pilot hole for the thumb and shaft of the distal phalanx, across the joint, and into the proximal phalanx.
- Advance the screw through this hole, compressing the articular surfaces. In this patient group, we have not found it necessary to denude the interphalangeal joint surfaces.
- Protect the thumb in a thumb spica splint or cast for 3 weeks.

In those cases with a fixed adduction contracture, perform surgical lengthening of the thenar muscles (19,49,66,104,143,144,149,193,199,204,220). Generally, all of the thenar muscles are spastic or contracted, and a proximal myotomy is required to reposition the thumb and decrease the underlying tone in order to improve pinch function. Avoid distal releases because these often result in a hyperextension deformity of the metacarpophalangeal joint of the thumb (19).

A modified extensor pollicis longus (EPL) tendon rerouting procedure in combination with intrinsic muscle releases has been suggested for the treatment of severe deformities. In this method, the EPL tendon is transected proximal to Lister's tubercle. The distal stump is passed through the first compartment tunnel and is sutured to the radial sensory nerve. Release the origin of the first dorsal interosseus from its origin on the base of the first metacarpal.

**Thenar Muscle Slide**

- Under tourniquet control, make an incision along the thenar crease on the palm.
- Protect the neurovascular structures and flexor tendons ulnarly (Fig. 67.23).

**Proximal myotomy of the thenar muscles used to correct a spastic thumb-in-palm deformity.**

- Detach the origins of the flexor pollicis brevis, opponens pollicis, and AP muscles from their origins while protecting the recurrent branch of the median nerve.
- Preserve the transverse carpal ligament; do not enter the carpal canal.
- Extend the thumb, allowing the released muscles to slide radially and reattach in an improved position, thereby preserving function and preventing a hyperextension deformity.
- Release the origin of the AP muscle from the third metacarpal. Carefully dissect to reattach the digital neurovascular bundles and flexor tendons to the index and long digits.
- Identify the deep palmar vascular arch and deep branch of the ulnar nerve as they penetrate the AP muscle between its oblique and transverse heads before adductor muscle release. Preserve the neurovascular supply of the adductor pollicis.
- If the first dorsal interosseous muscle is contracted, perform a release through a dorsal incision along the ulnar margin of the thumb metacarpal while protecting the radial sensory nerve. Release the origin of the first dorsal interosseus from its origin on the base of the first metacarpal.
- In persistent web space contractures despite appropriate muscle releases, perform a Z-plasty of the thumb web space.
- Postoperatively, immobilize the patient in a thumb spica splint for 3 weeks. Initiate active therapy a few days after surgery. The splint is removed for therapy but used at other times to position the thumb.

**Deformities from Intrinsic Spasticity**

When spasticity of the extrinsic flexors is present, intrinsic spasticity should be expected (15,21,25,28,29,103,104,105,106,107,108,114,115,117,121,122,125,126,128,133,136,145,146,189) However, intrinsic spasticity and contracture are frequently masked by the presence of extrinsic flexor spasticity or contracture. Extension of the fingers at the metacarpophalangeal joints may be blocked by spasticity of the interossei and lumbricals muscles of the hand. Another manifestation of intrinsic spasticity is the tendency to swan-neck or boutonnière positioning of the fingers. When a release or tendon lengthening of the spastic extrinsic flexor muscles has already been done, an intrinsic positive deformity of the hand is unmasked. These hand deformities can be painful and disfiguring. Such contractures often lead to maceration of the palmar skin and recurrent nail bed infections from poor hygiene.

The degree of tension caused by the intrinsic muscles can be demonstrated by comparing the amount of proximal interphalangeal joint flexion obtained with the metacarpophalangeal joint flexion with metacarpophalangeal joint extension, then the intrinsic tendons are tight. Perform this test both before and after a lidocaine block of the ulnar nerve at the wrist in order to distinguish between intrinsic tone and contracture. Boutonnière deformities are commonly associated with intrinsic spasticity. They result from a combination of intrinsic spasticity combined with FDS tone. Swan-neck deformities may also result from increased intrinsic tone (Fig. 67.24). The central extensor band is relatively shortened relative to the lateral bands because of tension exerted by the intrinsic and long extensor. In both of these cases, take care to distinguish between deformities caused by the intrinsic spasticity that should improve with treatment and deformities resulting from the more usual mechanisms such as traumatic central slip injury with lateral band subluxation or traumatic mallet finger, because if not caused by spasticity the deformity will not improve with treatment for spasticity.
Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Because it is impossible to delineate fully the relative contributions and balance of spasticity and contracture of the intrinsic and extrinsic muscles by clinical assessment alone, we routinely obtain dynamic EMG studies of the intrinsic muscles before embarking on treatment of hand deformities. This is especially important before considering any surgical intervention.

In the period of residual deficits and remediable function, three treatment options are available. The procedure chosen is based on considerations of contracture and the presence or absence of volitional activity in the intrinsic muscles. When no significant intrinsic contracture is present and dynamic EMG indicates that there is no volitional control in the intrinsic muscles, perform a neurectomy of the motor branches of the ulnar nerve in the palm (Fig. 67.7). Leave the sensory branches intact to preserve protective sensation in the hand. When a contracture of the intrinsic muscles is present and the dynamic EMG study shows no volitional activity, perform a release of the lateral bands of the extensor hood mechanism at the level of the proximal phalanx (Fig. 67.25). In these cases, neurectomy of the motor branches of the ulnar nerve is performed simultaneously to prevent recurrence of the intrinsic plus deformity from spasticity of the interosseous muscles. When there is either a dynamic or static intrinsic plus deformity but the EMG demonstrates volitional control, release the interossei from their proximal origins on the metacarpals and allow to slide distally (207,208). A static deformity is one in which a myostatic contracture is present. A dynamic deformity is one in which the deformity results mostly from increased tone with little or no fixed contracture.

**Ulnar Motor Neurectomy** Make an incision on the palmar surface of the hand radial to the pisiform bone and extend distally for 1 inch.

- Be careful to prevent harm to the ulnar artery. Expose the ulnar nerve and identify the motor branches using a nerve stimulator. Generally, two motor branches are seen. The main motor branch lies beneath the sensory branch and a smaller motor branch can be seen entering the hypothenar muscles (Fig. 67.7) (118,122).
- After identifying these features, transect the nerves, taking care to preserve the ulnar artery and the sensory branch of the ulnar nerve (Fig. 67.7).
- Unless the procedure is combined with other surgery, no splinting or casting is necessary postoperatively. Apply a soft dressing to the hand and begin active and passive exercises on the first postoperative day.

**Lateral Band Intrinsic Release** In a hand in which a contracture of the intrinsic muscles is present and the dynamic EMG study shows no volitional activity, perform lateral band releases (Fig. 67.26).

- Make a midline longitudinal incision over the dorsum of the metacarpophalangeal joint and proximal phalanx of each finger. Dissect on both the ulnar and radial sides of the extensor mechanism.
- Identify the palmar edge of the lateral bands. Transect the lateral band and oblique fibers of the extensor hood on each side. Take care to preserve the transverse fibers of the sagittal extensor hood.
- Recurrent intrinsic plus deformities are common. This is thought to be secondary to residual attachment of the interossei muscles to the base of the proximal phalanges. To prevent recurrent deformities, perform a concomitant neurectomy of the motor branches of the ulnar nerve in Guyon's canal.

**Intrinsic Slide**

- In a hand with volitional control of the intrinsic musculature, perform intrinsic slides (207,208).
- Make two dorsal longitudinal incisions, one between the second and third and one between the fourth and fifth metacarpals.
- Preserve the extensor tendons while exposing the origins of the interossei on the shafts of the metacarpals. Elevate these origins from the metacarpals and extend the metacarpophalangeal joints while the interphalangeal joints are flexed, causing the intrinsic to be lengthened.
- Postoperatively, immobilize the hand in a bulky dressing for one week.
- The abductor digiti quinti muscle may contribute to a flexion deformity of the metacarpophalangeal joint of the fifth finger. The muscle can be fractionally lengthened by transecting the tendon within the muscle belly. This allows lengthening while preserving the function of the muscle.

**Intrinsic minus deformities**

A less common deformity pattern is the intrinsic minus hand. In these patients, the intrinsic muscles have normal or weakened tone, but there is spasticity of the extrinsic finger flexors. There may be increased tone in the extrinsic extensors as well. This pattern results in a claw hand posture, with hyperextension of the metacarpophalangeal joints and flexion of the proximal and distal interphalangeal joints. Ulnar neuropathy must be considered as a possible diagnosis. Hyperextension contracture of the metacarpophalangeal joint capsule is common. When it is present, the contractures require surgical release. Treatment of this deformity may also require lengthening of the extrinsic digital flexors or STP transfers, as described earlier.

Release of the dorsal capsule of the metacarpophalangeal joints from the metacarpal is often needed. Zancoli capsulodesis may also be required to restore metacarpophalangeal flexion and place the hand in a more functional and cosmetic position (220,248). Postoperatively, splint the hand with the metacarpophalangeal joints flexed 70° for 3 weeks.

CHAPTER 68

RECONSTRUCTION OF THE UPPER EXTREMITY IN TETRAPLEGIA

Michelle A. James

PATHOPHYSIOLOGY

Tetraplegia resulting from spinal cord injury (SCI) is a devastating impairment. The abilities of the person with tetraplegia are drastically diminished. This loss of independence is especially catastrophic for young men with poor impulse control, the most common victims of SCI. People with complete tetraplegia have loss of normal use of their upper extremities and may require assistance with basic activities of daily living (ADLs), such as eating, dressing, and bladder and bowel care. They are unable to stand or walk, and because they lack sensation below the level of their SCI they must learn to protect their skin from pressure sores.

Before World War II, most people with tetraplegia survived only for a brief time, succumbing to pneumonia or renal failure. In the 1940s the prevention and care of the medical complications of tetraplegia began to improve, allowing people with this condition to survive longer. At this same time, the field of hand surgery was developing, and by the late 1940s hand surgeons began devising ways to improve upper extremity (UE) function in patients with tetraplegia. Pioneers in this field include Bunnell (2), Lipscomb et al. (37), Nickel et al. (47), and later Freehafer et al. (11,12), Lamb and Landry (34,35), Moberg (41,42), Zancolli (60,61), House et al. (21,22), McDowell et al. (39,40), Hentz et al. (17,18), Waters et al. (3,14,57), Allieu et al. (1), and others. Although current surgical techniques fall far short of returning normal function, the challenges of functional restoration in the tetraplegic hand have inspired some of the most innovative developments in hand surgery today.

PATHOPHYSIOLOGY

In adults, traumatic tetraplegia is always accompanied by bony or ligamentous injury to the cervical spine. The cervical spine injury may be stable (for instance, gunshot wounds typically cause stable injuries) or unstable. The highest orthopaedic priority in the treatment of acute tetraplegia is to recognize spinal instability, and to prevent the unstable spine from further damaging the spinal cord (see Chapter 139 and Chapter 140). After initial fixation of the cervical spine provides stability, the patient can sit and upper extremity function can be fully assessed.

Upper extremity function and its recovery (or lack thereof) following SCI reflects the level and type of injury to the spinal cord. The level of cord damage often does not correlate with the level of bony injury. The cord is frequently damaged above or below the level of spine injury, and cord damage of varying severity may occur over several levels. The cord may be transected, or more commonly crushed or confused, and the body's response to the injury may cause further damage. Other neurologic injury—including injury to the brain, cervical nerve roots, and brachial plexus—may accompany SCI. The presence of lower motor neuron injury compounding upper motor neuron injury reduces treatment options, because muscles without an intact lower motor neuron cannot contract in response to functional electrical stimulation (see the section on Indications, Assessment, and Relative Results, below).

SCI is incomplete in about 50% of cases (15). From a functional standpoint, the designation “incomplete” can mean anything from total upper and lower extremity paralysis with retained perianal sensation, to minimal upper or lower extremity weakness, or both. In the first months after injury, an incompletely injured spinal cord may partially recover (55). A completely injured spinal cord will not recover, but muscles that are weak but not paralyzed immediately after injury (due to less severe SCI cephalad to the complete injury) will usually regain normal strength in the year after injury (7,36). Surgical reconstruction of the upper extremity should wait until further improvement is unlikely (33,39,40,44,56).

The paralyzed upper extremity may undergo changes that make surgical reconstruction less effective or even contraindicated. Some changes, such as severe spasticity and pain, are difficult to prevent or treat. Other changes, such as contractures, may be preventable with passive range of motion (ROM) exercises.

PRINCIPLES OF TREATMENT

Repair of spinal cord injury is not yet possible. Steroids or other medications given within hours of injury may reduce further damage caused by the body's response to SCI. The major focus of treatment is rehabilitation, however, an on-going process in which people with SCI learn how to take care of themselves. As part of rehabilitation, upper extremity function may be improved or partially replaced by orthotic devices; modifications to cars, wheelchairs, and computers; environmental control units; service dogs; and upper extremity surgery. People with higher level tetraplegia require the help of another person with activities such as lower extremity dressing, food preparation, bathing, toileting, and transferring, and they must learn to instruct others in these activities (59).

The complex process of rehabilitation requires a focused team approach. The team is usually headed by a specialist in physical medicine and rehabilitation. Other physician team members include an orthopaedic spine surgeon, a urologist, a psychiatrist, and an upper extremity surgeon. Other professional team members include clinical nurse specialists in rehabilitation, physical and occupational therapists, therapeutic recreation specialists, and social workers. The patient and his family are important members of the team, because patient attitude and family support are the most important factors in successful rehabilitation. Although the team may have standardized goals determined by the level of SCI, they must also help the patient develop realistic goals and focus on these. Successful rehabilitation helps the patient reconnect with mainstream life, including returning to school or work. As a result of effective rehabilitation, many people with tetraplegia lead happy, fulfilling lives (Fig. 68.1).
Upper extremity reconstruction is discussed with the patient early on, but it is not usually part of initial rehabilitation. Surgery cannot be planned until upper extremity function is stable, which usually occurs 1 year after injury. In addition, a person with tetraplegia who has spent time at home following her initial rehabilitation has more realistic goals and expectations of surgery. The upper extremity surgeon can help the patient develop these goals, and provide encouragement and contact with other people with tetraplegia who have undergone upper extremity reconstruction. Contraindications to upper extremity reconstruction are listed in Table 68.1.

**Table 68.1. Contraindications to Upper Extremity (UE) Reconstruction in Tetraplegia**

The general principles of tendon transfer are followed when planning upper extremity reconstruction in tetraplegia (49,51), although the tetraplegic patient may have so few donor muscles available that the surgeon must be creative or even bend the rules. Ideally, muscles selected for transfer have normal strength and appropriate excursion for their new function, and they can be spared without detriment to function. In tetraplegia, partially paralyzed muscles may be transferred if this will augment function (for instance, transfer of a portion of the deltoid muscle to the triceps improves elbow extension even if the deltoid is partially paralyzed [23], and weakening one motion may be acceptable if the transfer supplies an entirely absent function (such as biceps-to-triceps or extensor carpi radialis longus [ECRL]–to–flexor digitorum profundus [FDP] transfers).

Elbow extension is the most useful function the surgeon can restore because it enables people with tetraplegia to extend their reach for eating, pushing elevator buttons, opening doors, transferring in and out of a wheelchair, and propelling a manual wheelchair (33,36,41). Following reconstruction of elbow extension, depending on which muscles are available for transfer, the surgeon may reconstruct key (lateral) pinch, which is very useful for everyday activities such as eating with a fork and writing with a pen (Fig. 68.2). If additional motors are available for transfer, the surgeon may also reconstruct hook grasp and release, and thumb opposition.

Figure 68.2. This patient is using surgically reconstructed key pinch to catheterize a stoma between the bladder and umbilicus. This enables her to catheterize herself in her wheelchair. A: Thumb extended. B: Key pinch.

People with tetraplegia are at increased risk of latex allergy, especially during surgery (54). All medical supplies that come into contact with people with tetraplegia should be latex free. They are also at risk of autonomic dysreflexia in response to noxious stimuli below their injury level, such as postoperative pain or bladder distention. In addition, they are at increased risk of postoperative pulmonary problems such as atelectasis or pneumonia because of paralysis of accessory muscles of respiration.

Because most patients with tetraplegia have impaired or absent sensation, the surgeon must liberally pad splints or casts applied postoperatively, to avoid causing pressure sores.

**INDICATIONS, ASSESSMENT, AND RELATIVE RESULTS**

Soon after injury, the rehabilitation team focuses on retaining passive range of motion (PROM) in the upper extremities. PROM exercises should be performed regularly, especially before the patient is able to sit. If these exercises are neglected, shoulder stiffness and pain will develop and delay rehabilitation.

Once the patient can sit, upper extremity passive and active ROM and strength are carefully evaluated and reevaluated at frequent intervals for the first year after injury. Formal planning of upper extremity reconstruction begins when function plateaus. Elbow flexion contractures are frequently seen in patients with absent elbow extension. These contractures diminish the patient’s ability to assist with transfers; unless these can be overcome with stretching or serial casting, reconstruction of elbow extension is contraindicated (15). Supination contractures are less common; these contractures may require osteotomy of the radius before pinch reconstruction. Other contractures are uncommon. See Table 68.1 for other factors that contraindicate upper extremity surgery.

**ELBOW EXTENSION**

The algorithm in Figure 68.3 outlines the surgeon’s planning strategy. Innervation of the triceps is variable (Fig. 68.4). If the triceps muscle is paralyzed, elbow extension should be reconstructed first. This is because pinch reconstruction uses the brachioradialis or pronator teres as a donor, and these muscles cross the elbow joint and are placed on optimal tension when the elbow is extended (3). Because the elbow must be immobilized in extension following tendon transfer to the triceps, this procedure is not readily combined with other upper extremity surgery.
The deltoid-to-triceps transfer is the type most commonly used to reconstruct elbow extension. In this operation, the posterior one third to one half of the deltoid muscle is detached at its origin and transferred to the triceps tendon, usually using an interposition graft. Fascia lata is easy to harvest and use as a graft (17). Good results have also been reported using toe extensor tendons and fibialis anterior (6.6,10,32,41,46), and using a turned-up portion of triceps to bridge the gap between the deltoid and the triceps (4.8). Graft interposition material tends to stretch out over time, diminishing active elbow extension; this deterioration may be reduced when the interposition graft is reinforced with nonabsorbable suture tape. Shoulder abduction strength is not diminished with this transfer, because the transferred deltoid is able to continue to function as a shoulder abductor (personal communication, Vincent R. Hentz, M.D). Transfer of a weak, partially paralyzed deltoid muscle provides useful elbow extension, also without diminishing shoulder abduction strength (23). People with tetraplegia are usually very pleased with the results of this procedure, which increases their reach and thereby their independence; it may allow them to assist with transferring in and out of their wheelchair, and propelling a manual wheelchair. In spite of the major drawbacks of this operation, such as postoperative immobilization with the elbow in extension, and prolonged rehabilitation to prevent the interposition graft from stretching out, patients consistently request the same procedure on the contralateral side (23,33).

Biceps-to-triceps transfer is indicated when the deltoid is paralyzed. Although this transfer weakens elbow flexion, the brachialis is usually strong enough to continue to flex the elbow against gravity (13,31,39,50). This operation may not be as consistently reliable as a deltoid-to-triceps transfer.

INTERNATIONAL CLASSIFICATION (IC)

IC-0

If all muscles below the elbow are paralyzed (IC-0; Table 68.2) the patient should be evaluated for a neuroprosthesis. Also called implanted functional electrical stimulation, and commercially known as the Freehand system, this complex system may provide grasp and key pinch when tendon transfers are not possible (5,29,26,28,46). A control unit implanted under the pectoralis muscle is programmed to stimulate muscles via implanted electrodes. The patient controls this unit by using a transducer attached to his chest wall and mechanically activated by contralateral shoulder motion (Fig. 68.5). In order to be stimulated by a neuroprosthesis, muscles must be paralyzed but not denervated (their lower motor neuron must be intact). The status of the peripheral nerves can be tested with transcutaneous stimulation to determine if the patient is a candidate for this operation. The surgeon and occupational therapist work together to determine which muscles are available for stimulation and transfer. If critically important muscles, such as wrist extensors, are denervated, their function may be replaced by transferring and stimulating a paralyzed but not denervated muscle. Planning, surgical implantation, and postoperative training are quite complex and require an experienced surgical and therapy team, and a highly motivated patient (53).
IC-1

If all muscles below the elbow are paralyzed except brachioradialis (IC-1; Table 68.2), the patient may be a candidate for a neuroprosthesi

Table 68.2. Classification of Spinal Cord Injury (52)

Sensibility

Moberg has stressed the importance of intact sensibility in the outcome of upper extremity reconstruction in tetraplegia (41,42). At his suggestion, O (for "oculo," or visual afferent) and Cu (for "cutaneous," or sensory afferent) are added to the IC scheme to denote the sensibility of the individual extremity (Table 68.3). Although lack of sensibility may adversely affect the outcome of the procedure, even Moberg, who considers sensibility of prime importance, notes that in the absence of sensation, "restored grip was useful nonetheless" (41).

OTHER CLASSIFICATIONS

The most common classification scheme used by orthopaedic surgeons and rehabilitation medicine specialists is based on level of nerve root injury (Table 68.3) (52). This system is not specific enough to help with planning upper extremity tendon transfers. Furthermore, individual muscles are innervated by multiple nerve roots (Table 68.2) and different innervations may have different innervation patterns. Triceps innervation is especially variable. For these reasons, the International Classification for the Upper Extremity in Tetraplegia (IC) was developed (Table 68.3). This is the classification system used to plan upper extremity reconstruction in tetraplegia.

Surgical Techniques

RE constellation of elbow extension: deltoid to triceps transfer (4,6,17,29,32,41)

- Perform the operation under general anesthesia. Place the patient on a large beanbag or other positioning device in the lateral decubitus position with the
operated side up. Pad the contralateral arm and both legs carefully. Inject the planned incision sites (Fig. 68.6), including the fascia lata graft donor site on the ipsilateral leg, with bupivacaine (Marcaine) with epinephrine (the patient probably has no sensation in the leg and the majority of the arm, but painful stimulus below the level of injury can cause autonomic dysreflexia).

![Image 102x77 to 302x218]

**Figure 68.6.** A: Incisions for deltoid to triceps transfer. B: Proximal surgical wound showing fascia lata graft attached to posterior deltoid.

- Through a curvilinear incision over the posterior deltoid, extending to the deltoid insertion, expose the deltoid muscle. The overlying fascia is not well developed. Visualize the anterior and posterior borders, and select one third to one half of the posterior deltoid to dissect free for transfer. Harvest peristemeum and brachialis fascia distally to supplement the deltoid insertion as a sturdy attachment point for the transfer. A leash of vessels is consistently located just posterior to the deltoid insertion. Leave the anterior portion of the deltoid insertion attached to the humerus.
- Dissect the posterior deltoid proximally, separating the fibers. Stop at least 5 cm distal to the acromion, or no more than 7 cm proximal to the insertion, to avoid damaging the axillary nerve (54). Test the passive excursion of the posterior deltoid; it should be at least 2 cm, preferably 3 to 4 cm.
- Through a separate posterior longitudinal incision, expose the triceps aponeurosis. Make two 3 cm transverse incisions about 2 cm apart in the triceps tendon, reinforcing the corners with #0 nonabsorbable suture. Create a subfascial tunnel between the two triceps tendon incisions, and a subcutaneous tunnel between the two skin incisions. Measure the distance between the end of the deltoid and the triceps tendon with the elbow in 10° to 20° flexion and add 5 cm; this is the length of fascia lata interposition graft needed.
- Through a straight lateral incision extending from just below the greater trochanter to 5 to 7 cm proximal to the knee joint, expose the fascia lata. Harvest a piece of fascia lata about 5 cm wide and as long as needed. Detach the fascia lata at one end and weave #5 nonabsorbable suture tape through the fascia lata, then detach the other end.
- Pass the fascia lata graft through the subcutaneous tunnel. Wrap the proximal end around the posterior deltoid tendon, attaching it with several #0 non-absorbable sutures. While holding the elbow in 10° to 20° flexion, pass the graft into the proximal incision in the triceps and out the distal incision, firmly attaching it at both contact points with several #0 nonabsorbable sutures. Fold the excess back on itself and suture in place. Do not allow the elbow to flex more than 20°.
- Close all wounds with deep interrupted absorbable sutures, and skin with running subcuticular sutures.
- Apply a well-padded long arm cast with the elbow in 10° to 20° flexion.

**General Rehabilitation and Post-operative Principles**

- Immobilize the arm, with the elbow in 10° to 20° flexion for 4 weeks. During immobilization, avoid active or passive adduction across the midline of the body, or forward flexion or abduction above 45°. When the cast is removed, fit the patient with a long arm splint with elbow hinges with hinge stops (Fig. 68.7). The purpose of this brace is to allow strengthening of the transfer without stretching out the interposition graft. Under the close supervision of a therapist, the patient actively strengthens the transfer by elbow extension exercises, starting with an arc of 20° to 0°, and increasing by 10° increments as soon as she can extend against gravity through the allowed arc. At night the brace is set at no more than 20° flexion. When the patient is able to extend against gravity from 90° to 0°, the brace is removed during the day. Nightime bracing should be continued for at least 6 to 12 months.

![Image 102x1208 to 302x1349]

**Figure 68.7.** Elbow hinge brace used after deltoid to triceps transfer.

**RESTORATION OF ELBOW EXTENSION: BICEPS TO TRICEPS TRANSFER**

- The indications for this operation are controversial and are still being developed. At present, it is indicated when the deltoid is paralyzed, which occurs rarely in patients eligible for tendon transfer. Please refer to Revol et al. (50) for details.

**IC 0 OR 1: RESTORATION OF KEY PINCH AND GRASP. IMPLANTATION OF A FUNCTIONAL ELECTRICAL STIMULATION SYSTEM (NEUROPROSTHESIS)**

- The implantation of this system is complex and highly individualized, and the details are beyond the scope of this text. Please refer to work by Keith and others for details (25,28,53).

**IC-1: RESTORATION OF KEY PINCH. BRACHIORADIALIS TO ECRB; FPL AND EPL TENODESIS; SPLIT FPL TRANSFER (11,20,24,41,45,48)**

- Perform the operation under general anesthesia and tourniquet. Inject subcutaneous bupivacaine preoperatively in the planned incision sites.
- Through a curvilinear incision on the dorsoradial border of the forearm, identify the brachioradialis muscle and detach its insertion (just proximal to the floor of the first dorsal compartment). Dissect it proximally, to approximately the distal three quarters and proximal one quarter junction of the muscle-tendon unit, or until it has 3 cm excursion. Do not damage the dorsal radial sensory nerve, which travels immediately deep to the brachioradialis.
- Split FPL transfer: Through a zig-zag palmar incision centered over the interphalangeal joint of the thumb, identify the FPL tendon just proximal to its insertion (Fig. 68.8). Transect the radial half of the tendon and dissect proximally, placing a nonabsorbable suture at the base of the split of the Y. Expose the EPL through a zigzag dorsal incision just proximal to the interphalangeal joint flexion crease. Reroute the radial split FPL around the radial side of the thumb and weave it through the EPL, adjusting the tension so that the thumb interphalangeal joint flexes less than 20° when the wrist is passively extended; attach it to the EPL with non-absorbable sutures, and splt the transfer internally with a transarticular Kirschner wire.
IC-2: RESTORATION OF KEY PINCH. BRACHIORADIALIS TO FPL; EPL TENODESIS; SPLIT FPL TRANSFER (8,45,48,55,59)

- Perform the operation under general anesthesia and tourniquet. Inject subcutaneous bupivacaine preoperatively in the planned incision sites.
- Perform the brachioradialis dissection and EPL tenodesis as outlined earlier (see the section on Restoration of Key Pinch for IC-1).
- Attach the brachioradialis tendon to the FPL tendon in the distal forearm with nonabsorbable suture. The FPL may be too small to accommodate weaving the brachioradialis; if this is the case, use an end-to-side attachment. Tension should be set with the elbow in 90° of flexion, so that the thumb contacts the long finger with the wrist in neutral.
- Close all wounds with absorbable suture and apply a bulky compressive dressing covered by a well-padded long arm cast, with the elbow in 90° extension, the forearm in neutral rotation and palmar abduction, with the interphalangeal joint in neutral.

General Rehabilitation and Postoperative Principles

- Immobilize the arm for 6 weeks, then begin active pinch training. No further protection is needed. Alternatively, remove the cast after 4 weeks and begin active ROM and pinch exercises supervised by an occupational therapist. Splint the wrist in 30° extension and the thumb in midradial abduction between exercises for 2 more weeks.

IC-3, IC-4, IC-5: RESTORATION OF KEY PINCH, HOOK GRASP, RELEASE, AND INTRINSIC BALANCE, AND (IC-4 AND IC-5 ONLY) RESTORATION OF THUMB ABDUCTION/OPPOSITION (6,8,16,12,14,21,22,27,38,44,60,61)

- Perform the operations under general anesthesia and tourniquet. Inject subcutaneous bupivacaine preoperatively in the planned incision sites.
- Perform the FPL tenodesis: Identify the FPL tendon proximal to the musculotendinous junction. Transect it, including the transverse carpal ligament. Capture the ulnar side of the FPL tendon with nonabsorbable suture as it passes through the carpal tunnel. Adjust the tension so that the thumb pad contacts the index finger when the wrist is in neutral. Attach it to the flexor retinaculum in the carpal tunnel. Close all wounds with absorbable suture and apply a bulky compressive dressing covered by a well-padded long arm cast, with the elbow in 90° flexion, the forearm in neutral rotation and palmar abduction, with the interphalangeal joint in neutral.

IC-5 flexor phase (at least 3 months after extensor phase; see General Rehabilitation and Postoperative Principles below). Perform a split FPL transfer as described above (see the section on Restoration of Key Pinch for IC-1). Transfer the EDC, EPL, and APL tendons. Transect them distal to their musculotendinous junctions. Perform tenodeses by passing the EDC and EPL tendons through two small elliptical holes in the dorsal radius and by looping the EPL and APL around their dorsal retinaculum. Adjust tension so that the fingers and thumb start to open (release) when the wrist is in neutral position, and fully relax the interdigital extensors in flexion. Attach the EDC to itself, and the EPL and APL to the retinaculum, with nonabsorbable suture. Close all incisions with absorbable suture. Apply a bulky compressive dressing covered with a short arm cast, incorporating the thumb and metacarpophalangeal joints of the fingers. The wrist should be in extension, the metacarpophalangeal joints in 45° of flexion, and the thumb in radial and palmar abduction.

IC-6 AND IC-7: RESTORATION OF KEY PINCH, HOOK GRASP, THUMB EXTENSION, INTRINSIC BALANCE, AND THUMB ABDUCTION/OPPOSITION (27,56)

- Perform the operations under general anesthesia and tourniquet. Inject subcutaneous bupivacaine preoperatively in the planned incision sites.
- Perform the brachioradialis transfer as described above (see the section on Restoration of Key Pinch for IC-1). Transfer the brachioradialis to the FPL as described earlier (see the section on Restoration of Key Pinch for IC-1). Through a dorsal curvilinear forearm incision, identify the EDC, EPL, and APL tendons. Transect them distal to their musculotendinous junctions. Perform tenodesis by passing the EDC and EPL tendons through two small elliptical holes in the dorsal radius and by looping them through the carpal tunnel, and attach the EDC to itself, and the EPL and APL to the retinaculum, with nonabsorbable suture. Apply a bulky compressive dressing covered with a long arm fiberglass cast, with the elbow in 90° of flexion, the forearm in neutral rotation, and the fingers in flexion at the metacarpophalangeal joints and in extension at the proximal interphalangeal joints.

- Close all incisions with absorbable suture. Apply a bulky compressive dressing covered with a long arm fiberglass cast, with the elbow in 90° of flexion, the forearm in neutral rotation, and the fingers in flexion at the metacarpophalangeal joints and in extension at the proximal interphalangeal joints.

General Rehabilitation and Postoperative Principles

- After the first stage, immobilize the arm for 6 weeks, then begin active transfer training and passive ROM exercises.
- Once the patient can activate the transfer well and ROM has returned to preoperative status (usually at least 3 months after the first operation), perform the second stage. After the second stage, immobilize the arm for 6 weeks, then resume active transfer training. No further protection is needed. Alternatively, remove the FPL free-end transfer and begin active pinch training. No further protection is needed. Alternatively, remove the cast after 4 weeks and begin active ROM and pinch exercises supervised by an occupational therapist. Splint the wrist in 30° extension and the thumb in midradial abduction between exercises for 2 more weeks.

IC-6 and IC-7: RESTORATION OF KEY PINCH, HOOK GRASP, THUMB EXTENSION, INTRINSIC BALANCE, AND THUMB ABDUCTION/OPPOSITION (27,56)

- Perform the operation under general anesthesia and tourniquet. Inject subcutaneous bupivacaine preoperatively in the planned incision sites.
- Perform the brachioradialis transfer as described above (see the section on Restoration of Key Pinch for IC-1). Transfer the brachioradialis to the FPL as described earlier (see the section on Restoration of Key Pinch for IC-1). Transfer the ECRL to the index, long, and small FDP as described earlier. Through the incision used to harvest the brachioradialis, identify and detach the PT. Transfer the PT to the ring FDS tendon in the distal forearm; because the PT tendon is broad, use an end-to-side or split and wrap around attachment, with nonabsorbable suture. Then detach the ring FDS at the chiasm, through a palmar incision at the level of the distal wrist flexion crease. Through a radial thumb incision at the level of the metacarpophalangeal flexion crease, expose the extensor pollicis brevis (APB) insertion. Split the ring FDS into two tails; attach one tail to the APB tendon and the other to the extensor hood, using nonabsorbable suture under enough tension to hold the thumb in radial abduction and to prevent it from supinating during pinch (9). Alternatively, the PT can be transferred to the FPL and the brachioradialis to the ring FDS (2).
- Close all incisions with absorbable suture. Apply a bulky compressive dressing covered with a long arm fiberglass cast, with the elbow in 90° of flexion, the forearm in neutral rotation, the wrist in neutral, the fingers with metacarpophalangeal joints flexed and proximal interphalangeal joints extended, and the thumb in radial and palmar abduction.

General Rehabilitation and Postoperative Principles

- After the first stage, immobilize the arm for 4 weeks, then begin active transfer training and passive ROM exercises.
- Once the patient can activate the transfer well and ROM has returned to preoperative status (usually at least 3 months after the first operation), perform the second stage. After the second stage, immobilize the arm for 6 weeks, then resume active transfer training. No further protection is needed. Alternatively, remove the FPL free-end transfer and begin active pinch training. No further protection is needed. Alternatively, remove the cast after 4 weeks and begin active ROM and pinch exercises supervised by an occupational therapist. Splint the wrist in 30° extension and the thumb in midradial abduction between exercises for 2 more weeks.

Perform the operation under general anesthesia and tourniquet. Inject subcutaneous bupivacaine preoperatively in the planned incision sites.

Perform the brachioradialis transfer as described above (see the section on Restoration of Key Pinch for IC-1). Transfer the brachioradialis to the FPL as described earlier (see the section on Restoration of Key Pinch for IC-1). Through a dorsal curvilinear forearm incision, identify the EDC, EPL, and APL tendons. Transect them distal to their musculotendinous junctions. Perform tenodesis by passing the EDC and EPL tendons through two small elliptical holes in the dorsal radius and by looping them through the carpal tunnel, and attach the EDC to itself, and the EPL and APL to the retinaculum, with nonabsorbable suture. Apply a bulky compressive dressing covered with a short arm cast, incorporating the thumb and metacarpophalangeal joints of the fingers. The wrist should be in extension, the metacarpophalangeal joints in 45° of flexion, and the thumb in radial and palmar abduction.

IC-3 flexor phase (at least 3 months after extensor phase; see General Rehabilitation and Postoperative Principles below). Perform a split FPL transfer as described above (see the section on Restoration of Key Pinch for IC-1). Transfer the ECRL to the index, long, and small FDP as follows. First, through a palmar curvilinear forearm incision, subcutaneous bupivacaine preoperatively in the planned incision sites. Through a longitudinal palmar incision over the distal forearm, identify the FPL tendon and transect it distal to its musculotendinous junction. Transect the ECRL as far as possible, and pass it through the window to the palmar side of the forearm. Split it longitudinally and wrap it around the FDP tendons distal to their interattachment. Adjust the tension so that the fingertips touch the palm when the wrist is extended, and attach the ECRL to the FDP with nonabsorbable suture.

IC-4 and IC-5 flexor phase (at least 3 months after extensor phase; see General Rehabilitation and Postoperative Principles below). Perform a split FPL transfer as described above (see the section on Restoration of Key Pinch for IC-1). Transfer the ECRL to the index, long, and small FDP as described earlier. Through a radial thumb incision at the level of the metacarpophalangeal flexion crease, expose the extensor pollicis brevis (APB) insertion. Through a longitudinal palmar incision over the distal forearm, identify the FPL tendon and transect it distal to its musculotendinous junction. Transect the ECRL as far as possible, and pass it through the window to the palmar side of the forearm. Split it longitudinally and wrap it around the FDP tendons distal to their interattachment. Adjust the tension so that the fingertips touch the palm when the wrist is extended, and attach the ECRL to the FDP with nonabsorbable suture.

Closed all incisions with absorbable suture. Apply a bulky compressive dressing covered with a long arm fiberglass cast, with the elbow in 90° of flexion, the forearm in neutral rotation, the wrist in 30° to 40° extension, the thumb in midrange radial and palmar abduction, and the interphalangeal joint in neutral.
radial and palmar abduction.

**General Rehabilitation and Postoperative Principles**

- Immobilize the arm for 6 weeks, then begin active pinch, grasp, and (IC-6 only) thumb extension training. No further protection is needed. Alternatively, remove the cast after 4 weeks and begin active ROM and pinch exercises supervised by an occupational therapist. Slight extension of the wrist in neutral, the thumb in midrange abduction, and the fingers in flexion at the metacarpophalangeal joints and in extension at the proximal interphalangeal joints.

**IC-8 AND IC-9: RESTORATION OF INTRINSIC BALANCE AND THUMB ABDUCTION/OPPOSITION**

- Perform the operations under general anesthesia and tourniquet. Inject subcutaneous bupivacaine preoperatively in the planned incision sites.
- Perform the intrinsic tenodesis as described earlier. Transfer the ring FDS to the APB as described earlier, except the proximal attachment to PT is unnecessary if the ring FDS is sufficiently strong enough to provide thumb abduction/opposition.
- Close all incisions with absorbable suture. Apply a bulky compressive dressing covered with a short arm fiberglass cast with the wrist in neutral, the fingers with metacarpophalangeal joints flexed and proximal interphalangeal joints extended, and the thumb in radial and palmar abduction.

**General Rehabilitation and Postoperative Principles**

- Immobilize the arm for 6 weeks, then begin active pinch and grasping. Further protection is needed. Alternatively, remove the cast after 4 weeks and begin active ROM and pinch exercises supervised by an occupational therapist. Slight extension of the wrist in neutral, the thumb in midrange abduction, and the fingers in flexion at the metacarpophalangeal joints and in extension at the proximal interphalangeal joints.

**PITFALLS AND COMPLICATIONS**

People with tetraplegia require expert and highly specialized preoperative, intraoperative, and postoperative care to prevent complications such as latex allergy, hypotension, pressure sores, pneumonia, wound infections, urinary tract infections, and autonomic dysreflexia.

**AUTHOR'S PERSPECTIVE**

- Upper extremity reconstruction in tetraplegia is best performed by an experienced hand surgeon, because proper tensioning of tendon transfers remains a skill honed by practice. The surgeon's job is easier and the results of surgery are probably better if a rehabilitation team is available to help care for the patient in the perioperative period.
- Many patients benefit from intensive in-patient occupational and physical therapy after cast immobilization is discontinued. Intensive (twice-per-day) therapy sessions before and after large muscle transfer, such as deltoid-to-triceps transfer, allow the patient to strengthen the transferred muscle, and thereby improve the outcome of this operation. Travel to and from the therapist can be difficult for people with tetraplegia, so performing the therapy in an in-patient setting also enhances compliance.
- People with tetraplegia who are contemplating surgery can benefit enormously from meeting with others who have undergone the same operation or operations. If possible, these meetings should take place away from the hospital or physician's office, so the patients can talk freely. Tetraplegics who have worked hard to gain independence may be especially reluctant to undergo surgery because of fear of decreased independence during immobilization or after surgery.
- Although neuromusculoskeletal approaches are an exciting development, from a practical standpoint, they are not widely useful. Implantation and postoperative therapy are very complicated and require a highly motivated patient, surgeon, and therapist. The cost of the system (excluding the cost of the implantation surgery and preoperative and postoperative therapy) is more than $25,000. The biggest drawback, however, is that the patient with a neuromusculoskeletal device requires assistance to don and doff the apparatus that makes the neuromusculoskeletal prosthesis work.
- The split FPL transfer is a simple and very useful operation that allows the patient to gain thumb tip stability while maintaining thumb interphalangeal joint flexibility.
- A weak deltoid muscle is not a contraindication to deltoid-to-triceps transfer. If the muscle is weak, a larger portion—or even the entire deltoid—can be transferred to increase elbow extension power.

1 Some experts believe that IC-2 cannot be distinguished from IC-3 on examination alone, and surgical exposure under local anesthesia is required to assess ECRL strength (38). In many cases, however, patients with IC-2 SCI will show radial deviation with active wrist extension. In patients with IC-3 SCI, a groove may be visible between ECRL and ECRL muscle bellies in the proximal forearm with resisted wrist extension (44).

2 Some authors have recommended performing the intrinsic tenodesis during the flexor stage instead of the extensor stage (123). In theory, this may reduce the likelihood of FDP adhesions, because active FDP motion will begin sooner after the flexor stage than after the extensor stage. In addition, the optimal position of immobilization following intrinsic tenodesis is more compatible with the flexor stage. However, immobilization of the metacarpophalangeal joints in neutral or extension, however desirable to optimize finger extension following extensor tenodesis, is likely to lead to extension contractures of these joints, rendering the intrinsic tenodesis less effective.

The hand connects the developing child to the world. The child's use of the hand enables the development of intelligence, and thereby language and culture (229). Remarkably, the child whose hands are malformed or even absent but whose brain is normal develops almost normally. As Southwood wrote in 1926 regarding congenital deficiency of the ulna, “From the functional viewpoint... the deformed limb is much more useful than its anatomical condition would have led one to expect” (190, p. 349). Few surgical operations have been conclusively proven to improve the function of the child's malformed hand, and surgeons tend to take credit for improvement that occurs because of growth and development.

PATHOPHYSIOLOGY

PRENATAL DEVELOPMENT OF THE HAND

In the human embryo, upper limb buds appear 26 to 28 days after fertilization. During the next 25 days, the upper limb is completely differentiated (59,237). The position of a cell on the limb bud during early development determines the fate of that cell. Growth occurs along three axes, and each growth axis is controlled by a key area of the upper limb: the apical ectodermal ridge (AER) promotes growth along the proximodistal axis; the zone of polarizing activity (ZPA) promotes growth along the dorsoventral axis (175,237).

Several different chemical signals induce or regulate activity of these key areas. These include fibroblast growth factors (FGF) expressed in the AER; FGF-8 may induce AER formation, and FGF-4 and FGF-8 together can replace AER function. Retinoic acid and sonic hedgehog protein together mediate the activity of the ZPA. Chemical signals from the AER and ZPA also regulate the expression of homeobox (Hox) genes, which control the expression of other genes, confer positional information on different cell types, and determine limb patterns such as digit identity (118,175).
Children between the ages of 4 and 8 years with transverse and longitudinal deficiencies may have difficulty performing advanced dressing and hygiene activities (see malformations. Infants with transverse or longitudinal deficiencies use both upper limbs or unilateral brachiothoracic grasp for prehension and may scoot instead of walking.

Most children younger than the age of 3 years do not notice a hand difference in themselves, and early motor development is unaffected by most upper extremity malformations. For example, thumb-index syndactyly release should be performed before the child starts school may reduce teasing by other children and prevent school absence. The parent and older child should share the surgeon's goals, and understand the risks and likely outcome of surgery.

Four different terms are used to refer to different mechanisms of dysmorphogenesis (173). Malformation is an interruption of normal morphogenesis, following which the affected structures fail to revert to normal form; most of the conditions described in this chapter are malformations. Deformation is the alteration in shape of structure that has differentiated normally. Disruptions or disruption sequences are structural defects resulting from destruction of a part that has differentiated normally, such as constriction ring syndrome. Dysplasia is the abnormal growth or differentiation of a structure.

**PRINCIPLES OF TREATMENT**

**TIMING OF SURGERY**

Whereas the surgeon focuses primarily on function, many parents and older children are extremely concerned about the appearance of the malformed hand. They may hope that surgery can make the hand appear normal, but normal appearance is possible only with certain types of malformations. Surgery to alter appearance is elective. If the outcome will be the same regardless of age, surgery should be postponed until the child is older than 2 years of age when general anesthesia is safer (108). Although this system has been used in at least two large studies of congenital hand anomalies (68,106), it is complex, many anomalies fit into more than one category, and some anomalies defy classification.

**GENETICS**

In large population studies, the reported incidence of congenital anomalies of the upper extremity varies between 3.4 and 16 cases per 10,000 live births (58,66,108,204). Most congenital malformations are more common in boys. Anomalies may be caused by genetic or environmental factors, or some combination of these. Genetic malformations are caused by chromosomal abnormalities, or single ( mendelian) or multiple (polygenic) gene disorders. The genetic addresses of several hand malformations (two types of polydactyly, cleft hand and foot, and brachydactyly) are known (237). The next step after genetic localization is identification of the nucleotide sequence mutation; the genetic mutations causing several different orthopaedic conditions have already been identified (60).

The geneticist is an important member of the congenital hand malformation team. He or she keeps up with the rapid accumulation of new information in the field of molecular genetics, helps diagnose anomalies outside the musculoskeletal system (which are associated with more than 80% of heritable limb deficiencies [239]) and provides genetic counseling to families (52). Many hand anomalies are visible on prenatal ultrasound (18,39,77,179); genetic counseling is especially useful in this event.

**CLASSIFICATION AND TERMINOLOGY**

The ideal classification system would be based on etiology, but little is known about the etiology of many congenital hand deformities. We know enough to understand that the same underlying cause can have many different effects, and the same effect can have a myriad of causes. Classification schemes also help the surgeon determine the prognosis and treatment, provide common nomenclature to describe observed conditions, and allow surgeons to communicate.

The most commonly used classification system for congenital upper limb malformations was originally proposed in 1968 by Swanson, Barsky, and Entin (196), and adopted in a modified form by the American Society for Surgery of the Hand and the International Federation of Societies for Surgery of the Hand (ASSH/IFSSH) in 1983 (Table 69.1) (196). Although this system has been used in at least two large studies of congenital hand anomalies (68,106), it is complex, many anomalies fit into more than one category, and some anomalies defy classification.

**Table 69.2. ASSH/IFSSH Classification of Congenital Upper Limb Malformations (195)**

Four different terms are used to refer to different mechanisms of dysmorphogenesis (173). Malformation is an interruption of normal morphogenesis, following which the affected structures fail to revert to normal form; most of the conditions described in this chapter are malformations. Deformation is the alteration in shape of structure that has differentiated normally. Disruptions or disruption sequences are structural defects resulting from destruction of a part that has differentiated normally, such as constriction ring syndrome. Dysplasia is the abnormal growth or differentiation of a structure.

**PRINCIPLES OF TREATMENT**

**TIMING OF SURGERY**

Whereas the surgeon focuses primarily on function, many parents and older children are extremely concerned about the appearance of the malformed hand. They may hope that surgery can make the hand appear normal, but normal appearance is possible only with certain types of malformations. Surgery to alter appearance is elective. If the outcome will be the same regardless of age, surgery should be postponed until the child is older than 2 years of age when general anesthesia is safer (108). In these cases, the increased risk of anesthesia is outweighed by the benefits of surgery, if an experienced pediatric anesthesiologist is available (69). When evaluating functional results of an operation performed on the hand of a small child, the surgeon should attribute to surgery only those functional improvements that are beyond what would be expected for a child of the same age with the same disability.

Most children younger than the age of 3 years do not notice a hand difference in themselves, and early motor development is unaffected by most upper extremity malformations. Infants with transverse or longitudinal deficiencies use both upper limbs or unilateral brachiothoracic grasp for prehension and may scoot instead of crawling, but these alternative developmental pathways are not deficiencies. Children in this age group adapt remarkably well to hand malformations, and parents of older infants and toddlers with hand malformations usually marvel at their child's abilities.

Children between the ages of 4 and 8 years with transverse and longitudinal deficiencies may have difficulty performing advanced dressing and hygiene activities (see...
the section entitled *Oncological Therapy and Therapeutic Recreation*. They are in the process of developing a self-image. Surgery that significantly changes the appearance of a malformed hand will be easier psychologically for children younger than age 4 or older than age 8 years, because between these ages, they are old enough to understand what is happening but not old enough to understand why. Assuming normal intellectual development, after age 8 years children begin to gain the ability to reason, make stable choices, and give assent to elective surgery. Giving assent refers to the capacity of the child with developing decision-making skills to understand the proposed operation and agree to proceed. Obtain the assent of children older than age 8 years before proceeding with any elective operation.

In most cases, simultaneous surgery on bilateral hand malformations is contraindicated, because postoperative bilateral immobilization is frustrating for the younger child and disabling for the older child. If the operations are small and do not require cast immobilization, or if the child is very young for whom anesthesia poses a high risk, the inconvenience of bilateral immobilization may be outweighed by the benefit of simultaneous bilateral surgery. Long arm (above-elbow) casts are used for the postoperative immobilization of the hands of infants and younger children, who tend to wiggle out of short arm casts.

**SKELETAL AGE**

Skeletal immaturity is not a contraindication to most operations used to reconstruct congenital hand malformations. The surgeon should take care to avoid injuring the physis of a growing bone unless the intent of the operation is to retard growth. Arthrodesis of digital joints can be performed in children without damaging the physis (105). Children with congenital hand malformations should be reexamined periodically until they reach skeletal maturity, to identify progressive deformities or recurrence of surgically corrected abnormalities (109).

**CONGENITAL HAND MALFORMATION TEAM**

Congenital hand malformations are rarely encountered by most physicians. Complex malformations are most effectively treated by an experienced hand surgeon with the support of a congenital hand malformation team. The hand surgeon directs the child's care, with the assistance and support of the nursing and social services staff, who help educate the family and coordinate care. Other team members include the occupational therapist (see later), the orthotist and prosthetist, child life and therapeutic recreation specialists, a geneticist, a pediatric anesthesiologist, and a medical librarian.

**PEER CONTACT AND SUPPORT GROUPS**

Parents of a newborn with a congenital hand malformation often feel bewildered and guilty, and underestimate their child's future abilities. The orthopaedic surgeon may be the first person parents encounter who is knowledgeable about their child's condition. The surgeon can be very helpful to the parents if he or she listens to them and answers their questions carefully and thoroughly. The first visit with parents of an infant with a hand deformity cannot be rushed.

Although some parents adjust rapidly, others have more difficulty accepting their child's malformation. Individual differences in parental adjustment do not relate to the severity or type of malformation, but rather to the amount of family support available (17) and other factors. Many parents benefit from meeting an older child with a similar malformation and his or her family. Parents and older children who are planning to proceed with an operation that changes the appearance of the hand, such as pollicization, may also benefit from meeting a child who has undergone the same procedure. The congenital hand malformation team can maintain a database of families willing to be peer contacts, to facilitate matching parents and children with an appropriate peer, and a list of family support groups for different syndromes, internet addresses for relevant websites, and handouts including Children with Hand Differences: A Guide for Families; and Superkids newsletter. The social worker can help refer families for psychological counseling when necessary.

**OCCUPATIONAL THERAPY AND THERAPEUTIC RECREATION**

Children whose malformations limit more advanced functional abilities benefit from consultation with an occupational therapist at around age 3 years and again when they are ready to start school. On-going occupational therapy is indicated when the child is not meeting developmental milestones or is unable to perform age-appropriate activities of daily living. The child life therapist or therapeutic recreation specialist can suggest play activities intended to support the child’s self-esteem and help the family and child adapt toys and recreational activities to the child’s abilities.

**PAIN CONTROL AND POSTOPERATIVE CARE**

Regional anesthesia is inadequate for pediatric hand surgery. Supplement general anesthesia with local anesthetic, and administer intravenous narcotic pain medication postoperatively until the child can take oral pain medication. Most children require pain medication for only 48 to 72 hours after surgery. Use a long arm fiberglass cast shell to cover the postoperative bulky compressive dressing (Fig. 69.1). If the cast does not turn a corner (the flexed elbow), the younger child will wriggle out of it. Release the tourniquet at least 10 minutes before dressing and cast application, to confirm the vascularity of the operated digit or digits and to allow for swelling. Apply the cast without stretching the fiberglass casting tape; the patient may be too young to complain of a too-tight dressing or cast.

*Figure 69.1. Long arm, flexed elbow fiberglass mitten cast shell, covering a bulky compressive hand dressing.*

**THE THUMB**

**POLYDACTYLY**

**Assessment, Indications, and Relative Results**

In the United States, polydactyly is the second most common congenital hand malformation (after syndactyly), and the thumb is the most common duplicated or split digit (59). In China, thumb polydactyly is the most common congenital hand anomaly (88). Although the incidence of thumb polydactyly is most often sporadic, when it is associated with syndactyly, or when one or both of the bifid thumbs is triphalangeal, it is more likely to be caused by a genetic mutation; in these cases, it has been mapped to a specific gene (69,181). Polydactyly is caused experimentally by early disruption of the ZPA (237).

Thumb duplication may occur at the level of the carpometacarpal joint (CMCJ), metacarpal, metacarpophalangeal joint (MPJ), proximal phalanx, interphalangeal joint (IPJ), or distal phalanx. Split thumbs are thinner and shorter than normal, and have stiff joints, hypoplastic tendons with anomalous interconnections, and abnormal vascular anatomy; thus, neither has completely normal function (57). The ulnar thumb is usually larger and more functional than the radial thumb (57,158,179,222), but when the two “halves” are equal in size, or when both are triphalangeal, both are likely to be severely hypoplastic (85).

The Wassef type I thumb (Fig. 69.2) may have a wider than normal distal phalanx, with the remainder of the thumb entirely normal; this condition does not require surgical reconstruction. Wassef type I thumbs with duplication of the distal phalanx, and Wassef type II thumbs may be treated with a combination procedure, as described by Bilhaut (14). In this procedure, the surgeon removes a central wedge of tissue (including bone, joint, physis, and nail bed and skin), and joins the two remaining parts together. No large series of Bilhaut procedures has been published. This procedure always causes a ridged nail, and if performed in a more proximal duplication, joint stiffness and growth arrest may occur (57,86,148,206). Most authors agree that this operation should be reserved for distally duplicated thumbs (Wassef type I or II) that are approximately equal in size.
For the remaining Wassel types, simple ablation of one split thumb is inadequate. Elements of the excised thumb, including collateral ligament, skin, and tendons, are used to augment the preserved thumb (29, 57, 85, 122, 158, 206), to reduce the risk of angulation and joint instability (50, 69, 117, 133, 148, 179, 222). Reconstruction includes collateral ligament reconstruction, tendon realignment, and osteotomy, with the goals of stable and well-aligned joints, with the physes perpendicular to the long axis of the thumb. Even the carefully reconstructed thumb may angulate or develop joint instability with growth. Schedule follow-up visits for the child until he or she is skeletally mature, because more surgery, including osteotomy or an MPJ arthrodesis, may be necessary (98, 105, 122, 149, 188).

Classifications

Geneticists divide thumb polydactyly into four types, based on associated malformations (201). Hand surgeons usually use the classification scheme described by Wassel, based on the level of duplication (Fig. 69.2 and Fig. 69.3) (222).

Horii et al. has subdivided Wassel type IV into four subtypes (Fig. 69.4) (85). Light has also modified the classification described by Wassel, focusing on clinically apparent differences; he points out that Wassel's illustration of type IV thumbs is inconsistent with the remainder of the classification, because two proximal phalanges share a single epiphysis (Fig. 69.2) (110).

Preoperative Management

Inform parents that the retained reconstructed thumb will always be smaller than the contralateral normal thumb, and that further reconstructive surgery may be required. Describe the thumb as split rather than as duplicated, to help parents understand why the preserved thumb will not be normal (57).

Preoperative Planning

Although many surgeons prefer to ablate the extra thumb and reconstruct the remaining thumb before the child’s first birthday (57, 86, 158), there is only anecdotal evidence that the benefits of early surgery outweigh the increased risk of general anesthesia in infants younger than 1 year of age. If both thumbs are equal in size and the child uses them both, postpone surgery until the child is old enough to undergo functional testing to determine which thumb is the more functional. The extrinsic tendon anomalies found at surgery usually cannot be specifically diagnosed preoperatively, so be prepared to transfer tendons and correct angulation by osteotomy.

The vascular anatomy of both thumbs is likely to be abnormal. In most cases, each thumb has only one digital artery, located on its ulnar side (102).

Operative Technique

1. Exploration, ablation of the smaller thumb, reconstruction of the retained thumb: types I and II when one thumb is smaller (Fig. 69.5B).
Combination procedure: types I and II when the thumbs are the same size (Fig. 69.5A). Exploration, ablation of the smaller thumb, reconstruction of the retained thumb: type III and IV thumbs. MPJ arthrodesis: type II and IV thumbs, if ligament reconstruction fails, resulting in painful thumb IPJ or MPJ instability before skeletal maturity (Fig. 69.5C).

2. Combination procedure: types I and II when the thumbs are the same size (Fig. 69.6 and Fig. 69.7).

- Use loupe magnification, and perform the operation with the patient under general anesthesia and tourniquet. Have a surgical microscope available; it may be necessary to separate the digital nerves of the two thumbs.
- Plan incisions to avoid a longitudinal incision along the radial border of the reconstructed thumb.
- Through a dorsal zigzag incision, expose the thumbs for tendon abnormalities. Detach the extensor tendon from the smaller thumb.
- For type II thumbs, dissect the IPJ radial collateral ligament (RCL) off the distal phalanx of the thumb to be ablated (Fig. 69.6B). Preserve the IPJ-RCL attachment to the proximal phalanx; if necessary, extend it using a periosteal flap (Fig. 69.5C) (122).
- If the nails are connected, remove a portion of the nail bed, retaining an appropriate-sized nail for the underlying distal phalanx.
- Remove the bone from the smaller thumb after detaching the flexor tendon at its insertion.
- Separate the digital nerves to the two thumbs, and transect the nerve to the smaller thumb as far proximally as possible.
- For type II thumbs, shave the distal radial portion of the proximal phalanx. If the joint surface is angulated, perform a closing wedge osteotomy of the proximal phalanx, and fix it with a small longitudinal Kirschner wire crossing the IPJ (Fig. 69.5D).
- For type II thumbs, if the pull of the retained extensor or flexor tendon angulates the thumb at the IPJ, reinsert it or transfer the tendon from the ablated thumb to correct the angle of pull. Otherwise, transect the tendon that was previously attached to the ablated thumb.
- For type II thumbs, reattach the IPJ-RCL using a nonabsorbable pullout suture.
- Close the skin with 5-0 chronic suture, augmenting the reconstructed thumb with eponychium and nail bed from the ablated thumb.
- Apply a bulky compressive dressing covered with a long-arm, flexed-elbow fiberglass cast shell.

Figure 69.5. Ligamentous periosteal flap for the treatment of Wassel type II or IV thumb polydactyly. See text for details.

Figure 69.6. Modification of combination (Bilhaut) procedure, which avoids damage to the physis and joint. See text for details. (Personal communication: H. Relton McCarroll Jr., M.D.)

Figure 69.7. Modified combination (Bilhaut) procedure for type I thumb polydactyly. A: Preoperative dorsal view. B: Preoperative palmar view, with incision marked. C: Dorsal view, after central wedge resection. D: Postoperative dorsal view.

- Use loupe magnification, and perform the operation with the patient under general anesthesia and tourniquet.
- Remove the nail plates. Resect a central wedge of dorsal nail matrix, eponychium, and skin, and a similar-sized wedge of palmar skin. Leave enough skin and soft tissue on either side of the wedge so that when the two sides are approximated, the thumb is nearly normal size (Fig. 69.6A).
- Using a small oscillating saw, resect the central portions of the bone of the two thumbs, leaving enough bone so that when approximated, the distal phalanx is nearly normal size. Do not extend these osteotomies into the physis or joint. Instead, make a transverse osteotomy just distal to the physis, to avoid the risk of growth arrest and joint stiffness (Fig. 69.6B).
- Using 0.028 Kirschner wires, pin the two pieces of distal phalanx together, then pin them both longitudinally to the preserved base of the distal phalanx. Extend the longitudinal pins across the IPJ (Fig. 69.6C).
- Approximate the nail bed and eponychium using small absorbable suture. Replace the nail plate with antibiotic-impregnated gauze if the original nail plate does not fit.
- Close the skin with interrupted 5-0 chronic suture.
- Apply a bulky compressive dressing, and cover it with a long-arm, flexed-elbow fiberglass cast shell that covers the tip of the thumb and the Kirschner wires.

3. Exploration, ablation of the smaller thumb, reconstruction of the retained thumb: type III and IV thumbs.
- Proceed as described earlier for type I and II thumbs when one is smaller, including tendon realignment and soft-tissue combination.
- Do not resect the base of the proximal phalanx for type III thumbs; preserve the physis and joint surface and the MPJ-RCL of the radial thumb.
- For type IV thumbs, detach the MPJ-RCL from the ablated thumb and reconstruct it, as described earlier for the IPJ-RCL of type II thumbs.
- For type IV thumbs, reattach the MPJ-RCL using a nonabsorbable pullout suture.
- For type IV thumbs, if the pull of the retained extensor or flexor tendon angulates the thumb at the IPJ, reinsert it or transfer the tendon from the ablated thumb to correct the angle of pull. Otherwise, transect the tendon that was previously attached to the ablated thumb.
- For type IV thumbs, reattach the MPJ-RCL using a nonabsorbable pullout suture.
- Close the skin with interrupted 5-0 chronic suture.
- Apply a bulky compressive dressing over the fingers and thumb, and cover it with a fiberglass cast shell.

4. MPJ arthrodesis: type II and IV thumbs, if ligament reconstruction fails, resulting in painful IPJ or MPJ instability before skeletal maturity (105).
- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
- Approach the joint from the dorsal aspect, if possible, or use incisions from previous operations.
- Use a sharp scalpel to remove articular cartilage sequentially from both joint surfaces. Expose the bony ossification center of the epiphysis of the proximal phalanx, but do not proceed beyond the ossific nucleus into the physisal plate. Expose the cancellous subchondral bone of the distal end of the metacarpal.
- Oppose the two cancellous articular surfaces with the joint in neutral position, and hold them together with two crossed Kirschner wires.
- Close the skin with interrupted 5-0 chronic suture.
- Apply a bulky compressive dressing over the fingers and thumb, and cover it with a fiberglass cast shell.

General Rehabilitation and Postoperative Principles

Remove the cast 4 to 6 weeks postoperatively, and check radiographs. Remove buttons and pullout sutures, and remove Kirschner wires after checking for bony union on radiograph (usually 6 to 8 weeks). Postoperative therapy is not necessary. Provide a custom-made splint when the IPJ or MPJ-RCL has been reconstructed for the
child to wear at night until 3 months after surgery.

**PITFALLS AND COMPLICATIONS**

If the retained thumb is not reconstructed according to the principles described earlier, angulation and instability will occur with growth. These complications also occur when the retained thumb is especially hypoplastic, even if it is carefully reconstructed.

**AUTHOR’S PERSPECTIVE**

Although some surgeons recommend thumb ablation and reconstruction at the age of 6 months (57,86,158), it is difficult to find room for two pullout sutures and a Kirschner wire in a tiny thumb. The operation is easier when the child is at least 1 year old, when the hand is considerably bigger.

Most children and their parents are pleased with the function of the reconstructed thumb if they can accept that it is not expected to be quite normal.

**HYPOPLASIA AND ABSENCE**

**Assessment, Indications, and Relative Results**

Thumb hypoplasia and absence are part of longitudinal radial deficiency, which may involve the thumb alone, or the entire radial hand, wrist, and forearm. This condition is rare, (1:30,000 to 1:100,000 live births) (60), frequently bilateral, and often associated with congenital anomalies of the lower extremities, spine and other organ systems (including the cardiopulmonary, gastrointestinal, and genitourinary systems) (92). Several syndromes are characterized by hypoplastic or absent thumbs, usually combined with radius deficiency, including the VACTERL association (Vertebral, Anal, Cardiac, Tracheo-Esophageal, Renal or Radial, Lung), Holt-Oram syndrome and thrombocytopenia-absent radius (TAR) syndrome (see the section entitled Radius Deficiency) (92).

The hypoplastic thumb must be examined carefully for presence or absence of thenar intrinsic muscles, MPJ—ulnar collateral ligament (UCL) stability, extrinsic muscles (flexor and extensor pollicis longus), and CMCJ stability. There are six types of thumb deficiency (Table 69.3).

**Table 69.3. Modified Blauth Classification (121)**

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
</table>
| 1    | Hypoplastic thumbs do not require surgical reconstruction. The function of type 2 thumbs is enhanced by first web deepening, MPJ-UCL reconstruction, and opponensplasty (63,103). The abductor digiti minimi (ADM) muscle or the middle or ring flexor digitorum superficialis (FDS) can be transferred to provide opposition (63,129,194). Type 3a thumbs benefit from extrinsic thumb muscle realignment, transfer or reconstruction if passive IPJ motion is present, in addition to the procedures recommended for type 2 thumbs (75,130). After reconstruction, type 2 and 3 thumbs function well, although they are always smaller and weaker than a normal thumb. The child with a type 2 or 3a deficiency recognizes the thumb and is able to use it to a limited extent. Surgical reconstruction can be postponed until the child is able to use the enhanced ability to manipulate small objects, around 2 to 4 years of age; older children also benefit. The MPJ of type 3a thumb is globally unstable and may eventually require arthrodesis. Reconstruction of types 3b and 4 thumbs is performed only in cultures in which the retention of a five-digit hand is of primary importance (130,151), because it requires multiple operations (including vascularized [151] or nonvascularized [207] bone graft from the patient’s foot), and the final functional result is inferior to thumb ablation and index pollicization (23,103).

| Type 3b, 4, or 5 (absent) thumb uses an index-long side-to-side pinch (20,30,62,103,124,129,212). Index pollicization improves this pinch. The index finger is shortened by removal of the index metacarpal and rotated so that it can function as a thumb, and the hypoplastic thumb is removed (Table 69.4). This procedure requires the surgical rearrangement of the skin, skeleton, muscles, nerves, and blood vessels. Carefully plan and mobilize skin flaps to create a first web of appropriate depth, extending from the MPJ of the new thumb to the MPJ of the long finger. A pollicized index finger functions like a thumb (124), but the base is less mobile and stable; the appearance is usually quite satisfactory (Fig. 69.8 and Fig. 69.9). Increasing severity of thumb hypoplasia is associated with increased stiffness of the more radial fingers, especially the index finger; pollicization of the stiff index finger has a less satisfactory outcome than the same procedure performed on a more flexible finger.

Figure 69.8. Index pollicization (this patient has already undergone centralization of the carpus on the ulna; see Fig. 69.48). A: Preoperative palmar view. B: Preoperative dorsal view. C: Postoperative palmar view. D: Postoperative palmar view.

Figure 69.9. Index pollicization (different patient from the one shown in Fig. 69.8). A: Tip pinch using new thumb. B: Tip pinch showing pronation of new thumb. C and D: Grasp using new thumb.

The timing of pollicization is somewhat controversial. Buck-Gramcko (20) and Flatt (63) argue for pollicization in the second 6 months of life, to allow the child to recognize the pollicized digit as a true thumb, and to give the former index finger the maximum amount of growth and development possible in its new position. Manske (124) has shown, however, that enhanced hand function following pollicization is not age dependent. Although pollicization is performed primarily to enhance function, it significantly changes the appearance of the hand; the most significant benefit of early surgery may be that this change occurs before the child has a fully developed self-image.

Occasionally, thumb deficiency is associated with severe mental retardation or developmental delay. This is a relative, but not absolute, contraindication to thumb reconstruction or pollicization. If the surgeon, occupational therapist, and parent agree that the thumb deficiency limits the child's function, the operation appropriate for the type of thumb hypoplasia (reconstruction or pollicization) is indicated.

Classification

Thumb hypoplasia is classified according to a modification of the Blauth scheme, which helps determine prognosis and treatment. (Table 69.3 and Fig. 69.10) (16,63,92,103,130). The thumbs of children with TAR syndrome do not fit this classification scheme (91). This classification can be used in combination with a modification of the Bayne scheme for radius deficiency (Table 69.11) (91).

Figure 69.10. Thumb deficiency: modified Blauth classification. A: Type 1, with mild flattening of thenar eminence. B: Type 2 (right hand). C: Type 3a, with lack of flexion at distal interphalangeal joint. D: Type 3a, with base of the thumb metacarpal present. E: Type 3b. F: Type 3b, with base of thumb metacarpal absent. G: Type 4. H: Type 4. I: Type 5. J: Type 5.

Preoperative Management

Some of the anomalies associated with thumb deficiency may increase the risk of general anesthesia; postpone surgery until general anesthesia is safe.

If the radius is deficient and the hand requires centralization, perform centralization before index pollicization (see the section entitled Radius Deficiency). Hands with thumb hypoplasia amenable to reconstruction (types 2 and 3a) usually do not have radius deficiency requiring centralization (91).

Before surgical reconstruction, the child with a type 2 or 3a thumb may benefit from the application of a soft short opponens splint to preposition the thumb. If the child refuses to use the splint, it is probably not helpful and can be discarded.

Do not discourage the child with a deficient thumb from using side-to-side pinch between the index and long or ring and small fingers. The development of this type of pinch is associated with more severe thumb hypoplasia and is an indication that the thumb is probably not amenable to reconstruction; the child would benefit from thumb ablation and index pollicization (23).

Operative Technique

1. Reconstruction of the type 2 hypoplastic thumb: fourfold Z-plasty, MPJ-UCL reconstruction and ADM opponensplasty (Fig. 69.11, Fig. 69.12 and Fig. 69.13)

Figure 69.11. Fourfold Z-plasty.
Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.

Deepen the first web using a fourfold Z-plasty (Fig. 69.11). The angle of each flap tip should be 45° (63,233). Release the first dorsal interosseous and adductor pollicis fascia, release of the muscles is not usually necessary in the younger child, but if contractures of these muscles have developed, they can be partially released near their insertions (103).

Sharply dissect free a proximally based flap of the MPJ-UCL, joint capsule and adductor pollicis insertion through the incision created by raising the skin flaps for the Z-plasty. Pull the flap light, and secure it with nonabsorbable suture by passing the suture through a hole drilled distal to the proximal phalanx physis and tying it over a button on the radial side of the proximal phalanx (Fig. 69.11). Pin the thumb MPJ in 0° extension and neutral radioulnar deviation.

Transfer the ADM to provide opposition (Fig. 69.12 and Fig. 69.13). Make a straight incision along the ulnar border of the palm, and curve it toward the palm, ending over the pisiform. Detach the ADM distally from the base of the small finger metacarpal, and elevate it proximally. Leave the muscle origin attached to the pisiform, to provide a firm proximal anchor and maintain the blood supply to the muscle (47,63). Create a generous subcutaneous tunnel across the palm, and pass ADM muscle through it, opening it like a book at its origin. Split the ADM tendon, and weave one slip of tendon into the radial capsule of the MPJ, and the other into the extensor pollicis longus (EPL) and tightened MPJ-UCL (63,128). Suture it in place with nonabsorbable 4-0 or 5-0 suture.

Close the skin with 5-0 chromic suture.

Apply a bulky compressive dressing over the thumb and fingers, and cover it with an above-elbow fiberglass cast shell.

2. Reconstruction of the type 3a hypoplastic thumb.

Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.

Deepen the first web, reconstruct the MPJ-UCL, and transfer the ADM as for the type 2 thumb, with one modification. Because the MPJ RCL is lax in type 3a thumbs, instead of inserting one slip into the radial capsule and the other into the EPL and ulnar capsule, attach one slip to the radial side of the base of the proximal phalanx and the other to the EPL (63,128).

Reconstruct the extrinsic tendons if passive IPJ motion is present. Tailor the reconstruction of the extrinsic tendons (EPL and flexor pollicis longus [FPL]) to the individual anomaly (75,130). The EPL may be hypoplastic or absent, the FPL aberrant or absent, or the two tendons may be interconnected. If both EPL and FPL are to be reconstructed, perform these two procedures in 2 stages.

If EPL is absent, transfer the extensor indicis proprius (EIP) to the extensor surface of the base of the distal phalanx, using a pullout technique to attach the transfer.

If the FPL is absent, transfer the ring FDS to the flexor surface of the base of the distal phalanx using a similar attachment technique; if pulley reconstruction is necessary, use local tissue or a toe extensor tendon (see Chapter 47 and Chapter 48 [flexor pulley reconstruction]).

If the EPL and FPL are interconnected radially, release the connection and reroute the aberrant tendons, or if length is insufficient, transfer the EIP or FDS as described earlier.

Close the skin with 5-0 chromic suture.

Apply a bulky compressive dressing over the thumb and fingers, and cover it with an above-elbow fiberglass cast shell.

3. If collateral ligament reconstruction fails, resulting in painful thumb MP joint instability, perform MPJ arthrodesis (105) (see the section entitled Polydactyly for a description of this technique).

4. Pollicization of the index (type 3b, 4 or 5 hypoplastic thumb) (Fig. 69.14 and Fig. 69.15).

Figure 69.12. ADM opponensplasty.

Figure 69.13. ADM opponensplasty. A: ADM muscle (bottom of photo, with suture attached). Attachment site is at base of the thumb. B: ADM muscle showing path of transfer.

is performed away from the surgeon, so the families can discuss advantages and disadvantages freely, and the opportunity to view preoperative and postoperative

photos of a pollicized index finger.

See Table 69.5 for the most common pitfalls of pollicization, and the best ways to avoid them. Necrosis of the new thumb is extremely rare (Buck-Gramcko reports one
case of necrosis, in a patient with index finger arterial anomalies, in a series of 460 pollicizations [23]).

</tr>
<tr>
<td>Supplemental opponensplasty is most commonly needed when the first dorsal interosseous is hypoplastic (129). The surgeon can prepare the family for this possibility following the pollicization.</td>
</tr>
</tbody>
</table>

PITFALLS AND COMPLICATIONS

If the subcutaneous tunnel for the ADM opposition transfer is too tight, or if the origin of the muscle is kinked, the transfer will not function well. If the reconstructed

MPJ-UCL is too tight, or if the new thumb is kinked, the transfer will deviate in an ulnar direction at the MPJ.

Most parents of children with hypoplastic or absent thumbs appreciate the opportunity to visit and talk with another child who has already undergone pollicization

(preferably away from the surgeon, so the families can discuss advantages and disadvantages freely), and the opportunity to view preoperative and postoperative

photos of a pollicized index finger.

AUTHOR'S PERSPECTIVE

This is a challenging operation that is best performed by an experienced hand surgeon. The wounds are easier to close and their appearance is better if the operation

is completed in less than 2 hours without releasing the tourniquet. Careful wound closure, with meticulous trimming of excess skin, also improves the appearance of the
TRIGGER THUMB

Assessment, Indications, Relative Results

Trigger thumb is a relatively common condition; the incidence is estimated to be 3 in 1000 live births (174). Trigger thumb in children is probably acquired, not congenital; recent reports indicate that experienced examiners found no trigger thumbs in two large series of newborns (174,186). In theory, the normal infant thumb position (lightly clenched in the palm until about 2 months of age, with a strong grasp reflex [99]) may contribute to the development of trigger thumb by pulling the flexor tendon tight against the opening of the proximal pulley (174), causing tendon inflammation and edema at the theca.

The infant's thumb rarely "triggers," or snaps (as does the adult's trigger digit), but instead usually presents as a fixed flexion contracture at the IPJ (average 35° [186]) (Fig. 69.16), or rarely as a fixed extension contracture (when the enlarged portion of the flexor pollicis longus [FPL] tendon gets trapped at the distal margin of the proximal pulley) (45,51,70,174,185,186,193). A palpable nodule in the FPL at the MPJ flexion crease of the thumb is almost always present; this nodule is probably caused by the bunching up and swelling of the FPL, which are attributable to chronic pressure from the proximal pulley (135,153,174). Differential diagnosis includes congenital clasped thumb and thumb hypoplasia.

The largest study of the natural history of this condition reported 12% spontaneous resolution for 131 trigger thumbs in 107 children observed for 6 months (average age at diagnosis was 2 years); for trigger thumbs noted at birth, the spontaneous resolution rate was 31% by 1 year of age. In this study, children who underwent surgery within 3 years of diagnosis did not have a residual flexion contracture of the IPJ, but children older than 4 years of age at surgery had a high rate of residual IPJ flexion contracture (21). Other authors have found a lower incidence of spontaneous correction (70,193) and no residual flexion contracture in children whose trigger thumbs were released after 3 years of age (185). Trigger fingers may also occur in children, but they are much rarer than trigger thumbs and more likely to resolve spontaneously (193).

Trigger digits in children have been reported to be associated with mucopolysaccharide storage disorders (215), juvenile arthritis (163), and diabetes mellitus (163,235). There is a slight familial predisposition, and bilateral involvement is not uncommon (41,183,214,436).

Although splint therapy was successful in 24 of 43 digits according to one report (159), surgical release of the A1 pulley (45) (Fig. 69.17) is the treatment of choice. This is a simple and very successful operation; of 402 reported releases of trigger digits, 401 were successfully released (51,70,163,174,185,186,193,232), with only one recurrence (163) and no other significant complications. Do not use steroid injections for this condition in children (135).

Preoperative Planning

There is no compelling indication to release a trigger thumb in an infant before the age of 1 year. The trigger thumbs of children older than 3 years of age at the time of presentation are very unlikely to resolve spontaneously, and should be released to enhance the child's hand function and prevent a permanent flexion contracture of the IPJ.

Operative Technique

Release of trigger thumb.

- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
- The radial digital nerve to the thumb may be stretched over the nodular enlargement of the FPL tendon, in the region of the surgical incision. Make a transverse incision through dermis only, at the proximal digital flexion crease of the thumb, and do not hyperextend the thumb MPJ.
- Use blunt dissection to expose the flexor sheath. Locate and retract the ulnar and radial digital neurovascular bundles.
- Find the proximal margin of the A1 pulley, and sharply incise it from proximal to distal. Excision of the pulley is not necessary; it will fall open as it is incised. Move the IPJ through its new passive range, and observe that the tendon nodule no longer impinges. If it continues to impinge when the joint is hyperextended, release a small amount of additional pulley. Do not debride the nodule (unless the patient has a mucopolysaccharide storage disease, in which case debridement may be necessary [215]).
- Pull on the FPL tendon with a Ragnell retractor to demonstrate that there are no other impediments to its excursion.
- Close the skin incision with interrupted 5-0 chromic suture.
- Apply a light compressive dressing, and cover it with Coban. A cast is not necessary.
- Remove the dressing after 7 to 10 days. No postoperative rehabilitation is necessary.

PITFALLS AND COMPLICATIONS

Complications of this procedure are the result of errors in surgical technique. Do not release the oblique pulley, or the FPL tendon may bowstring; this result is cosmetically unappealing and reduces FPL efficiency. Take great care with the skin incision, because the radial digital nerve to the thumb is immediately...
subcutaneous, especially when tented over the FPL nodule.

**AUTHOR'S PERSPECTIVE**

A longitudinal skin incision may be slightly safer for the less experienced surgeon, but the radial digital nerve, which runs very close to the midline, can also be damaged with this incision, and the appearance of a healed transverse incision is much more satisfactory.

If the trigger thumb is diagnosed before the child is 1 year of age, observe the child until after the first birthday, when the risk of general anesthesia is lower and the trigger thumb is unlikely to resolve spontaneously. Trigger thumb in children should not be confused with trigger digit in adults, because the pathophysiology, natural history, and treatment differ (see Chapter 50: Trigger Digits).

### CLASPED THUMB

#### Assessment, Indications, and Relative Results

Congenital clasped thumb is a rare condition seen in isolation or as a feature of syndromes such as Freeman-Sheldon syndrome or arthrogryposis (135,208). It is diagnosed after age 2 months, when the infant's normal palmar grasp pattern has diminished but the thumb remains in the palm. There is a genetic predisposition toward this condition, which is usually bilateral and occurs more often in males than in females (208).

If the thumb can be passively fully extended at the MPJ, casting or splinting in abduction and extension usually restores normal thumb position. This type of clasped thumb is due to hypoplastic extensor tendons overpowered by thumb flexor tendons, and positioning the thumb in extension for several months allows the extrinsic tendons to recover their balance (135).

When the thumb cannot be passively extended at the MPJ, associated thumb anomalies are commonly seen, including MPJ-UCL laxity, thenar muscle hypoplasia, and thumb CMCJ adduction contracture (135). Splitting may reduce the thumb MPJ flexion contracture but will not affect the other anomalies. Surgical correction should be tailored to the particular deformities and may include MPJ contracture release, FPL lengthening, ADM opponensplasty, tendon transfer to the EPL, and skin Z-plasty or thick split-thickness skin graft (135,139). Attempt splinting and stretching until the child is 2 to 3 years of age before resorting to surgery. Reconstruction may improve the position of the thumb, but does not restore normal function.

#### Classifications

McCarroll has classified clasped thumbs as supple and complex. Supple thumbs have good passive range of motion. Complex clasped thumbs have passive contractures, and may be associated with arthrogryposis and Freeman-Sheldon syndrome (Fig. 69.18, 135,136). Other, more elaborate schemes have been described (208,226,227), but they do not assist the surgeon with the prognosis and treatment more than McCarroll's simple scheme.

![Figure 69.18. Complex clasped thumb. A: Preoperative view. B: Postoperative view (following release; dorsal rotation flap was not necessary).](image)

#### Preoperative Management and Planning

The initial treatment of all clasped thumbs is splinting and stretching exercises. Supple thumbs will probably correct themselves, and complex clasped thumbs may improve, making surgery unnecessary or at least simpler.

Release may require a thick split-thickness skin graft for coverage. Graft harvested from just below the anterior iliac crest leaves a scar in an inconspicuous location and does not bear hair when the child enters puberty (see the section entitled Syndactyly.)

#### Operative Technique

1. Tendon transfer (when supple thumbs that cannot be actively extended and splinting has failed).
   - Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
   - Explore the dorsum of the thumb through a zigzag incision. Determine the best attachment point for the transferred tendon: either the hypoplastic EPL or extensor pollicis brevis (if it pulls through) or extensor hood tissue on the dorsal base of the proximal phalanx.
   - Through a separate transverse incision at the level of the distal end of the dorsal extensor retinaculum of the wrist, explore the fourth dorsal compartment for the EIP tendon. This is the preferred tendon to transfer to the thumb extensor mechanism, but it is usually absent in patients with clasped thumbs (139). If it is present, transect it as far distal as possible, create a blunt subcutaneous tunnel between the wrist and thumb incisions, pass the EIP tendon through the tunnel, and weave it through the chosen recipient tissue, suturing it in place with nonabsorbable 4-0 suture. If the EIP is absent, transfer either the extensor carpi radialis longus (ECRL) (extended with a tendon graft from palmaris longus) or the ring FDS tendon (112,135,139,298). Adjust the tension of the transfer so that the thumb tip touches the index finger in a key pinch position when the wrist is passively extended and the thumb MPJ position is 0° when the wrist is in neutral position.
   - Close the thumb incision with interrupted 5-0 chromic suture, and close the wrist incision with a running absorbable subcuticular 4-0 suture and Steri-Strips.
   - Apply a bulky compressive dressing over the thumb, fingers, and hand, and cover it with an above-elbow fiberglass cast shell.

2. Thumb flexion-adduction contracture release and reconstruction (complex clasped thumbs).
   - Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
   - Explore the dorsal thumb through a longitudinal incision centered over the MPJ. Release the dorsal capsule of the MPJ if it is adherent to the metacarpal head, because it can block MPJ extension (135).
   - Explore the first web and palmar MPJ structures through a fourfold Z-plasty (Fig. 69.19) or, if necessary, plan and raise a large, radially based dorsal rotation-advancement flap (Fig. 69.19) (67,136). Release the palmar plate of the MPJ and, if necessary, the RCL. Release the first dorsal intersosseous fascia; the muscle does not usually require release.
ADM Opponensplasty (may be performed at the same time as release and reconstruction, discussed earlier, or as a second stage for the complex clasped thumb MPJ arthrodesis (for a painful or unstable MPJ in the older child).

Removal of accessory phalanx (hypoplastic middle phalanx; opposable triphalangeal thumb) (Fig. 69.20).

Operative Technique

1. Radiographic study is necessary to determine the size and shape of the extra phalanx, and to plan a reduction osteotomy.

Preoperative Planning

Operative Technique

1. Removal of accessory phalanx (hypoplastic middle phalanx; opposable triphalangeal thumb) (Fig. 69.20).
   - Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
Approach the accessory phalanx through a midlateral incision on the convex side of the thumb. Incise the collateral ligament and the adjacent periosteum longitudinally, and remove the accessory phalanx. Close the skin with 5-0 chromic suture. Apply a bulky compressive dressing over the thumb and hand, and cover it with an above-elbow fiberglass cast shell.

2. Reduction osteotomy (opposable triphalangeal thumb) (Fig. 69.21) (94).

![Figure 69.21. Reduction osteotomy for triphalangeal thumb. See text for details. (From Jennings JF, Peimer CA, Sherwin FS. Reduction Osteotomy for Triphalangeal Thumb: An 11 Year Review. J Hand Surg 1992;17A:8.)]

- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
- Approach the middle phalanx and the distal IPJ (DIPJ) through a dorsal incision, detaching the extensor tendon (Fig. 69.21A).
- If necessary, narrow the nail and distal phalanx (Fig. 69.21B).
- Pass a fine Kirschner wire through the proximal IPJ (PIPJ), to orient transverse osteotomies (Fig. 69.21C).
- Excise the epiphysis of the distal phalanx, using a scalpel to transect the physis (Fig. 69.21D).
- Cut the middle phalanx perpendicular to the PIPJ, retaining the PIPJ collateral ligaments. This closing wedge shortens and realigns the thumb (Fig. 69.21E).
- Fix the osteotomies with longitudinal Kirschner wire or wires (Fig. 69.21F).
- Repair the extensor tendon with nonabsorbable nylon suture.
- Close the skin with 5-0 chromic suture.
- Apply a bulky compressive dressing over the thumb, fingers, and hand, and cover it with an above-elbow fiberglass cast shell.

3. Epiphysiodesis (opposable triphalangeal thumb):

- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
- Through midlateral incisions on each side of the thumb, approach the physes of the three phalanges. The metacarpal physis is approached from a dorsal incision.
- Using Fluoroscan guidance, use small curets (size 0000) to ablate the physeal cartilage.
- Close the skin with 5-0 chromic suture.
- Apply a soft bulky compressive dressing over the thumb and hand, and cover it with Coban.

4. Pollicization and opponensplasty (staged; nonopposable triphalangeal thumb) (see the section entitled Hypoplasia and Absence).

**General Rehabilitation and Postoperative Principles**

Remove the cast (and pin, if used) after 6 weeks with radiographic evidence of healing of osteotomies. Allow the child to use the hand as tolerated; therapy and splint immobilization are usually unnecessary.

**PITFALLS AND COMPLICATIONS**

Because of the rarity of this malformation, only small series of patients have been reported. Postoperative instability and stiffness have not been reported, but undercorrection and overcorrection and recurrence of the deformity have occurred (84,157).

**AUTHOR’S PERSPECTIVE**

If possible, excise the hypoplastic accessory phalanx early. Treatment of the well-developed triphalangeal thumb is more complex. If the thumb functions well, and the parents are not bothered by the appearance, defer treatment until the child is older, when epiphysiodesis is an option.

**THE FINGERS**

**POLYDACTYLY**

**Assessment, Indications, and Relative Results**

Finger polydactyly is a relatively common congenital malformation; in the United States, it is slightly less common and more often associated with a syndrome, than is thumb polydactyly. Finger polydactyly may be associated with chromosomal abnormalities, eye and orofacial abnormalities, bone dysplasias, and mental retardation (56). The small finger is the most commonly duplicated finger, especially in blacks (1 in 143 to 300 live births, compared with 1 in 1339 live births of whites [56,223]). Duplication of the index, long, or ring finger is quite rare and is usually associated with other hand anomalies, including cleft hand.

A duplicated small finger with a tiny pedicle may be ligated by a suture soon after birth. Remove duplicated digits with more substantial pedicles or those connected to other digits by webs (Fig. 69.22) when the child is older, because a large pedicle may bleed with suture ligation. The functional result of removal of a duplicated small finger is usually quite good, although suture ligation often leaves a bump. The outcome of removal of a duplicated index, long, or ring finger depends on the associated anomalies. Retained fingers are less likely to require reconstruction than are retained duplicated thumbs.

![Figure 69.22. Postaxial polydactyly. A: Small pedicle, but not small enough for suture ligation. B: Well-developed postaxial polydactyly, also not suitable for suture ligation.](image)
Classifications

Duplication of the index, long, or ring finger is described as central or axial, and duplication of the small finger is postaxial. The duplicated digit may articulate with a broad metacarpal head, or, less commonly, the metacarpal may also be duplicated (56). Temtamy and McKusick divided postaxial polydactyly into type A (fully developed extra digit) and type B (rudimentary or pedunculated extra digit) (201).

Preoperative Planning

When the duplicated fingers are approximately equal in size, wait until the child is older than 1 year of age, and observe his or her use of the fingers to plan treatment. Determine which finger functions best and preserve it. Delay surgery until age 3 years of age in most cases. Ligate the type B finger in the newborn; inform the parents that the digit will turn black and fall off.

Operative Technique

1. Suture ligation (type B postaxial duplication).
   - If the pedicle is broad, do not use suture ligation. Instead, perform a formal amputation under general anesthesia, through a zigzag incision.
   - If the pedicle is small, ligate the pedunculated digit at its base with undyed 2-0 Vicryl suture.
   - Apply a bulky compressive dressing and cover with Coban.
2. Ablation of a type A postaxial duplication (56).
   - Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
   - If the ulnarmost finger is to be removed, use an elliptical incision along the midaxial line. Detach and preserve the insertions of the ADM and the (MPJ-UCL).
   - If the metacarpal is duplicated, extend the incision to remove it.
   - If the retained metacarpal head has an ulnar bulge, shave it.
   - Reattach the ADM and UCL to the retained finger.
   - Close the skin with interrupted 5-0 chronic suture.
   - Apply a bulky compressive dressing over the fingers and hand, and cover it with an above-elbow fiberglass cast shell.
3. Reconstruction of the duplicated index, long, or ring finger.
   - In the case of duplicated index, long, and ring finger, each of these hands has a unique set of anomalies, which may include stiff joints, a longitudinal epiphyseal bracket, complex syndactyly, transverse phalanx, rotational or angulatory malalignment, and cleft hand. See the section entitled “Cleft Hand” and follow these basic principles; tailor the operation to the malformations:
     - Establish as normal a skeleton as possible. Combine parts from two fingers, if necessary.
     - Avoid damaging epiphyses and physes.
     - Correct bony alignment with phalangeal osteotomy.
     - Separate syndactyly, and plan flaps incorporating skin from the ablated digit so that no additional skin graft is needed.
     - Close the skin with interrupted 5-0 chronic suture.
     - Apply a bulky compressive dressing, and cover it with an above-elbow fiberglass cast shell.

General Rehabilitation and Postoperative Principles

Keep the hand immobilized long enough for soft-tissue and bony healing, as appropriate. Splinting and therapy are not usually necessary.

PITFALLS AND COMPLICATIONS

Suture ligation of the type B digit causes necrosis, which is distressing to some parents. Sometimes the necrotic digit does not fall off, and requires surgical removal. The residual bump left by suture ligation can be unsightly (223).

AUTHOR’S PERSPECTIVE

Reconstruction of complex central duplications should be performed by an experienced hand surgeon. Residual deformity is common even when the hand is reconstructed by an expert. Sometimes, when both duplicated fingers are inadequate, removal of both (leaving a three-fingered hand) may be preferable.

TRANSVERSE FAILURE OF FORMATION (HYPOPLASIA AND ABSENCE)

Assessment, Indications, and Relative Results

This discussion pertains to fingers that have failed to form normally; differentiate them from fingers that are deformed prenatally by constriction ring syndrome (see the section entitled Constriction Ring Syndrome, and Table 69.6). Transverse failure of formation, or terminal deficiency, occurs in about 1.5 in 10,000 births (this estimate includes failure of formation at levels proximal to the fingers) (108), and 98% are unilateral (234). Short digits are often incompletely separated.

Table 69.6. The Differential Diagnosis of Short and Absent Fingers: Transverse Failure of Formation vs. Congenital Constriction Ring Syndrome (96, 142, 163)

Parents and children frequently request lengthening of short fingers, and surgeons have devised numerous ways to augment length. No single procedure, however, is vastly superior to any other; normal appearance is usually unattainable, and lengthening the digits of a child with a normal hand on the contralateral side does not improve function. Children with one normal hand perform most functional activities at about the same developmental age as children with two normal hands. Indications for reconstructing the unilateral aphasisic hand are based on the following principles:

1. Children will put almost any sensate reconstructed digit to good use.
2. More digits usually function better than fewer, as long as one does not get in the way of the others.
3. Increased length usually enhances function, although a stiff digit should be shorter than flexible ones (73).
4. When short digits are incompletely separated, web deepening enhances function and appearance.

Surgical reconstruction is not recommended for digits that have failed to develop metacarpals, with the exception of the thumb (see the section entitled Hypoplasia and Absence—Pollicization).
Operations designed to augment digital length include ablation of nubbins, “on-top-plasty,” in which one short digit is transplanted onto the top of another (42,49,61,166); web deepening (49,61); and single-stage osteotomy, distraction, and insertion of intercalary bone graft. Also included are distraction lengthening with or without second-stage bone grafting (61,101,164,166,168); nonvascularized toe phalanx transfers (22,61,73,90,169); and microvascular toe-to-hand transfer (71,85,105,113,114,220).

Nubbin ablation does not enhance function. “On-top-plasty” is technically difficult and diminishes the number of digits present. Web deepening is simple and useful, either by itself or when combined with another operation, but if webs are made deeper than normal, the metacarpals are “phalangized” and the appearance of the hand is usually aesthetically displeasing. Distraction lengthening of finger phalanges is not usually indicated, because stiff fingers should be short, or they will interfere with the function of more flexible fingers. Distraction lengthening of short metacarpals may enhance function and appearance.

Nonvascularized toe phalanx transfers are possible when a soft-tissue tube large enough to hold bone graft has developed distal to the metacarpal; toe phalanges are selected as a source of graft because terminally placed bone graft is resorbed unless it is cortically perimetered (61). The indications for free toe-to-hand transfer for transverse defects and symbrachydactyly are controversial, and the arterial supply, venous drainage, and nerves and muscles in a malformed hand are always abnormal and sometimes nonexistent. This operation is sometimes technically feasible, however, and it seems to preserve growth in many cases (89,220).

Classifications

There are many different types of congenitally short digits and even more different names for them. Brachydactyly is the term most commonly, consistently, and accurately used to describe short fingers. Ectrodactyly is also used as a general descriptive term, but different authors define it differently; most commonly, it connotes digital absence. Some terms are used to describe specific types of short fingers, such as aphasis (phalanges failed to develop, some soft-tissue structures may be present; Fig. 69.23), symbrachydactyly (short, webbed digits, more deficient centrally, previously called atypical cleft hand, Fig. 69.24), and symphalangia (absence of the proximal interphalangeal joints, Fig. 69.25), among many others.

---

**Figure 69.23. A and B:** Aphasis.

**Figure 69.24.** Symbrachydactyly.

**Figure 69.25.** Symphalangia.

Geneticists use extensive classification systems, such as Bell’s classification of brachydactyly, to describe and categorize short fingers, because some types of short fingers have a dominant inheritance pattern. These systems do not help the surgeon predict function or plan treatment.

Preoperative Management

Many parents are emotionally devastated by the birth of a child with aphalangia, especially when the deformity was not diagnosed prenatally. They may want to donate their own fingers or toes to their child, or obtain a cosmetic prosthesis immediately. Counsel parents early on that surgery cannot bring about normal appearance in most cases of aphalangia and that enhancing function will be the primary goal, at least until the child is old enough to participate in decision making, when enhancing appearance may take precedence. Peer contacts can be very valuable.

Preoperative Planning

Several studies of toe proximal phalanx transfers have shown that the transferred toe phalanx physis is more likely to remain open and grow in younger patients (22,73,90,168). Growth of a transferred toe phalanx is negligible in many cases, however, and never normal, so surgery may be postponed until the child is older and the phalanx larger. Before performing toe proximal phalanx transfers, obtain radiographs with 10 cm markers of the affected hand or hands and feet; these radiographs provide an estimate of magnification, enabling accurate measurement of the toe phalanx. The transferred toe phalanx can be attached either to the end of the metacarpal (in which case it is effectively a one half joint transplant) or to a hypoplastic proximal phalanx.

Operative Technique
1. Nubbin ablation.
   - Perform the operation with the patient under general anesthesia and tourniquet.
   - Remove all of the finger nubbins together, via an elliptical incision around the base of the nubbins.
   - Close with 5-0 chronic suture.
   - Apply a bulky compressive hand dressing, and cover with Coban.

2. Web deepening (see the section entitled Syndactyly).

3. On-top plastic: this operation is rarely indicated. See Dobyns (42) for details.

4. Metacarpal distraction lengthening (see Chapter 32 and Chapter 71) (101,161,164,188)

5. Nonvascularized toe proximal phalanx transfer (Fig. 69.26).

Fig. 69.26. Nonvascularized toe proximal phalanx transfers. A: Preoperative palmar view. B: Preoperative radiograph view, with soft-tissue tubes distal to metacarpals. C: Postoperative radiograph, following toe proximal phalanx transfers to index, long, ring, and small fingers. D: Palmar view, 2 years after phalanx transfer. E: Radiograph, 2 years after phalanx transfer. Note the open physis of the ring phalanx, and the resorption of the tips of the long and small phalanges. F: Feet, 4 years after phalanges were harvested from third and fourth toes of both feet.

- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquets.
- Drape free the affected hand and selected foot or feet. If four toe phalanges are needed, select the third and fourth toes of each foot.
- Explore the digits chosen to undergo toe phalanx transfer through dorsal chovan incisions. Split the extensor tendon, which inserts into subcutaneous tissue distally.
- Create a pocket in each digital tube, but take care not to remove too much subcutaneous tissue distally. Release the arm tourniquet while you harvest the toe proximal phalanges.
- Approach the selected toe or toes through a dorsal chovan incision. Split the extensor tendon.
- Dissect the toe proximal phalanx from distal to proximal. Stay superoperostial distally, but leave the periosteum with the phalanx proximally. Remove the metatarsophalangeal collateral ligaments and part of the plantar plate with the phalanx; leave the flexor tendon intact.
- Suture the flexor and extensor tendons together. Close the wound with 5-0 chronic. After harvesting all of the toe phalanges needed, deflate the leg tourniquet or tourniquets.
- Reexsanguinate the hand and arm. and reinflate the arm tourniquet.
- Skewer the toe phalanx on a 0.035 or 0.045 in. Kirschner wire. Pass the wire antegrade by hand out of the tip of the previously prepared digital tube, then drive it retrograde into the finger hypoplastic proximal phalanx or metacarpal or both. If the fit seems tight, remove the phalanx, and trim the distal end before reinserting it.
- If after all the phalanges have been inserted, deflate the tourniquet. If the tip of a digit is not vascularized, remove the phalanx, trim it, and reinsert it.
- If there is no proximal phalanx remnant present, attach the collateral ligaments to the metacarpal periosteum with absorbable suture.
- Check the Kirschner wire placement radiographically.
- Close the skin with interrupted 5-0 chronic suture.
- Apply a bulky compressive dressing over the fingers and hand, and cover it with an above-elbow fiberglass cast shell.
- Dress the foot or feet and apply a short-leg walking cast or casts.

6. Free toe-to-hand transfer (see Chapter 35 and Chapter 36).

General Rehabilitation and Postoperative Principles

Following nonvascularized toe proximal phalanx transfer, remove the leg cast or casts in 3 weeks. Change the hand cast under sedation in 6 weeks, and remove the second hand cast and Kirschner wires in the clinic 12 weeks after surgery. Obtain radiographs of the hand every 6 months, with markers placed 10 cm apart so magnification can be calculated, and the growth of the phalanx can be accurately measured. At a later date, deepen web spaces and lengthen transferred phalanges and metacarpals as indicated.

PITFALLS AND COMPLICATIONS

The most common complications of toe proximal phalanx transfers are tip necrosis, physeal arrest, and resorption. Avoid early tip necrosis by taking care to trim the transferred phalanx to fit the digital tube. Late tip necrosis can occur if growth of the phalanx is especially vigorous, and may require a second operation to trim the tip of the phalanx. Toes from which proximal phalanges have been harvested are short, but toe complaints are rare following this operation. Do not fail to deflate the leg tourniquet after you have harvested all the toe phalanges needed.

AUTHOR'S PERSPECTIVE

For nonvascularized toe proximal phalanx transfers, physeal arrest seems less likely to occur in younger children (especially those younger than 18 months of age at surgery) (22,73,169), but even the phalanges achieving the most growth do not grow as much or for as long as they would if they had been left in the toe (80). Waiting until the child is older and the phalanx is bigger seems sensible.

Counsel parents and older children about what they can expect from surgery. Often, they believe it can make short fingers normal. Peer contact with other children and families who have adjusted well to similar malformations is especially useful for children with short fingers. Sometimes, no matter how carefully they are counseled, parents and children are disappointed with the results of any operation.

Do not set the web more proximal than usual when separating short, webbed fingers. This procedure “phalangizes” the metacarpals, making the hand appear aesthetically displeasing. In addition, it requires release of the intermetacarpal ligament, which may make the digit unstable, and ligation of one of the digital arteries, which puts the digit at unnecessary risk of vascular insufficiency.

Free toe-to-hand transfer is not usually indicated for a unilateral malformation, because this operation does not restore normal appearance, and children with one normal hand are able to perform most developmental tasks.

SYNDACTYLY

Assessment, Indications, and Relative Results

Syndactyly is the most common congenital hand malformation (1.2500 births): it may occur as an isolated anomaly (usually inherited in an autosomal dominant pattern) or as part of a syndrome (80). Syndromes commonly associated with syndactyly include Poland’s syndrome (sporadic occurrence of symbrachydactyly associated with variable deficiency of the pectoralis major muscle), probably part of the subclavian artery supply disruption sequence (10,89,203) (Fig. 69.27); and acrosyndactyly, which occurs with congenital constriction band syndrome. Apert’s syndrome is a complete and complicated form of syndactyly of multiple digits that is associated with craniosynostosis (Fig. 69.28) (203,219). Pfeiffer’s syndrome is a milder syndactyly associated with acrosyndactyly (203). Other associated syndromes have been
Syndactyly occurs most commonly between the long and ring fingers, followed by ring-small, index-long, and least commonly, thumb-index (65) (see the section entitled Cleft Hand in this chapter for a discussion of thumb-index syndactyly). The normal level of a finger web is halfway between the MPJ and PIPJ; for the thumb-index configuration, the normal web extends from the index MPJ to the thumb MPJ. If the distal web extends proximal to the PIPJ and extends no farther distal to normal level than the palm is deep, it can be adequately deepened with a butterfly flap without using skin graft. If the web extends distal to the PIPJ, release requires full-thickness skin graft. Harvest the graft from an inconspicuous location such as the groin (from an area that will not bear pubic hair at a later date, or the graft will bear hair in its new location).

Classifications

Hand surgeons classify syndactyly on the basis of clinical and radiographic findings, by both the degree of webbing and the presence of bony fusion or other bony anomalies (63,65,74). Syndactyly is described as incomplete when the web does not extend to the fingertips, and complete when the web extends to the tips; in complete syndactyly, the fingers may share a common nail (synonychia). The term simple is used to describe syndactyly that involves only soft tissues, complex when synostosis is present, and complicated when the webbed digits conceal polydactyly, dislocations, longitudinal epiphyseal brackets, and other bony malformations.

Geneticists have also classified syndactyly. Temtamy and McKusick propose five types based on localization of syndactyly in the hands and feet; these phenotypes seem to be correlated with genotype for isolated syndactyly (202).

Preoperative Planning

Obtain radiographs of both hands (and feet, if toe syndactyly is present) to help classify the syndactyly.

Neurovascular anomalies commonly accompany syndactyly, and the common digital arteries may branch distally, with one branch requiring ligation at the time of release. (A distally branching common digital nerve can be split into fascicles supplying each finger). Thus, when the syndactyly involves more than two digits, stage the releases to avoid operating on both sides of the same digit in the same procedure. At the second stage, refer to the report from the previous operation to ascertain whether a digital artery was ligated; if so, do not ligate the other artery to the same finger.

Time the surgery on the basis of the digits involved and the degree and complexity of the syndactyly. Release border digits early (usually around 6 to 12 months of age), because their length discrepancy may cause the longer digit to develop a flexion contracture and angulate toward the shorter one with growth. Although there is no such urgency to release long-ring or index-long syndactyly, parents may prefer early surgery. As long as anesthetic risk is not increased by airway, pulmonary, or cardiac anomalies, the experienced hand surgeon can honor this preference without compromising the long-term result.

If other hand or foot parts are to be ablated (e.g., a duplicated toe), schedule this operation for the same anesthetic as the syndactyly release, and harvest skin from the amputated part, because the color of foot skin better matches the hand than does groin skin.

Operative Technique

1. Butterfly flap (incomplete syndactyly release; Fig. 69.29).

   - Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
   - Draw the flaps, aligning the proximal margin of the palmar Z with the normal level proximal digital flexion creases of the other digits. Each limb of the palmar Z and each limb of the dorsal rectangle should be the same length. The dorsal rectangle originates several millimeters proximal to the palmar proximal digital flexion creases, in order to create the normal dorsal-palmar slope of the web.
   - Raise the dorsal rectangle at the subdermal level, taking a thin layer of subdermal fat with the flap.
1. Raise palmar Z flaps of the same thickness.
2. Transect distal fascial bands, protecting the digital neurovascular bundles.
3. Interdigitate the dorsal and palmar flaps, attaching the corners of the dorsal rectangle to the palmar side at the normal level of the proximal digital flexion crease and wrapping a palmar flaps around the base of each digit.
4. Close with interrupted 5-0 chromic suture.
5. Apply a bulky compressive dressing, covered with either Coban (for the older child who can keep the dressing clean and dry) or an above-elbow fiberglass cast shell.

2. Complete syndactyly release (for syndactyly extending distal to the PIPJ; Fig. 69.30, Fig. 69.31 and Fig. 69.32).

**Figure 69.30.** Incisions for syndactyly release.

**Figure 69.31.** Syndactyly tip release.

- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
- Prepare and drape the full-thickness graft donor site.
- Carefully plan and mark all flaps before inflating the tourniquet.
- Place the base of the palmar V at the normal level of the proximal digital flexion crease. Place the base of the dorsal rectangle several millimeters proximal to the V, to create the normal dorsal-palmar slope of the web. The palmar V and the dorsal rectangle should be slightly longer than the depth of the palm. The sides of the dorsal rectangle should not extend beyond the midline of either digit (Fig. 69.30 and Fig. 69.31).
- If the syndactyly is complicated, and there is no redundant soft tissue between the digits, consider using crossed triangles instead of the dorsal rectangle-palmar V technique described here.
- Plan the palmar and dorsal triangular flaps on the fingers to interdigitate with each other after the fingers are separated.
- Elevate all flaps with a thin layer of subdermal fat.
- Separate the synonychia, if present (Fig. 69.31 and Fig. 69.32). Plan two long narrow flaps across the fingertips, one based on each fingertip. Each flap is the length of the nail. Raise these flaps carefully, and divide the nail, the nail bed, and any synostosis of the distal phalanges. Fold each flap down alongside the divided side of the nail to create the nail wall.
- Separate the digits carefully, searching for the neurovascular bundles.
- If the common digital artery and nerve bifurcate distal to the new web margin, separate the fascicles of the common digital nerve into the two proper digital nerves. Ligate the smaller of the two digital arteries, or the artery that does not supply a border digit (for example, preserve the radial digital artery to the small finger, since the ulnar digital artery to the small finger is often hypoplastic).
- Secure the flaps in place with 5-0 chromic suture. Split the dorsal rectangular flap longitudinally, almost to its base. Wrap half around each finger, suturing the corner closest to the midline of the flap in the triangular defect adjacent to the palmar triangular flap.
- Grafts are always needed on the proximal dorsal aspect of each finger. Usually one finger can be closed without any additional graft, and the remaining finger needs 3 to 5 grafts to fill in defects not covered by flaps.
- Make patterns of all defects requiring grafts.
- Deflate the tourniquet.
- Transfer the patterns to the groin. Harvest thick split-thickness graft in the shape of the patterns. Stretch the skin while transferring the patterns and harvesting the grafts, or the grafts will be too big. Remove the remaining dermis from the groin wound and close in layers as a full-thickness defect.
- Attach the grafts to the hand using interrupted 5-0 chromic suture.
- Dress hand wounds with xeroform gauze and cotton balls soaked in normal saline. Apply a bulky compressive dressing, and cover it with an above-elbow fiberglass cast shell.
- Carefully plan and mark all flaps before inflating the tourniquet.
- Elevate all flaps with a thin layer of subdermal fat.
- Separate the synonychia, if present (Fig. 69.31 and Fig. 69.32). Plan two long narrow flaps across the fingertips, one based on each fingertip. Each flap is the length of the nail. Raise these flaps carefully, and divide the nail, the nail bed, and any synostosis of the distal phalanges. Fold each flap down alongside the divided side of the nail to create the nail wall.
- Separate the digits carefully, searching for the neurovascular bundles.
- If the common digital artery and nerve bifurcate distal to the new web margin, separate the fascicles of the common digital nerve into the two proper digital nerves. Ligate the smaller of the two digital arteries, or the artery that does not supply a border digit (for example, preserve the radial digital artery to the small finger, since the ulnar digital artery to the small finger is often hypoplastic).
- Secure the flaps in place with 5-0 chromic suture. Split the dorsal rectangular flap longitudinally, almost to its base. Wrap half around each finger, suturing the corner closest to the midline of the flap in the triangular defect adjacent to the palmar triangular flap.
- Grafts are always needed on the proximal dorsal aspect of each finger. Usually one finger can be closed without any additional graft, and the remaining finger needs 3 to 5 grafts to fill in defects not covered by flaps.
- Make patterns of all defects requiring grafts.
- Deflate the tourniquet.
- Transfer the patterns to the groin. Harvest thick split-thickness graft in the shape of the patterns. Stretch the skin while transferring the patterns and harvesting the grafts, or the grafts will be too big. Remove the remaining dermis from the groin wound and close in layers as a full-thickness defect.
- Attach the grafts to the hand using interrupted 5-0 chromic suture.
- Dress hand wounds with xeroform gauze and cotton balls soaked in normal saline. Apply a bulky compressive dressing, and cover it with an above-elbow fiberglass cast shell.

3. Separation of syndactyly at the PIPJ: Syndactyly associated with Apert syndrome can be classified into several different types. All are complex, and involve at least one border digit. Because multiple operations will be necessary to separate the digits, operate as early as the pediatric anesthesiologist deems safe. If possible, coordinate syndactyly release to be performed at the same anesthetic as the craniofacial surgery these infants require. Reconstruct three fingers instead of four if bony and soft tissue are inadequate. The details of the treatment of this condition are too complex to cover in this chapter. See Upton (210) and Van Heest (216) for details.

4. Separation of thumb-index syndactyly (see the section entitled Cleft Hand).
General Rehabilitation and Postoperative Principles

Instruct the parents to keep the cast dry. If it becomes wet, especially within the first week after surgery, the cast must be removed and the dressing changed, or the graft may fail. Remove the cast and dressing after 4 weeks; the child may then use the hand without restrictions. No splinting or therapy is necessary.

PITFALLS AND COMPLICATIONS

Hypertrophic scarring in the web and “web creep” (a web margin that ends up more distal than the surgeon intended) are most commonly caused by too much tension in the web space closure. Plan pedicle flaps carefully so they cover the base of the web, because graft at the base will contract and narrow the web. Use graft generously, but avoid making each individual graft too large for its space, or the contour will not be smooth.

AUTHOR’S PERSPECTIVE

This operation is not as simple as it seems. Like many hand operations, if it is not done well the first time, it is very difficult to redo well.

CAMPTODACTYLY

Assessment, Indications, and Relative Results

Camptodactyly is a Greek word meaning “bent finger,” which is used to describe a flexion contracture of the PIPJ, usually of the small finger. The incidence of camptodactyly is unknown.

The etiology of camptodactyly is multifactorial. Malformation of several different anatomic structures has been cited as the underlying cause of this deformity: anomalies of musculotendinous structures such as the lumbrical (87,141), the FDS (84,160,189), both of these (137), and the extensor mechanism (104,105).

Regardless of etiology, the initial treatments are splinting and stretching of the flexion contracture. The older child and adolescent should wear a static splint at night and a dynamic splint for 30- to 60-minute intervals during the day. The infant uses the static night splint only. Splinting usually improves the contracture (72,145,163), especially for isolated infantile camptodactyly (13), but many patients and parents find splinting and stretching too burdensome.

Surgical release is rarely indicated. Failure of the patient to use a splint is not an indication for surgery, inasmuch as postoperative management includes therapy and splinting. Surgery should be considered only when the contracture worsens in spite of splinting and interferes with function. The results of surgical release are often poor (less than 50% of fingers with postoperative increased range of motion) (46,183) and tend to deteriorate with follow-up (13).

Classifications

Camptodactyly is classified by the age of the patient when initially seen, and whether the condition is associated with a syndrome (13). Type I, the most common type, is an isolated anomaly affecting the small finger. It is present in the infant and almost always improves with splinting and stretching. Type II is similar to type I, except that the patient with type II camptodactyly is first seen in adolescence (Fig. 69.33). This type also improves with splinting, and even if the deformity is severe, it rarely interferes with function (55). In type III camptodactyly, multiple digits are involved, the contractures are more severe than types I and II, and the child has an associated syndrome. Type III also improves with splinting, but is the most likely of the three types to require surgery.

Preoperative Management and Planning

Use static splints custom fabricated by an experienced occupational therapist; for infants, the splint is forearm based, and for older children, the splint is hand or finger based. Finger-based dynamic splints are commercially available. Always first try splinting and stretching before surgical release.

Measure passive and active ranges of motion and any change in these ranges with wrist position, in order to help differentiate intrinsic from extrinsic causes. Obtain a lateral radiographic view of the involved digit; if the palmar aspect of the distal end of the proximal phalanx is flattened, the deformity is less likely to respond to surgical release than if it is not (55).

Operative Technique

1. Corrective soft-tissue release and tendon transfer (small finger, less than 40° PIPJ flexion contracture) (55).
   - Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
   - Plan the incision to allow skin coverage for the straightened finger (midline palmar incision, which can be converted to Z-plasties; obtain consent for full-thickness skin graft) and to allow exploration of the palm.
   - Explore the full length of the fourth lumbrical; free any adhesions. Inspect the fourth palmar interosseous insertion.
   - Divide the small FDS just proximal to the vincula longa, through a window in the flexor sheath. Withdraw it into the palm. If possible, separate it from any adhesions to the ring FDS, pass it dorsal to the transverse metacarpal ligament, and transfer it to the radial lateral band of the extensor expansion. If the small FDS cannot be separated from the ring FDS, excise the small FDS and transfer the ring FDS instead.
   - If the PIPJ contracture is still greater than 30°, release as described in the next section.

   - Use loupe magnification and perform the operation under general anesthesia and tourniquet.
   - Approach the PIPJ from the dorsum. Release the subluxated lateral band by transecting the transverse retinacular ligament; plicate the central slip.
   - Transfer the FDS to the radial lateral band of the extensor expansion, either through the dorsal incision, or through a separate palmar incision.
   - If the PIPJ flexion contracture is still greater than 30°, release as described in the next section.

3. PIPJ flexion contracture release.
   - Through a window in the flexor tendon sheath, release the proximal origin of the palmar plate and the check-rein ligaments. Stop here if the PIPJ can be straightened.
   - If not, release the proximal origins of the collateral ligaments. Stop here if the PIPJ can be straightened.
   - Release the FDS, if you have not already done so.
   - Hold the PIPJ as straight as possible with a Kirschner wire. Release the tourniquet; if the finger is not well vascularized, remove the Kirschner wire, allow the PIPJ to flex, and pin it in more flexion, ascertaining that the finger is well vascularized in the position of immobilization.
Close the incision with Z-plasties of the longitudinal incision, or if necessary, full-thickness skin graft, using interrupted 5-0 chromic suture.
Apply a bulky compressive dressing and cover with a fiberglass cast shell.

**General Rehabilitation and Postoperative Principles**

Remove the cast and pin after 4 to 6 weeks. Splint the finger in extension full time (except during bath or flexion exercises, which should be performed several times each day) for 4 to 6 more weeks. Splint at night indefinitely.

**PITFALLS AND COMPLICATIONS**

The results of surgical treatment of camptodactyly are not very good, and any postoperative gains tend to diminish over time (49). The finger often loses as much flexion as it gains extension.

**AUTHOR’S PERSPECTIVE**

Surgery is rarely indicated for this condition.

**CLINOPIACTY AND LONGITUDINAL EPIPHYSEAL BRACKET (DELTA PHALANX)**

**Assessment, Indications, and Relative Results**

Clinodactyly is the deviation of a finger in the radioulnar plane (Fig. 69.34). It is usually caused by malformation of the distal end of the middle phalanx but may also be due to a longitudinal epiphyseal bracket (LEB, or delta phalanx) or to soft-tissue contracture (35). Although it can occur in any finger, it is most common in the small finger. This condition is quite common; in the United States, radial deviation of the small finger at the DIPJ may occur in up to 1% of normal children and 10% of children with other congenital anomalies (35); other series report up to 21% incidence in certain populations (200). Familial clinodactyly shows autosomal dominant inheritance with reduced penetrance and is not usually associated with other anomalies (200).

**Figure 69.34.** Clinodactyly of bilateral small fingers.

Clinodactyly does not usually interfere with function. Splinting does not affect the deformity. Surgical treatment is indicated for worsening clinodactyly caused by an LEB, or when the patient is bothered by crossing of the flexed fingers.

Clinodactyly due to an LEB is likely to progress. This abnormal epiphysis occurs in bones with a proximal epiphysis (224), and extends longitudinally along the diaphysis and transversely across the opposite end of the affected bone, forming a C shape (Fig. 69.35)(154,218,231). For this type of clinodactyly, simple division of the abnormal LEB is not reliably successful (55). If the patient is skeletally immature, remove a portion of the midzone or isthmus of the continuous epiphysis and replace it with fat graft (physiolysis) (218). For clinodactyly of any etiology, regardless of skeletal maturity, an ulnar closing wedge osteotomy corrects the angulation (35,224). If modest lengthening is desired in addition to straightening, in the larger hand, a reversed-wedge osteotomy can be performed by removing a wedge of bone from the convex (usually ulnar) side, reversing it, and inserting it on the concave (usually radial) side (27-39).

**Figure 69.35.** Longitudinal epiphyseal bracket. A: Preoperative radiograph. B: Following closing wedge osteotomy.

**Classifications**

Geneticists have included clinodactyly in the classification for brachydactyly (200); others have hypothesized that it is a manifestation of polydactylysm (224). Hand surgeons classify clinodactyly by the tissue involved and subclassify by severity of angulation and the presence of other malformations (Table 69.7) (35).

**Table 69.7.** Classification of Clinodactyly (35)
The LEB has been termed delta phalanx, longitudinally bracketed diaphysis, and C-shaped epiphysis. LEB has been classified into five types by the shape of the bone, and the presence and shape of the epiphysis (Table 69.8) (55).

Table 69.8. Classification of Longitudinal Epiphyseal Bracket (LEB) (55)

Preoperative Planning

Examine the involved finger or fingers radiographically to determine if the angulation is due to an LEB. Physiolysis requires further growth of the phalanx for straightening to occur; 7 years is the earliest age at which this operation has been reported, although the author estimates that the optimal age for this operation would be about 3 years (218). Osteotomy is difficult in very small phalanges; serial radiography helps the surgeon determine if the deformity is progressive and whether the phalanx is big enough for this operation.

Operative Technique

1. Physiolysis (218).
   - Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet. Have radiography (Fluoroscan) available.
   - Through a midlateral incision on the radial (concave) side of the affected digit, reflect the periosteum to expose the diaphysis.
   - Use Kirschner wires or fine needles and radiography to locate the area to be removed.
   - Remove the isthmic region of the continuous epiphysis and physis with a fine rongeur.
   - Use a fine curet to remove bone from the metaphysis, leaving the cartilage of the longitudinal physis more prominent than the bone.
   - Close the periosteum to hold the graft in place.
   - Close the wound with interrupted 5-0 chromic suture.

2. Wedge osteotomy (closing or opening) (Fig. 69.36).
   - Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet. Have radiography (Fluoroscan) available.
   - If possible, approach the affected phalanx from the dorsum. If this approach will damage the extensor mechanism, approach from the convex side of the deformity.
   - Insert a fine Kirschner wire or needle across the joint proximal to the affected phalanx. Plan the proximal cut of the wedge parallel to this wire.
   - Plan the distal cut of the wedge at an angle to the proximal limb sufficient to correct the angulation of the phalanx.
   - Close the wound with interrupted 5-0 chromic suture.

3. Reverse wedge osteotomy.
   - Proceed as described earlier, except for the following:
   - Use a dorsal approach.
   - Plan the second, distal cut of the osteotomy to slightly undercorrect the deformity.
   - After adequate correction, pass a fine Kirschner wire antegrade through the osteotomy and out the tip of the digit, the back across the osteotomy. Cross as few joints as possible. If possible, pass another fine Kirschner wire to cross the osteotomy at an angle.
   - Close the wound with interrupted 5-0 chromic suture.

General Rehabilitation and Postoperative Principles

After osteotomy, immobilize the hand and wrist (and elbow, if necessary, to keep the cast in place) for 4 to 6 weeks. Then remove the Kirschner wires if radiographic signs of healing are present. Splints and therapy are not usually necessary.

PITFALLS AND COMPLICATIONS

Osteotomy of a small phalanx is a difficult operation. The reverse wedge technique is especially challenging in a small child's finger. Adjacent structures, including the interphalangeal joints, flexor and extensor tendons, and the neurovascular bundles are easily damaged.
Although physiolysis is appealing as prophylactic operation, only one small series of this operation has been reported (218). I have used a similar operation for Madelung deformity with success (see the section entitled Madelung deformity in this chapter) (219).

In the growing child, osteotomy should be reserved for clinodactyly associated with an LEB. Clinodactyly associated with deformity of the distal end of the middle phalanx is unlikely to progress or cause functional limitations; wait until skeletal and emotional maturity before proceeding with surgical correction of this cosmetic deformity.

CONSTRUCTION RING SYNDROME

Assessment, Indications, and Relative Results

The incidence of constriction ring syndrome (CRS) has been estimated at 1 in 15,000 live births (54). It is seen more commonly in spontaneously aborted fetuses than in term infants (6). The etiology of CRS is unclear; it is not genetic, but has been reported in identical twins (234), and is associated with clubfoot (66) and craniofacial clefts (31). Anomalies similar to those seen in CRS have been reported to be associated with maternal cocaine use and chorionic villus sampling (63). Leading theories about causation include disruption during blastogenesis; embryonic vascular disruption; and mechanical disruption (ensnaring of fetal fingers in the chorion) (6). CRS should be differentiated from transverse deficiency (142-162) (Table 69.6).

Multiple digits are usually involved, most commonly the index, middle, and ring fingers (Fig. 69.37) (111). Digits may be amputated, constricted by a partial or complete ring (a tight band of tissue), or webbed. Webbed fingers are typically short and fenestrated, with a sinus at the original web location (acrosyndactyly); syndactyly may be nonadjacent (148). Nail deformities are common (54). Surgical treatment includes Z-plasty of constriction rings and release of acrosyndactyly, usually when the child is older than 1 year of age. When the condition is severe with multiple-digit involvement, simple finger separation in the first 10 days of life can prevent serious later deformities. Deep circumferential rings may need to be released earlier if lymphedema is severe, if the vascular supply of the digit or extremity is compromised, or if the ring is causing a peripheral nerve palsy (209,228).

Shallow constriction rings, or rings that occur in the normal location of a digital flexion crease, do not require release; the appearance will improve with growth and absorption of infant fat (54). With growth, angulatory or rotational malalignment may occur and require correction. Deformed nails may require ablation, if they become bothersome. Distraction osteogenesis and free toe transfers may be indicated; unlike finger hypoplasia, proximal neurovascular and musculotendinous structures are probably normal.

Classifications

Many different names have been used to describe CRS, including constriction bands, annular rings or bands, amniotic band syndrome, and Streeter's syndrome. Acrosyndactyly is the term used to describe syndactyly associated with CRS: fusion of two or more digits with epithelial lined sinuses at or distal to the normal location of the web margin, indicating that the digits fused together after developing a web (24). Constriction rings, acrosyndactyly, and nonadjacent syndactyly are pathognomonic for CRS.

CRS has been classified into four types, all of which may occur in the same patient (165):

1. Simple constriction rings.
2. Constriction rings with distal deformity, with or without lymphedema.
3. Constriction rings with distal fusion (acrosyndactyly).
4. Intratrualine amputation.

Acrosyndactyly, or type 3, has been subclassified into mild (three phalanges, two interphalangeal joints in affected digits); moderate (two phalanges and only one interphalangeal joint); and severe (one phalanx and no interphalangeal joints) (65). Mild involvement is the least common.

Operative Technique

1. Z-plasty of constriction ring (Fig. 69.38).

- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
- Draw serial Z-plasties along the constriction ring. Release the entire circumference, if necessary (76). If the ring occurs at a normal digital flexion crease, that portion of the ring does not need to be released. The serial Z-plasty must start and end with a Z, or the flaps will not interdigitate properly.
- Raise the flaps as marked, including a thin layer of subdermal fat. Remove additional subcutaneous fat and lymphedematous tissue, or redistribute as necessary to improve the contour of the digit (Fig. 69.38) (211).
- Interdigitate the flaps, and suture in place with 5-0 chronic suture.
- Apply a bulky compressive dressing, and cover it with an above-elbow fiberglass cast shell.
2. Acrosyndactyly release.
   - Each of these conditions of the hands has a unique set of anomalies. Some resemble a bunch of grapes (54), and it may be difficult to match the fingertip with the finger. Follow these basic principles, and tailor the operation to the malformations:
     i. In especially severe cases, separate the digits to the level of the epithelial sinus early, and deepen the webs later when the child is older.
     ii. Use the epithelial sinus as the base of the web if it is found at the approximate normal web location. Excise the entire sinus if its location or size is inappropriate.
     iii. Plan local flaps to cover the web surface and, if necessary, the fingertips.
     iv. Defat to reduce the coverage needed and improve the contour; use a full-thickness skin graft as needed.
     v. Defat and use skin from any amputated parts as graft.
     vi. If necessary, revise webs when the child is a teenager.
3. Nail ablation (see Chapter 38).
4. Distraction osteogenesis (see Chapter 32 and Chapter 171).
5. Free vascularized toe transfer (see Chapter 35 and Chapter 36).

**General Rehabilitation and Postoperative Principles**

For constriction band release and acrosyndactyly release, remove the cast and dressing after soft-tissue healing has occurred (about 3 weeks). Splinting and therapy are not usually necessary.

**PITFALLS AND COMPLICATIONS**

If a constriction ring is simply excised and the edges sutured (rather than treated with Z-plasty) the ring will recur.

If the epithelial sinus is not properly opened (to form the base of the web) or removed, an epidermal inclusion cyst will form, and eventually require surgical incision.

**AUTHOR'S PERSPECTIVE**

Reconstruction of the severely involved hand should be performed by an experienced hand surgeon, because residual deformity is common even when the hand is reconstructed by an expert. Sometimes, when the skeleton is inadequate to support five digits, the surgeon may elect to reconstruct a four-digit hand.

**THE HAND, WRIST, AND FOREARM**

See Chapter 165: Congenital Shoulder and Elbow Malformations for a discussion of transverse deficiency, and the section entitled Transverse Failure of Formation (Hypoplasia and Absence) in this chapter.

**CENTRAL DEFICIENCY (CLEFT HAND)**

**Assessment, Indications, and Relative Results**

Flatt has described the cleft hand as “a functional triumph and a social disaster” (53) (Fig. 69.39). In the cleft hand, central bony elements are missing. The deficiency varies from absent long finger phalanges, to absent index, long, and ring finger rays (53), to monodactyly, or even absence of all digits (119). Wider clefts are associated with more adducted and deficient thumbs (53,127). Children and adults with this malformation are able to function almost normally, but they may hide their hands to avoid embarrassment.

**Figure 69.39.** Cleft hands.

Cleft hand is a very rare anomaly, with an incidence between 1:90,000 and 1:150,000 live births (198). It is frequently inherited in an autosomal dominant pattern, with highly variable expression and penetrance (25,198). Chromosome defects associated with cleft hand have been mapped to two different loci: 7q21.2-q21.3 (25) and 10q25. Fibroblast growth factors 2 and 8, and 2 different HOX genes have also been mapped to 10q25 (168).

Cleft hand is usually associated with syndactyly (especially thumb-index) and cleft feet (Fig. 69.40), and is frequently associated with other musculoskeletal anomalies including central polydactyly, camptodactyly, longitudinal epiphyseal bracket, and absence of the tibia, and anomalies of other organ systems including cleft lip and palate (144,156,198,199). Cleft hand is also frequently associated with various syndromes (199). The true cleft hand should be differentiated from symbrachydactyly, formerly called atypical cleft hand (Table 69.9; see the section entitled Transverse Failure of Formation (Hypoplasia and Absence)) (125).

**Table 69.9.** Differential Diagnosis of Cleft Hand vs. Symbrachydactyly (53)
Because of the variable expressivity of this condition, different combinations of anomalies are seen in different cleft hands. Surgical treatment is not always indicated, and surgical planning is complex, because various operations may be indicated in varying combinations. Normal appearance is rarely attainable.

Surgery is usually indicated to improve thumb mobility by releasing the adducted thumb or thumb-index syndactyly, to separate other syndactylies, and to remove transverse bony blocks. Surgical closure of the cleft, correction of camptodactyly, and rotational osteotomies may be indicated, but these operations should be postponed until the child is older and the surgeon can be more certain that they will not interfere with function.

Classifications

This condition was previously called lobster-claw hand; this term is no longer used. Ectrodactyly is sometimes used to describe cleft hand, but this term, which usually means missing digits, is used differently by different authors. Geneticists frequently call this condition split hand. Until recently, cleft hand was divided into two types—typical and atypical (6,121,176,198). Atypical cleft hand is now termed symbrachydactyly, and typical cleft hand is called cleft hand, or true cleft hand (Table 69.9) (53,125).

Nutt and Flatt described a classification of cleft hand based on which bones are missing; this complicated classification has 11 subtypes (152), but these subtypes do not help determine prognosis or treatment of this condition. Manske has classified cleft hand based on the characteristics of the thumb web (Table 69.10) (127). Types I and II are treated with thumb-web deepening and cleft closure; type III with web deepening, often combined with index-to-long metacarpal transposition or excision of bony remnants of the index; types IV and V did not usually require surgical correction.

</tbody>
</table>

In addition to mapping the gene for cleft hand, geneticists have described two types of nonsyndromal cleft hand based on two different inheritance patterns: in the first, cleft hand or foot is inherited in an autosomal dominant pattern with high penetrance; in the second, the gene is nonpenetrant, and expression may skip several generations (240). The second pattern implies the existence of another gene, which controls the expression of the cleft hand and foot gene.

Preoperative Planning

Study both hands radiographically to determine which bones are absent or anomalous. If a transverse phalanx is present, remove it as soon as possible because it will cause the cleft to widen with growth. Thumb-web deepening can be combined with cleft closure, by transposing the index to the base of the long metacarpal and shifting the excess skin from cleft closure to the first web. If the thumb and index are syndactylized, however, cleft closure should be postponed, because the child may prefer prehension using the digits on either side of the cleft instead of the thumb, and cleft closure would interfere with this pattern.

If the child requires closure of foot clefts in order to wear shoes, schedule syndactyly release for the same anesthetic, because skin removed in order to close the foot cleft can be used as graft on the hand.

Operative Technique

1. Deepening of thumb web.
   - Fourfold Z-plasty: see the section entitled Hypoplasia and Absence.
   - Dorsal rotation flap: see the section entitled Clasped Thumb in this chapter (this operation is inadequate for thumb-index syndactyly [67]).
2. Release of thumb-index syndactyly (Fig. 69.41)

   - Syndactyly release: see the section entitled Syndactyly, with the following changes:
     i. Plan the base of the dorsal rectangular flap at the level of the thumb MPJ. Make this flap as wide as possible, but do not extend the sides of the rectangle past the midline of the thumb and index fingers.
     ii. Release the first dorsal interosseous and adductor pollicis fascia (217).
3. Removal of transverse phalanx (Fig. 69.42).
Removal of a transverse phalanx is combined with other operations including thumb web release and cleft closure, as indicated.

- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
- Approach the transverse phalanx through a longitudinal zigzag dorsal incision.
- Remove the entire phalanx, including the periosteum. Removal is more difficult than it appears, because the phalanx is larger than radiography indicates (because of incomplete ossification) and is intimately connected to surrounding structures.
- If removal of the transverse phalanx destabilizes the MPJs, reconstruct collateral ligaments using available tissue.
- Reconstruct the transverse intermetacarpal ligament with nonabsorbable suture (see the section entitled Closure of Cleft).
- Close the skin incision with interrupted 5-0 chromic suture.

4. Closure of cleft (Fig. 69.44 and Fig. 69.44).

- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
- Plan skin incisions to produce zigzag interdigitations on both palmar and dorsal surfaces. Create a flap along the side of one digit to form the new web. A diamond shape works well for this (Fig. 69.43A).
- Remove any bony or soft tissue holding the metacarpals apart.
- Construct an intermetacarpal ligament out of adjacent soft tissue. If no tissue is available, drill holes in the metacarpals as far distal as possible, but avoid damaging the epiphyses, and pass nonabsorbable suture through these holes to hold the metacarpals together.
- Close the skin with interrupted 5-0 chromic suture, excising excess skin as necessary and contouring the closure to create a normal web slope (Fig. 69.43B, Fig. 69.43C).
- Apply a bulky compressive dressing designed to support the cleft closure. Cover with an above-elbow fiberglass shell.

5. Transposition of the index finger (combined cleft closure and first web deepening) (Fig. 69.45).

- Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
- Approach the cleft and base of the index through a curved dorsal incision, combined with other incisions designed to transfer excess cleft skin to augment the first web (Fig. 69.45A, Fig. 69.45B).
- Detach the index metacarpal at its base, releasing the adductor pollicis and first dorsal intersosseous fascia, and possibly the thumb attachment of the first
dorsal interosseous.

- Move the index to the stump of the long metacarpal or its space. Check rotation, and pin it in place using Kirschner wires (Fig. 69.45C, Fig. 69.45D).
- Repair or create an intermetacarpal ligament (see the section entitled Closure of Cleft).
- Close the skin with interrupted 5-0 chromic suture (Fig. 69.45E).
- Apply a bulky compressive dressing over the fingers and hand, and cover it with an above-elbow fiberglass cast shell.

**General Rehabilitation and Postoperative Principles**

Keep the hand immobilized for 6 weeks after reconstruction of the transverse intermetacarpal ligament. Check bony healing radiographically and remove the pin or pins at 6 weeks postoperatively for index transposition. No splinting or therapy is necessary.

**PITFALLS AND COMPLICATIONS**

The cleft is frequently used for prehension; do not close it until you are certain that thumb function can be restored. If the cleft is closed without construction of a transverse intermetacarpal ligament, it will widen (it may do so anyway). If the cleft is closed too tightly, or if the surgical scar contracts, the fingers may overlap, impairing function.

**AUTHOR’S PERSPECTIVE**

This is a complex, highly variable condition that is best treated by an experienced hand surgeon. The treatment must be tailored to the individual cleft hand. Complete thumb-index syndactyly cannot usually be released to the normal thumb web level. If the only space available for prehension is the cleft (Fig. 69.39), surgery is not indicated, but peer contacts and counseling are often helpful.

**RADIUS DEFICIENCY**

**Assessment, Indications, and Relative Results**

Radius deficiency is a rare condition (approximately 1:30,000 live births [198]) that is nearly always associated with thumb and carpal deficiencies and frequently associated with other upper extremity anomalies, anomalies of other organ systems, and syndromes (60,79,91,107,126,164,198). The newborn with radius deficiency should be carefully examined for signs of the VACTERL association (not inheritable; it may be accompanied by Vertebral, Anal, Cardiac, Tracheo-Esophageal, Renal or Radial, and Lung anomalies), Holt-Oram syndrome (autosomal dominant inheritance of cardiac septal defects associated with upper limb anomalies), and TAR syndrome (autosomal dominant or recessive inheritance of completely absent radius with a near-normal thumb and thrombocytopenia) (1,8,12,177,180,199). Multiple other syndromes, many inheritable, are associated with radius deficiency. Radius deficiency is usually bilateral, although the two sides are frequently asymmetric; when the condition is unilateral, it is more common on the right (91,107).

All of the radial forearm structures are deficient to varying degrees. Flatt has described radial clubhand as “a profoundly abnormal hand joined to a poor limb by a bad wrist” (60), and he has meticulously documented multiple abnormalities of muscles, nerves, and blood vessels found in anatomical dissections of upper limbs with radius deficiency (154). The radial wrist extensors and extrinsic thumb motors are usually absent or aberrant. The radial nerve is usually absent below the elbow, and the median nerve is always present and often the most prominent structure on the radial side of the wrist. The radial artery is usually absent.

Children with type 0, 1, or mild type 2 radial deficiency (Fig. 69.46 and Table 69.11) usually require stretching and splinting, and no surgical treatment. Moderately severe type 2 is treated with radius lengthening; severe type 2 with centralization of the carpus on the end of the ulna. The wrist instability and radial deviation associated with types 3 and 4 (Fig. 69.46 and Table 69.11 and Table 69.12) is treated with centralization of the carpus on the end of the ulna, with the best results if aberrant radial wrist extensors are transferred to help maintain the new position, and if the operation is performed before the child is 1 year of age (60). Before centralization, serial casting or application of a distraction device (149,187) helps stretch the radial structures. Stabilization of the wrist enhances the appearance and function of the hand (60) but is difficult to maintain throughout growth; radial deviation tends to recur unless the wrist is quite stiff. Centralization is contraindicated for the following patients:

---
Infants younger than 6 months of age for whom major organ defects may not yet have been diagnosed.

Children without adequate elbow flexion for the hand to reach the mouth after the wrist is straightened.

Adults with firmly established functional patterns (see Centralization (ulnar approach) ).

Operative Technique

Stretching until centralization is performed.

Continue with splinting and flexed elbow cast in the maximally corrected position with the elbow flexed. Change the cast weekly, stretching the wrist further at each cast change. When the wrist reaches neutral, apply a custom fabricated above-elbow orthoplast splint and instruct the parents to stretch the wrist several times each day.

Start serial casting for the infant with radius deficiency as soon as possible after birth. Gently stretch the wrist as close to neutral as possible, and apply an above-elbow cast for radius deficiency.

Blauth scheme for classifying thumb hypoplasia ( ).

James, McCarroll, and Manske have modified Bayne's classification scheme ( ).

The best known classification scheme for radius deficiency, described by Bayne, includes four types based on increasing radiographic severity of the radius deficiency (Table 69.12 ) (1). In order to define Bayne type 1 better, and to include patients with deficiency of the thumb or carpus in the presence of a normal-length radius, James, McCarroll, and Manske have modified Bayne's classification scheme (Table 69.11 and Fig. 69.46 ) (91). This scheme is used in combination with the modified Blauth scheme for classifying thumb hypoplasia (Table 69.3 ).

Preoperative Management

Start serial casting for the infant with radius deficiency as soon as possible after birth. Gently stretch the wrist as close to neutral as possible, and apply an above-elbow flexed elbow cast in the maximally corrected position with the elbow flexed. Change the cast weekly, stretching the wrist further at each cast change. When the wrist reaches neutral, apply a custom fabricated above-elbow orthoplast splint and instruct the parents to stretch the wrist several times each day.

Operative Technique

Centralization (ulnar approach) (131) (Fig. 69.48).

Use loupé magnification and perform the operation with the patient under general anesthesia and tourniquet.

Begin the incision at the level of the distal end of the ulna, near the dorsal wrist extension crease, just radial to the midline. Extend it ulnaward, initially transverse, then forming an ellipse in order to excise excess skin and subcutaneous tissue after the carpus is reduced onto the ulna.

Identify and preserve the dorsal ulnar sensory nerve.

Identify and retract the finger extensor tendons radially. If radial wrist extensors are present, detach them and retract them proximally.

Identify the extensor carpi ulnaris; detach it from its insertion into the base of the fifth metacarpal, and retract it proximally.

If the ulna is quite bowed, perform a closing wedge osteotomy through a separate proximal incision.

Pin the carpus on the distal ulna using a long Kirschner wire. The wire can exit either through the distal end of the long finger metacarpal or through the proximal ulna. If an ulnar osteotomy has been performed, use the same Kirschner wire to fix it.

If the ulna is quite bowed, perform a closing wedge osteotomy through a separate proximal incision.

1. Centralization (ulnar approach) (131) (Fig. 69.48).

Use loupé magnification and perform the operation with the patient under general anesthesia and tourniquet.

Begin the incision at the level of the distal end of the ulna, near the dorsal wrist extension crease, just radial to the midline. Extend it ulnaward, initially transverse, then forming an ellipse in order to excise excess skin and subcutaneous tissue after the carpus is reduced onto the ulna.

Identify and preserve the dorsal ulnar sensory nerve.

Identify and retract the finger extensor tendons radially. If radial wrist extensors are present, detach them and retract them proximally.

Incise the wrist capsule transversely, exposing the distal ulna. The carpal bones will be palmar and radial to the distal ulna, and may be difficult to identify.

Free the ulna of soft-tissue attachments distal to the physis. Detach the carpal bones from the palmar capsule.

Serially carve away central carpus and shave distal ulna until the carpus fits on the end of the ulna without tension. Do not injure the distal ulna physis or attached soft tissue. Very tight wrists may require resection of the lunate and part of the capitale before the wrist can be reduced.

If the ulna is quite bowed, perform a closing wedge osteotomy through a separate proximal incision.

Pin the carpus on the distal ulna using a long Kirschner wire. The wire can exit either through the distal end of the long finger metacarpal or through the proximal ulna. If an ulnar osteotomy has been performed, use the same Kirschner wire to fix it.

Imbricate the wrist capsule.

Transfer radial wrist extensors into the distal fragment of the extensor carpi ulnaris. Reattach the extensor carpi ulnaris, advancing it to increase soft-tissue tension on the ulnar side.

Pass the retinacular flap underneath the finger extensors.
Ulnar lengthening (Fig. 69.49).

- Excise excess skin and subcutaneous tissue.
- Close the skin with interrupted 5-0 chromic suture.
- Apply an above-elbow bulky compressive dressing, and cover with a fiberglass cast shell.

2. Ulnar lengthening (Fig. 69.49).

- Follow the principles of Ilizarov lengthening of the forearm described in Chapter 32 and Chapter 171.
- Use two half-pins and one transfixion wire proximal to the osteotomy, and one half-pin and two transfixion wires (one in the ulna and one in the metacarpals) distal to the osteotomy.
- If the hand is radially deviated, correct the deviation at the same time as application of the fixator, using a closing wedge osteotomy through the carpus or distal ulna, and fixing it with Kirschner wires. Otherwise, radial deviation will worsen when the fixator is removed, because of increased tension placed on the radial soft tissue by the lengthening.

General Rehabilitation and Postoperative Principles

Keep the postcentralization cast and pin in place for 6 to 12 weeks. Apply a custom-made above-elbow orthoplastic splint to maintain wrist position. Prescribe full-time wear for 3 to 6 months, then nighttime wear indefinitely.

For ulnar lengthening, wait 5 to 7 days before beginning to lengthen the ulna, then proceed at a rate of approximately 1 mm per day in three increments (the nuts in the pediatric Ilizarov set are six sided, so the child can advance 1/3 turn three times per day). Check progress on radiograph when lengthening begins and weekly thereafter, adjusting the lengthening rate depending on regenerate formation. Teach the child and family to perform the lengthening and pin care and to maintain elbow and digit motion. Stop lengthening when the regenerate appears threadlike or the elbow or digits start to develop flexion contractures. The ulna can usually be lengthened by 30% to 50%. Leave the fixator in place until four cortices are visible in the regenerated bone (this usually takes three times as long as bone lengthening), then remove the fixator under general anesthesia, and apply an above-elbow fiberglas cast.

PITFALLS AND COMPLICATIONS

Preoperative serial casting, stretching, and splinting make reduction of the carpus on the distal ulna easier, but reduction is nonetheless difficult to accomplish. The postcentralization cast must be carefully molded and the elbow flexed to 90° or it will fall off—or worse, it will slip partway off with the child's wrist wedged in the flexed portion of the cast. With long-term follow-up, centralized wrists tend to be either stiff and straight, or flexible and deviated.

Nearly every patient who has undergone the Ilizarov procedure acquires at least one pin tract infection. Treat these infections with oral antibiotics unless the patient has a fever or cellulitis, in which case intravenous antibiotics are necessary. If the area is not carefully monitored, regenerated bone can heal too quickly (requiring a second osteotomy) or too slowly (requiring bone grafting). The proximal half-pins are the most troublesome; they tend to loosen if the fixator needs to remain in place for more than 6 to 8 months.

AUTHOR'S PERSPECTIVE

Serial casting is difficult. The cast is best applied by two experienced people. Centralization is a technically demanding operation that is best performed by the experienced hand surgeon.

Ulnar lengthening is a tedious process, requiring realistic expectations and emotional stamina on the part of the patient. It should be reserved for the mature older child or teenager with good family support who can manage the care of the external fixator. Preoperative peer counseling (by another patient with a fixator in place) and preoperative psychological assessment by the social worker are helpful. The support of an Ilizarov procedure team (including a nurse, social worker, and occupational therapist) is very helpful to the surgeon.

ULNA DEFICIENCY

Assessment, Indications, and Relative Results

Children with ulna deficiency, a very rare anomaly (approximately 1:100,000 live births [198]), have hypoplasia of the entire upper extremity. The elbow is malformed or absent (Fig. 69.50) in the majority of cases [197]. Deficiency of the ulna may be partial or complete, and a cartilaginous ulna "anlage" is often present [198, 26, 132, 140, 155]. All children with ulna deficiency have hand and carpal anomalies; about 90% of hands are missing digits, 30% have syndactyly, and 70% have thumb abnormalities [33, 84, 123, 197]. Unilateral involvement is twice as common as bilateral involvement [197]. This condition is often associated with other musculoskeletal anomalies, most commonly proximal femoral focal deficiency, fibula deficiency, phocomelia, and scoliosis [85, 197, 199], but it is rarely associated with anomalies of other organ systems [123, 197, 199]. In spite of their upper extremity malformation, children with ulna deficiency usually function well [15, 64, 190].

In one small study, patients with ulna deficiency who underwent thorough functional testing had no deficits in bimanual function but performed one-handed tasks much more slowly with the affected side. Patients with humeroradial synostosis and absent or stiff fingers fared worst, and no correlation was found between functional abilities and classification systems based on the elbow or forearm (see the section entitled "Classifications, later") [15].

Because ulna deficiency is so uncommon, most published series of patients with this condition are small, and authors disagree about its natural history. Two sequelae of ulna deficiency are especially controversial: progressive ulnar deviation at the wrist, and forearm instability. Some authors report that ulnar deviation at the wrist always worsens and is due to tethering by the ulna anlage; they advocate early excision of the ulna anlage to prevent progression [26, 155]. More recent reports disagree, and indicate that ulnar deviation usually does not progress; they advocate anlage resection only if progression is documented [64, 132, 140]. In order to treat forearm instability, some authors advocate surgical construction of a one-bone forearm by cross-union between the radius and ulnar remnant [62]; others believe that loss of forearm rotation is not a good trade-off for forearm stability [64].

Thumb reconstruction, release of syndactyly, and external rotation osteotomy of the humerus are well-accepted treatments for malformations associated with ulna deficiency. First web deepening, opponoplasty, thumb metacarpal rotational osteotomy, pollicization, and syndactyly release should be performed when the child is old enough to benefit from the operations, usually by age 1 to 4 years. The child in whom the hand rests on the buttock or flank and cannot reach the mouth or top of the head because of internal rotation of the arm and forearm, combined with humeroradial synostosis, benefits from external rotation osteotomy of the humerus (Fig. 69.50) [33, 84, 123, 140]. Lengthening may improve the appearance of a short forearm but is indicated only when the elbow is stable and has active elbow flexion.
Classifications

The use of the term ulnar clubhand is diminishing; the preferred name for this condition is longitudinal deficiency of the ulna, or ulna deficiency.

Most classification systems for ulna deficiency are based on elbow and forearm anomalies (Kummel [106], Ogden [155], Riordan and Bayne [172], Swanson et al [197], Miller et al [140], and Dobyns et al [43]). (Table 69.13). Ogino and Kato (159) have used hand anomalies as the basis for classification. Cole and Manske have described the only classification system for ulna deficiency that correlates with treatment; their system is based on thumb and first web deformities, and can be combined with one of the elbow and forearm classifications (preferably that of Ogden, Bayne, or Swanson, because these classifications address both forearm and elbow anomalies) (Table 69.14).

Operative Technique

1. Thumb reconstruction (first web deepening, opponensplasty, pollicization) (see the section entitled Hypoplasia and Absence).
2. Syndactyly release (see the section entitled Syndactyly).
3. Rotational osteotomy of the humerus (140).
   - Perform the operation with the patient under general anesthesia, and if possible, tourniquet (a sterile tourniquet may be necessary).
   - Use a lateral incision to approach the distal humerus subperiosteally. Score the bone longitudinally to mark the preosteotomy alignment, or place parallel Kirschner wires above and below the planned osteotomy site.
   - Make a transverse osteotomy, and rotate the distal fragment enough to place the hand in front of the trunk. If the soft tissue is tight, shorten the bone to prevent traction injury to neurovascular structures.
   - Fix the bone with crossed Kirschner wires or a small A-O plate.
   - Close the subcutaneous tissue with absorbable suture, and the skin with running subcuticular absorbable suture.
4. Creation of one-bone forearm. This operation is rarely indicated. See Lloyd-Roberts (116) or Spinner et al. (191) for details.
5. Forearm lengthening (lizarov technique). (See Chapter 32 and Chapter 171, and the section entitled Radius Deficiency.)

PITFALLS AND COMPLICATIONS

Because the child undergoing a humerus osteotomy usually has a humeroradial synostosis in extension, the postoperative cast cannot turn a corner and will tend to slip off, unless a Velpeau wrap is applied.

AUTHOR’S PERSPECTIVE

There is scant evidence that surgery other than thumb reconstruction, syndactyly release, and rotational osteotomy improves function. Some authors have advocated combining a closing wedge osteotomy with the rotational osteotomy, in order to place the elbow in flexion. This procedure is probably not necessary, because children with humeroradial synostosis have a short upper limb and can usually reach the mouth once rotation is corrected. Similarly, although the forearm is usually supinated,
Madelung deformity is excessive radial and palmar angulation of the distal radius associated with an ulna-plus wrist, caused by a growth disturbance of the palmar and ulnar portion of the distal radial physis. This growth disturbance may be due to a combination of a bony lesion in the ulnar portion of the distal radius physis and an abnormal palmar ligament tethering the lunate to the radius proximal to the physis (219). The growth disturbance is the final common pathway for many different disorders, including dysplasia, trauma, chromosomal abnormalities, infection, and tumors. Girls are affected more often than boys, and the disorder is usually bilateral, appearing most commonly between the ages of 6 and 13 years (34,37,44,44-205).

Madelung deformity is most commonly due to dysplasia associated with Leérr-Weill syndrome (dyschondrosteosis), which is inherited in an autosomal dominant fashion with 50% penetrance (119,122). It may also be associated with other syndromes, including nail-patella syndrome (onycho-osteodysplasia) (88). Repetitive loading of the wrist in the growing child may cause Madelung deformity in gymnasts (gymnast wrist) (26) or in javelin throwers (37).

If the deformity is not painful, no treatment is necessary, although untreated Madelung deformity has been associated with spontaneous extensor tendon rupture, probably due to the ulna-plus deformity and disruption of the distal radioulnar joint (69,83). If the deformity is painful, and the patient is not skeletally mature, physiolysis may reduce pain and, with additional growth, improve the deformity (219). In the skeletally mature patient with wrist pain associated with Madelung deformity, correction of the deformity may be helpful. Correction may be attained by Ilizarov radial correction, radial closing wedge osteotomy, and ulnar shortening; radial opening wedge osteotomy (147), radial osteotomy and distal ulna resection (215,225), or radial osteotomy and Sauveé-Kapandji procedure (176). Although osteotomy will also improve appearance, the magnitude of the operation renders it unjustifiable for this indication alone.

Classifications

Rarely, growth may be disturbed on the dorsal and ulnar physis, causing a reverse Madelung deformity, in which the distal radius is angulated dorsally and radially (37,219). This type of Madelung deformity has the same underlying etiologies. One patient has been reported to have classic Madelung deformity on one side and reverse Madelung deformity on the other side (218).

Preoperative Planning

If distal radius osteotomy is planned, use radiography to estimate the size and shape of the wedge to be removed or inserted. See wedge 4 determined by lines 1 and 2 in Fig. 69.51.

Operative Technique

1. Physiolysis (Fig. 69.51).
   - Use loupe magnification and perform the operation with the patient under general anesthesia and tourniquet.
   - Use a palmar transverse incision 1.5 cm proximal to the most proximal wrist flexion crease. Pass ulnar to the palmaris longus and flexor carpi radialis tendons, and protect the radial artery and median nerve. Locate and elevate the distal edge of the pronator quadratus muscle.
   - Raise a longitudinal flap of distal radius, based ulnarward, approximately 5 mm from the distal radioulnar joint. Take care not to injure the lunate. A sagittal section of the distal radius is now visible. Remove fibrous tissue and bone until the physis is identified; at first, it will be narrow and wavy. When physeal cartilage is clearly defined, use a burr to remove bone from the metaphyseal side so that the cartilage profile is proud from dorsal to palmar periosteum.
   - Release the tourniquet, and obtain hemostasis.
   - Reinflate the tourniquet, wash the cavity, obtain fat from a separate incision in the proximal medial forearm, and fill the cavity with fat.
   - Apply soft tissue to fall together to hold the fat in place.
   - Close the skin with a running absorbable subcuticular suture. Release the tourniquet.
   - The same procedure can be done dorsally for reverse Madelung deformity.

2. Dorsal closing wedge osteotomy of the distal radius and ulnar shortening (Fig. 69.52).
   - Perform the operation with the patient under general anesthesia and tourniquet. Have Fluoroscan or C-arm fluoroscopy available.
   - Approach the ulna diaphysis (at approximately the distal 1/4, proximal 3/4 junction) through a longitudinal ulnar incision. Select a four-hole dynamic compression plate (244 series); prepare the distal two holes, then make a transverse osteotomy. Sharply dissect the interosseous membrane from the proximal fragment so that the cut ends can overlap.
   - Approach the distal radius through the third and second dorsal compartments. Remove Lister’s tubercle. Score the radius longitudinally across the planned osteotomy location to help maintain correct rotation. Using fluoroscopy guidance, insert Kirschner wires distally close to the radiocarpal joint, one parallel to radial angulation and the other parallel to palmar angulation. Plan the distal cut to reduce radial angulation to 20° and palmar angulation to 10°. Make the proximal cut transverse. The radius osteotomy should be as close to the radiocarpal joint as possible, leaving room for a T or L plate for internal fixation.

Figure 69.51. Physiolysis for Madelung deformity. (From Vickers D, Nielsen G. Madelung deformity: surgical prophylaxis (physiolysis) during the late growth period by resection of the dyschondrosteosis lesion. J Hand Surg 1992;17B:401.)

Provisionally fix the osteotomy with Kirschner wires.
- Contour the selected plate. Apply to the dorsal distal radius. Remove the Kirschner wires.
- Under fluoroscopic guidance, pull the distal ulnar fragment proximally until the distal end of the ulna is neutral or slightly ulna-minus. Resect the appropriate amount of ulna; morselease the resected portion and use for graft around the osteotomies if desired (avoid placing graft between the radius and ulna). Fix the two ends of the ulna with a four-hole plate, using the distal holes drilled earlier, and compressing at the osteotomy site.
- Close any available periosteum over the plates. Close subcutaneous tissue with absorbable suture and the skin with running subcuticular absorbable suture.
- Apply a bulky compressive dressing, and cover with an above-elbow plaster splint.

3. Sauvek-Kapandji procedure: see Chapter 43.

**General Rehabilitation and Postoperative Principles**

Immovilize the arm for 2 to 3 weeks following physiolysis. Therapy and splitting are not usually necessary. Following osteotomy, immobilize it in an above-elbow splint for 2 to 3 weeks, followed by a below-elbow cast for 3 more weeks. Remove hardware 1 year after surgery.

**PITFALLS AND COMPLICATIONS**

If the physis is not adequately exposed or the fat graft not in intimate contact with the surgical defect, the physeal tether may recur following physiolysis.

**AUTHOR’S PERSPECTIVE**

Like the physiolysis procedure Vickers has described for clinodactyly (see the section entitled Clinodactyly $(218)$, the author's results have not yet been widely reproduced. I have found this operation to provide pain relief.

Of the various osteotomies, radius closing wedge and ulnar shortening restores distal radius angulation and the relationship between the distal radius and ulna well, without requiring additional bone graft. The Sauvek-Kapandji procedure is preferable to distal ulna resection, but it should probably be used only as a salvage procedure if radius osteotomy and ulnar shortening fail to relieve pain.

**ACKNOWLEDGMENTS**

Thank you to Deana Simonis, medical librarian, Shriners Hospital Northern California, for her assistance with references, and Julia Serat, photographer, Shriners Hospital Northern California, for her assistance with clinical photographs and radiographs. H. R. McCarroll, Jr., M.D. was the technical consultant for the section entitled Dorsal Closing Wedge.

---

* In most texts, this procedure is described as the Bilhaut-Cloquet procedure. No treatise by Cloquet on the treatment of thumb polydactyly has been found.

Osteoarthritis (OA) and rheumatoid arthritis (RA) are the most common disease processes leading to deformity in the hand. It is important for the surgeon to be familiar with them and with some of the less typical arthritides, as well. Gout and psoriatic arthritis, for example, have certain unique characteristics with which the hand surgeon must deal (Table 70.1).

Primary degenerative OA most frequently affects the interphalangeal (IP) and thumb carpometacarpal (CMC) joints. It is most common in perimenopausal and postmenopausal women. While OA of the thumb basal CMC joint can occur as an isolated entity, arthritis of the distal interphalangeal (DIP) joint often involves multiple digits, and arthritis of the proximal interphalangeal (PIP) joint usually occurs in conjunction with OA of the DIP joint. Interphalangeal OA in a single digit is often a sequela of trauma or sepsis. Symptoms of primary OA include gradual swelling and stiffness with minimal to mild pain. Marginal osteophytes appear in the DIP joint (Heberden’s nodes) and PIP joint (Bouchard’s nodes). With progression, the joint develops a mild flexion deformity and may deviate radially or ulnarily with collateral ligament involvement. A mucous cyst is a ganglion arising from the DIP joint via a pedicle, which often develops in conjunction with OA (33).

A more aggressive form of OA, erosive osteoarthritis, can affect the IP joints and is more likely to occur in middle-aged women (42,53). Erosive osteoarthritis causes pain, synovitis, and stiffness; radiography reveals progressive destruction of the IP joints. This condition may be differentiated from RA by the absence of systemic manifestations and certain radiographic characteristics (osteoporosis, more proximal joint involvement) (42).

The thumb CMC joint is the second most common site of OA in the hand (5), Postmenopausal women are affected ten times as frequently as men (5). It is usually an idiopathic condition in women; previous trauma is the usual etiology in men. Patients complain of pain at the base of the thumb and thenar eminence, with occasional radiation distally into the metacarpophalangeal (MP) joint and proximally into the wrist and forearm. Swelling, crepitus, weakness of pinch, and dorsoradial subluxation occur as arthritis and instability progress (Table 70.2). Tenderness over the palmar-radial aspect of the CMC joint and a positive axial grind test aid in diagnosis. Other causes of pain in this region that must be considered in the differential diagnosis include carpal tunnel syndrome, de Quervain’s tenosynovitis, flexor carpi radialis (FCR) tendinitis, radiocarpal and triscaphe (scaphotrapeziozatopezoid) arthritis, and volar wrist ganglion. Radiographic evaluation should include Robert’s hyperpronation view and the stress view as described by Eaton (Figs. 70.1) (22,56).

Table 70.2. Classification of Thumb Carpal Metacarpal (CMC) Osteoarthritis

Stage I  Early, interphalangeal, positive CMC grind test
Stage II  Crepitation, subluxation, degenerative changes on radiography
Stage III  Post-synovial arthritis
Stage IV  Degenerative changes in metacarpophalangeal joint

Degenerative arthritis of the MP and remaining CMC joints of the hand is much less common, and it is usually secondary to fracture, ligamentous instability, or sepsis. OA of the second or third carpometacarpal joints is called a carpal boss. This dorsal osteophyte develops gradually as a firm, tender mass on the dorsum of the hand. Symptoms may be aggravated by tendinitis of the overlying extensor carpi radialis brevis and longus. Some cases are associated with small dorsal ganglions. The carpal boss is best demonstrated on a lateral radiograph with the hand supinated 30°. Arthritis of the small-finger CMC joint is usually a result of trauma. This joint is best viewed on an anteroposterior (AP) radiograph with the forearm pronated 30°.

Osteoarthrosis of the wrist usually occurs secondary to ligamentous injury, malunited or nonunited fractures, Kienbock's disease, or crystal pyrophosphate deposition disease. Reviewing a large series of wrist radiographs, Watson and Ballet reported a 5% incidence of wrist OA (73). Of these cases, 57% involved a pattern that they termed scapholunate advanced collapse (SLAC). Arthritis first develops between the scaphoid and radius, followed sequentially by degenerative changes in the capitulonate and lunotriquetral joints (Fig. 70.2). It is most commonly a sequela of chronic scapholunate ligamentous instability or a scaphoid nonunion. Patients may complain of stiffness, pain, intermittent swelling, and clicking.

Approximately another 40% of cases of wrist arthritis involve the triscaphe joint alone or a combination of triscaphe and SLAC patterns (74). Triscaphe arthritis is characterized by pain at the base of the thumb; it may coexist or be confused with arthritis of the CMC joint of the thumb.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is an inflammatory disease of the synovial tissues of joints, tendon sheaths, and bursae. The hallmark of this disease is proliferation of inflamed synovium that leads to progressive joint destruction and deformity. This disease is often symmetric and occurs two to four times more often in women than in men.

In evaluating a patient with RA, the physician must remember that it is a systemic disease; examination of the hand begins with the cervical spine and encompasses the entire upper extremity. Rheumatoid nodules, tenosynovitis, nerve compression, acute synovitis, and damage to periarticular soft tissues and articular cartilage secondary to chronic synovitis may lead to pain and dysfunction in the rheumatoid hand.

Rheumatoid arthritis of the wrist frequently leads to ulnar subluxation of the carpus with radial deviation of the hand. Dorsal subluxation of the distal ulna often occurs concomitantly. Because the finely balanced forces of intrinsic and extrinsic muscles are disrupted, these proximal deformities often result in palmar and ulnar subluxation of the MP joints, with secondary deformities of the IP joints.

Nodules may be cosmetically unacceptable or may interfere with function because of the direct pressure they apply or their location over a joint or tendon. They may erode through skin, and occasionally they can become infected. Rheumatoid nodules occur in 20% to 25% of RA patients, usually in association with an aggressive form of the disease.

Tenosynovitis can affect both the extensor and flexor tendons. Early in the course of the disease, symptoms of flexor tenosynovitis include pain and crepitus over the tendons. Digital range of motion becomes limited. Carpal tunnel syndrome is very common in RA patients, secondary to compression of the median nerve in the wrist by hypertrophic flexor tenosynovium. Involvement of digital flexor tendon sheaths results in fusiform swelling of the digits, limited finger flexion, and triggering. In later stages, tendons may rupture. Flexor pollicis longus (FPL) and index flexors are the most common tendons to rupture on the palmar side, often secondary to attrition over a palmar scaphoid osteophyte (23). Further ruptures may progress sequentially in a radial-to-ulnar direction.

Extensor tenosynovitis is painless and demonstrates very obvious swelling distal to the extensor retinaculum. Direct synovial invasion or attrition over the distal ulna (Vaughan-Jackson syndrome) may cause extensor tendon rupture (71). The extensor digitii quinti is usually the first tendon affected; remaining tendons rupture progressively from ulnar to radial. Because of the already limited motion in their hands, many patients will not be aware of ruptured extensor tendons; the physician must look closely for loss of active MP joint extension. This condition must also be differentiated from subluxing extensor tendons and from posterior interosseous nerve palsy. With ulnar subluxation of the extensor tendons over the MP joint, passive extension of the MP joint allows centralization of the tendons; the patient will then be able to maintain MP joint extension. In the presence of posterior interosseous nerve palsy, passive MP joint extension can be demonstrated by a tenodesis effect, in which passive wrist palmar flexion tightens intact digital extensors, resulting in subtle MP joint extension.

Symptoms of acute synovitis are pain, swelling, and transient stiffness; radiographs are normal. The presence of joint crepitus, permanent limitation of motion, and joint narrowing or erosion on radiographs indicates articular destruction secondary to long-standing synovitis (Fig. 70.3 and Fig. 70.4). The physician needs to look for subtle signs of fullness in the wrist and joint tenderness over the radiocarpal or distal radioulnar joints (DRUJ). Arthritis of the DRUJ or more proximally at the elbow may limit forearm rotation.
Figure 70.3. PA (A) and lateral (B) radiographs of the hand and wrist demonstrate generalized osteopenia, dorsal subluxation of the distal radioulnar joint, and ulnar translation of the carpus with loss of all contact between the radius and lunate.

Figure 70.4. PA (A) and lateral (B) radiographs of another patient with rheumatoid arthritis. There is mild involvement of the proximal interphalangeal joints, more significant involvement of the metacarpophalangeal joints with bony destruction, and severe involvement of the wrists with marked bony destruction and loss of carpal height.

Swollen MP joints may progress to flexion and ulnar-deviation deformities as continued synovitis causes extensor tendon subluxation, intrinsic tightness, and actual subluxation of the joint (Fig. 70.4). Chronic synovitis of IP joints can lead to digital deformities that can occur in many conditions but have come to be associated with RA. Primary mallet deformity occurs rarely when the terminal extensor tendon is stretched by dorsal synovitis of the DIP joint. Attenuation of the central slip caused by PIP joint dorsal synovitis may lead to a boutonnière deformity. Swan-neck deformity can be caused by intrinsic tightness, palmar synovitis leading to attenuation of the palmar capsule, flexor digitorum sublimis (FDS) rupture, or overpull of the extensor secondary to a mallet deformity. The thumb may be similarly involved; these deformities are classified I through V on the basis of symptoms and primary joint of involvement (Table 70.3) (49).

PSORIATIC ARTHRITIS

Psoriatic arthritis (PA) is a seronegative inflammatory polyarthritis that occurs in 5% to 7% of patients with psoriasis. Skin lesions usually precede the arthritis by months to years (35). Eighty percent of patients demonstrate nail changes, especially in association with arthritis of the DIP joint (76). This form of arthropathy differs from RA in that inflammation occurs without significant synovitis (46). It often leads to stiffness and spontaneous fusion rather than to the instability seen in RA (6). The hand may be involved in as many as 84% of patients with PA (70).

Isolated involvement of the DIP joint and severe joint destruction (“arthritis mutilans”) have been described as pathognomonic for PA. However, only 10% of patients with hand involvement have such symptoms (56). Most patients exhibit varying degrees of arthropathy affecting multiple joints. Clinically, PIP joint involvement is most severe; radiographically, however, DIP, PIP, and MP joints are affected with similar frequencies (6,70).

Distal IP joints are rarely symptomatic or deformed, although many may go on to spontaneous fusion. PIP joints often develop significant flexion contractures and spontaneous fusion, while the MP joint often stiffens in extension (Fig. 70.5). This finding does not occur in those 5% of patients with psoriatic arthritis mutilans, in which severe osteolysis of the phalanges and metacarpals leads to significant digital shortening and instability of IP and MP joints (56,46,72). This collapse and telescoping of the phalanges has been called main en lorgnette (opera glass deformity) (41). Fusiform swelling of the digits, acute dactylitis psoriatica, may be confused with flexor tenosynovitis. Fusiform swelling, however, involves the soft tissues of the entire digit and is often intermittent in nature. In wrists of moderately to severely affected patients, narrowing or obliteration of joint spaces and bony erosions often lead to stiffness or spontaneous fusion in functional positions (6).

Figure 70.5. Radiographic appearance of psoriatic arthritis in the hand. Distal interphalangeal joints as well as proximal interphalangeal joints of the small finger have undergone spontaneous fusion. There is bony destruction of the proximal interphalangeal joints of the long and ring finger with severe shortening of the ring finger (opera glass deformity). There is less significant involvement of the metacarpophalangeal joints. Clinically, this patient’s wrists were asymptomatic.
Characteristic radiologic findings in early PA include joint-space narrowing, erosions, and subchondral osteopenia. More advanced stages reveal acro-osteolysis, “pencil-in-cup” deformities, IP joint ankylosis, and severe joint destruction.

GOUT

Gout is a disorder of uric acid metabolism most commonly seen in men in the second to fourth decades. Tophaceous gout occurs in 50% to 70% of untreated patients, often many years after the initial episode of acute arthritis (32). More recent experience indicates that approximately 10% of patients under stable medical management will develop clinically significant tophi (32,64). Urate crystals may be deposited in cartilage, periarticular soft tissues, and subcutaneous tissues. Progressive stiffness and aching of joints often develops into destruction and deformity by insidiously enlarging tophi. DIP and PIP joints are involved much more frequently than are MP joints. Symptoms of gout in the hand include median nerve compression; joint contractures; and chronic tenosynovitis, tendon ruptures, and digital flexion contractures secondary to flexor tendon involvement (Fig. 70.6) (14,17,29,47,51,64).

Figure 70.6. A: Tophaceous gout has caused progressive flexion contractures of the digits as well as carpal tunnel syndrome in this patient. B: Carpal tunnel release and flexor tenosynovectomy were performed in this patient. Tophaceous deposits were also seen within the tendon substance.

Nodular soft-tissue masses, with or without calcification, are the earliest radiographic findings in tophaceous gout (67). Extra-articular tophi may erode into bony cortex, creating the “punched-out” lesions typically associated with gout. Intraarticular erosions begin in the periphery of the joint and proceed centrally; the joint space is usually preserved until late in the course of the disease (69).

NONSURGICAL MANAGEMENT

Early stages of hand arthritides may be treated with a judicious combination of medical management, splinting, and hand therapy (Table 70.4). A multidisciplinary approach is needed, with participation of the surgeon, the hand therapist, and, in the inflammatory arthritides, the internist or rheumatologist. Knowledge of a patient's goals, expectations, vocation and avocations, social situation, and limitations of activities of daily living is necessary to formulate an individualized treatment plan.

Table 70.4. Management of Hand Arthritis

Before instituting treatment, evaluate the entire patient, because many of these conditions involve more than just the hand. Arthritis of the more proximal joints of the upper extremity, cervical and lumbar spine, and lower extremities must be diagnosed. For successful restoration of hand function, the patient must have enough elbow and shoulder motion to properly position the hand in space. Lower-extremity disease may need to be controlled first to dispose of ambulatory aids that may be exacerbating upper-extremity symptoms. Alternatively, management of severely involved hands may take precedence in anticipation of rehabilitation following lower-extremity reconstruction. Extraarticular manifestations of inflammatory arthropathies (e.g., rheumatic cardiac or pulmonary disease) may affect the decision to treat a patient conservatively or with reconstructive surgery.

The goals of nonsurgical management include elimination of pain, reduction of inflammation, restoration of function, prevention of deformity, and a slowdown of the inevitable progression to joint destruction (Table 70.5). In the patient with inflammatory arthritis or gout, medical management by an internist (or rheumatologist) is crucial in alleviating acute episodes and bringing the entire disease process under control; therapy may take 3 to 4 months before it is effective (45).

Table 70.5. Treatment Goals for Hand Arthritis

Nonsteroidal antiinflammatory drugs (NSAIDs) are the first line of treatment for early hand arthritis. I do not hesitate to combine this therapy with splinting and rest of the affected joints. Together, these are helpful in minimizing pain and inflammation. Resting splints may be used prophylactically for activities that exacerbate a patient's symptoms. In certain instances, such as a flare-up of OA of the DIP or the thumb basal joints, I often recommend continuous use of a splint for 2 to 3 weeks, followed by nighttime use for another 2 weeks.
The physician should work together with the therapist in prescribing the appropriate splint. A palmar splint with the wrist in neutral to 20° of extension is effective for treating arthritis of the wrist and carpal tunnel syndrome. The thumb with basal joint arthritis is best immobilized with a long opponens splint, leaving the IP joint free; a hand-based splint does not provide sufficient leverage to immobilize the CMC joint.

A combination of resting and functional splints can be effective in early stages of the inflammatory arthritides. Resting splints to immobilize the wrist can be used to treat flare-ups of acute synovitis or tendinitis of wrist flexors and extensors. A splint incorporating the MP joints may be helpful for acute synovitis or to treat early palmar and ulnar subluxation of these joints. IP joints may be included when treating exacerbations of flexor tenosynovitis. The physician or therapist should be aware of the increased susceptibility of rheumatoid skin to breakdown under these splints. Development of psoriatic skin lesions due to irritation beneath splints may also occur. Psoriatic dermatitis, known as the Koebner phenomenon, also has been observed at surgical incision sites and other wounds. Treat these lesions with daily application of topical steroid (69).

Functional splints, which correct mild deformities such as MP joint ulnar deviation and swan-neck and boutonnière deformities, may improve overall function by realigning the hand and digits in patients who may not be ideal surgical candidates. Adaptive aids may be instrumental in improving specific activities of daily living (ADL). The therapist can provide individualized exercise programs and guidance in performing ADL, based on the patient's current stage of disease and her specific limitations. An appropriate exercise program will prevent joint stiffness and muscle atrophy.

Steroid injections are another nonsurgical method used by the physician. Inject joints (excluding the DIP joints), tendon sheaths, peritendinous insertions, and carpal tunnels that have not responded initially to an appropriate period of splinting and oral NSAIDs. A 1:1 ratio of 1% lidocaine and betamethasone sodium phosphate, using a 25- or 27-gauge needle, is preferred. Injections must be used judiciously because excessive intraarticular or peritendinous steroid administration can hasten cartilage degeneration (60) or lead to tendon ruptures (7). More effective responses can be expected when steroid injections are combined with 3 weeks of continuous splinting, as they maximize anti-inflammatory effects (28,75). In many cases, this combination of methods has been successful when previous steroid injection alone was not.

A variety of new antiarthritis medications currently are in limited clinical use: COX-2 inhibitors, glucosamine and chondroitin sulfate, intraarticular hyaluronic acid substitutes, and antirheumatic biological agents. The indications for these agents in hand and wrist arthritis have not yet been established.

**SURGICAL INDICATIONS FOR HAND ARTHRITIS**

Consider palliative or reconstructive surgery when conservative therapy is no longer effective. The surgeon and patient must be aware of the goals and relative priorities of surgical treatment of arthritis of the hand, described by William Souter (63). Although Souter was writing about RA, these principles are applicable to any type of hand arthritis (Table 70.6).

Before performing surgery on the patient with inflammatory arthritis, the physician needs to take other factors into consideration. Be aware of possible involvement of the cervical spine, take appropriate radiographs and alert the anesthesiologist. Patients on maintenance doses of steroids may need perioperative parenteral corticosteroid supplementation. High doses of chronic steroids may interfere with wound healing. Discontinue use of aspirin and other NSAIDs 1 week before surgery to minimize platelet dysfunction. Other antirheumatic medications may adversely affect immunologic or hematopoietic function; take appropriate precautions on the basis of preoperative laboratory studies.

**OSTEARTHROSIS**

Treat stable, painful DIP joints with mucous cyst excision and marginal osteophyte debridement. Excision of mucous cysts alone has a 25% to 50% recurrence rate (20,33). Cyst aspiration similarly has a high recurrence rate and may lead to an increased incidence of septic arthritis (59). Arthrodesis is the preferred treatment for an unstable, painful DIP joint.

Satisfactory treatment of the functionally impaired osteoarthritic PIP joint remains a problem. Arthrodesis of index and long fingers is superior to arthroplasty in restoring pinch strength. Arthrodesis provides more consistent results in the ulnar digits at the expense of grip strength and dexterity. Although silicone arthroplasty of these PIP joints may provide improved function, a recent report noted 20% to 35% bone resorption around these implants at 2 to 4 years after surgery (63).

Posttraumatic osteoarthritis of the small-finger CMC joint can be significantly disabling, in part because of the normal mobility of this joint. Excessive laxity secondary to chronic subluxation may be treated by arthrodesis; take care to maintain the metacarpal arch by fusing this joint in adequate flexion (7). Painful malunions of small-finger CMC fractures-dislocations also may be treated with arthrodesis, or with partial resection arthroplasty (7).

The CMC joint of the thumb is the joint in the hand most commonly treated surgically for osteoarthritis. The severity of arthritis has been classified into four stages based on clinical and radiographic involvement (Table 70.7) (10). Patients with stage I disease are most likely to respond to conservative treatment, including splinting,
Reconstructive and salvage procedures for osteoarthritis of the wrist include various intercarpal arthodeses, proximal row carpectomy, and total wrist arthrodesis (see Table 70.8).

- NSAIDs, injection, activity modification, and thenar strengthening exercises. If symptoms continue after an adequate trial of conservative management, or in later stages of arthritis, surgical intervention may be indicated. A wide range of surgical techniques for the arthritic thumb CMC joint have been described (Table 70.8).

## Table 70.8. Thumb CMC Joint Reconstruction

Eaton et al. recommend ligament reconstruction with a split FCR tendon for CMC joints with no or minimal radiographic changes (21,22). More advanced CMC arthritis requires partial or total trapezium excision combined with a reconstructive procedure. Trapezial excision alone (48), silicone implant arthroplasty (62), and soft-tissue interposition arthroplasty (1,43,44) result in residual weak pinch and proximal metacarpal migration. Another problem with silicone implants is fragmentation and foreign-body giant-cell synovitis occurring in patients who use their thumbs a great deal (52,60). Various resurfacing arthroplasties have been advocated, but proceed cautiously because rates of 10% to 35% of subluxation and dislocation are reported (19,54,66).

Arthrodesis of the CMC joint is useful for young laborers who require a strong, pain-free thumb and are willing to sacrifice some mobility (including the ability to flatten the hand) (4). This procedure is contraindicated in patients with scaphotrapezial or trapeziometacarpal arthritis.

### Carpal Boss Excision

Surgery is indicated for the symptomatic carpal boss that has not responded to cortisone injections and splinting.

- Approach the osteophyte and associated ganglion through a transverse wrist incision over the bump.
- Retract the digital extensor tendons ulnarily and the wrist extensors radially.
- Excise the ganglion with its stalk and attached capsule.
- Approach the CMC joints through separate longitudinal incisions.
- With sharp osteotomes, excise any osteophytes down to normal cartilage.
- Reapproximate the capsule and periosteum.
- Immobilize the hand in a splint or cast for 4 to 6 weeks.

Patients can expect lasting symptomatic relief in more than 95% of cases (27).

### CMC Arthroplasty—Author’s Preferred Technique

The modification of Eaton and Little’s ligament reconstruction described by Burton and Pellegrini has resulted in a high percentage of satisfied patients (12,23). The ligament reconstruction, tendon interposition (LRTI) arthroplasty uses autogenous tissue, restores strength, and minimizes metacarpal migration. With complete trapezium excision, this procedure may be used for all stages of basal joint arthritis. The LRTI arthroplasty, as originally described, uses a split FCR tendon to reconstruct the palmar oblique ligament and function as a tendon spacer (Fig. 70.7). More recently, I have used the entire FCR tendon, as advocated by Burton (11): It is easier to harvest, and no adverse effects on recovery have been reported.

![Figure 70.7. Ligament reconstruction, tendon interposition arthroplasty. The forces producing proximal migration and radial subluxation of the metacarpal are neutralized by ligament reconstruction as indicated in the vector diagram. a, Ligament reconstruction; b, metacarpal resurfacing; c, tendon arthroplasty spacer. (From Burton RI, Pellegrini VD Jr. Surgical Management of Basal Joint Arthritis of the Thumb. Part II. Ligament Reconstruction with Tendon Interposition Arthroplasty. J Hand Surg [Am] 1986;11:324.)](image)

- Expose the CMC joint through a longitudinal incision along the radial border of the thumb metacarpal. Curve the proximal incision ulnarily into the distal wrist crease to expose the FCR tendon.
- Identify and protect the sensory branch of the radial nerve, the radial artery, and the palmar cutaneous branch of the median nerve.
- Reflect the thenar muscles distally and ulnarily from the metacarpal and trapezium.
- Identify and protect the sensory branch of the radial nerve, the radial artery, and the palmar cutaneous branch of the median nerve.
- Longitudinally incise the fibro-osseous canal of the FCR to expose the tendon distal to the trapezium.
- Longitudinally incise the palmar radial capsule to expose both the carpometacarpal and scaphotrapezial joints.
- Split the trapezium into two or four pieces with an osteotome or saw and remove them with a rongeur. Avoid injury to the joint capsule and FCR tendon.
- Excise the base of the thumb metacarpal perpendicular to its lateral axis. Place a hole in the metacarpal base between the extensor pollicis brevis (EPB) and the extensor pollicis longus (EPL) tendons with a gouge or drill positioned perpendicular to the plane of the thumbnail.
- Harvest 10–12 cm of the FCR tendon through two to three short transverse incisions in the forearm, transecting it proximally at its musculotendinous junction.
- Free the distally based tendon from its insertion and pass it into the metacarpal medullary canal and out of the dorsal cortical hole.
- Place a nonabsorbable figure-of-eight stitch in the deep capsule for later use. With the thumb in palmar abduction, stabilize the metacarpal by inserting two 0.045 in. Kirschner wires (K-wires) into the index metacarpal and trapezoid.
- While applying tension to the FCR tendon, suture it to the lateral metacarpal periosteum and then back to itself. Fold the remainder of the tendon on itself and suture it into the trapezial fossa with the previously placed deep capsular stitch (Fig. 70.7).
- Close the capsule with nonabsorbable suture. Close skin incisions and immobilize the arm in short-arm thumb spica for 4 weeks.

Begin rehabilitation with removal of the cast and K-wires at 4 weeks. Apply a removable thumb spica splint, which the patient should wear for another 2 to 4 weeks except when performing gentle assisted range-of-motion (AROM) exercises. Begin strengthening exercises at 6 to 8 weeks.

Functional improvement can occur as late as 1 year postoperatively. More than 80% of patients undergoing this or similar ligament reconstruction procedures demonstrate pain-free function and improved grip strength (12,21,69).

Reconstructive and salvage procedures for osteoarthritis of the wrist include various intercarpal arthodeses, proximal row carpectomy, and total wrist arthrodesis (see Table 70.8).
RHEUMATOID ARTHRITIS

Low-profile functional splints may assist patients with mild Swan-neck and boutonnière deformities. A variety of reconstructive procedures are available for patients with more severe impairment. Similarly, significant involvement of MP and wrist joints may require surgical intervention. Although distal ulna resection has been more successful in the rheumatoid population, a Sauvé-Kapandji procedure is more appropriate in certain patients. This operation is preferable for younger, more active patients who require a stable radiocarpal surface (for arthroplasty support), who demonstrate ulnar translocation of the carpus (less than 50% radiocarpal contact), or who require augmentation of radiocarpal fusion (68).

PSORIATIC ARTHRITIS

The goals of surgery for patients with PA are different from those for patients with RA because of the fixed soft-tissue contractures and spontaneous joint fusions that accompany PA. MP arthroplasties for extension contractures may restore some function, but recurrent stiffness is not unexpected. Arthrodesis of PIP joints that have spontaneously fused in severe flexion allows more functional positioning of these digits (see Chapter 21). Arthritis mutilans may require more complex reconstruction, including a combination of arthrodesis and lengthening, to replace resorbed phalanges (68,69,70).

Surgery is rarely required for DIP joint and wrist deformity, because these become fixed in functional positions. The surgeon should also be aware of the increased infection rates reported in patients with PA (6). Preoperative betadine washing of the involved extremity has been suggested as a means to decrease perioperative infections.

GOUT

Most patients with gout respond well to allopurinol, colchicine, and uricosuric agents (see Chapter 99). Five percent to 10% of patients require surgical intervention. Indications for surgery include nerve compression, tendon involvement (entrapment or rupture), diagnosis and control of infection, significant joint destruction, and cosmetically unacceptable tophi (38,47,84).

Treat nerve compression and tendon entrapment with judicious excision of tophi, tendon debulking, and synovectomy. Tendon rupture may be managed with side-to-side repair or tendon transfers. It is best to treat isolated ruptures of FDS tendons nonoperatively if there is no functional impairment. Unstable, painful joints may require arthroplasty or arthrodesis.

PITFALLS AND COMPLICATIONS

BASAL JOINT ARTHRITIS

Interview and examine the patient on a number of occasions before deciding to perform thumb CMC arthroplasty on an arthritic CMC joint. Some patients with stage III and IV radiographic changes have few symptoms and remain surprisingly functional.

Inspect both proximal and distal aspects of the trapezium during exposure. Radiography does not reveal degenerative changes of the scaphotrapezial joint in one third of cases (60). If there is no scaphotrapezial arthritis or thumb web-space contracture, the proximal one half of the trapezium may be left in place; most surgeons prefer a total trapeziectomy.

Carefully evaluate the MP joint preoperatively. For hyperextension instability greater than 30°, stabilize the joint with a volar plate advancement or MP arthrodesis.

DRUJ RECONSTRUCTION

One potential disadvantage of resection techniques is instability of the end of the proximal ulna. Ulnar instability is most likely to occur in patients with significant preoperative DRUJ instability; neither this procedure nor other excisional arthroplasties of the distal ulna adequately addresses this problem. In these cases, continue above-elbow immobilization for 3 to 4 weeks before instituting gentle active range-of-motion exercise.

GOUT

Traumatized tophi may undergo liquefaction with subsequent development of erythema, warmth, pain, and drainage of thick, opaque fluid. Differentiation of acute tophaceous gout from infection may require aspiration and crystal analysis or occasional incision and drainage.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

The primary indication for arthroplasty of the metacarpophalangeal (MCP) joints is advanced painful destruction of the joint by rheumatoid arthritis. The systemic effects of rheumatoid arthritis on the metacarpophalangeal joints are mediated by the formation of a pannus that is destructive to both the soft tissue and bone. In patients without advanced bone destruction at the MCP joints, intermediate procedures such as synovectomy and crossed intrinsic transfers can be utilized to improve function and decrease pain, although eventual progression and bony destruction will most commonly occur. Patients who suffer from isolated posttraumatic arthritis of the MCP joint, most commonly secondary to fracture, may also benefit from arthroplasty; the increased demands of these generally younger patients must be taken into account in assessing implant use, however. In osteoarthritis, implant use is most satisfactory in nonborder digits and in patients who will not accept joint fusion as a primary treatment modality.

The ideal candidate for arthroplasty is the rheumatoid patient who presents with significant pain or severe destruction of the MCP joints involving palmar subluxation of the proximal phalanx and early fixed hyperextension deformity of the proximal interphalangeal joint. The concept of MCP joint implant arthroplasty was first reported in 1959, with goals to both relieve pain and correct deformity. Since that time, a variety of implants have been developed and used for MCP replacement, with improved durability in materials coming with time. The primary prostheses used today are fashioned of silicone. The major implants in use today are the original Swanson implant (Wright Medical, Arlington, TN), now used with metal grommets in an attempt to prevent implant failure; the neutral Avanta (Avanta, San Diego, CA) block design implant; and the newer anatomically neutral NeuFlex (DePuy, Warsaw, IN) implant, designed to decrease implant failure and improve functional arc of motion.

Carefully assess the rheumatoid patient prior to upper extremity surgery. Functional status, lower extremity problems, and level of pain are important issues prior to deciding whether or not implant surgery should go forward. Many patients with rheumatoid arthritis can function well with painful advanced deformities of the joints of the hand, although deformity, despite being relatively painless, should not be allowed to progress to a point where arthroplasty becomes technically very difficult. In addition, the status of the wrist also affects MCP arthroplasty outcome in that uncorrected fixed radial deviation of the wrist in the face of MCP joint replacement often leads to rapid recurrent ulnar drift and implant failure at the MCP joints postoperatively. Most authors advocate staged or simultaneous wrist fusion or arthroplasty to provide a stable fulcrum for MCP joint arthroplasty in these patients. In the majority of patients with rheumatoid arthritis, all four MCP joints are generally replaced at a single setting. The thumb MCP joint is generally not treated by implant arthroplasty due to the high forces that occur during function, and the relative lack of disability associated with fusion of the thumb MCP joint. In patients who have significant disease at the thumb MCP joint, fusion of this joint can frequently be undertaken simultaneously with implant arthroplasty of the index through small-finger MCP joints.

The majority of patients gain significant pain relief and increased level of function after MCP arthroplasty. The correction of ulnar deviation (Fig. 71.2), improved ability to perform activities of daily living, and improvement of extensor lag have been documented in several outcome studies. Change in range of motion has been variable, with some series reporting losses or gains of up to 10° from preoperatively (4,11,14,16). Until recently, the main objection to MCP joint arthroplasty has been the inability to obtain full flexion postoperatively. Anatomically neutral implants appear to allow improved functional flexion of the digits without a significant increase in extensor lag, thereby improving the overall arc of motion (Fig. 71.3). In addition, in anatomically neutral implants the compressive and tensile forces on the silicone is more evenly distributed through the functional arc of motion. Nevertheless, no long-term data are available on failure rates for anatomically neutral implants, and whether theoretical improvements lead to clinical improvements remains to be seen. All implants available in the United States and abroad have initially been found to be satisfactory, but with long-term follow-up they tend to fail.
**Figure 71.2.** Ulnar deviation and an inability to extend the digits completely are fairly uniform in patients with longstanding rheumatoid arthritis.

**Figure 71.3.** The NeuFlex implant is a departure from prior designs as it undertakes an anatomically neutral axis to decrease implant forces and improve functional arc of motion for the patient.

**OPERATIVE TECHNIQUES**

Two different surgical approaches are available. Use either a double longitudinal incision (B₁, B₂, Fig. 71.4), with one incision between the index and middle finger metacarpal heads and the second between the ring and small finger metacarpal heads, or a transverse incision at the level of the MCP joints (A, Fig. 71.4A). We favor the double longitudinal incision technique since postoperative range of motion exercises do not cause tension on the wound; if wound complications do occur, the implants are not directly exposed even in cases of wound dehiscence.

*Figure 71.4. The two types of incisions that can be utilized for metacarpophalangeal joint arthroplasty. See text for details.*

- Use a #15 blade to make a 5–6 cm longitudinal incision from the finger web space proximally between the index and middle finger and ring and small finger metacarpal heads.
- Utilizing curved dissecting scissors, carefully dissect the subcutaneous tissues off the extensor tendon and extensor hood of both MCP joints immediately adjacent to the surgical incision.
- Utilizing a #15 blade, longitudinally incise the tight ulnar extensor hood.
- Use a Hohmann retractor and scissors to completely radially sublux the extensor tendon and hood of both MCP joints (Fig. 71.5).

*Figure 71.5. After longitudinally incising the ulnar extensor hood, the extensor tendon and surrounding structures are subluxed radially, exposing the metacarpophalangeal joint.*

- The ring and small finger joints can also be exposed to allow sequential implantation of all implants in the same procedure.
- Now prepare the metacarpal head and proximal phalanx to allow placement of the proper-size implant.
- Protect tendinous structures using Hohmann retractors.
- Using a microsagittal saw, transect the MCP joint head at the distal metaphyseal flare (usually at the origin of the collateral ligaments) (Fig. 71.6).
Figure 71.6. Saw cuts at the distal flare of the metacarpal shaft just proximal to the metacarpal head exposing the joint space for preparation.

- Use a rongeur to remove any sharp pieces of bone and to debride any osteophytes present on the proximal phalanx base. Do not osteotomize the proximal phalanx except in cases of severe long-term subluxation, in which case remove some of the volar cortex to allow appropriate spacing between the phalanx and the metacarpal.

For appropriate implant sizing, utilize sequential broaching in both the metacarpal and phalangeal shafts. Use the presized broaches to rasp the intramedullary canals to as large a size as possible.

- Use a sharp awl to place a starting hole in both the metacarpal and phalangeal shafts (Fig. 71.7).

Figure 71.7. A sharp awl is used to begin the starting hole in both the metacarpal and the phalangeal shafts.

- Perform a trial reduction using the trial implant size that corresponds to the last broach used (Fig. 71.8).

Figure 71.8. Broaching should commence in progressively increasing sizes until the broach can no longer be seated, followed by trial implant placement with assessment of joint stability.

- Make sure that full flexion and extension can be obtained without implant pistoning, excessive tightness or laxity, or rotational deformity during motion.
- In the index finger, reconstruct the proximally and radially detached collateral ligament through drill holes in the metacarpal shaft to provide resistance for pinch.
- Then place the definitive implant and relocate the extensor tendon to the dorsal midline (Fig. 71.9 and Fig. 71.10). If excessive shortening and palmar subluxation is noted, release of the volar capsular structures may be required to get full flexion and extension and implant stability. It is imperative to reconstruct the radial extensor hood in an imbricated fashion to prevent recurrent ulnar subluxation of the extensor tendon.

Figure 71.9. Definitive correctly sized implant is placed in the metacarpal shaft first, followed by placement in the phalangeal shaft. The implant should rest appropriately between the metacarpal and proximal phalanx, allowing full passive flexion and extension without restriction due to soft-tissue structures.

Figure 71.10. Centralization of the extensor tendon may be accomplished by imbricating the radial hood with horizontal mattress sutures after the implant has been well seated.

- Use several horizontal 4-0 braided nonabsorbable mattress sutures to reef the radial extensor hood in a position to allow maintenance of the extensor tendon over the MCP joint dorsally.
- Check to make sure that a full range of motion occurs after reefing of the radial extensor hood without excessive joint tightness or resubluxation of the extensor tendon.
- Irrigate the wounds and close the skin using 5-0 interrupted horizontal mattress sutures (Fig. 71.11). Place a small drain in each of the wounds to prevent hematoma formation, if necessary. Apply a bulky dressing with a volar plaster splint that maintains all four fingers in full extension.
Figure 71.11. The wounds are closed using interrupted 5-0 nylon sutures, taking care to protect the skin edges with small drains, placed for 1 day postoperatively to avoid hematoma formation. The patient is placed in a full-extension splint with all the fingers included except the thumb.

POSTOPERATIVE CARE

Patients are generally admitted overnight for observation and 24 hours of intravenous antibiotics and pain medication. The splint and dressing remain in place for 5 to 10 days postoperatively (longer in patients who have had significant MCP joint palmar subluxation and shortening preoperatively). Remove the drains prior to hospital discharge. Remove sutures at the first postoperative visit. Have the patient evaluated by a hand therapist and have a molded full-extension pan splint placed as well as a dynamic extension splint to allow early range of motion of the digits while maintaining the extensor attitude of the MCP joints themselves (Fig. 71.12). We recommend splints for the first 4 to 6 weeks, with gradual reduction of their use by 2 to 3 months. In general, maximal functional range of motion is obtained at 3 to 4 months postoperatively (Fig. 71.13). These basic principles and techniques are germane to the use of all silicone arthroplasty implants available.

Figure 71.12. A dynamic extension splint is helpful in maintaining metacarpophalangeal joint extension while allowing active flexion to occur in the postoperative rehabilitation period.

Figure 71.13. Patient at 3 months after metacarpophalangeal arthroplasty. Anteroposterior radiograph (A) demonstrates excellent alignment of the MCP joints, with the ability to obtain full extension (B), and flexion at all metacarpophalangeal joints of 75° (C).

PITFALLS AND COMPLICATIONS

Complications of MCP joint arthroplasty include wound infection, prosthetic failure, recurrence of deformity, tendon adhesions, and wound dehiscence. Implant fracture can be expected to occur over time, although recent design changes may prolong implant survival (Fig. 71.14). A recent report utilizing the Avanta MCP joint arthroplasty demonstrated surprisingly high fracture rates postoperatively at relatively early follow-up (2). Fracture of the implant is a radiographic diagnosis and on occasion is not clinically apparent, with patients maintaining some functional range of motion (although generally decreased) with only minimal increases in pain (11,16). Recurrence of deformity occurs after implant failure. Revision is not required unless symptoms warrant.

Figure 71.14. A Swanson implant removed at revision metacarpophalangeal arthroplasty demonstrates implant failure at the stem–hinge interface (the most common site of implant failure with this design).

Recurrence of deformity, particularly ulnar deviation, is seen to some extent in almost every patient over time (11,14). Extensive soft-tissue release to balance the forces on the joint can prevent recurrent ulnar deviation. Functional splints also help prevent recurrent deformity during rehabilitation.

Infection is a relatively rare complication and generally will require implant removal. Avoid wound dehiscence and hematoma formations by using gentle and meticulous
**ARTHROPLASTY OF THE PROXIMAL INTERPHALANGEAL JOINTS**

**PRINCIPLES OF TREATMENT**

The proximal interphalangeal (PIP) joint is susceptible to destruction by synovial proliferation as seen in the MCP joints in rheumatoid arthritis. Painful PIP joints with loss of function are the primary indication for replacement (21). Advanced osteoarthritic destruction of the PIP joint can also produce similar symptoms. PIP joint arthroplasty for osteoarthritis is far more commonly seen than at the MCP joint level (15). Frequently, the distal interphalangeal joint (DIP) is also involved in this process. Although arthroplasty for the DIP joint has been reported (2,3), results in general have been less than satisfactory. Most surgeons recommend fusion of the DIP joint by one of several methods as a definitive form of treatment for painful deformities (5). PIP joint arthroplasty for osteoarthritis, although not commonly performed, is a treatment option after failed conservative therapy. Arthroplasty of the PIP joints is best reserved for the nonborder digits, as is the case with the MCP joints due to the high forces generated by pinch and use of the hand (19). The same principles apply to the rheumatoid patient, although in general deformity is far more advanced and bone quality poor in the rheumatoid patient.

Options for implants at the PIP joints include silicone replacements similar to those used for the MCP joints as well as various metal/high-density-polymer designs (3). Recent reports have demonstrated excellent decrease in pain and relatively good long-term durability with silicone implant arthroplasty (1). Overall range of motion postoperatively, however, has demonstrated mixed results, generally equaling the preoperative abilities. Combining various metal/high-density-polymer designs with the use of bone cement simulates a more anatomic articulation; however, prosthetic loosening, fracture, and protrusion through the cortex have been noted (13). Nevertheless, the attractive anatomic contouring of these devices has led several investigators to continue their development and refinement.

**OPERATIVE TECHNIQUES**

Dorsal, volar, and ulnar lateral approaches are used to approach the PIP joint. We favor a dorsal approach although we have used the volar approach quite successfully. Regardless of the approach used, several basic principles, if followed, allow appropriate implant placement and acceptable postoperative function.

- Incise the extensor mechanism between the central tendon and the lateral band so that no disruption of the central slip attachment occurs (Fig. 71.15).

- Use a sagittal oscillating saw to resect the proximal phalanx distal condyles at the end of the flare, allowing exposure of the middle phalanx base. Use a rongeur to remove any osteophytes present on either side of the joint.
- Enlarge the endosteal cavities by using a small awl and then a dental burr followed by appropriate-size broaches to prepare the canals.

**Figure 71.15**. For proximal interphalangeal joint arthroplasty using the dorsal approach, an incision between the central tendon and lateral band can be performed so as not to disrupt the central slip, decreasing the propensity for extensor lag postoperatively.

- The trial prosthesis should have enough give-and-take that both stems can be advanced without buckling during flexion and extension of the finger.
- If any buckling or migration of the implant occurs, either a smaller implant should be used or the bone should be resected further to provide a larger gap.
- After the implant is placed, irrigate the joint and repair the extensor tendon using figure-of-eight 4-0 braided nonabsorbable sutures. Close the skin with horizontal mattress interrupted 5-0 nylon sutures. Apply a light bulky dressing as well as a volar splint holding the finger in full extension.

**HINTS AND TRICKS**

Advantages to utilizing the volar approach are that the extensor mechanism is not compromised and postoperative extension does not need to be maintained for as long (Fig. 71.16).

**Figure 71.16**. The volar approach utilizes a standard Brunner skin-type incision, retraction of the flexor tendons, and proximal detachment of the volar plate, exposing the condyles of the distal proximal phalanx, which are then resected allowing implant placement and reconstruction of the volar plate through drill holes in the proximal phalanx.

**POSTOPERATIVE CARE**

Keep the patient in a postoperative extension splint for 7 to 10 days, at which time the sutures are removed. Then fit a removable Orthoplast splint to maintain the PIP joint in full extension until 2 weeks after surgery, at which time gentle range-of-motion exercises can begin. Use the extension splint between exercises to prevent any extensor lag from occurring. If a volar approach is utilized, less attention needs to be directed toward extension splinting. With the volar approach, start early flexion as soon as possible to prevent adhesions to the flexor tendons. Recurrence of ulnar deviation (which is commonly seen preoperatively) can occur following PIP joint arthroplasty. Splint training of the digit may be required.

**PITFALLS AND COMPLICATIONS**

As with MCP joint arthroplasty, a major complication is prosthetic failure. This complication may not be clinically significant unless recurrent pain and significant deformity occur. Other complications include prosthetic loosening, migration, and recurrence of deviation deformity. Erosion of the prosthesis through delicate skin can...
lead to disastrous results in rheumatoid patients. Gentle skin retraction and care during the procedure is paramount. Infection is an uncommon complication; if present, it generally requires implant removal until well controlled.

**ARTHROPLASTY OF THE CARPOMETACARPAL JOINT OF THE THUMB**

**PRINCIPLES OF TREATMENT**

Painful degeneration of the thumb carpometacarpal (CMC) joint is most often secondary to osteoarthritis. This clinical entity is most commonly seen in postmenopausal women. Rheumatoid arthritis, repetitive stress injury, and hormonally induced changes have also been implicated as causes for basilar joint arthritis, but this occurs far less frequently than degenerative osteoarthritis (17). The extent of degenerative change in the CMC joint can be staged radiographically according to the classification of Eaton and Littler (Table 71.1) (9).

Table 71.1. The Eaton-Littler Classification of Basal Joint Arthritis

Initial treatment of thumb CMC arthritis is conservative. A trial of nonsteroidal antiinflammatory medication and hand-based splinting of the thumb CMC joint is often successful in early and moderate cases. In addition, an injection of corticosteroid into the CMC joint can occasionally provide dramatic pain relief and increased function in patients, although long-term relief is not common. Some patients with extensive radiographic disease have minimal pain, and others with minimal radiographic disease have extensive pain; therefore, base treatment on the patient's symptoms rather than on the radiographs alone.

Historically, multiple surgical procedures have been performed for painful thumb CMC arthritis. Silicone implantation to replace the resected trapezium was developed by Swanson in 1968 (20). Smaller silicone wafers utilized in a hemitrapezial excision have provided excellent early symptomatic improvement, although silicone synovitis resulting in pain and bony destruction has occurred in long-term studies. As a result, silicone implantation of the thumb CMC joint has been all but abandoned. Metal implants have recently been advocated, although experience is limited and outcome uncertain (7). Arthrodesis of the thumb CMC joint is a viable option and is useful in younger, manual laborers who perform heavy work. It gives a predictable painless result despite sacrificing some range of motion (17,19).

Currently, some combination of excision of the trapezium and tendon interposition or ligament reconstruction is most commonly performed for arthroplasty of the thumb CMC joint (8). In 1970, Froimson introduced the concept of using a ball of tendon as an interpositional spacer between the carpus and thumb metacarpal after excision of the trapezium (10). Due to the potential for proximal migration of the thumb metacarpal, others have advocated ligamentous reconstruction utilizing the flexor carpi radialis tendon woven through the base of the thumb metacarpal (6). Outcome studies have not demonstrated that one technique provides substantially improved results over another (13). In fact, some authors have advocated excision of the trapezium alone without any interposition or reconstruction at all (12). Having utilized both techniques, we currently favor excision of the trapezium and tendon interposition without ligament reconstruction.

**OPERATIVE TECHNIQUES**

- Make a 3.5 cm curvilinear incision dorsally over the thumb CMC joint.
- Protect the sensory branch of the radial nerve as it passes over the capsule.
- Incise the capsule longitudinally, exposing the trapezium.
- Excise as much capsule off the trapezium as possible and then use an osteotome and rongeur to morselize and remove the trapezium (Fig. 71.17).  

![Figure 71.17.](image_url) The trapezium, after exposure through a longitudinal capsular incision, can be quartered with an osteotome and then removed piecemeal by a rongeur. The trapezium is large; ensure that all pieces are removed including any osteophytes or loose bodies present at the junction of the bases of the first and second metacarpals.

- Make sure that all osteophytes at the junction of the bases of the first and second metacarpals are removed.
- Place a small osteotome between the bases of the first and second metacarpal shafts and then transfer the thumb metacarpal in appropriate alignment by using a 0.045 Kirschner wire passed from the first metacarpal into the second metacarpal (Fig. 71.18).  

![Figure 71.18.](image_url) A postoperative radiograph demonstrates fixation of the thumb metacarpal “in space” to the index metacarpal via a single Kirschner wire with the distraction between the bases allowing soft-tissue interpositional ingrowth. Note the space where the trapezium has been excised and a soft-tissue tendon interposition performed. The Kirschner wire is generally left in for 4 weeks, after which it is removed and the cast discontinued to begin therapy.

- Now, make a transverse 1 cm incision over the palmaris longus at the wrist.
- After identifying the palmaris longus, use a Brand tendon stripper to harvest the palmaris longus and close the skin wound.
- Form a tendon ball or “anchovy” with the palmaris longus tendon using a braided 4-0 nonabsorbable suture (Fig. 71.19).  

![Figure 71.19.](image_url)
Figure 71.19. Using a 4-0 nonabsorbable suture passed in a back-and-forth fashion through a free tendon graft (most commonly, the palmaris longus), sewing the suture onto itself, a tendon ball or “anchovy” can be fashioned and placed in the interposed position.

- Place the tendon anchovy beneath the distal-most portion of the flexor radialis tendon at the floor of the excised trapezium.
- Suture the anchovy so that it is fully interposed between the first and second metacarpal bases.
- Close the CMC capsule carefully, using interrupted absorbable sutures.
- Leave the Kirschner wires exposed outside the skin.
- Apply a large bulky dressing including a thumb spica splint that allows interphalangeal joint motion.

**POSTOPERATIVE CARE**

Maintain the splint and dressing until 7 to 10 days postoperatively, then remove the sutures. Apply a below-elbow thumb spica cast allowing interphalangeal thumb motion and full MCP motion of the other digits. Maintain the cast for 4 weeks. Then remove the Kirschner wire in the office and place the patient in a removable Orthoplast splint. Begin hand therapy at 4 weeks with gradually increasing range-of-motion and strengthening exercises. Four weeks of therapy is usually required.

**PITFALLS AND COMPLICATIONS**

Avoid injury to the sensory branch of the radial nerve. Avoid infection by administering intravenous antibiotics during the procedure. Patients undergoing thumb CMC arthroplasty can have significant swelling postoperatively. Avoid tight dressings.

SMALL-JOINT ARTHRODESIS IN THE HAND AND WRIST

Pain-free use of the hand is critical to independent functional and productive living. There are numerous medical conditions that limit the use of the small joints of the hand because of pain, deformity, dysfunction, and instability. Among these are trauma, infection, connective tissue disease, arthritides, osteoarthrosis, paralytic disorders, failed surgical procedures, and congenital deformities. Many medical and surgical advances have been made to improve the hand function of affected patients. One of the mainstays has been to perform arthrodeses of selected joints of the hand and wrist. Arthrodesis, or joint fusion, remains one of the most time-tested, reliable, and useful hand surgery procedures (48,59). Reasons to perform small-joint arthrodesis are to correct deformity, to relieve pain, to control instability, and to improve loss of function caused by neurovascular disease (4,6,15,74,89). A properly performed small-joint arthrodesis can markedly improve hand function and the overall quality of life for an afflicted patient.

INDICATIONS FOR SURGERY

FINGER METACARPOPHALANGEAL, PROXIMAL INTERPHALANGEAL, AND DISTAL INTERPHALANGEAL JOINTS

Osteoarthritis commonly affects the distal interphalangeal (DIP) joints of the fingers and, to a lesser extent, the interphalangeal (IP) joint of the thumb. Other diseases that less commonly affect the DIP joints are psoriatic arthritis, rheumatoid arthritis, and infection. In all these diseases, hand function is limited by painful motion of the joints. Arthrodesis of the DIP joint is a successful way to eliminate the pain associated with these disorders.

The proximal interphalangeal (PIP) joints are more commonly involved in rheumatoid arthritis as well as osteoarthritis. Posttraumatic arthrosis of a single PIP joint is a common problem. The disability for the rheumatoid patient is the associated swan-neck or boutonniere deformity, while for the posttraumatic arthritic patient it is usually pain. Arthrodesis of the PIP joints is a reliable method of returning function to these fingers, and it is especially appropriate for the index and small fingers because of their unique position as border digits.

Metacarpophalangeal (MCP) joints may be affected in multiple fingers in rheumatoid arthritis, or singly in posttraumatic arthritis. Arthroplasty is usually preferred for the MCP joints of the fingers to preserve good motion and function. Arthrodesis is useful for joints when arthroplasty is not indicated, or when a previous arthroplasty has failed.

Carpometacarpal arthrodesis, although less commonly performed, can also improve functional outcomes, particularly in the fourth and fifth carpometacarpal joints, which may have osteoarthritis as a late sequela of fracture dislocations (15,17). Elimination of pain and increased stability improves hand function.

THUMB INTERPHALANGEAL, METACARPOPHALANGEAL, AND CARPOMETACARPAL JOINTS

The thumb interphalangeal (IP) joint is not unlike the IP joints of the digits. It is important for stable power pinch, which may be compromised in osteoarthritis because of pain or connective tissue disease caused by joint laxity.

The thumb MCP joint is different from the other MCP joints in that significantly more stress is placed on the ligamentous restraints than in the finger joints. This is because of the unique position of the thumb and its role in pinch and grasp. Instability of this joint is common because of chronic laxity after a missed acute tear of the ulnar collateral ligament (gamekeeper’s thumb) and rheumatoid arthritis (19,48). While ligament reconstruction and soft-tissue procedures are usually preferred, in the arthritic thumb MCP joint, arthrodesis (Fig. 72.1, Fig. 72.2) provides a more lasting option and is generally preferred to arthroplastic techniques for a number of different disorders (36).
In the thumb, the joint most commonly affected with osteoarthritis is the carpometacarpal (CMC) joint (6). This is perhaps the most commonly involved joint in postmenopausal women with early osteoarthritis. It has been postulated to be secondary to laxity of the metacarpal volar beak ligament, allowing enough subluxation and incongruity of the joint to become pathologic. A second commonly affected group is young people with high demands on their hands (e.g., manual laborers) who have posttraumatic arthritis after an old intraarticular fracture of the base of the metacarpal (Bennett's or Rolando's fracture). Eaton et al. (28a) have classified this pattern of osteoarthrosis of the first CMC joint into four stages. Stage I has normal intraarticular cartilage with joint-space widening. In stage II, there is narrowing of the joint space but the articular contours are normal. Stage III disease has significant destruction of the thumb CMC joint, but the scaphotrapeziotrapezoidal (STT) joint is normal. In stage IV disease, there is destruction of the STT joint in addition to the first CMC joint. Arthrodesis of the thumb CMC joint is indicated for stage III disease but is contraindicated in the presence of any scaphotrapeziotrapezoidal disease (stage IV).

Patients who benefit most from an arthrodesis of the thumb CMC joint are usually young, active people who require a strong, stable, pain-free thumb to perform work activities (6,29). House et al. (43) found that arthrodesis of the first CMC improved hand function in patients with tetraplegia following spinal cord injury (see Chapter 68). Arthrodesis is the best salvage procedure for failed arthroplasty or previous infection of the first CMC joint. Older patients and patients whose demands for strength of pinch and grip are not high are better served with an arthroplasty (see Chapter 70). Moore et al. (72) reported successful use of arthrodesis for a rare problem, laxity of the thumb CMC joint in patients with Ehlers-Danlos syndrome. Thumb CMC arthrodesis significantly limits thumb motion, although some compensatory motion occurs at the STT and the MCP joints; therefore, in patients who require motion of the thumb, arthrodesis is contraindicated.

SURGICAL PLANNING

Surgeons differ in the choice of skin incision; the approach to the soft-tissue envelope about a joint; the manner in which the joint surfaces are prepared; whether to use bone graft or other substitutes, or no graft; fixation methods; and postoperative treatment, including rehabilitation (27). The goals of arthrodesis in the small joints of the hands are uncomplicated soft-tissue and skin healing, appropriate joint position, and bony union in the shortest possible time (15). The best techniques are simple, straightforward, and reliable, and they allow early motion of the remainder of the hand. Successful fusion requires a good soft-tissue envelope about the joint as well as well-vascularized bone at the fusion site. Address any deficiencies prior to undertaking a fusion.

SURGICAL TECHNIQUES

INCISIONS AND EXPOSURE OF THE JOINTS

- Straight longitudinal incisions are the best incisions for fusions in the small joints of the hand. Use gentle curved incisions, and H, Y, V, and other types of incisions, only in good-quality, well-vascularized skin and soft tissue. Expose the thumb carpometacarpal joint through a Wagner type of anterior incision or through a dorsal incision directly over the joint (see Chapter 37).
- Approach the DIP joints of the fingers and the IP joint of the thumb by transversely dividing the extensor mechanism and capsule. Debride the soft tissues as needed. We prefer excision of the radial and ulnar collateral ligament complexes prior to arthrodesis.
- Remove all marginal and dorsal osteophytes.
- Approach the digital PIP joints by dividing the extensor tendon mechanism longitudinally. Careful dissection preserves the interval between the extensor mechanism and the dorsal joint capsule. Preserve the joint capsule if possible.
- Approach the MCP joints of the fingers by dividing the ulnar sagittal fibers. Retract the entire extensor mechanism to one side and visualize the joint capsule. Then make a direct longitudinal approach through the capsule.
- Approach the MCP joint of the thumb by dividing the radial sagittal fibers, detaching the extensor pollicis brevis insertion, and pulling the extensor pollicis longus (EPL) ulnarly. Incise the joint capsule longitudinally and debride as indicated.
- For the carpometacarpal joint of the thumb, make a volar anterior approach.
- Elevate the origin of the thenar musculature from the thumb metacarpal and trapezial area.
- You may partially detach the thenar muscle and bone insertions of the abductor pollicis longus if necessary for exposure of the carpometacarpal joint. Pay careful attention to preserving the joint capsule for closure.

PROPER POSITIONING

A patient who has disease throughout the small joints of the hand will generally be better served with an arthroplasty of the finger MCP joints and arthrodeses of the PIP and DIP joints. The position for arthrodesis in the fingers is critical to hand function. In general, there should be a gentle cascade from radial to ulnar with more flexion of the ulnar digits, as can be appreciated in the normal hand at rest.

- Fuse the MCP joint of the index finger in 25° to 30° of flexion, adding another 5° of flexion at each joint, moving ulnarly, to end at 40° to 45° of flexion in the small-finger MCP joint.
- There should be no radial or ulnar deviation at the MCP joints. Ensure that there is no rotational deformity, although some have suggested that gentle supination may help with thumb-pad pinch. There should be more flexion at the PIP joints than at the MCP joints in each digit.
- Fuse the index-finger PIP joint at 40° to 45° of flexion, with an additional 5° of flexion added at each PIP joint to end at 55° to 60° of flexion at the small-finger PIP joint.
- The DIP joints are very important to hand function. Fusion in too much flexion is disabling and cosmetically undesirable. Our experience is that too much extension of these joints is tolerated better than too much flexion. Fuse the DIP joint at 0° to 15° of flexion.
- The thumb position is most critical to hand function because of its unique role. Fuse the thumb MCP joint in approximately 10° flexion with no radial or ulnar deviation.
- Fuse the thumb IP joint in a position of 0° to 15° of flexion.

PROPER POSITIONING

A patient who has disease throughout the small joints of the hand will generally be better served with an arthroplasty of the finger MCP joints and arthrodeses of the PIP and DIP joints. The position for arthrodesis in the fingers is critical to hand function. In general, there should be a gentle cascade from radial to ulnar with more flexion of the ulnar digits, as can be appreciated in the normal hand at rest.

- Fuse the MCP joint of the index finger in 25° to 30° of flexion, adding another 5° of flexion at each joint, moving ulnarly, to end at 40° to 45° of flexion in the small-finger MCP joint.
- There should be no radial or ulnar deviation at the MCP joints. Ensure that there is no rotational deformity, although some have suggested that gentle supination may help with thumb-pad pinch. There should be more flexion at the PIP joints than at the MCP joints in each digit.
- Fuse the index-finger PIP joint at 40° to 45° of flexion, with an additional 5° of flexion added at each PIP joint to end at 55° to 60° of flexion at the small-finger PIP joint.
- The DIP joints are very important to hand function. Fusion in too much flexion is disabling and cosmetically undesirable. Our experience is that too much extension of these joints is tolerated better than too much flexion. Fuse the DIP joint at 0° to 15° of flexion.
- The thumb position is most critical to hand function because of its unique role. Fuse the thumb MCP joint in approximately 10° flexion with no radial or ulnar deviation.
- Fuse the thumb IP joint in a position of 0° to 15° of flexion.
FUSE THE THUMB CARPOMETACARPAL JOINT IN 15° TO 20° OF EXTENSION, 45° OF PALMAR ABDUCTION, AND 5° TO 10° OF PRONATION.

CHECK THE POSITIONING OF ALL JOINT ARTHRODSES INTRAOPERATIVELY BY TEMPORARILY FIXING THE JOINTS WITH KIRSCHNER WIRES (K-WIRES) PRIOR TO PERMANENT FIXATION.

PREPARATION OF BONY SURFACES

SUCCESSFUL ARTHRODESIS OF A SMALL JOINT IN THE HAND REQUIRES CAREFUL PREPARATION OF THE BONE SURFACES OF THE JOINT (15,48). EXCELLENT CANCELLOUS-TO-CANCELLOUS BONE CONTACT GIVES THE BEST CHANCE FOR FUSION.

CONVEX–CONCAVE TECHNIQUE

- REMOVE MAINTENANCE OF THE NORMAL CONTOUR OF THE JOINT; THEREFORE, MINIMAL SHORTENING IS REQUIRED AND POSITIONING IS EASY IN FLEXION/EXTENSION, RADIAL/ULNAR DEVIATION, AND ROTATION.

CUP AND CONE PREPARATION

THE CUP AND CONE TECHNIQUE CAN BE USED WITH ALL FIXATION SYSTEMS. IT IS CONSIDERED ADVANTAGEOUS BECAUSE IT PRESENTS LARGE, OPPOSING CANCELLOUS SURFACES FOR FUSION (19,68), BUT IT DOES INCREASE DIGITAL SHORTENING. RECENTLY, CUP AND CONE REAMERS HAVE BEEN MADE AVAILABLE COMMERCIALY THAT PROVIDE MATCHING SURFACES IN THE JOINT.

THIS METHOD IS GENERALLY USED MORE COMMONLY AT THE MCP JOINTS. THE CMC JOINT OF THE THUMB CAN BE FUSED USING THIS METHOD, WITH THE CONE BEING MADE FROM THE FIRST METACARPAL BASE AND THE CUP BEING FASHIONED IN THE TRAPEZIUM. CARROLL (16) HAS SHOWN EXCELLENT RESULTS.

METHODS OF FIXATION

MANY TECHNIQUES TO STABILIZE SMALL-JOINT ARTHRODSES HAVE BEEN USED, AND MULTIPLE STUDIES HAVE DESCRIBED CONSISTENT SUCCESS USING DIFFERENT TECHNIQUES (5,9,12,15,16,17,19,20,27,31,36,45,48,49,50,54,55,58,66,67,74,82,83,85,86,88,93,96,102,103,107). THEY DIFFER WITH REGARD TO THE DEGREE OF DIFFICULTY OF USING THE INSTRUMENTATION, WHETHER BONE GRAFTS ARE HARVESTED FROM OTHER SURGICAL SITES, AND TECHNICAL DIFFICULTY.

IN A BIOMECHANICAL STUDY, KOVACH ET AL. (54) COMPARED CROSSED K-WIRES, TENSION BAND WIRING, AND AN INTEROSSEOUS LOOP SUPPLEMENTED BY A K-WIRE IN A PIP ARTHRODESIS MODEL. TENSION BAND WIRING WAS FOUND TO BE THE STRONGEST. IN A COMPARISON STUDY OF FOUR METHODS OF FIXATION FOR CMC ARTHRODESIS USING CROSSED K-WIRES, CERCLAGE WIRING, AND CUP AND CONE WITH SINGLE K-WIRE AND TENSION BAND WIRING, STOKEL ET AL. (66) FOUND THAT TENSION BAND WIRE AND CERCLAGE TECHNIQUES PROVIDED THE MOST STABLE CONSTRUCT. BAMBERGER ET AL. (6) HAVE USED THE CUP AND CONE METHOD ORIGINALLY DESCRIBED BY CARROLL AND HILL (19) WITH STAPLE OR K-WIRE FIXATION. THEY FOUND A 42% DELAYED UNION/NONUNION RATE FOR THE STAPLE METHOD COMPARED TO AN 11% RATE OF DELAYED UNION FOR THE K-WIRE GROUP.

CROSSED K-WIRES AND TENSION BAND

THE CROSSED K-WIRE (15,19) (FIG. 72.3, FIG. 72.4) AND TENSION BAND TECHNIQUES (45,50,85,93) ARE THE MOST FREQUENTLY USED OF ALL FIXATION TECHNIQUES IN SMALL-JOINT FUSIONS (9,48). THEY PROVIDE STABLE FIXATION, ARE RELATIVELY UNCOMPlicated TECHNICALLY, AND MAY BE USED IN CONJUNCTION WITH CUP AND CONE, MITER, OR STRAIGHT CUT TECHNIQUES. THEY ALLOW EASIER ADJUSTMENT OF THE ARTHRODESIS SITE THAN MANY OTHER TECHNIQUES. BOTH TECHNIQUES ARE EXCELLENT FOR THE PATIENT WITH RHEUMATOID ARTHRITIS, IN WHOM INADEQUATE BONE STOCK MAY NOT ALLOW SCREW TECHNIQUES.

PREPARE BOTH BONE ENDS AT THE JOINT FOR ARTHRODESIS AND ENSURE GOOD BONE-TO-BONE CONTACT. THEN STABILIZE THE ARTHRODESIS BY DRIVING TWO CROSSED K-WIRES FROM DISTAL TO PROXIMAL ACROSS THE JOINT. PINS DRIVEN FROM PROXIMAL TO DISTAL MAY DISTRACT THE ARTHRODESIS.

DRIVE ONE PIN FIRST, AND THEN CHECK THE ARTHRODESIS POSITION BY INTRAOPERATIVE RADIOGRAPHS OR IMAGING ON A FLUOROSCOPE. IF THE POSITION IS ACCEPTABLE, DRIVE THE SECOND PIN AND CHECK THE POSITION ONCE MORE. POSITION THE PINS TO AVOID PROMINENCE THAT MIGHT CAUSE SOFT-TISSUE DAMAGE.

WE DO NOT LEAVE K-WIRES EXPOSED BUT CUT THEM OFF BELOW THE LEVEL OF THE SKIN. REMOVE THE PINS WHEN FUSION IS HEALED, WHICH IS USUALLY IN 4–6 WEEKS.
For the tension band technique, prepare the joint surfaces and position the joint. Drill two K-wires parallel to each other, leaving a dorsal wire protruding from the proximal portion of the distal bone, 6 mm distal to the cut surface. Drill a transverse hole through the proximal fragment and pass a malleable monofilament stainless steel wire of appropriate size through the hole. Tightly coapt the fusion site and pass the monofilament wire in a figure-eight fashion dorsally. Pass it beneath and tighten it around the ends of the K-wires. The arthrodesis site will be compressed as the figure-eight wire is tightened. Cut the pins as low as possible and contour them to fit closely to the bone dorsally. (See Chapter 11 for more details.)

When the fusion is healed, most pins and wires need to be removed as they are superficial and tender. Do not use tension band wire techniques at the DIP joint because of the possibility of injury to the germinal matrix of the nail.

Internal Fixation—Screw Techniques

Screw methods for fixing an arthrodesis provide stable rigid fixation, which is best used in young, active patients with high activity demands. Screw fixation usually permits early motion of the hand with a reduced risk of loss of fixation when compared to K-wire fixation. Many varieties of screws are currently available and all of them can be used to provide compression across the arthrodesis. Screw techniques require careful attention to technical detail.

Herbert Screw

The Herbert screw (Zimmer, Warsaw, IN) is a headless screw (see Chapter 11) originally used to fix fractures of the scaphoid. To perform an arthrodesis on a PIP joint utilizing the Herbert screw, prepare the joint surfaces as previously described. Drill a pilot hole with an 0.045 K-wire. Drill from the dorsal surface of the proximal phalanx into the medullary canal of the middle phalanx. We have found that starting the hole relatively proximal makes the dorsal cortical bridge larger, preventing fracture. Use a small-diameter Herbert screw drill bit to enlarge the drill hole through its entire length, from proximal to distal. Avoid breaking the dorsal cortical bridge between the entry hole and the fusion site. Enlarge the cortical opening with a small rongeur. Using a large-diameter Herbert screw drill, overdrill the hole in the proximal phalanx. Then insert a Herbert screw tap through the arthrodesis site. Use intraoperative radiography or fluoroscopy to help determine the size of the screw to be chosen. The screw should be at least 2 mm shorter than the measured length to allow the screw head to sink into the proximal phalanx and not cause soft-tissue irritation. Place the Herbert screw of appropriate size. It is important to hold the arthrodesis site compressed in appropriate position as the screw is tightened.

Arthrodesis can also be performed on the DIP joint using Herbert screw fixation (Figs. 72.5, Fig. 72.6).

Figure 72.5. Intraoperative confirmation of distal interphalangeal joint arthrodesis with Herbert screw fixation.

Figure 72.6. Intraoperative confirmation of position, Herbert screw fixation, lateral view.

After preparing the joint surfaces, make a K-wire pilot hole drilling from proximal to distal through the center of the distal phalanx. The wire exits just under the hard nail, through the distal skin. Make a transverse skin incision at this level and enlarge the pilot hole, using the small-diameter drill bit, from distal to proximal. Position the arthrodesis site, and pass the small-diameter drill across the joint from distal to proximal. Tap the drill hole from distal to proximal with the Herbert screw tap. Use intraoperative fluoroscopic imaging to determine the length of the screw. Place an appropriate-length Herbert screw from distal to proximal, countersinking the proximal threads of the Herbert screw deep enough to keep it from irritating the tip of the finger (Fig. 72.7). Take care, as germinal matrix injuries can occur. Note that this technique at the DIP joint requires more extension than other techniques (Fig. 72.7, Fig. 72.8).

Figure 72.7. Distal interphalangeal joint arthrodesis with Herbert screw fixation, AP view.
**Acutrak Screw** The Acutrak variable pitch conical screw (Acutrak, Acumed, Beaverton, OR) has been designed specifically for small-joint fusions. Techniques are as previously described for the Herbert screw.

**AO Screw Fixation** Joint arthrodesis using the AO screw technique generally proceeds as described for the Herbert screw, with the following differences (88). The AO 2.7 mm screw is a standard screw with threads on one end and a head on the other; therefore, compression requires lag technique. Overdrill the proximal phalange with a 2.7 mm drill bit to gain compression. Countersink the drill hole before you place the screw, which allows the screw to sit flush with the bone.

This screw can be inserted in a retrograde fashion for fusion of the DIP joint. In our experience, the AO screw head is too prominent, causing too much pain in the fingertip; therefore, we currently do not use it for DIP joint fusion.

**Internal Fixation—Plate Fixation**

Plate-and-screw fixation is the most stable construct available for performing an arthrodesis in the hand. Plating is an excellent technique when bone grafting is required. It requires significant soft-tissue stripping and is more complex, so it is used less commonly for a simple primary arthrodesis. Plate fixation is used more commonly for salvage of failed previous procedures.

- After the joint ends have been exposed and prepared for arthrodesis, expose the dorsal aspects of the proximal and distal bone surfaces as necessary for plate application.
- Once the bone ends are prepared and any bone graft has been selected, tailored, and placed, select a mini-semitubular plate that allows for at least two screws in the middle phalangeal shaft and two screws in the proximal phalangeal shaft. Generally, a four-hole plate will not bridge a significant defect, so a five- or six-hole plate may be required.
- Contour the plate to fit over any bone graft dorsally.
- Fix the plate with screws to the dorsal aspect of the distal bone first. Check the screw lengths using intraoperative fluoroscopy or radiographs.
- Use the dynamic compression principle (Chapter 11) to apply compression between the bone ends and across any graft that is needed.

Because of the extensive surgery as well as the prominence of the plate and screws, removal and/or extensor tenolysis may be required as a second-stage procedure.

**External Fixation**

Compression arthrodesis is possible with mini-external fixators (12,83). Fusion rates are excellent but we feel that most external fixation devices are too bulky and limit the motion of other digits. The transverse wires and compression devices may cause scarring of the extensor mechanism. External fixators are most appropriate for fusions after severe articular surface bone and soft-tissue injuries complicated by joint infection and osteomyelitis (102). We do not recommend external fixation for uncomplicated phalangeal and MCP joint arthrodeses.

**WOUND CLOSURE AND AFTERCARE**

- We prefer absorbable sutures for closure of the joint capsule and extensor tendon mechanism because the lack of joint motion after fusion takes tension off the tendon repair. Nonabsorbable sutures may cause patient discomfort after surgery by irritating the skin edges.
- After closure of the deep soft tissues, injection of 0.5% bupivacaine may diminish postoperative discomfort.
- Close the skin with interrupted nonabsorbable sutures.
- Apply a well-padded bulky dressing, and splint the fused joints for comfort and to protect the arthrodesis. At 10–14 days, change the dressings and encourage motion at joints other than the fusion. Fashion an orthoplast splint to the fused joint and keep it in place until the fusion is radiographically solid. Protect thumb MCP and carpometacarpal fusions in thumb spica casts for 4–6 weeks.

**PITFALLS AND COMPLICATIONS**

Although uncommon, complications in fusions of the small joints of the hand can be minimized by meticulous surgical technique (55,84,93). Management of complications begins with understanding the potential for them prior to surgery, and making the patient aware of them. Detect vascular compromise by carefully observing capillary refill in the operated digit after tourniquet deflation. Any impairment requires immediate intervention to prevent loss of the digit. Pin track infection can be minimized by keeping pins under the patient’s skin. Diminish wound problems by using straight longitudinal dorsal incisions, especially in patients with immunocompromised status, such as those with diabetes mellitus or connective tissue diseases. Prevent nonunion by establishing broad bone contact at the arthrodesis site and stable fixation.

Progression of arthritis in adjacent joints is a concern in any arthrodesis because stress is added across these joints. Carroll (16) found no evidence of STT arthritis after CMC joint fusion in patients less than 50 years old who were followed for 3–25 years. More recently, Bamberger et al. (6) had radiographs of their series of patients reviewed independently for progression of STT arthritis after CMC arthrodesis. They found progression of STT arthritis in 2 of 12 patients but attributed this to error in technique. Guiral et al. (38) reported a rare complication of arteriovenous fistula with venous aneurysm after thumb carpometacarpal joint arthrodesis. This was treated by ligation and resection of the aneurysm. A painful scar from injury to the branches of the radial sensory nerve is avoided by careful technique. Problems with painful implants can be resolved by removal.

**LIMITED WRIST FUSION**

Limited wrist arthrodesis and intercarpal arthrodesis are useful for treating degenerative arthritis, carpal instability (57), fracture nonunion, ligament tears, Kienböck’s disease (80,79), osteonecrosis of the carpus, and congenital synchondrosis or partial fusion of various carpal intercarpal joints (47,83,84,75,91,86,88,109 and 101,108). A less desirable alternative in some cases is proximal row carpectomy (8,25,46,52).

Successful treatment using these surgical procedures is based on the biomechanical principle of load transfer from one side of the carpus to another. The intercarpal mobility that is preserved compensates for the motion lost to arthrodesis.

Currently, the most commonly performed limited wrist fusion procedures include STT fusion; scaphocapitate (SC) fusion; lunotriquetral (LT) fusion; and fusion of the capitale, hamate, lunate, and triquetrum, which is known as a four-bone fusion.

**FUNCTIONAL WRIST MOTIONS**

Recent studies have evaluated the range of motion needed for normal activities of daily living (ADL). Palmer et al. (73) showed that the range of motion of the wrist required for ADL is 5° of flexion, 30° of extension, 10° of radial deviation, and 15° of ulnar deviation. Brumfield and Champoux (14) showed that 10° of flexion and 35°
of extension are required. Ryu et al. (63) showed that 40° of extension, 40° of flexion, and 40° of combined radial and ulnar deviation are needed to perform ADL.

INDICATIONS FOR SURGERY

DEGENERATIVE DISORDERS

The scaphoid is unique in that it spans both the proximal and the distal carpal rows. Because of its unusual anatomy, deformity of the wrist follows well-delineated patterns when the scaphoid or its ligamentous restraints are injured (see Chapter 41 and Chapter 42). One of these patterns, the scapholunate advanced collapse (SLAC) pattern of wrist arthritis, accounted for 57% of degenerative wrist arthritis when Watson and Ballet (98) reviewed 4,000 radiographs. These authors also reported primary triscaphe joint arthritis in 27% of these patients and a combination of both in 15% of patients. The primary disorder in the SLAC wrist is that of scapholunate dissociation secondary to scapholunate interosseous ligament rupture (3). This allows for unopposed volar flexion of the scaphoid and the dorsal intercalated segmental instability (DISI) pattern (26). Lateral radiographs may show the scapholunate angle to be increased beyond 60°, which is felt to be the upper limit of normal. On an anteroposterior (AP) radiograph, the scaphoid appears foreshortened, has a “cortical ring” sign and there is a scapholunate gap of greater than 3 mm.

The SLAC pattern of arthritis begins in its earliest stage, stage 1 arthritis, with destruction of the distal aspect of the radioscapophoid joint (2). This is caused by the incongruity between the scaphoid and the scaphoid facet of the radius when the scaphoid is extremely volar flexed. In stage 2, the entire radioscapophoid joint is arthritic. Stage 3 is characterized by further separation between the scaphoid and the lunate, allowing the capitate to migrate proximally. When this occurs, the SC and capitolunate joints become arthritic. Stage 4, in which the radiolunate joint becomes arthritic, is rarely seen because the spherical shape of the proximal lunate and the lunate fossa of the radius make incongruity unlikely except in the most severe cases.

A nonunion of a fracture of the scaphoid also leads to a predictable pattern of wrist arthritis when not treated. Because of its similarity to the SLAC pattern in both progression and treatment, it has been called the scaphoid nonunion advanced collapse (SNAC) pattern. In it, volar flexion of the distal pole of the scaphoid leads to radioscapophoid arthritis (101). The proximal pole, restrained by the scapholunate interosseous ligament, remains in normal alignment with the lunate. Given the dissociation between the proximal and distal rows as a result of the nonunion, a DISI pattern of deformity results. If left untreated, the wrist will undergo the same degenerative pattern seen in a SLAC wrist.

Treatment of these two similar disorders has been mainly proximal row carpectomy (46) or scaphoid excision (52) and lunate-capitate-hamate-triquetral (four-corner) arthrodesis (Figs. 72.8 and 72.10). Although it is not yet clear whether proximal row carpectomy or four-corner fusion provides better results (108) for stage 2 or 3 SLAC/SNAC disease, it is clear that scapholunate excision and four-corner fusion are preferred to proximal row carpectomy when the capitate head is arthritic.

A less common but equally disabling degenerative pattern of arthritis in the wrist occurs between the lunate and the triquetrum (24,42,51). This pattern of arthritis is most probably a result of a chronic lunotriquetal ligament tear that has not healed. Patients typically have the radiographic findings associated with volar intercalated segmental instability (VISI). The scapholunate angle on a lateral radiograph is less than 30°, the lower limit of normal. This indicates that the ligamentous complex between the lunate and the triquetrum is disrupted, allowing the lunate to volar-flex and align with the scaphoid. Another cause of isolated LT arthritis is incomplete carpal coalition of the lunate and triquetrum (1).

Degenerative wrist disease evolves when scaphoid nonunion is left untreated, and in the SLAC wrist deformity. Watson and Weinzeig (101) described the use of STT arthrodesis to manage scaphoid nonunion for three specific indications: scaphoid fractures with a very small proximal fragment, a distal scaphoid nonunion causing malalignment of the triscaphe joint, and scaphoid fracture in association with scapholunate dissociation. With small scaphoid proximal fragments, Watson prefers a dorsal approach with bone grafting of the nonunion, with a simultaneous triscaphe arthrodesis. STT arthrodesis is used in distal scaphoid nonunions to improve alignment in the STT joint. Scapholunate dissociation may be treated by intercarpal arthrodesis when it is associated with scaphoid fracture.

CARPAL INSTABILITY

A detailed description of carpal instability can be found in Chapter 41. Instabilities result from a wide range of injuries that are either static or dynamic (24,65). Static instabilities have malalignments seen on standard radiographs. Dynamic instabilities may appear normally aligned on standard radiographs but are often exhibited on stress views or other special projections. Acute injuries (up to 1 week old) have the maximum potential to go on to primary healing of the ligaments. Subacute injuries (1–6 weeks old) still can heal and do not display fixed deformity or arthritis. Chronic injuries older than 6 weeks have the least potential for healing, may have fixed deformities or arthritis, and often require surgical repair and reconstruction. It is apparent that early detection is most important. The position of the lunate as seen on lateral radiographs is one of the key elements used to determine loss of normal carpal alignment. The terms dorsal intercalated segmental instability and volar intercalated segmental instability describe the malaligned dorsal or volar tilted lunate of unstable wrists (61). Although many instability classifications have been...
proposed, none have gained universal acceptance, which underscores the complexities of these injuries and the lack of our present comprehension of this subject.

The effects of intercarpal arthrodesis on wrist kinematics is not well understood. When choosing the surgical procedure, consider the amount of wrist motion that will remain and to what extent compensatory increases in wrist motion will occur over time. Although the proximal and distal rows function separately, an intercarpal arthrodesis that links these rows will have long-term effects on wrist motion and on radiocarpal and ulnocarpal loading that could lead to degenerative arthritis in the long term. Gellinon et al. (35) showed that fusion within a carpal row has minimal effect on wrist motion in all planes. Their study demonstrated that two thirds of flexion occurs at the radiocarpal joint and one third occurs at the mid-carpal joint. It also showed that capitulunate fusion caused the greatest loss of motion in a flexion/extension arc, with STT fusion causing the greatest loss of motion in the radioulnar plane.

Garcia-Ellis et al. (34) studied the effects of intercarpal arthrodeses on wrist range of motion. They showed that STT fusions had a greater loss of flexion than SC fusion, which resulted in a greater loss of extension and radial deviation. Shear stress was noted to be increased at the radiolunate joint. Viegas et al. (83) reported that STT and SC fusions decrease axial load through the radioscapoid fossa, while scapholunocapitate and capitulunate fusions distribute load through both the radioscapoid and radiolunate fossae.

**SURGICAL TECHNIQUES**

**PRINCIPLES OF INTERCARPAL ARTHRODESES**

Watson and Weinzweig (101) have outlined three major principles that apply to limited wrist arthrodesis:

1. Unaffected joints must be left unfused.
2. Normal external dimensions of carpal bones included in the arthrodesis must be preserved.
3. Bone fixation must include only those bones that are involved in the arthrodesis.

Adherence to these principles is important. STT (triscaphe) fusion results in a single bony unit that preserves the external dimensions of these three carpal bones. Current indications for STT fusion are STT arthrosis, Kienböck's disease, and carpal instability, including static or dynamic rotary subluxation of the scaphoid.

**WATSON AND ASHMEAD’S TECHNIQUE FOR STT FUSION**

- Make a dorsal transverse incision on the wrist just distal to the radial styloid (10).
- Expose the radial styloid through an incision in the capsule overlying the radiocarpal articulation.
- Remove the distal 5 mm of the styloid with a rongeur, sloping in a palmar direction from distal to proximal.
- Make a transverse dorsal capsular incision and evaluate the radioscaphoid interval.
- Watson and Ashmead (82) recommend performing a SLAC wrist reconstruction rather than a triscaphe arthrodesis if there is any articular cartilage damage. It is critical in an STT fusion to have normal articular cartilage between the distal radius and the proximal scaphoid.
- Remove the articular surfaces between the scaphoid, trapezium, and trapezoid with a small rongeur, taking only the proximal half of these joints.
- Remove the hard subchondral bone down to softer cancellous bone.
- Use the distal radius as a source of cancellous bone for grafting (71). To harvest the graft, make a second, transverse incision 3 cm proximal to the radial styloid, extending from Lister's tubercle to just palmar to the first dorsal compartment. A flat surface on the radius can always be identified between the first and second extensor compartments, and a constant periosteal artery is seen in this area.
- Incise the periosteum and make a cortical window. Remove cancellous bone from the distal radius and replace the cortical window after harvesting the graft.
- The most important part of this procedure is the reduction of the scaphoid. Watson and Ashmead (82) do this by placing a 5 mm spacer, which is usually the handle of a small bone hook, into the scaphotrapezial space to maintain the original external dimensions of the triscaphe joint and manipulate the scaphoid into proper position. Then drive one or two K-wires from the trapeziun and trapezoid into the scaphoid, avoiding impingement of the radioscapoid joint.
- Remove the spacer and pass a second K-wire on the ulnar side of fusion construct (Fig. 72.11).
- Pin the scaphoid to lie at approximately 55° of palmar flexion relative to the long axis of the radius when seen on a lateral radiograph. When the wrist is placed in full radial deviation and 45° of dorsiflexion, the scaphoid tuberosity should be reduced.
- Densely pack cancellous bone into the spaces between the trapeziun, the trapezoid, and the scaphoid.
- Use the bone graft from the distal radius as a source of cancellous bone for grafting (71). To harvest the graft, make a second, transverse incision 3 cm proximal to the radial styloid, extending from Lister's tubercle to just palmar to the first dorsal compartment. A flat surface on the radius can always be identified between the first and second extensor compartments, and a constant periosteal artery is seen in this area.
- Incise the periosteum and make a cortical window. Remove cancellous bone from the distal radius and replace the cortical window after harvesting the graft.
- The most important part of this procedure is the reduction of the scaphoid. Watson and Ashmead (82) do this by placing a 5 mm spacer, which is usually the handle of a small bone hook, into the scaphotrapezial space to maintain the original external dimensions of the triscaphe joint and manipulate the scaphoid into proper position. Then drive one or two K-wires from the trapeziun and trapezoid into the scaphoid, avoiding impingement of the radioscapoid joint.
- Remove the spacer and pass a second K-wire on the ulnar side of fusion construct (Fig. 72.11).
- Pin the scaphoid to lie at approximately 55° of palmar flexion relative to the long axis of the radius when seen on a lateral radiograph. When the wrist is placed in full radial deviation and 45° of dorsiflexion, the scaphoid tuberosity should be reduced.
- Densely pack cancellous bone into the spaces between the trapeziun, the trapezoid, and the scaphoid.
- Cut the K-wires short and leave them under the skin.
- Close only the skin and subcutaneous tissues.

**Postoperative Care**

Apply a bulky noncompressive dressing, incorporating a long-arm plaster splint to place the hand in a functional position, with the wrist in slight extension and radial deviation, the forearm in neutral position, and the elbow at 90° of flexion. Three to 5 days later, change this and apply a long-arm thumb spica cast. At 4 weeks exchange the cast for a short-arm thumb spica cast. At 6 weeks after surgery, if there is radiographic evidence of healing, remove the K-wires. Begin range-of-motion exercises once fusion is ensured.

**SCAPHOCAPITATE FUSION**

Indications for scaphocapitate (SC) fusion include rotary subluxation of the scaphoid and scaphoid instability, resistant scaphoid nonunion, and Kienböck's disease.

- Make a longitudinal skin incision of sufficient length over the third dorsal compartment, and open the retinaculum.
- Free the EPL tendon proximally and distally, and transpose it radially. This allows retraction of the radial wrist extensors, the EPL, and the digital extensors.
- Expose the radial styloid through an incision in the capsule overlying the radial styloid.
- Make a dorsal transverse incision on the wrist just distal to the radial styloid (10).
- Expose the radial styloid through an incision in the capsule overlying the radiocarpal articulation.
- Remove the distal 5 mm of the styloid with a rongeur, sloping in a palmar direction from distal to proximal.
- Make a transverse dorsal capsular incision and evaluate the radioscaphoid interval.
- Watson and Ashmead (82) recommend performing a SLAC wrist reconstruction rather than a triscaphe arthrodesis if there is any articular cartilage damage. It is critical in an STT fusion to have normal articular cartilage between the distal radius and the proximal scaphoid.
- Remove the articular surfaces between the scaphoid, trapezium, and trapezoid with a small rongeur, taking only the proximal half of these joints.
- Remove the hard subchondral bone down to softer cancellous bone.
- Use the distal radius as a source of cancellous bone for grafting (71). To harvest the graft, make a second, transverse incision 3 cm proximal to the radial styloid, extending from Lister's tubercle to just palmar to the first dorsal compartment. A flat surface on the radius can always be identified between the first and second extensor compartments, and a constant periosteal artery is seen in this area.
- Incise the periosteum and make a cortical window. Remove cancellous bone from the distal radius and replace the cortical window after harvesting the graft.
- The most important part of this procedure is the reduction of the scaphoid. Watson and Ashmead (82) do this by placing a 5 mm spacer, which is usually the handle of a small bone hook, into the scaphotrapezial space to maintain the original external dimensions of the triscaphe joint and manipulate the scaphoid into proper position. Then drive one or two K-wires from the trapeziun and trapezoid into the scaphoid, avoiding impingement of the radioscapoid joint.
- Remove the spacer and pass a second K-wire on the ulnar side of fusion construct (Fig. 72.11).
- Pin the scaphoid to lie at approximately 55° of palmar flexion relative to the long axis of the radius when seen on a lateral radiograph. When the wrist is placed in full radial deviation and 45° of dorsiflexion, the scaphoid tuberosity should be reduced.
- Densely pack cancellous bone into the spaces between the trapeziun, the trapezoid, and the scaphoid.
- Cut the K-wires short and leave them under the skin.
- Close only the skin and subcutaneous tissues.

**SLAC RECONSTRUCTION AND HAMATE-CAPITATE-LUNATE-TRIQUETRAL FUSION**

A SLAC wrist reconstruction along with excision of the scaphoid is an excellent method to treat radioscapoid degenerative arthritis and chronic nonunion of the...
of Wrist Arthrodesis

Postoperative Care
Apply a short-arm thumb spica splint, and exchange it 5–7 days later for a short-arm spica cast. Generally, leave wires in for 6 weeks. At that time, remove the K-wires if early union is seen.

LUNOTRIQUETRAL ARTHRODESIS
Lunotriquetral (LT) arthrodesis is indicated in patients with LT instability, LT arthritis, or LT ligament disruption.

Postoperative Care
Apply a padded long-arm splint and keep it in place for 5–7 days, then exchange it for a long-arm cast. Keep this in place for 6 weeks to allow for adequate healing, as evidenced clinically and radiographically. Then remove pins and use a short-arm splint for 4–6 weeks.

PITFALLS AND COMPLICATIONS
Complications of limited wrist arthrodeses may be split into two categories: intraoperative complications and problems with long-term outcomes (13,53,109). Major complications from STT arthrodesis include radiocarpal arthritis, trapeziometacarpal arthritis, nonunion, osteomyelitis, and radial styloid scaphoid impingement (79). This last complication has been diminished by radial styloidecomy at the time of surgery. Inadequate reduction of the scaphoid in this procedure leads to a predictable progression of radiocarpal arthritis. The proximal pole of the scaphoid must be reduced anatomically into the scaphoid fossa of the radius, and the radiocarpal angle must be approximately 45° to 55°.

Similar complications have been reported for SC arthrodesis. Long-term follow-up has shown a greater loss of wrist flexion with the latter procedure. Relatively few complications have been reported with the SLAC wrist reconstruction or four-bone arthrodesis. Nonunion has been rare, and the development of radiolunate arthritis and impingement between the fusion mass and the distal radius have been reported. The most common complication of LT joint arthrodesis is nonunion, with a reported incidence of 10% to 50% (13,62,83,87,106,109).

RADIOCARPAL OR WRIST ARTHRODESIS
Radiocarpal or wrist arthrodesis involves fusion of the radiocarpal and mid-carpal joints, including the radiolunate, radioscaphoid, and radiocapitate joints. It is one of the oldest, most common, longest-used, and most successful reconstruction procedures for the wrist (39,44,59). It predictably relieves pain, but it does eliminate all radiocarpal motion.

INDICATIONS FOR SURGERY
Currently, the most common indication for total wrist arthrodesis is posttraumatic degenerative arthritis of the radiocarpal and midcarpal joints (61). This includes chronic carpal dissociations as well as complex intracarpal and distal radius intraarticular fractures. Other indications for arthrodesis include the following:

- Chronic infection unresponsive to limited surgical debridement (29,30)
- Paralysis about the wrist and hand (arthrodesis provides the stability required for tendon transfers about the thumb and digits) (87)
- Rheumatoid arthritis and other inflammatory disorders involving the radiocarpal joint (18,28,63,64)
- Limited arthrodeses that have not provided stability or pain relief
- Loss of soft tissue and bone as a result of severe trauma or tumor resection

Spastic paralysis of the wrist from cerebral palsy, strokes, or polio can lead to severe disfigurement of the extremity and loss of hand function. Stabilization of the wrist makes the flexor and extensors of the wrist available as transfers to restore power and function to the fingers. Pomerance and Keenan (79) demonstrated that by performing total wrist fusion, tendon transfers, and muscle releases in a single staged procedure, they were able to correct the severe contractures of the hand and wrist with resolution of the preoperative hygiene problems. (See Chapter 66, Chapter 67 and Chapter 68 for more details.)

Most patients who are considered for arthrodesis have undergone failed attempts at both conservative and surgical treatments. Hastings et al. (41) reported that 71% of the 112 wrists that underwent arthrodeses for posttraumatic arthritis had undergone 137 prior surgical procedures, for an average of 2.3 procedures each. Field et al. (106) found that 97% of the patients undergoing arthrodesis for posttraumatic conditions had some form of prior treatment, and most of these patients had undergone at least two surgical procedures. Hastings et al. (41) found that function after radiocarpal fusion was comparable to that for limited wrist fusion. Whereas Jebsen et al. (47) and Purdue (50) found hand function to be poor based on testing, Field et al. (106) found that all patients were satisfied and would have had the procedure sooner. Weiss et al. (105) found that most patients functioning well after wrist arthrodesis for posttraumatic conditions and that the most difficult tasks were perineal care and manipulating the hand in tight spaces. Rayan et al. (78) reviewed the function of nine rheumatoid arthritis patients and found that even among those who underwent bilateral radiocarpal arthrodesis, seven of nine had improvement of subjective function, two of nine remained the same, and no patient was made worse.

BIOMECHANICS
The usual recommendation is to fuse the wrist in dorsiflexion from 0° to 30° to preserve grip and pinch strength. Colonna (23) described power grip as maximal with the wrist in slight extension and slight ulnar deviation. Kraft and Deletis (66) simulated wrist arthrodesis in varying degrees of flexion and extension in 20 normal volunteers by immobilizing them in leather gauntlets. This study showed that from 15° of flexion to 30° of extension, the grip strength was equal in all positions except for 15° flexion, where it was decreased. Their overall recommendation was to avoid fusing the wrist in flexion. They recommended placement of the wrist in palmar flexion only when there is bilateral involvement and one wrist is placed in extension, the other in flexion to improve independent feeding and perineal care.
Vicar and Burton (94) compared the results of arthroplasty versus radiocarpal arthrodesis in rheumatoid arthritis patients. They found that the arthrodesis group had overall 97% good results compared to 75% good results in the arthroplasty group. The arthrodesis group had an 18% complication rate, while the arthroplasty group had a 25% complication rate, 4 of 37 requiring revision, at an average follow-up of 51 months.

Radiocarpal arthrodesis seems to be the treatment of choice for the most severe wrist deformities, but efforts to perfect wrist arthroplasty and motion-preserving operations continue. While it is likely true that most patients would prefer a motion-sparing procedure to radiocarpal arthrodesis, function after complete wrist fusion is surprisingly good and therefore this remains the gold standard to which all other procedures should be compared. With the right indications, radiocarpal arthrodesis can salvage function for an otherwise debilitated patient.

Position for radiocarpal arthrodesis is directly related to the final function desired, and although a wrist fused in a poor position may be pain free, function suffers. The ideal position for radiocarpal arthrodesis is controversial. Several studies recommended fusion in 20° to 30° of extension (11,18,21,22,32,41,44,59,62,64,68,70,81,104) and Clayton and Ferlic (21) recommended neutral position. Although the ideal position for radiocarpal fusion likely will continue to be debated, functional outcome studies show that a position in 0° to 10° of extension and 0° to 10° of ulnar deviation seems to give the best results.

The methods advocated for radiocarpal arthrodesis are quite numerous. Techniques utilizing a distal radius sliding graft (22), an AO plate (191), and intramedullary pins or rods (84,85) have been described.

SURGICAL CONSIDERATIONS

Evaluate patients medically and understand the medical diagnosis underlying the wrist deformity in patients with systemic disease before performing surgery. This is most important in evaluating patients with rheumatoid arthritis.

Rheumatoid arthritis is a systemic disease affecting many joints in the body. These patients often have a “Z-collapsed” deformity, where deformity in a proximal joint provokes a reciprocal deformity at a distal joint (19). Surgical procedures performed on any of these joints affect the more distal or proximal joints. In patients with rheumatoid arthritis, keep procedures minimal and simple. Wrist fusion using a Steinmann pin for intramedullary fixation is better than using a dorsal plate, as it is less likely to cause problems with the skin and extensor tendons. Stability is adequate, immobilization is shortened, an iliac crest graft is usually not required, and splitting and partial weight bearing early is possible. Millender and Nalebuff (68) reported that patients were able to walk with platform crutches 1 week after surgery using this technique. Another advantage of this procedure is that it can be performed rapidly enough to allow other surgical procedures to be performed concomitantly, as is necessary in many patients with severe rheumatoid arthritis (69). (See Chapter 70 for more details on treatment of the rheumatoid hand.)

Patients with posttraumatic arthritis place heavier loads and higher demands on their hands and wrists than do patients with rheumatoid arthritis. Rigid internal fixation is crucial. Recent studies have shown that plate fixation with the application of local bone graft provides reliable fusion and early rehabilitation (11,104).

SURGICAL TECHNIQUES

STEINMANN PIN TECHNIQUE

Perform surgery with preoperative intravenous antibiotics and axillary block or general anesthesia. All patients with connective tissue diseases or in whom there is concern of cervical spine instability are prescreened with cervical spine radiographs. Perform all surgery under tourniquet control, through a dorsal longitudinal skin incision just ulnar to Lister’s tubercle. Use a longitudinal skin incision just ulnar to Lister’s tubercle.

- Make a longitudinal incision through the fascia of the third dorsal compartment, and transpose the EPL tendon.
- Incise the floor of the third compartment and extend it distally to the base of the third metacarpal, staying ulnar to the extensor carpi radialis brevis (ECRB) tendons.
- Using a subperiosteal dissection, raise medial and lateral flaps to expose the entire distal radius, ulna, and carpus.
- We resect the posterior interosseous nerve in the floor of the fourth compartment to provide lasting pain relief. Because of the commonly associated disease of the distal radioulnar joint (DRUJ) in patients with rheumatoid arthritis, we prefer to perform a Darrach resection of the distal ulna by transecting the distal ulnar shaft just proximal to the ulnar head, using an oscillating saw (see Chapter 43).
- Use a subperiosteal approach to excise the entire distal ulna. Preserve the ulnar head for use as autogenous bone graft.
- Using a small rongeur, resect the remaining radiocarpal and intercarpal articular surfaces, including the third CMC and intercarpal joints, until you expose cancellous bone. Use the harvested distal ulna to fill the defects between the intercarpal joints. If more bone graft is needed, use a curet to harvest any needed bone from the distal radius through the base of Lister’s tubercle.
- Insert a 3.2 or 3.6 mm Steinmann pin either down the medullary canal of the third metacarpal shaft or between the second and third metacarpal bases for more ulnar deviation, and bring it out distally through the skin.
- Reduce the wrist into final position, and slip a drill guide over the distal end of the pin. Slide a similar-size pin into the guide and tap the pin across the wrist into the radius in a retrograde fashion. Bury the pin distally under the skin.
- Confirm adequate pin position with intraoperative radiographs or insert the pin under fluoroscopic control.
- Transpose approximately one third to one half of the extensor retinaculum palmar to the extensor tendons, and suture it into place with absorbable sutures. Place a suction drain deep into the wound and bring it out distally for ease of removal the following day. Place subcutaneous sutures and then close the skin with nonabsorbable sutures in an interrupted fashion.

Postoperative Care

Apply a palmar plaster splint and dressing to control rotation. Remove the drain in 24 hours. After 1 week, remove the dressing and inspect the wound. Generally leave sutures in for 2 weeks and keep the patient in a splint or cast until their removal. At 2 weeks postoperatively, remove the sutures and place the patient into a short-arm cast for an additional 2–4 weeks, or until clinical and radiographic union is achieved. Encourage the patient to mobilize his or her fingers as much as possible until the sutures are removed and the patient can wear a short-arm cast for an additional 2–4 weeks, or until clinical and radiographic union is achieved. Encourage the patient to mobilize his or her fingers as much as possible until the sutures are removed. At that time, evaluate the patient and treat any remaining stiffness with aggressive hand therapy.

AO WRIST FUSION PLATE

When performing radiocarpal arthrodesis for indications other than rheumatoid arthritis, we prefer to use the AO method of plate fixation popularized by Hastings (39) and others (81) (Fig. 72.12 and Fig. 72.13). Most commonly, the indication for this type of arthrodesis is posttraumatic arthritis of the wrist or failed wrist arthroplasty.

![Figure 72.12. Radiocarpal arthrodesis using wrist fusion plate, AP view.](image-url)
Postoperative Care

Apply a sterile bandage and a short-arm volar splint. After 1 week, remove the bandage and splint; inspect the wound and remove the sutures if it is adequately healed. Apply a custom-molded plastizote splint and begin a controlled-motion hand therapy protocol. Do not permit active exercises against resistance until clinical and radiographic union is achieved, usually in 6–10 weeks.

PITFALLS AND COMPLICATIONS

Numerous authors using different surgical techniques have reported complications of radiocarpal arthrodesis. Clendenin and Green (22) divided these into major complications (requiring revision surgery or prolonged hospitalization) and minor (when morbidity is prolonged but resolves without further hospitalization). Major complications include nonunion, wound infection, painful neuramias, fracture of a previously healed fusion, iliac crest bone graft site complications, acute carpal tunnel syndrome, plate failure, DRUJ and ulnocarpal impingement (33,77,92), and chronic pain syndromes. Minor complications include postoperative pain caused by tight dressings, sensory neurapraxias, minor skin irritations, and necrosis. Hastings (39) noted that major complications are less common in internal fixation with a wrist fusion plate than in other surgical methods. Bone graft donor site morbidity can be diminished by using local bone graft for radiocarpal arthrodesis.

Overall rates of nonunion range from 5% to 20% (22,39), whereas rates of nonunion with the AO wrist fusion plate technique have been reported to be from 0% to 2% (32,41,104).

CHAPTER 73

INFECTIONS OF THE HAND

Robert M. Szabo and Carl F. Palumbo

Infection in the hand is common and can result in serious and permanent disability if appropriate management is delayed (6,7,13,15,16,30,33,34 and 35,41,52,54,55,63). Because loss of hand function follows an inadequately treated infection, make every effort to achieve complete and expedient resolution. In our experience treatment requires aggressive debridement when surgery is indicated, use of antimicrobials that cover the full spectrum of infecting agents known to be present in hand infections, and appropriate follow-up care.

Hand infection most often begins with penetration of the skin barrier and inoculation of the tissues. Tissue necrosis and impairment of circulation create an ideal environment for bacteria to flourish. Bacterial proliferation produces the initial signs of infection: erythema, calor, swelling, and tenderness. The local tissue reaction causes edema and further impairment of local circulation, with eventual abscess formation. The venous drainage of the hand (palmar to dorsal) and the fact that the skin is less tethered on the dorsum explain the preponderance of dorsal swelling in hand infections. Infection must be differentiated from noninfectious conditions such as gout, collagen vascular disease, inflammatory tenosynovitis, acute soft-tissue calcification, foreign-body reaction, and more rarely, neoplastic processes.

PRINCIPLES

The goal of initial treatment is to arrest bacterial proliferation and remove purulent and necrotic tissue while leaving behind the well-vascularized and viable tissue (5,18-30). Whereas cellulitis is treated with antibiotics without surgery, once an abscess has become evident, surgical drainage is necessary (Fig. 73.1). Excise the abscess cavity, its walls, loculations, and all infected tissue as well. Thorough debridement improves blood supply, enabling natural humoral and cellular antibacterial factors and antibiotics to enter the infected area. Leave wounds open to allow drainage, except in larger joints (the wrist and proximally), in which closed-suction drainage may be used. After surgery, keep the hand initially immobilized and elevated. Once the wound is nontender, nonerythematous, and not indurated, encourage active motion to prevent stiffness that results when edema fluid is allowed to consolidate into fibrous tissue.

The surgical objectives require a bloodless field, good lighting, skilled assistance, appropriate instruments, and anesthesia. Lancing in the emergency department is of limited use; the extent of infection in various compartments and tissue planes may not be recognized and thus go untreated (7,30,35,61). Lancing alone often delays resolution of the infection and leads to further tissue destruction (18,58).

Use a tourniquet to obtain a bloodless field so that neurovascular structures may be visualized, but exsanguinate by gravity only; an Esmarch bandage may spread the infection locally and proximally. Either a regional block or a general anesthetic is required; local anesthetics in inflamed tissues rarely give adequate anesthesia.

Antibiotics are essential in the treatment of hand infections (Table 73.1). Antibiotic use alone in initial stages often cures the infection and prevents serious sequelae. It is vitally important, however, that the antibiotic be chosen on the basis of the bacteria likely to be found in the wound. Gram-positive and gram-negative anaerobic organisms are often found in hand infections, in addition to the common and well-known gram-positive aerobic organisms Streptococcus and Staphylococcus (1,9,16,18,20,21,22 and 23,32,38,43,44,50).
drug users, abscesses of the upper extremity vary in size and location but are mostly seen on the dorsum of the hand and forearm, in the antecubital fossa, and near the puncture wound that inoculates the subcutaneous tissue, is recognized clinically as a raised area of erythema and induration with notable fluctuance. When seen in IV drug users, abscesses of the upper extremity vary in size and location but are mostly seen on the dorsum of the hand and forearm, in the antecubital fossa, and near

In surgical treatment, preserve as many of the veins as possible to reduce the deleterious effect of venous congestion. An abscess, which is usually the result of a foreign-body—type reaction or nonspecific inflammation (18,43,58), is provided by cefoxitin (Mefoxin) (19). Clindamycin is bacteriostatic, and although it is effective against many anaerobes, it is ineffective against an important facultative anaerobic pathogen, Eikenella corrodens (9). Bactericidal agents are preferred.

Gram-negative enteric organisms are found in certain hand infections, including those in intravenous (IV) drug abusers and in mutilating injuries in dirty environments, such as that associated with farm machinery (16,44,52,62). Add an aminoglycoside antibiotic for initial treatment of these types of infections (61).

Tetanus immunization must be current. A booster is needed if the patient has not had one in the 5 years before the infection or injury. If the patient has had no previous immunization, administer 250 to 500 units of tetanus immune globulin in addition to tetanus toxoid. Follow up with a complete immunization schedule.

TABLE 73.1. Empiric Antibiotic Recommendations for Hand Infections*

In choosing an antibiotic, consider the following factors: Penicillinase-resistant penicillins (e.g., nafcillin) are ineffective against many anaerobic pathogens (15,20,22,59). Most hand infections are polymicrobial in nature (Table 73.2) (18,20,59,62). Incorrect initial selection of an antibiotic leads to a poor outcome in hand infections (18,43,58).

TABLE 73.2. Organisms Cultured in 175 Hand Infections in Hospitalized Patients

Lack of identification on initial Gram stain of subsequently cultured organisms is sufficiently common that Gram stains should not be used to exclude initial broad-spectrum coverage (43).

Initial treatment usually requires two antibiotics. Effective anaerobic coverage is provided by penicillin; effective aerobic gram-positive coverage is provided by either a penicillinase-resistant penicillin (e.g., nafcillin) or by a first-generation cephalosporin such as cefazolin (Ancef, Kefzol). Anaerobic coverage in penicillin-allergic patients is provided by cefoxitin (Mefoxin) (21). Clindamycin is bacteriostatic, and although it is effective against many anaerobes, it is ineffective against an important facultative anaerobic pathogen, Eikenella corrodens (3). Bactericidal agents are preferred.

Gram-negative enteric organisms are found in certain hand infections, including those in intravenous (IV) drug abusers and in mutilating injuries in dirty environments, such as that associated with farm machinery (16,44,52,62). Add an aminoglycoside antibiotic for initial treatment of these types of infections (61).

Tetanus immunization must be current. A booster is needed if the patient has not had one in the 5 years before the infection or injury. If the patient has had no previous immunization, administer 250 to 500 units of tetanus immune globulin in addition to tetanus toxoid. Follow up with a complete immunization schedule.

CLASSIFICATION

PYOGENIC BACTERIAL INFECTIONS

Aerobic

Infection appearing 24 to 48 hours after injury is typical of Streptococcus, whereas Staphylococcus usually takes 4 to 6 days to make itself known. Less common but often present are gram-negative bacteria of the Enterobacteriaceae such as Escherichia coli, Enterobacter cloacae, Proteus, and Pseudomonas (10,58,62). The latter are more common in infections related to IV drug abuse or contaminated environments such as farms, stagnant lakes, or sewers (16,30,44,52,62). In most hand infections, multiple pathogens are isolated on culture (58). Treat polymicrobial infection (Table 73.2) with broad-spectrum antibiotic coverage from the outset to avoid a poor outcome (18,43,58). Single antibiotic use rarely covers all offending organisms (18,34,58).

Anaerobic

Anaerobic bacteria are commonly overlooked as pathogens except in special circumstances such as clostridial infection in gas gangrene. Crush injuries that result in infection create an ideal environment for anaerobic organisms. Gram-positive anaerobic organisms, such as Peptococcus and Peptostreptococcus, are more frequently recognized, but gram-negative anaerobic bacteria are common isolates in hand infections (Table 73.2), either alone or with Staphylococcus and Streptococcus, especially in clenched-fist and human bite injuries (18,20,22,35,47). These anaerobes are common human mouth flora and are important pathogens found in infections associated with IV drug abuse infections, because of the common practice of using saliva to lubricate the needle or moisten cotton used to strain impurities (23,44,59). The aerobic and anaerobic, gram-positive and gram-negative bacteria that infect hands are numerous, and we again emphasize the need to consider all pathogens when selecting an antibiotic (7).

NONPYOGENIC INFECTIONS

Herpetic infections are common in the hands of health-care workers who deal with the mouth, such as dentists, dental hygienists, nurses, and anesthesiologists (31). They are self-limiting, and recognition of them is important to prevent overtreatment. Laboratory tests can confirm these infections, but the diagnosis is usually clinical.

The immune response to the mycobacteria, fungi, and related organisms is cell mediated rather than humoral antibody mediated, and therefore, often presents as a foreign-body—type reaction or nonspecific inflammation (3,10,12,25,65). Delay in diagnosis is common, and the diagnosis is often made only after failure of other treatment modalities. These organisms commonly infect the synovium. Once the diagnosis has been made, surgical intervention may be necessary; antibiotic treatment alone, however, is often indicated.

SPECIFIC TREATMENT AND TECHNIQUES

SUBCUTANEOUS ABSCESS IN THE HAND AND FOREARM

In surgical treatment, preserve as many of the veins as possible to reduce the deleterious effect of venous congestion. An abscess, which is usually the result of a puncture wound that inoculates the subcutaneous tissue, is recognized clinically as a raised area of erythema and induration with notable fluctuance. When seen in IV drug users, abscesses of the upper extremity vary in size and location but are mostly seen on the dorsum of the hand and forearm, in the antecubital fossa, and near
indicated at the time of surgical drainage of the known infected space. The hand is compartmented by the structures that pass through it (24,44,55). The classic signs and symptoms are erythema, pain, advancing cellulitis, crepitance, skin necrosis, skin bullae, high fever, and other systemic signs of infection. When these patients are first seen, they may have a benign-appearing cellulitis. A tender, erythematous, swollen, and hot area quickly becomes tense, shiny, smooth, and more painful. Lymphadenitis and lymphangitis are rare (26). Within a few days, the skin color darkens and blisters, and bullae develop. These infections are usually associated with a significant leukocytosis (52). Radiographs may demonstrate soft-tissue gas. One organ system other than the integumentary or musculoskeletal system often is in failure (e.g., delirium, shock, respiratory failure, or renal failure).

Necrotizing fasciitis, historically called hospital gangrene or hemolytic streptococcal gangrene, manifests as an overwhelming infection within a short period of time. Necrotizing fasciitis is potentially a limb-threatening or life-threatening infection that more commonly affects patients with diabetes and IV drug abusers, who are especially at risk because of the decreased effectiveness of the immune response (24,44,55). The classic signs and symptoms are erythema, pain, advancing cellulitis, crepitance, skin necrosis, skin bullae, high fever, and other systemic signs of infection. When these patients are first seen, they may have a benign-appearing cellulitis. A tender, erythematous, swollen, and hot area quickly becomes tense, shiny, smooth, and more painful. Lymphadenitis and lymphangitis are rare (26). Within a few days, the skin color darkens and blisters, and bullae develop. These infections are usually associated with a significant leukocytosis (52). Radiographs may demonstrate soft-tissue gas. One organ system other than the integumentary or musculoskeletal system often is in failure (e.g., delirium, shock, respiratory failure, or renal failure).

NECROTIZING FASCIITIS

Necrotizing fasciitis, historically called hospital gangrene or hemolytic streptococcal gangrene, manifests as an overwhelming infection within a short period of time. Necrotizing fasciitis is potentially a limb-threatening or life-threatening infection that more commonly affects patients with diabetes and IV drug abusers, who are especially at risk because of the decreased effectiveness of the immune response (24,44,55). The classic signs and symptoms are erythema, pain, advancing cellulitis, crepitance, skin necrosis, skin bullae, high fever, and other systemic signs of infection. When these patients are first seen, they may have a benign-appearing cellulitis. A tender, erythematous, swollen, and hot area quickly becomes tense, shiny, smooth, and more painful. Lymphadenitis and lymphangitis are rare (26). Within a few days, the skin color darkens and blisters, and bullae develop. These infections are usually associated with a significant leukocytosis (52). Radiographs may demonstrate soft-tissue gas. One organ system other than the integumentary or musculoskeletal system often is in failure (e.g., delirium, shock, respiratory failure, or renal failure).

CLOSED-SPACE INFECTIONS

The hand is compartmented by the structures that pass through it (Table 73.3). Infection in one compartment generally is manifested by pain and swelling throughout the hand, with exquisite tenderness in the confines of the involved space. Knowledge of the anatomic boundaries of these spaces is important for diagnosis and treatment.

### Extension of Space Infections

Infection in one compartment can extend to a contiguous compartment (Table 73.4). Adequate assessment, a necessary part of the preoperative examination, requires that the surgeon be aware of the possible patterns of extension (Fig. 73.3). Visual inspection offers clues, but as Kanavel notes, "The most conspicuous and valuable sign is the extension of the exquisite tenderness to the area involved" (28). If there is any doubt, exploration of the space where extension may have occurred is indicated at the time of surgical drainage of the known infected space.
The deep spaces of the hand consist of the subfascial webspace, the dorsal subaponeurotic space, the midpalmar space, and the thenar space. These closed compartments are susceptible to infection, usually from direct traumatic inoculation, extension from an infected contiguous compartment, or less commonly, from hematogenous spread. The two most superficial deep spaces are the webspace and the dorsal subaponeurotic space; identifying infection in these spaces is easier; determining the involved space in the deep palm is more difficult.

**Webspace Infections**

Symptoms of webspace infections are swelling and erythema over the palmar and dorsal surfaces of the involved webspace; characteristically swelling is greater dorsally than palmarly because of the greater suppleness of the dorsal skin. A webspace infection often occurs from deep spread of a superficially infected palmar callus. The fingers bordering the webspace involved are splayed because tissue pressure holds them apart. This type of infection is also called a collar button abscess after the old-fashioned dumbbell-shaped collar buttons. The infection begins palmarly, then spreads dorsally around or through the transverse metacarpal ligament to the dorsal webspace. Thus two abscess spaces are created, connected by a thin stalk. A neglected webspace infection can spread to the palm spaces through the lumbrical canals.

Two incisions are needed (Fig. 73.4). Palmarly, make an oblique incision following the skin lines. Stay away from the web edge; an incision into or through the edge will cause contracture. The abscess is just below the skin, so deeper dissection is not indicated. Remember that in this area, the neurovascular structures lie just beneath the skin, so use great care.

Dorsally, make a longitudinal incision between the metacarpal heads that stays at least 5 mm proximal to the web edge. Excise the dorsal abscess cavity and break up all loculations. Place drains into the incisions after irrigation. Begin IV antibiotics after fluid or tissue for culture is obtained. Follow with the usual aftercare.

**Dorsal Subaponeurotic Space Infections**

The dorsal subaponeurotic space is a potential space on the dorsum of the hand beneath the extensor tendons. Infection usually begins with direct inoculation beneath the extensor tendons. The patient has dorsal hand swelling and erythema, and often it is difficult to delineate a subcutaneous infection from one involving the subaponeurotic space. The fingers bordering the space are splayed because tissue pressure holds them apart. This type of infection is also called a collar button abscess after the old-fashioned dumbbell-shaped collar buttons. The infection begins palmarly, then spreads dorsally around or through the transverse metacarpal ligament to the dorsal webspace. Thus two abscess spaces are created, connected by a thin stalk. A neglected webspace infection can spread to the palm spaces through the lumbrical canals.

Two longitudinal incisions; one over the second metacarpal shaft and another over either the fourth or the fifth metacarpal shaft (Fig. 73.2B) to allow better coverage of the extensor tendons dorsally.

Try to preserve the dorsal veins, which are important to control swelling.

Explore deep to the extensor tendons, taking care not to injure them.

Allow incisions to heal by secondary intention.

Important: Prevent extensor lag by initiating early motion of the wrist and finger joints. Continue therapy during the entire healing stage.

**Palm Space Infections**

The palm spaces are potential spaces bounded by fascia in the central hand (Fig. 73.3). Anatomists do not agree on their exact anatomic boundaries. They lie dorsal to the flexor tendons and palmar to the intrinsic muscles of the hand, and proximally and distally, they merge to form potential extensions to other hand and forearm spaces. These extensions are a source of spread of infection.

**Thenar Space Infections**

What is commonly called the thenar space is more appropriately identified as either the anterior or posterior adductor spaces (Fig. 73.3). Most thenar space infections involve the anterior adductor space. Its anterior boundary is the index finger flexor tendons and the midpalmar septum; its posterior boundary is the fascia over the adductor pollicis. Radially, the thenar intermuscular septum and ulnarly the midpalmar (oblique) septum complete this potential space.

Symptoms include pain, tenderness to palpation, and tense swelling in the space. Thumb adduction and opposition decrease the potential thenar space and cause an increase in pain. Therefore, the attitude of the hand with a thenar space infection is with the thumb in palmar abduction. Infection in the thenar space can spread from flexor tenosynovitis of the index finger. Distinguishing between an anterior adductor space infection and a posterior adductor space infection can be difficult. Usually, the anterior space is involved first and as the infection progresses, purulence tracts over the adductor pollicis to the posterior adductor space. If there is any...
Anterior Adductor (Thenar) Space

- Make a curvilinear incision in the palm parallel to the thenar crease on the ulnar side at the base of the thenar eminence (Fig. 73.5).
- Gently spread the palmar fascia in line with the incision. Identify and tag the digital nerves and flexors to the index finger.

**Figure 73.5.** Incision for drainage of thenar space infections.

- Gently retract the nerves.
- Enter the space beneath the flexors by blunt dissection, remembering that the superficial and deep palmar arches and recurrent branch of the median nerve are in this area.
- Open sufficiently to allow easy drainage.
- Send fluid for aerobic and anaerobic culture, then start IV antibiotics.
- Irrigate well. Place a Penrose drain to keep the space open. Close the skin loosely.

Posterior Adductor Space

- Make a longitudinal incision dorsally between the thumb and index metacarpals (Fig. 73.5). Stay away from the edge of the thumb-index webspace to avoid webspace contractures.
- Incise the fascia, then retract the first dorsal interosseous muscle ulnarly and the extensor pollicis longus tendon radially. Take care to avoid the radial artery, which is in the proximal portion of the incision.
- Bluntly enter the space between the retracted muscles. Open sufficiently to allow easy drainage. Send fluid for aerobic and anaerobic cultures, then begin IV antibiotics.
- Irrigate well. Place a Penrose drain to keep the space open. Close the skin loosely.

Midpalmar Space Infections

The midpalmar septum arises beneath the flexor tendons of the index finger, coursing obliquely posteriorly to its attachment on the third metacarpal. It divides the palm into the two main spaces of the anterior adductor (thenar) space and midpalmar space. Midpalmar space infections (Fig. 73.3) are less common than thenar space infections and occur from direct inoculation of this potential space (11) or spread from tenosynovitis of the long, ring, or small fingers. The midpalmar space is bordered anteriorly by the flexor tendons of the ring, long, and small fingers. Posteriorly, the second, third, and fourth palmar interossei, the third dorsal interosseus, and the ulnar third and the entire fourth metacarpal define this space. Its ulnar border is the hypothenar muscular septum, and the radial border is the midpalmar (oblique) septum (27).

- Make a transverse incision parallel and just proximal to the distal palmar crease, just through the skin at the ring finger. It will be over the area of the swelling. The digital neurovascular structures lie just below the skin, so take extreme care when making the skin incision (Fig. 73.6).

**Figure 73.6.** Incision for drainage of midpalmar space infection.

- Once through the skin, gently dissect longitudinally and identify the digital nerves. Tag these features and retract them gently. Identify the deep and superficial flexor tendons to the ring finger. Because the space is dorsal to the flexors, blunt exploration radial and deep to these tendons will gain entrance into the space.
- Spread gently and open sufficiently to allow adequate drainage. Send fluid for aerobic and anaerobic cultures, then begin IV antibiotics.
- Irrigate, and place a Penrose drain to keep the space open. Close the skin loosely.

SUPPURATIVE FLEXOR TENOSYNOVITIS

Suppurative flexor tenosynovitis requires aggressive, appropriate, and prompt treatment to avoid severe disability of the digit or amputation. Acute flexor tenosynovitis is an infection of the tendon sheath that surrounds the flexor tendons. The synovial sheath consists of a visceral layer or epitenon that is adherent to the tendon and a parietal layer, which join at their most distal and proximal ends. The sheath extends from the midpalmar crease (metacarpal neck) to just proximal to the distal interphalangeal joint. The small finger flexor sheath is continuous with the ulnar bursa in the palm that surrounds the superficial and deep flexor tendons. The sheath around the flexor pollicis longus is continuous with the radial bursa (Fig. 73.7). Both of these palmar bursae extend just proximal to the transverse carpal ligament and, in 80% of individuals, they communicate (42).

**Figure 73.7.** Anatomy of the radial and ulnar bursae.

Flexor tenosynovitis can develop from the most innocuous-appearing small abrasions and tiny punctures; do not be fooled. These minor wounds are the indication that
the sheath has been inoculated with bacteria. The ring, long, and index fingers are most commonly involved; however, any digit may be affected. Kanavel (29) described four cardinal signs of infection of the flexor sheath:

1. Symmetric, fusiform swelling of the entire finger (sausage finger)
2. Semiflexed position of the digit
3. Exquisite tenderness over the course of the sheath
4. Exquisite pain on extending the finger

In advanced cases, all four signs will be seen, but in early cases, only one or two of these may be detected. The most reliable sign is tenderness over the flexor sheath (42).

When examining a patient with a flexor sheath infection, examine the other spaces of the hand as well, because extension of a sheath infection can occur into the palmar spaces, webspace, carpal canal, palm bursa, and Parona's space (see later). Although spread to any of the hand spaces can occur, typically flexor sheath infections of the middle, ring, and small fingers extend into the midpalmar space, and index finger infections extend into the anterior adductor space (thenar space).

The goal of treatment is to drain the infection and allow continued drainage without compromising the function and anatomy of the delicate structure that is the flexor tendon and its canal. Drainage can easily be accomplished, but the drainage procedure itself must not be detrimental to the sheath if the smooth gliding of the flexor tendon within the sheath is to occur after eradication of the infection. We believe that this technique is best accomplished through the intermittent irrigation of the sheath using a catheter (41,42).

Continuous irrigation through the catheter tube has the advantage of constant cleansing of the sheath. If fluid does not drain easily from the distal wound, it can be hydraulically forced into the sheath and surrounding tissues. Intermittent irrigation requires the observation of ready egress while infusing to avoid this potential problem. Antibiotic irrigation within the sheath is not recommended because it has not been proven to be superior to saline irrigation alone. Also, the effect of antibiotics on the flexor sheath with respect to inducing adhesions has not been studied.

**Operative Technique**

- Use two incisions (Fig. 73.8). Make a transverse incision proximally in the area of the A1 flexor pulley (metacarpophalangeal joint). This incision is made at the proximal palm crease in the index finger, at the distal palm crease in the ring finger, and between the two for the long finger. Incise the skin only about 1 cm in length.

![Figure 73.8. Closed tendon sheath irrigation for flexor tenosynovitis.](image)

- Gently dissect longitudinally in line with the palmar fascia (perpendicular to the incision), locating the digital nerves on either side of the tendon. Tack and gently retract them.
- Identify the tendon and the A1 pulley in the base of the wound. Open the palmar synovial and fibrous covering that is the beginning of the flexor sheath; pus or, more commonly, slightly cloudy fluid will egress. Send a sample for culture; then start IV antibiotics.
- Make a second incision along the midlateral line of the digit on the ulnar side at the distal interphalangeal joint crease of the index and long fingers, or the radial side of the ring and little fingers. The midlateral line is that line created by connecting the dots that can be made at the end of the flexion creases when the finger is maximally flexed. Incise the skin. Bluntly dissect deeper to enter the flexor sheath.
- At the proximal wound, lift the A1 pulley and thread a small catheter (#10 pediatric feeding tube fenestrated on its end) into the sheath for about 2 cm.
- Attach a syringe to the catheter end in the palm and irrigate saline through the catheter. Fluid should easily exit from the distal wound. If it does not, reposition the catheter or enlarge the opening distally. Several positioning attempts may be needed to achieve easy flow.
- Irrigate at least 500 ml of normal saline through the sheath to thoroughly cleanse it.
- Place a rubber wick made from a Penrose drain into the sheath through the distal wound to prevent closure. Suture the wick distally and the irrigating tube proximally to the skin to prevent their accidental removal. Approximate the proximal wound with one or two nylon sutures.
- Apply a bulky hand dressing that allows visualization of the distal wound but covers the palmar wound, and bring the catheter out through the dressing.

**Postoperative Care**

Irrigate 20 to 30 ml of room-temperature saline slowly over 30 to 60 seconds through the catheter every 2 to 4 hours. Postoperative orders should include nursing precautions that when irrigating the catheter with saline, resistance to flow should be minimal, that egress should be seen, and that the patient will experience some discomfort. If resistance is excessive, flow is not seen distally, and the patient experiences excessive pain, the catheter may have become kinked or may have moved to an inappropriate area. Remove the catheter if easy flow cannot be regained. Continue the irrigation until the sheath is nontender (36 to 72 hours), then remove the catheter and wick, and apply a moist dressing for 2 to 3 more days, continuing IV antibiotics. Begin active range-of-motion exercises of the digit after catheter removal to prevent stiffness. Allow the wounds to close secondarily.

**RADIAL AND ULNAR BURSAE INFECTIONS**

Infections may occur in the flexor sheaths of the little finger and thumb flexor tendons and their bursae (Fig. 73.6). The proximal extension of the thumb flexor sheath is the radial bursa. It extends proximally to the transverse carpal ligament. The proximal extension of the small finger flexor sheath is the ulnar bursa that also surrounds the superficial and deep flexor tendons and extends proximal to the transverse carpal ligament as well. As stated earlier, in approximately 80% of individuals, these bursae communicate. Infection that spreads between these two bursae can create a "horseshoe abscess."

Kanavel's signs of suppurative flexor tenosynovitis are present in the digit; in addition, there is swelling, tenderness, and color into the respective side of the palm and wrist. Treat these symptoms with catheter irrigation as described earlier; described below are the modifications appropriate to the anatomy of each digit and its bursa.

**Radial Bursa**

- Make a distal thumb incision along the radial side at the interphalangeal joint crease. Stay dorsal to the neurovascular bundle. Identify and enter the flexor sheath.
- Pass a probe or other blunt instrument carefully down the canal until it presses up at the palmar wrist crease. Do not push the probe if you meet resistance. Gently redirect it. Make a longitudinal incision that does not cross the wrist crease.
- Enter the space and identify your probe.
- Pass a #10 pediatric feeding tube from proximal to distal for about 2 cm. Suture a wick distally and the irrigation tube proximally, as described for suppurative flexor tendosynovitis.
- The rest of the procedure is the same as for flexor tendosynovitis. Do not hesitate to make an additional incision in the palm if threading the catheter is difficult.

**Ulnar Bursa**

The technique for treating an ulnar bursa is similar to that for a radial bursa, except the distal incision on the small finger is on the ulnar side of the digit at the distal interphalangeal joint (Fig. 73.9).
HUMAN BITE AND CLENCHED-FIST INFECTIONS

Draining the Wrist

Drainage of Metacarpophalangeal and Interphalangeal Joints

Aspirate with as large a needle as can be entered into the joint, ideally an 18 gauge needle or larger. A 20 or 22 gauge needle is usually the largest that will gain entrance into smaller joints. The joint space for the metacarpophalangeal joint is easily palpated just ulnar or radial to the extensor hood; take the edge of your fingernail and press. Aspirate after an antiseptic preparation. Giving a local anesthetic usually causes more discomfort than the single stick of the aspirating needle, but patients are not easily convinced of this fact.

The interphalangeal joint spaces can be located in a similar fashion. This location just next to the extensor tendon dorsally would correspond to a 10 o'clock or 2 o'clock position if the extensor tendon (top or dorsal) is considered as 12 o'clock.

- Use a large needle, ideally 18 or 20 gauge, or the largest needle that will enter the joint space.
- Palpate the joint space for the metacarpophalangeal joint, ulnar or radial to the extensor hood with the edge of your fingernail, feeling for the depression of the joint space.
- Aspirate after an antiseptic wash.
- Locate the interphalangeal joint in a similar fashion. Enter at the 10 or 2 o'clock position, with the extensor tendon as 12 o'clock.
- Aspirate after an antiseptic wash.

Drainage of Metacarpophalangeal and Interphalangeal Joints

- Base the incision dorsally over the involved joint.
- Incise longitudinally through either the extensor tendon at the metacarpophalangeal joint or through the extensor mechanism at the proximal or distal interphalangeal joints.
- Enter the involved joint and thoroughly irrigate it.
- Leave a small wick (penrose drain) in the joint space to facilitate drainage. Reapproximate the extensor mechanism and loosely close the skin.
- Remove the penrose drain in 48 to 72 hours.

Aspiration of the Wrist

The wrist joint includes the radiocarpal, radioulnar, ulnocarpal, and midcarpal joints. Septic arthritis may be found in any one or all of these joints; these spaces may or may not normally communicate. Direct the preoperative examination toward localizing the joint or joints involved. Pronation or supination pain indicates involvement of the radioulnar joint; flexion or extension pain indicates involvement of the radiocarpal, ulnocarpal, or midcarpal joints. Aspiration with an 18-gauge needle confirms that the joint is septic. Septic arthritis or infection of a joint space may affect any of the joints in the digits, thumb, or wrist. It is most likely secondary to direct penetration of the joint capsule, but hematogenous spread occurs as well. If there is no history of a bite, puncture near the joint, or a recent laceration, it is important to ask the patient about recent tooth abscesses, ear infections, other skin infections, gastrointestinal (GI) infections, and genitourinary (GU) infections. Gonococcal septic arthritis can be treated with antibiotics alone; it is important to question the patient about his or her sexual history.

A patient with a joint infection has a swollen, painful, erythematous, and warm digit, thumb, or wrist, localized to a specific joint. The pathognomonic sign of joint infection is exquisite pain on attempted motion of that joint. Cellulitis over a joint causes pain on motion, but the tenderness elicited by slow, gentle, passive motion in cellulitis is much different from the severe pain caused by any attempt at motion of an infected joint.

Diagnosis of a joint infection can be confirmed following joint aspiration. Send the aspirate for cell count with differentiation, Gram stain, anaerobic and aerobic culture, glucose, and crystal analysis. A white blood cell differential of greater than 50,000 (usually more than 75% segmented neutrophils), or the presence of bacteria on Gram stain or culture is diagnostic. A synovial fluid glucose of 40 mg less than the fasting blood glucose is consistent with an infectious process. Finally, a crystal analysis is necessary to rule out gout or pseudogout as a cause of the painful, red, swollen joint.

Aspiration of Phalangeal and Metacarpophalangeal Joints

Aspirate after an antiseptic wash.

The joint space for the metacarpophalangeal joint is easily palpated just ulnar or radial to the extensor hood; take the edge of your fingernail and press. Aspirate after an antiseptic preparation. Giving a local anesthetic usually causes more discomfort than the single stick of the aspirating needle, but patients are not easily convinced of this fact.

The interphalangeal joint spaces can be located in a similar fashion. This location just next to the extensor tendon dorsally would correspond to a 10 o'clock or 2 o'clock position if the extensor tendon (top or dorsal) is considered as 12 o'clock.

- Use a large needle, ideally 18 or 20 gauge, or the largest needle that will enter the joint space.
- Palpate the joint space for the metacarpophalangeal joint, ulnar or radial to the extensor hood with the edge of your fingernail, feeling for the depression of the joint space.
- Aspirate after an antiseptic wash.
- Locate the interphalangeal joint in a similar fashion. Enter at the 10 or 2 o'clock position, with the extensor tendon as 12 o'clock.
- Aspirate after an antiseptic wash.

Drainage of Metacarpophalangeal and Interphalangeal Joints

- Base the incision dorsally over the involved joint.
- Incise longitudinally through either the extensor tendon at the metacarpophalangeal joint or through the extensor mechanism at the proximal or distal interphalangeal joints.
- Enter the involved joint and thoroughly irrigate it.
- Leave a small wick (penrose drain) in the joint space to facilitate drainage. Reapproximate the extensor mechanism and loosely close the skin.
- Remove the penrose drain in 48 to 72 hours.

Aspiration of the Wrist

The wrist joint includes the radiocarpal, radioulnar, ulnocarpal, and midcarpal joints. Septic arthritis may be found in any one or all of these joints; these spaces may or may not normally communicate. Direct the preoperative examination toward localizing the joint or joints involved. Pronation or supination pain indicates involvement of the radioulnar joint; flexion or extension pain indicates involvement of the radiocarpal, ulnocarpal, or midcarpal joints. Aspiration with an 18-gauge needle confirms clinical suspicions. The radial and ulnar styloids offer convenient landmarks; enter just distal to them.

Draining the Wrist

- Enter the radiocarpal, radioulnar, midcarpal, and ulnocarpal joints through either a transverse or longitudinal dorsal skin incision. A transverse incision has the advantage that if you take care to isolate and preserve veins, you can make a completely circumferential incision so that all wrist joint spaces can be entered until the infected space can be found and drained.
- Make the skin incision, and then enter the joint space by blunt dissection between the appropriate extensor compartments. Enter between the third (extensor pollicis longus) and fourth (extensor indicis proprius, extensor digitorum communis) compartments to drain the radiocarpal, radioulnar, and midcarpal joints. Enter around the extensor carpi ulnaris or extensor digiti quinti tendons to drain the ulnocarpal joint.
- Send fluid for aerobic and anaerobic cultures. Begin IV antibiotics.
- Irrigate thoroughly with a pulsatile lavage system.
- Place a closed suction system drain. Close the joint capsule and skin incision over the drain. Leave the drain in for 3 to 5 days.
- Begin gentle active assisted and active range-of-motion exercises after drain removal.
- Continue IV antibiotics for at least 1 week. Follow with an oral agent for several weeks after hospital discharge. Antibiotic sensitivities and minimum inhibitory concentration (MIC) help guide the appropriate oral antibiotic regimen. Ideally, the oral dose will have been determined by greater than 1.8 serum bactericidal levels against the bacterium or bacteria isolated.

HUMAN BITE AND CLENCHED-FIST INFECTIONS
Hand infections due to human bites are common and can have significant sequelae if they are not recognized and treated correctly (6,7,15,19,22,23,34). There are four classic mechanisms of infection, and these include self-inflicted (caused, for example, by nail biting), traumatic amputation (usually at the distal interphalangeal joint or pulp) from a bite, full-thickness bite wounds on any part of the hand, and finally a clenched-fist bite injury, usually following an altercation (14). The complications of incompletely treated human bite infections include arthritis, joint stiffness, osteomyelitis, toxic shock syndrome, and infrequently, death. Human mouth organisms inoculated into tissue are quite virulent (6,7,13,15,19,22,23,33-34 and 35,38,63).

In the preantibiotic era, amputation as a means to control a human-bite infection occurred in up to half of the affected patients. Death secondary to morsus humanis was reported as well. The introduction of antibiotics has not eliminated the complications associated with these infections. Even with antibiotics, 6% of human bites need amputation to control infection, 4% require late amputation, and 28% develop either osteomyelitis or other causes for stiff, disabled fingers (34).

The clenched-fist injury occurs with the fist closed, and the overlying dorsal skin and extensor tendon stretched distally. The tooth penetrates the skin, part or all of the tendon, the dorsal joint capsule, and potentially the metacarpal head. With the hand open, it may be difficult to recognize the extent of injury because the injury to the joint capsule and bone may be distal to the skin laceration and injury to the extensor tendon is proximal to the skin laceration (Fig. 73.10). Often, there is intra-articular violation with the potential for septic arthritis. Sometimes, osteochondral fractures of the metacarpal head or fracture of the metacarpal head or neck occur. The clenched-fist injury commonly involves the metacarpophalangeal joint of the long, ring, or little fingers, but any hand joint or digit can be involved.

![Figure 73.10](image) A fight bite occurs during flexion (A) of the metacarpophalangeal joint. During extension (B) of the injured joint, the tendon or osteochondral injury may be obscured leading to a closed intra-articular injury.

For clenched-fist injuries, those that are treated early (i.e., in less than 24 hours) have a better prognosis than those seen later than 24 hours from the time of injury (25,34). Clenched-fist injuries may resemble a simple puncture wound over the metacarpophalangeal joint, but there usually is more extensive damage to the soft tissue and bony structures underneath.

The most common organisms responsible for human bite infections are *Staphylococcus aureus*, *Streptococcus organism*, and *E. corrodens*. A plethora of microbes are isolated from the human mouth flora, however, and thus it is not uncommon to see mixed infections that could include *Bacteroides* sp., *Neisseria* sp., *Clostridia* sp., *siprochlees*, *Miccococcus*, and rarely, *Actinomyces* (13,25,22,34-36).

Although *E. corrodens* is not the most common pathogen in human bite infections, it certainly seems to be the type most often associated with “fight bites.” *E. corrodens* has been isolated in 7% to 29% of human bite infections (4,20,47). Although it is a normal part of the human mouth flora, it is more readily cultured from dental scrapings than from saliva (27). It is a gram-negative rod and a facultative anaerobe and thus grows best in 10% CO2.

Treatment begins in the emergency department with cultures (anaerobic, aerobic, 10% CO2), radiographs to rule out a fracture or foreign body (i.e., tooth), and wound exploration. Dorsal puncture wounds around the metacarpophalangeal joint are considered to be clenched-fist injuries unless proven otherwise.

Fully flex and extend the involved metacarpophalangeal joint to determine extensor tendon involvement. A saline arthrogram may assist in determining joint involvement. A history of a human bite or lacerations (especially over a joint) obtained during a fight must be treated aggressively. Treatment requires surgical debridement of dead or questionably viable tissue and thorough irrigation of the subcutaneous space (especially a joint). Leave the wound open.

Antibiotics effective against gram-positive aerobic and gram-positive and gram-negative anaerobic bacteria are mandatory. First-generation cephalosporins such as cefazolin, cephalothin, and cephradine, or penicillinase-resistant penicillins are effective against the common gram-positive aerobic bacteria. Many anaerobes commonly isolated from clenched-fist and human bite infections, however, are resistant to penicillinase-resistant penicillins and clindamycin, which are common first choices in the treatment of skin infections (3,49,60). The use of first-generation cephalosporins against human oral flora is variable, so a second antibiotic is necessary (21,49). The antibiotic of choice for these anaerobes is penicillin. Cefoxitin is effective against gram-positive aerobic bacteria and the anaerobes described, so it may be used as a single agent for penicillin-allergic patients (21).

Operative Technique

- Extend the traumatic wound proximally and distally.
- Remove the necrotic and infected tissue from the subcutaneous layer. The infection often extends beyond the obvious site of injury. Explore nearby potential areas of invasion such as the dorsal subcutaneous space.
- Always open the joint if the injury is over or near a joint. The joint often appears uninvolved until arthrotomy is performed and the pus wells out. Enter the joint dorsally, making a 1 cm longitudinal incision in the capsule through the extensor tendon.
- Inspect the cartilaginous surfaces for lesions. An osteochondral defect or tooth indentation is common. Record such a finding and also the condition of the cartilage in the operative record. Divots and unhealthy-appearing cartilage are poor prognostic factors.
- Irrigate thoroughly by pulsatile lavage. Leave the wound open.

**ANIMAL BITES**

Ninety percent of all animal bites to humans are dog bites (57). Cats account for another 5% of animal bites. Although several bacteria including *S. aureus*, *Streptococcus viridans*, and *Bacteroides* species may produce infection, *Pasteurella multocida*, a gram-negative anaerobic bacterium, has been identified as an important pathogen in animal bite infections (1,21) (more commonly from cat than from dog bites). The presence of cellulitis, lymphangitis, sepsis, or purulent drainage within 12 to 24 hours after a cat or dog bite strongly suggests *P. multocida* as the offending organism (1).

Initial treatment consists of thorough irrigation and debridement of necrotic and damaged tissue. Be sure to culture the wound even if gross purulence is not found. Penicillin is the drug of choice for *P. multocida*, with tetracycline and cephalosporins as alternatives. Administer penicillin intravenously in combination with cefazolin; alternatively, amoxicillin-clavulanate potassium can be given orally for less severe infections (Table 73.1).

**FELON**

A felon is an infection in the pulp of a digit. Beneath the skin of the pulp lies fat. Numerous fibrous septae that tether the skin to the bone cause compartmentation of the fat to make shock-absorbing spaces. Infection in the digit pulp is therefore a series of small, closed-space infections, each needing incision and drainage. A felon is an infection in the pulp of a digit. Beneath the skin of the pulp lies fat. Numerous fibrous septae that tether the skin to the bone cause compartmentation of

- Drain a felon that points palmar and midline by a midline approach (Fig. 73.11A). Drain a felon that does not point midline with a midlateral incision (Fig. 73.11B).
Note the self-limited nature of this illness. If incision and drainage are performed, no purulence will be expressed, and deeper tissues will be exposed to the 
over 2 to 3 weeks may rise to greater than four times normal levels.

decreasing erythema. The hemorrhagic areas crust and then desquamate, leaving normal tissue.

Infection that tracks deep to the nail plate and involves the nail bed is a subungual abscess and has more serious implications. The localized superficial nail skinfold 
infection is not serious, but deep infection may invade bone and result in nail destruction, osteomyelitis, and amputation. A patient with a nail bed infection has swelling, 
pain, and erythema at the base of the fingernail or on the side of the nail. The bacterium that infects is almost exclusively 
Staphylococcus.

Infection is not serious, but deep infection may invade bone and result in nail destruction, osteomyelitis, and amputation. A patient with a nail bed infection has swelling, 
pain, and erythema at the base of the fingernail or on the side of the nail. The bacterium that infects is almost exclusively 
Staphylococcus.

Chronic paronychia involves a different pathologic process. Women who work with their hands in moist environments are more susceptible. The infection comes and 
goes throughout its course and leads to a painful thickened eponychial fold that sometimes accumulates whitish thick material. Most often, Candida albicans is the 
offending yeast. Conservative treatment of topical steroids and antifungals has met with limited success. Chronic paronychias often require marsupialization.

**Paronychia and Eponychia**

After metacarpal block, use a Freer elevator or other blunt instrument and, beginning distally, elevate a few millimeters of the nail fold from the nail as far 
proximally as the infection extends. A blunt instrument helps prevent scoring that can later produce nail ridging. (Note: An incision usually is not needed for simple 
cases. A more extensive abscess may need a small incision adjacent to the eponychial fold and parallel to the nail plate.)

Using an 18-gauge needle, prick the infected area to drain and break up loculations. Expect only a few drops of pus. Send these drops for culture, and begin an 
antibiotic effective against Staphylococcus.

**Chronic Paronychia**

Use a digital block. Perform an eponychial marsupialization by excising a small crescent-shaped piece of the eponychial fold.

If the nail plate is involved (damaged), remove the entire nail.

Place xeroform gauze under the nail fold to promote drainage and keep the nail fold from closing.

**Subungual Abscess**

If the nail has been elevated off the matrix by infection, a subungual abscess is present. Incise along the borders of the nail fold. Elevate the nail fold (Fig. 73.12).

![Figure 73.12. Incision for drainage of a subungual abscess. After folding back the eponychium, the proximal nail plate is cut with scissors and removed.](image)

Remove the overlying nail plate to allow adequate drainage. If there is any question as to the extent of the subungual abscess, remove the entire nail. Remember, 
gently free the nail plate from the matrix with a blunt instrument to avoid injury to the matrix, which may result in ridging of the nail as it grows back.

After removing nail plate, scoop the abscess contents out with a curet, gently scraping the surface of the nail matrix.

If the nail is removed from the nail fold, place xeroform gauze under the nail fold.

Request aerobic and anaerobic culture on the fluid. Begin IV antibiotics.

Using an 18-gauge needle, prick the infected area to drain and break up loculations. Expect only a few drops of pus. Send these drops for culture, and begin an 
antibiotic effective against Staphylococcus.

**Herpetic Infection and Herpetic Whitlow**

Herpetic infection in the hand most often occurs in the distal finger (31). It is most commonly seen in health care providers exposed to oral secretions such as dentists, 
nurses, and dental hygienists. Pain is the initial symptom. Vesicles 1 to 2 mm in diameter containing clear fluid occur on an erythematous base; as the infection 
progresses, the vesicles coalesce into bullae. The fluid may turn cloudy after being initially clear, but it is never purulent. Purpuric lesions can develop beneath the 
nails. Lymphangitis and lymphadenopathy may also occur and confuse the picture, simulating a bacterial infection. The pain continues for 2 to 4 weeks, with 
decreasing erythema. The hemorrhagic areas crust and then desquamate, leaving normal tissue.

Laboratory confirmation can be obtained by early culture of the vesicles, which grow characteristic plaques within 1 to 3 days. Serum titers of antibody to herpesvirus 
over 2 to 3 weeks may rise to greater than four times normal levels.

Note the self-limited nature of this illness. If incision and drainage are performed, no purulence will be expressed, and deeper tissues will be exposed to the
Coccidioides immitis, Histoplasma capsulatum
usually not helpful.

Treatment ranges from empirical antibiotic therapy to surgical drainage, followed by antibiotics. Acute osteomyelitis may initially be treated with antibiotics,
findings on aspiration do not rule out the possibility of infection.

blood cell count with or without an increase in polymorphonucleocytes, and an elevated erythrocyte sedimentation rate. Radiographic evidence of osteomyelitis is
and because its dosage is only once a day, it may prove to be more tolerable.

early, whereas a more subcutaneous nodule discolors, darkens, and then erupts through the skin. Spontaneous healing of the ulcer follows, but new lesions erupt.

After the
The cutaneous mycoses, including sporotrichosis, chromomycosis, mycetoma, and phycomycosis, also produce hand infections The most common subcutaneous
lesions. Fungal hand infections occur after trauma with implantation of the fungus or its spore into the skin, or as part of systemic spread, usually from a primary pulmonary
infection that began with inhalation of spores (10,65). Catarrhal infections can be divided into cutaneous lesions, subcutaneous infections, and deep or systemic infections
(48).

Primary cutaneous fungal infections of the hand are found most often in gardeners and others engaged in activities around soil, where fungi are ubiquitous. Cutaneous
lesions are caused by dermatophytes that colonize nonliving cornified appendages such as skin, hair, and fingernails. Examples include dermatophytic infection of the
glabrous skin (linea corporis), the interdigital areas of the palms (linea manus), and the fingernails (onychomycosis or tinea unguium) (49). A scaling, pruritic skin
lesion (usually not responsive to or exacerbated by topical steroids) is present on an obvious thickened and deformed fingernail. Potassium hydroxide microscopic slide
preparations may provide a preliminary diagnosis, but fungal cultures need to be performed for a definitive diagnosis.

Most cutaneous lesions are readily treatable with a topical antifungal cream such as trolamine, miconazole, clotrimazole, or econazole. Have the patient apply it
topically for 4 to 6 weeks. More severe or unresponsive lesions may require systemic griseofulvin or ketoconazole. Fingernail infections are resistant to treatment, but
long-term systemic griseofulvin has met with the most success, with cure rates as high as 80%.

Cutaneous infection with one of the systemic mycoses—Coccidioides immitis, Histoplasma capsulatum or Blastomyces dermatitidis—also occurs after trauma or can
actually be a systemic manifestation of a primary lesion elsewhere. After traumatic implantation and an incubation period of several days to months, a subcutaneous
nodule appears that may or may not be painful. A fistula or ulceration develops and enlarges with a raised, discolored, and venous border. Epithelial hyperplasia follows.
Lymphatic invasion can occur; the lymph channels become cordlike. Nodules develop, ulcerate, and then spontaneously resolve, only to be replaced by new lesions.

The cutaneous mycoses, including sporotrichosis, chromomycosis, mycetoma, and phycomycosis, also produce hand infections The most common subcutaneous
fungal infection is sporotrichosis (48). Sporotrichosis classically occurs after a prick from a rose thorn by subcutaneous inoculation of the spores of Sporothrix schenckii.
After the S. schenckii organism incubates for a period of days to months, a small, nontender, movable, subcutaneous nodule develops. Epidermal infection ulcerates
early, whereas a more subcutaneous nodule discolors, darkens, and then erupts through the skin. Spontaneous healing of the ulcer follows, but new lesions erupt.
Lymphatic invasion occurs, raising cordlike tracks along the hand and arm. The other cutaneous mycoses present in a similar fashion.

The diagnosis of fungal infection is made by excisional biopsy of one of the lesions or by culture of drainage. A definitive diagnosis of sporotrichosis requires S.
schenckii to be isolated on fungal culture. The treatment of choice is potassium iodide for 6 to 8 weeks. Itraconazole has recently been shown to be effective as well,
and because its dosage is only once a day, it may prove to be more tolerable.

Deep fungal infections of the hand present on a delayed basis most commonly as tenosynovitis, septic arthritis, or osteomyelitis. Definitive diagnosis requires
identification by a fungal culture, and treatment usually involves IV amphotericin B for more virulent fungal infections and oral ketoconazole or itraconazole treatment for
more benign infections.

HAND INFECTIONS IN ACQUIRED IMMUNODEFICIENCY SYNDROME AND HUMAN IMMUNODEFICIENCY VIRUS

In the United States, an estimated 573,800 cases of acquired immunodeficiency syndrome (AIDS) were reported in persons older than 13 years old from 1981 through
1996, according to the Centers for Disease Control and Prevention HIV/AIDS Surveillance Report. The true incidence of human immunodeficiency virus (HIV) infection
currently exceeds 1 million people.

Although there is little written on hand infections in the HIV-positive person, there is a known high prevalence of infections in this population. At one institution, nearly
20% of patients hospitalized for upper extremity infections were HIV positive. An even more alarming discovery is that less than 10% of these individuals admitted to
being HIV positive (65).

In a recent study, not only was IV drug abuse the most common risk factor for HIV infection, it also was the most common cause of upper extremity infections in the
HIV-positive person (38). Although these infections may present atypically, the responsible organisms are usually similar to those that infect the immunocompetent
hand with S. aureus being the most common pathogen (36). Furthermore, spontaneous infections may occur, herpetic infections may appear more virulent, and
seemingly benign infections may need a more aggressive surgical approach. Any individual with an unusual hand infection should be tested for HIV infection.

OSTEOEMLITIS

Osteomyelitis can involve any of the bones in the hand. It is caused most frequently by open fractures or spread from neighboring infected soft tissues. The infection rate in
open fractures ranges from 1% to 11%, with a higher risk coming from the more contaminated wounds with more severe soft-tissue injury (17,33). Although S. aureus and
Streptococcus remain the most common pathogens, open injuries predispose to gram-negative, anaerobic, and polymicrobial organisms.

Pain, redness, warmth, and swelling are the usual clinical indications of osteomyelitis. Systemic manifestations are less common but include fever, an elevated white
blood cell count with or without an increase in polymorphonuclear leukocytes, and an elevated erythrocyte sedimentation rate. Radiographic evidence of osteomyelitis is
usually seen in the subacute or chronic stage and includes the presence of periosteal new bone formation, osteolysis, or a sequestrum. A bone scan is more sensitive
and can suggest the presence of osteomyelitis much earlier than plain radiography (46). Diagnosis may be made by subperiosteal aspiration of pus, but negative
findings on aspiration do not rule out the possibility of infection.

Treatment ranges from empirical antibiotic therapy to surgical drainage, followed by antibiotics. Acute osteomyelitis may initially be treated with antibiotics,
imobilization, and elevation. Failure of an early and discernible response warrants surgical incision, but cultures taken following the administration of antibiotics are
usually not helpful.
TREATMENT OF CHRONIC OSTEOARTHRITIS REQUIRES SURGICAL INTERVENTION. A SEQUESTRECTOMY, DIAPHYSECTOMY, AND EVEN DIGIT OR RAY AMPUTATION ARE POTENTIAL INTERVENTIONS TO HELP CONTROL AND ELIMINATE INFECTED BONE. SLANTED PROCEDURES WITH ANTIBiotic-IMPREGNATED POLYETHYLENE SPACERS, FOLLOWED BY BONE GRAFTING AND SKIN COVERAGE, ARE OFTEN NECESSARY. LOCAL ROTATIONAL AND FREE FlAPS ALLOW SUBSEQUENT ELEVATION FOR RECONSTRUCTION AND ARE PREFERRED TO PEDICLED FlAPS. THEY MUST BE PLACED IN A CLEAN AND VASCULARIZED WOUND BED.

POSTOPERATIVE CARE

LEAVE WOUNDS OPEN AND COVER THEM WITH WET SALINE GAUZE TO PROMOTE DRAINAGE. APPLY A PLASTER SPLINT—REINFORCED LONG-ARM BULKY HAND DRESSING, INCORPORATING A CORD TO PERMIT CONTINUOUS DRAINAGE. CHANGE THE DRESSING AT 36 TO 48 HOURS TO A MACERATION-TYPE DRESSING OF 25% STRENGTH DAKIN'S SOLUTION, WHICH IS CHANGED DAILY. BEGIN ACTIVE HAND MOTION TO PREVENT STIFFNESS. DISCHARGE THE PATIENT WHEN THE WOUND IS WITHOUT ERYTHEMA, TENDERNESS, INDURATION, OR SWELLING.

CHANGE WET-TO-DRY DRESSINGS THREE TIMES A DAY AT HOME FOR THE OPEN WOUNDS; ANTIBIOTICS ARE PRESCRIBED ON THE BASIS OF CULTURE RESULTS AND THE DISEASE PROCESS. CONTINUE DRESSING CHANGES UNTIL THE WOUND IS HEALED.

PITFALLS AND COMPLICATIONS

AN UNDRAINED AREA OF INFECTION IS A COMMON REASON FOR FAILURE TO IMPROVE AFTER INITIAL DEBRIDEMENT. PHYSICAL EXAMINATION DIRECTED TOWARD DISCOVERING POSSIBLE PLACES OF SPREAD BEFORE SURGERY WILL HELP UNCOVER THESE EXTENSIONS. WHEN IN DOUBT, OPEN THE SPACE AT THE TIME OF SURGERY.

KEEP INCISIONS OUT OF SKIN CREASES. IF AN INCISION FOR DRAINAGE MUST CROSS THE CREASE, ANGLE IT LESS THAN 60°; FAILURE TO DO SO RESULTS IN CONTRACTURE. DO NOT PENETRATE THE WEBSPACES FOR THE SAME REASON.

FLAPS IN THE PRESENCE OF INFECTION ARE PRONE TO NECROSIS. USE ONLY LONGITUDINAL OR GENTLY CURVED INCISIONS.

DO NOT MISS A HERPETIC WHITLOW MASQUERADE AS A FELON OR PARONYCHIA. INCISION OF THIS ALREADY-COMPROMISED TISSUE MAY LEAD TO SECONDARY BACTERIAL INFECTION.

ANTIBIOTIC SELECTION MUST BE EFFECTIVE TO ERADICATE ALL ORGANISMS PRESENT IN A HAND INFECTION. COVERAGE AGAINST GRAM-POSITIVE COCCID AND GRAM-NEGATIVE ANAEROBES IS NECESSARY. STAPHYLOCOCCUS AND STREPTOCOCCUS, AS WELL AS THE ANAEROBIC STREPTOCOCCUS, IS NECESSARY. GRAM-NEGATIVE ANAEROBES ARE OFTEN PRESENT, ESPECIALLY IN CLENCHED-FIST, HUMAN BITE, AND IV DRUG ABUSE INFECTIONS. INITIAL ANTIBIOTIC SELECTION SHOULD BE BASED ON THE TYPE OF INJURY KNOWN OR SUSPECTED. THINK OF HIV INFECTION IN THE IV DRUG ABUSER OR THE PATIENT WHO IS NOT IMPROVING IN SPITE OF CUSTOMARY TREATMENT.

OVERVIEW

Managing a patient with a neoplasm in the upper extremity will always be challenging; it is sometimes complex and may also be frustrating. Considerable skill and careful thought are needed to analyze diagnostic, treatment, and reconstructive problems, as well as to treat the patient to ensure survival and function while treating the tumor. The first issue is that an enlarging mass that represents an invasive or life-threatening tumor in the upper limb is unusual; circumspection and attention to detail should govern the approach to all tumors.

Hand tumors include soft-tissue and bone neoplasms (distal to the elbow, soft-tissue neoplasms predominate when serious diagnoses are considered); the majority are reactive nodules and cysts, connective tissue proliferations, foreign bodies, infections (that mimic neoplasms), and posttraumatic sequelae. Table 74.1 and Table 74.2 list tumors of the soft-tissues and hard tissues, respectively. Lesions that are small and appear innocent can be deadly, whereas large and seemingly worrisome masses may be easy to treat (Fig. 74.1). The surgeon who evaluates and treats tumors of the hand needs to be familiar with limb anatomy, tumor biology, and the range of treatment possibilities and their limitations. Ideally, the hand surgeon or orthopedist is part of a team consisting of medical and surgical oncologists, reconstructive surgeons, and therapists, who can offer state of the art experience in integrating care of the tumor, balancing patient survival against the desire to retain function. Lesions in the hand more often present earlier in their course than those at other sites, just because they are—by definition—more likely to be superficial and easily noticed. However, hand tumors that require a clean surgical margin will have a significant and often profound functional impact after treatment.

Table 74.2. Tumors of Hard Tissue
Hyperplasia: An accumulation of cells resulting from accelerated proliferation.

Hamartoma: Congenital anomaly in which a tissue island is effectively excluded from regional maturation and cellular differentiation. This lesion has a structure similar to its tissue of origin; it is often multicentric and/or hemi corporal in locations. Hyperplasias and hamartomas stop growing when skeletal maturity is achieved.

Neoplasia: A new growth of cells that enlarges in an atypical, autonomous, progressive course.

In another sense, benign lesions can be categorized with respect to their temporal behavior.

- Latent (stage I) lesions are entirely quiescent. Latent tumors in bone and soft tissue may require only observation to ensure they have been correctly categorized.
- Mixed (stage II) lesions remaining in a limited anatomic zone are considered a separate category (stage II). Actively growing tumors may be controlled by local intralesional or marginal excision.
- Aggressive (stage III) lesions are characterized by regional invasion and spread (in a sense, they meet the generic minimum standards for Campanacci’s neoplasia). Aggressive tumors require surgical margins wide enough to effect en bloc excision encompassing the entire lesion, and generally with a contiguous margin (“ cuff”) of normal surrounding tissue to minimize recurrence.

Malignancies are another story altogether.

MALIGNANT TUMORS

The Musculoskeletal Tumor Society (MSTS) staging system, proposed by Enneking et al. (44,65) and others (69,102), constitutes the basis for treating and reporting malignant sarcomas, including those in the hand (Table 74.3). Nonetheless, there are as yet no standards of appropriate or safe surgery based on reproducible clinical data, because of the limited number and varying histologic types of cases historically reported using several methods and classifications (15,38,102,129,129,147).

Therefore, what exactly constitutes a safe, clean surgical margin, and how much function need be sacrificed to ensure a patient’s survival, are not irrefutably established (17,60,67). Use and reporting of larger numbers of cases with the same staging system will make treatment comparisons and definitions easier and more accurate. However, the pathologic implications of compartmentalization—based on the presence of a tissue barrier that inhibits easy extension of tumor cells—has a more limited application in the hand. That is to say, it is easy to understand a medial or lateral compartment in the thigh, and a volar or dorsal compartment in the forearm. However, the flexor sheath in the thumb extends from its interphalangeal joint to the wrist, and it communicates with the entire flexor compartment of the forearm and elbow. Yet, is the flexor surface of the thumb truly different from the flexor surface of the index where the synovial sheath is not continuous? The critical issue is that a surgical margin is not compromised when it endangers the primary goal of treatment—that is, permanently ridding the patient of the tumor. Musculoskeletal tumor surgery requires local control; but surgery now needs to be seen as part of a treatment paradigm that includes medical and radiation therapies, delivered to the patient or the tumor region before, during, and after the operation in appropriate cases (17,18,38,76,88,102,108,145,156).

Malignant sarcomas, including those in the hand, are often classified according to the system of Campanacci (23). These can be divided into three grades: latent (stage I), mixed (stage II), and aggressive (stage III) (Table 74.3).

Imaging techniques and experience with their interpretation have improved notably in the past decade. High-resolution CT with reconstructed images of various views, and MRI sequences, sometimes enhanced with gadolinium, have improved identification of anatomic structures, have refined preoperative differential diagnosis, and have redefined and clarified tumor margins.

**BIOPSY METHODS**

It is not likely that a diagnosis can be made without a tissue sample. The biopsy of a potentially malignant lesion should be planned as carefully as that of the definitive surgical resection. The biopsy track will later have to be incorporated into the planned resection to allow for its removal with the tumor. Open incisional biopsy with intraoperative frozen section reviewed by an experienced musculoskeletal pathologist to confirm the acquisition of an adequate tissue sample remains the standard. Definitive diagnosis may require permanent sections and special techniques. Improvements in cytopathologic tissue processing have advanced the utilization of fine-needle aspiration and core needle biopsies in the diagnosis management of sarcoma. Cytopathology requires considerably greater attention to detail by both the surgeon and the pathologist to ensure that a complete and accurate diagnosis is made. Reliable immunohistochemical and cytogenetic evaluations could potentially be obtained by needle aspirates, but presently fine-needle biopsy is confined to academic musculoskeletal and cancer centers where a large experience can be accumulated.

Biopsy is not a simple surgical procedure, and it is critical to the outcome of treatment. If a surgeon or the team available at the institution is unprepared, ill equipped, or inexperienced in completing all diagnostic studies and proceeding with definitive, comprehensive management, the patient should be referred before the biopsy is performed. The patient and surgeon must be prepared for the unexpected. “Benign growths” that otherwise appear “different” need to be biopsied; avoid an invasive attempt at excision of an unknown lesion that may contaminate surgical margins with tumor cells.

**Figure 74.2.** A: Radiograph showing a soft-tissue mass with calcifications, plus erosion of the third metacarpal and proximal phalanx in a 27-year-old man. The findings suggest an aggressive tumor, quite possibly a (malignant) synovial sarcoma. B: MRI demonstrates absence of marrow involvement by this well-defined circumferential soft-tissue tumor (arrow). These findings clearly support the diagnosis of benign, noninvasive neoplasm, but one that would require dorsal and palmar incisions for complete excision. Synovial chondromatosis was confirmed at surgery.

Hand and upper-limb surgeries are best performed in a bloodless field. Tourniquet control is safe for performing the biopsy and when treating tumors of the hand. Do not exsanguinate the extremity because this may cause dissemination of seed tumor cells—or bacteria—from the affected site. Elevate the arm for 2–4 minutes before inflating the pneumatic tourniquet. Do not use intravenous Bier block anesthesia (which requires exsanguination) when performing a biopsy or when removing an undiagnosed or known serious hand tumor. Very small tumors up to 1.0 cm in diameter can be effectively biopsied and excised simultaneously if limited to one tissue plane or compartment. Skin defects can be covered with synthetic semiocclusive materials until biopsy results are known. Hemostasis is required for deep biopsy wounds; therefore, release the tourniquet before wound closure to ensure a dry field. Do not use drains. Biopsy of bone tumors is best done by making a cortical window and harvesting a limited sample. Postoperative care and splinting follow routine principles.

**TREATMENT PRINCIPLES**

**BENIGN TUMORS**

Benign tumors of soft tissue and bone can be removed utilizing intrallesional or marginal surgical resection, often described as shaving out or bony curettage. Tumors with special characteristics and those that ought to have additional consideration because of their anatomic location and biologic potential will be discussed in later sections.

**AGGRESSIVE TUMORS**

When invasion occurs from a primary musculoskeletal malignancy or as a metastatic nidus, hand tumors may be serious. Therapy was started 2 weeks after surgery and motion recovered rapidly. Aneurysmal bone cyst, which was treated at a separate operation by en bloc second-metacarpal resection and iliac graft replacement. To maintain functional skeletal continuity, the second metacarpal head was transfixxed to the third before bone resection. The Kirschner wires were left in place until union was solid. Therapy was started 2 weeks after surgery and motion recovered rapidly.

**Figure 74.3.** A: Clinical appearance of the hand in a 24-year-old woman who reported a 10-week history of an enlarging, painful mass on the dorsum of the hand. B: Radiographs revealed endosteal invasion of the second metacarpal diaphysis and metaphysis without new bone formation, suggestive of a rapidly growing lesion. C: The CT scan revealed actual cortical destruction along the ulnar side of the metacarpal shaft. D: A small dorsal longitudinal incision (located so as to be entirely excisable) was used for the incisional biopsy under tourniquet control, without exsanguination. E: Radiograph of specimen. Permanent sections revealed an aneurysmal bone cyst, which was treated at a separate operation by en bloc second-metacarpal resection and iliac graft replacement. F: To maintain functional skeletal continuity, the second metacarpal head was transfixxed to the third before bone resection. The Kirschner wires were left in place until union was solid. G: Therapy was started 2 weeks after surgery and motion recovered rapidly.
Aggressive neoplasms that are truly malignant must be distinguished from those that are only locally invasive and regionally destructive. Nonmalignant tumors can be safely and adequately handled by en bloc excision as long as the tumor is contained within the specimen. Aggressive but nonlethal tumors do not justify excision of important nerves and vessels, with rare exceptions. Improvements in imaging techniques and nonsurgical care allow the musculoskeletal oncologist to cut closer than the traditional 3–5 cm margin for bone and 1–2 cm margin for soft tissue without an increased risk of local recurrence. Close, but safe, negative margins decrease the loss of function in the extremity (Fig. 74.5). This approach requires intensive and extensive multidisciplinary preoperative planning from the musculoskeletal radiologist, radiation and medical oncologists, the oncologic surgeon, and the reconstructive upper-extremity surgeon. At the time of excision, carefully examine the margins of the specimen and sample histologically together with the pathologist. If the tumor has not been clearly resected, the margins have to be expanded; additional regional adjuvants and systemic treatments may need to be added. If a safe and adequate tumor resection will destroy hand function, amputation is advised (Fig. 74.6).

Wound closure is generally best done with local tissues, local flaps, and skin grafts. Do not use distant pedicle flaps for primary closure because of the risk of residual tumor cells in the resection area contaminating an otherwise clean donor area. Finger fillet flaps and local rotation flaps from portions of retained fingers, for example, are ideal for coverage in such circumstances. Complex reconstructive procedures that include vascularized soft tissue, bone, or composite flaps require integrated preoperative planning; they require a team of specialists in surgical tumor excision and hand reconstruction working simultaneously. Even seemingly traditional reconstructive procedures, such as pollicization, can be done primarily at the time of tumor resection if planning has been adequate and the local conditions are appropriate (Fig. 74.7).
The focus of treatment for aggressive tumors of soft tissue and bone in the hand and forearm is surgery; however, the judicious use of pre- and postoperative radiation and chemotherapy will improve both local control and patient survival. Radiation therapy is probably the most widely used adjuvant. It can improve local control of malignant lesions when surgical margins are up to 1.0 cm in thickness. Careful planning after diagnosis and before treatment by experienced radiation and medical oncologists is required. Palliative external beam radiation can be used for patients with painful lesions in the hand and upper extremity. Preoperative radiation therapy and regional or systemic medications are useful if a lesion is close to a vital and potentially preservable structure. Brachytherapy can be similarly useful but may be difficult to utilize and more typically requires additional or special soft-tissue coverage methods. Chemotherapy management of osteogenic sarcoma, Ewing's sarcoma, and rhabdomyosarcoma is now well documented as discussed in Chapter 126, Chapter 128, and Chapter 129. However, present chemotherapy methods have not yet been proven to augment survival of patients with soft-tissue sarcomas in the hand other than rhabdomyosarcoma.

TUMORS OF SOFT TISSUE

CYSTIC LESIONS

Ganglion Cyst

The ganglion cyst, the most common tumor in the hand, is found more often in women. The most common sites are the dorsal carpus, generally arising from the scapholunate ligament, or at the palmar wrist, with origin from the scaphotrapezial and/or trapeziometacarpal joints. They often occur spontaneously as well as after trauma and in patients with osteoarthritis (Fig. 74.8). The ganglion cyst may also arise on the palmar surface of the fibroosseous (flexor) sheath; these are termed retinacular cysts, sesamoid ganglia, or seed or pea ganglia. These occur as very small but firm, even hard, and often painful lesions over the palmar aspect of the metacarpophalangeal joint.

A ganglion cyst is mucus filled, with a fibrous wall, and it is not a true neoplasm. The lesion is typically connected to an underlying joint capsule or tendon sheath by a stalk that may be tortuous. The lesion may be tender as it expands or when it is impacted, and it hurts at the extremes of joint motion. Surgical excision is recommended for these lesions when they are unsightly or painful, interfere with function, and have not responded to conservative care such as needle aspiration and steroid injection. Our preferred technique for surgical excision is to aspirate and suction the cyst empty to improve the visualization and retraction of surrounding structures. This allows it to be excised through an extensile but small incision. Excision is usually curative in 95% of cases if the cyst and its stalk are removed with a very small cuff of contiguous joint capsule (Fig. 74.8).

Mucus Cyst

A mucus cyst is identical to a ganglion cyst. It usually arises dorsally from the distal interphalangeal joints of the fingers and thumb. These cysts may involve the distal germinal nail matrix, causing nail depression and grooving secondary to chronic local pressure. Spontaneous rupture or patients' attempts at aspiration can lead to serious complications such as septic arthritis and osteomyelitis.

As with removal of the ganglion cyst, excision of a mucus cyst must include its stalk, local small osteophytes, and joint capsule. Protect the terminal (extensor) tendon and germinal nail matrix. Closure of the skin may require a small rotation flap, skin advancement, or skin graft. If the underlying joint is arthritic and painful, arthrodesis may be indicated (see Chapter 72).

Epidermal Inclusion Cyst

An epidermal inclusion cyst derives from buried epidermal cells, typically secondary to a traumatic or surgical wound. The original injury may be entirely unrecognized or unremembered, given the frequency with which small cuts occur in the hand. The mass is attached to skin and contiguous subcutaneous tissue; it contains keratin and may enlarge to a significant size. Carefully excise these cysts, taking care to avoid spilling the contents or damaging adjacent normal anatomy. Intraossseous components need to be curetted.

SKIN TUMORS

Squamous Cell Carcinoma

Squamous cell carcinoma accounts for the vast majority of soft-tissue (skin and skin organ) malignancies of the hand. It is most commonly seen in older patients, and those with a history of chronic exposure to chemicals, ionizing radiation, and the sun. Logically, this tumor is found most often on exposed, often dorsal, skin surfaces, and it may be accompanied by ulceration (Fig. 74.9). The nail bed is a less common site for this lesion (Fig. 74.10). In contrast to keratoacanthoma (discussed next), these true malignancies are actually less rapidly growing. Because primary squamous cell carcinoma rarely metastasizes, it is amenable to cure by local excision, including clean margins of greater than 1 cm of normal skin. The depth of excision required depends on the size and extent of the lesion. Removal of superficial tumors leaves a defect that is coverable by direct local flap advancement or by skin graft. Treat tumors that extend into adjacent tendon or bone by en bloc resection or local amputation.
Keratoacanthoma

Keratoacanthoma is a benign neoplasm that resembles squamous cell carcinoma. It is found in the same sites and locations and in the same older patient group as squamous cell carcinoma, but it is usually a much more rapidly growing tumor. It is usually diagnosed at excisional biopsy. Recurrences are uncommon, and the lesion is rarely locally aggressive.

Malignant Melanoma

Malignant melanoma is an aggressive and increasingly frequent skin cancer that too often is lethal. As the frequency of chronic sun exposure has increased, the incidence of the melanoma epidemic has increased as well. These tumors may be dark, multicolored, and multivariate, or they may have no pigment at all. Lesions are graded according to the level of skin invasion and the size or thickness of the tumor (Table 74.4). Most tumors can be treated surgically with a clean margin of 1 cm for level I or II lesions, to 5 cm for level III, IV, or V lesions and nodular lesions (Table 74.5).

Lymph node dissection is rarely indicated unless there is clearly nodal enlargement or the primary tumor is quite large. Sentinel node biopsy to evaluate the draining node basin is more common with melanoma (see later).

Lymph node evaluation by sentinel node biopsy and lymphatic mapping is being used in an increasing number of these cases, as well as in certain circumstances of squamous cell carcinoma.

The technique of sentinel node biopsy (lymphadenectomy) with lymphatic mapping requires participation of an experienced tumor surgeon familiar with the precise methods required. In overview, this is an inventive application of two vital-staining techniques used to precisely identify the primary (sentinel) lymph node in a node-basin draining an extremity. The idea behind the technique is that if this sentinel node can be accurately and reproducibly located, and it is found to be tumor free on biopsy, node dissection is not warranted. On the other hand, if this node is positive for tumor, at least additional node sampling, or a full node-basin dissection, will be required for staging and treatment. The method utilizes a combination of one visual and one nuclear stain. The affected extremity is injected with a microquantity of fat-based, colored dye and simultaneously with a microquantity of radioactive tracer. Both are absorbed into the lymphatic system. After approximately 1–2 hours, a
Geiger counter is applied to the axilla to locate the first (sentinel) node in the chain with significant uptake; this site is marked on the skin. Immediate surgical biopsy is aided by a sterile nuclear counter probe and the fact that the node has also been stained from the visible dye.

It has not yet been proven that this method is absolutely predictable for all tumors, but it has been highly dependable for common tumors of squamous cell origin.

Only the recognition of the malignant potential of an enlarging, multicolored, or irregularly bordered lesion leads to early treatment. Early treatment—before the tumor has invaded and metastasized—significantly increases chances for survival. The use of chemotherapy and other adjuncts has not been uniformly helpful, however.

Fibrous Tumors

Nonneoplastic Lesions

Nonneoplastic lesions include keloid, fasciitis, Dupuytren's disease, and fibromatoses, which have variable presentations and occur at different ages (2,49,68,82,109,115,117,135).

Keloids are posttraumatic phenomena. They generally occur in patients 10 to 25 years of age and are more common in blacks and others with darker skin color, most often with a family history. A keloid may continue to grow, albeit slowly, for months or years, or involute spontaneously. Surgical excision and radiation usually provide only temporary relief. Intradermal steroid injections and use of elastic garments can be helpful.

Palmar fasciitis (non-Dupuytren's) is also posttraumatic and is common in the same general age group.

Fibromatoses are often locally infiltrative, recurring lesions. This subset includes subdermal fibromatosis in infancy, infantile dermal fibromatosis/juvenile fibromatosis, calcifying aponeurotic fibroma, and palmar fibromatosis (i.e., Dupuytren's disease). These lesions sometimes need to be evaluated by an experienced histopathologist to distinguish them from aggressive processes and malignant fibrosarcomas or malignant fibrous histiocytomas. The benign fibromatoses tend to recur locally if incompletely excised.

Muscle Origin Tumor—Rhabdomyosarcoma

Rhabdomyosarcoma makes up approximately 15% of primary sarcomas in the hand and forearm. However, it is the most common soft-tissue tumor from childhood to young adulthood. The tumor tends to differentiate "foward" typical striated muscle. Rhabdomyosarcomas have been subdivided into embryonal, alveolar, and pleomorphic subtypes. Often these tumors present as painful enlargements, but numbness or paresthesias secondary to nerve compression may be the original symptom.

The alveolar subtype seems to be the most common variant found in the hand; overall, it is reported as the second most common in frequency for this tumor. When presenting in the hand, the neoplasm may develop in an interosseous muscle with secondary bone changes, and with enlargement evident on the palmar or dorsal regions of the hand.

Treatment of rhabdomyosarcoma requires multidisciplinary surgical and medical oncology combined with radiation therapy. Control the disease locally by wide surgical resection, radiation, or the combination. Current survival rates are improving (17,18,36,82).

Fibrous Histiocytoma

Fibrous histiocytomas, both benign and malignant, occur predominantly in men in their fourth decade of life (2,135,159). Benign fibrous histiocytoma has a recurrence rate of about 10% to 15%; marginal or wide en bloc excision is indicated, especially for larger masses. Malignant fibrous histiocytoma (MFH) seems to be the most common primary soft-tissue sarcoma distal to the elbow in adults. The majority of MFH cases are in patients 50 to 70 years of age. Although these sarcomas predominate in the lower extremity, particularly the proximal thigh, the upper limb is the next most common site. This tumor can manifest a wide range of histologic and clinical features; it may invade along subcutaneous or intermuscular planes. Most often, MFH arises in muscle and deep fascial structures and enlarges within its compartment of origin. The tumor is macroscopically solitary but often multicentric. Although it appears well circumscribed, this malignancy has satellite lesions nearby, with "reactive tissues" surrounding the mass. Micrometastases are common when dissection is performed within the tumor pseudocapsule. See Chapter 129 for a discussion of the treatment of MFH.

Fibroma

Fibromas are benign, encapsulated lesions; they have a low rate of recurrence after local removal. Such tumors arise from the tendon sheath (tenosynovial fibromas) or adjacent to the fingernails (periungual).

Extra-abdominal Desmoid Tumors, or Desmoplastic Fibroma

Extra-abdominal desmoid tumors are aggressive and nonmetastatic but are likely to recur. Recurrent lesions will progressively invade and may destroy (in conjunction with repeated attempts at surgical cure) function in the affected limb. Effective local treatment requires a wide en bloc excision, or even an amputation for recurrent and destructive cases (Fig. 74.6).

Regular, serial reexaminations of the patient are required because of the tendency of these tumors to recur. Treat recurrences promptly. These tumors are notable because they are more aggressive clinically than their histologic appearance would suggest. They behave like low grade sarcomas and may be quite difficult (88,110,121).

Fibrosarcoma

Fibrosarcoma is sometimes a highly aggressive malignancy. It can be found in anatomic areas that have undergone chronic traumatization or burns. Treatment varies with tumor location, grade, and stage; en bloc excision or amputation is needed (2,32,48,60,65,71,72,122) (see Chapter 129).

Vascular Tumors

Vascular tumors may be congenital or acquired, malignant or benign. Most lesions are benign and congenital; many may be considered hamartomatous, and these are believed to be due to failure of differentiation of embryonic vascular channels. Acquired lesions include arteriovenous fistulae, false and true aneurysms, pyogenic granulomas, and glomus tumors (30,60,87,118,136).

Arteriovenous Malformation

Congenital arterial venous malformation (AVM) is uncommon. Whether congenital or acquired, it is an arteriovenous shunt. These tumors can be difficult to excise if they are not localized to a limited anatomic region. They may involve adjacent bone, nerve, tendon, muscle, and subcutaneous tissue as well as skin. Lesions not effectively treatable by debulking may necessitate digital or ray amputation. Some limited lesions can be effectively treated by ligating the feeding vessels. In the upper extremity, when these malformations occur, most are low-flow and their treatment relates to the aesthetics and function of the extremity (118). The high-flow lesions risk a neonate's survival, necessitating emergency treatment by a skilled pediatric cardiovascular team to reverse the process.

Aneurysm

False aneurysm is the most common posttraumatic vascular abnormality in the hand. Following trauma, patients develop a painful, pulsatile, locally tender mass (85,125). The diagnosis is made by arteriography. Treat with excision. If excision will compromise blood flow to the distal tissues, simultaneous arterial/microvascular reconstruction will be needed. True aneurysms are a rarity but not unknown.

Hemangioma
Liposarcomas are extremely rare in the upper extremity. See Liposarcoma.

Patients complain of a slowly enlarging, painless, and often asymptomatic mass that at presentation may be of such impressive size that it interferes with function. The lipoma is a common, benign soft-tissue tumor in the upper limb. It is more often found in women, and a bit more commonly on the flexor surface of the hand. Lipoma

LIPID TUMORS

necessitating nerve excision or partial amputation. Branches of the digital nerve with preservation of the nerve trunk. Unfortunately, gradual, local neurologic deterioration can be anticipated in many of these cases, enlarged finger that may need amputation. More than one finger may be affected. Early treatment with physeal arrest is warranted. Some advocate removal of the Digital gigantism associated with the presence of this tumor in the median or ulnar nerves has been described (43). Children with this present with a grotesquely painful. Preoperative arteriography helps to determine the probability of distal-part survival following tumor resection, or the need for vascular reconstruction, if possible (Fs. 74.11). At surgery, release the tourniquet before wound closure to ensure hemostasis, as vigorous and persistent local bleeding may occur following extirpation (30,118,160).

Figure 74.11. A: An enlarging, painful cavernous hemangioma in a 9-year-old. B: The venogram best demonstrated the lesion, but angiography revealed good flow to all digits. C: Dorsal and palmar incisions were required to remove the tumor. Note preservation of the motor branch of the ulnar nerve (arrow).

Glomus Tumor

Glomus tumors are relatively uncommon; they may go undiagnosed for long periods. They tend to occur in adults 20 to 60 years of age and are commonly subungual. They are very painful. Patients may complain of relatively short-term or acute onset of pain, marked local tenderness, and extreme sensitivity to cold at the site of the lesion. Careful inspection of the tissues in the area of pain often reveals a small, round nodule, or a bluish discoloration under the skin or nail, which is also characterized by marked local tenderness. Patients may note severe pain if an ice cube is applied to the site of the suspected lesion. MRI is very useful in diagnosing glomus tumors, especially when patients have localized obscure pain and no other positive findings (141).

Treat with marginal excision. If the tumor is beneath the nail, excision requires removal of the nail and longitudinal incision of the nail matrix with removal of the lesion beneath (including curettage of bone, where appropriate). Reapproximate accurately the sterile and/or germinal matrix with fine, absorbable sutures. Replace the nail or insert nonadherent gauze in the eponychial fold. Neither need be sutured to the cuticle.

Kaposi's Sarcoma

Kaposi's sarcoma (KS) historically was a rare vascular malignancy. Now, chronically immunocompromised patients such as those with acquired immunodeficiency syndrome (AIDS) or those who have had an organ transplant can suffer from these sarcomas (9,53,84,87). KS appears as a reddish purple or reddish brown skin tumor or nodule on the extremities or trunk and may be an early indication of human immunodeficiency virus (HIV) infection or progressing AIDS. These lesions should be treated palliatively, in conjunction with the patient’s medical management. Where warranted, local treatment may be requested by the primary physician, but this is not common.

NERVE TUMORS

Schwannoma/Neurilemoma

The schwannoma (neurilemoma) is a common, solitary, and benign lesion arising from the Schwann cell. It is the most common tumor of the peripheral nerves, nerve trunks, and their branches. It is more frequent (or more frequently noticed) on a flexor surface. These tumors are generally less than 4.0 cm in diameter; masses 5.0 cm or more in diameter may be malignant (43,78,133,144). In general, symptoms are the result of nerve compression. Surgical treatment requires extirpation. Use magnification during the surgical dissection to minimize injury to adjacent and secondarily compressed, atrophic, but otherwise normal fascicles. Because the neurilemoma is well encapsulated, it can be dissected from the surrounding fascicles. Recurrences are unusual following excision.

Malignant schwannoma is not a degeneration of the benign variant; rather, it arises as a complication of neurofibromatosis. Malignant schwannoma requires wide excision and primary reconstruction; amputation may be needed for the aggressive, poorly differentiated tumors, which can have an extremely bad prognosis (see Chapter 129).

Neurofibroma

The neurofibroma is a diffuse, mixed growth of Schwann cells, axons, and fibrous tissue, which occurs as a solitary lesion or may be part of multiple nerve and cutaneous tumors (von Recklinghausen's disease). Solitary neurofibroma is unlikely to recur following excision; however, multiple plexiform neurofibromas cannot be enucleated easily. Symptomatic plexiform neurofibromas that require removal usually require complete resection. Nerve grafting is necessary for reconstruction (107,138,144).

Lipofibromatous Hamartoma

Lipofibromatous hamartoma is not a true tumor, as its name implies; its cause is unknown. The lesion is rare. It usually appears as a slow-growing painless mass in childhood. In the median nerve, its presence is associated with symptoms like those of carpal tunnel syndrome (4,85,119,123,136).

The treatment is controversial. Most agree that in symptomatic patients operative exploration is warranted and should include nerve decompression. At the carpal tunnel, release of the transverse carpal ligament and a small incisional biopsy of the nerve is done. Division of the antebrachial fascia may be necessary. Occasionally—perhaps rarely—epineurotomy is appropriate. Intraneural dissection often results in functional loss and is best avoided primarily.

Digital gigantism associated with the presence of this tumor in the median or ulnar nerves has been described (4). Children with this present with a grotesquely enlarged finger that may need amputation. More than one finger may be affected. Early treatment with phseal arrest is warranted. Some advocate removal of the branches of the digital nerve with preservation of the nerve trunk. Unfortunately, gradual, local neurologic deterioration can be anticipated in many of these cases, necessitating nerve excision or partial amputation.

LIPID TUMORS

Lipoma

The lipoma is a common, benign soft-tissue tumor in the upper limb. It is more often found in women, and a bit more commonly on the flexor surface of the hand. Patients complain of a slowly enlarging, painless, and often asymptomatic mass that at presentation may be of such impressive size that it interferes with function. Symptoms of compression neuropathy (when the lesion is in the carpal tunnel or a similar location) may be the presenting complaint. Excision of the tumor and pseudocapsule is usually a straightforward, curative procedure (83,151,113,135,157).

Liposarcoma

Liposarcomas are extremely rare in the upper extremity. See Chapter 129 for details on diagnosis and management.
**SYNOVIAL TUMORS**

**Giant Cell Tumor of Tendon Sheath**

The giant cell tumor of the tendon sheath (fibrous xanthoma) is a soft-tissue lesion that is not related to, and should not be confused with, a giant cell tumor of bone. The two are of different origin, presentation, frequency, and behavior. These lesions are common on the flexor surface of the hand, where tenosynovial tissues predominate. Most of these tumors are found in the fingers, wrist, or palm. As they slowly enlarge, they have the potential to envelope tendons, invade bones and joints, and to surround neurovascular structures. Treatment is by thorough local excision while avoiding injury to adjacent anatomy (Fig. 74.12). The incidence of recurrence is reported to exceed 15%, but recurrence quite probably occurs from incomplete, inadequate excision (49,99,113,115). Should a recurrent tumor present, reexcision is indicated.

*Figure 74.12. Giant cell tumor of tendon sheath must be completely removed to prevent recurrence, while preserving the flexor pulleys and avoiding injury to the neurovascular bundles.*

**Epithelioid Sarcoma, Synovial Sarcoma, and Clear Cell Sarcoma**

The epithelioid, synovial, and clear cell sarcomas are among the more common primary soft-tissue malignancies in the distal portion of the upper extremity, distal to the elbow (1,8,18,22,35,46,47,61,74,77,83,106,111,114,126,139,148,152,155).

These lesions are grouped together because of their similar aggresive behavior and their tendency to present in a confusing and atypical fashion. Their spread is seemingly unpredictable, and they can include skin, vessels, and lymphatics at secondary regional and distant sites. Unfortunately, these neoplasms have a grave prognosis. For that reason, an otherwise benign-appearing, solid soft-tissue lesion in the hand or wrist must be approached with caution. Incisional biopsy with appropriate technique (Chapter 129) is important, as the tumor may turn out to be one of these potentially lethal sarcomas.

Once the diagnosis is established, appropriate multidisciplinary evaluation and staging, and surgical and medical treatment, including axillary node dissection (increasingly preceded by sentinel node biopsy) is advised. Radiation has been helpful in some cases; the value of radiation and chemotherapy is not yet well defined or entirely dependable, but it is increasingly part of the primary treatment.

**SKELETAL TUMORS**

**CARTILAGE TUMORS**

**Enchondroma**

The solitary enchondroma is arguably the most common bone tumor in the hand. In the vast majority, the tumor presents as a pathologic fracture. It is most common in young adults. This speckled osteolytic lesion may be discovered incidentally on radiographs taken for another reason (Fig. 74.13), or because of enlargement of a finger or hand. However, pain is unusual without fracture.

*Figure 74.13. A: Expansile lytic lesion of the proximal phalanx of the middle finger was found incidentally on radiographs done for a little finger injury. Speckled radiographic appearance is typical for an enchondroma. The patient declined treatment of this relatively large, albeit asymptomatic, lesion. B: Two years later, a radiograph following a minor trauma showed a pathologic fracture through the slightly further enlarged tumor. C: Curettage and bone grafting were performed to treat the tumor and stabilize the phalanx. Graft incorporation and remodeling occurred without incident.*

Very small enchondromas need only periodic observation. Plan to treat larger and enlarging tumors, as well as those associated with fractures. The presence of a fracture through the lesion does not ensure spontaneous tumor resolution during the course of bone healing. These tumors are amenable to adequate curettage. Most commonly, autogenous bone graft is added; but thorough curettage is the most important surgical step.

We prefer to treat both the lesion and the pathologic fracture simultaneously, to minimize morbidity and avoid double disability. In some patients, the addition of internal fixation, commonly with Kirschner wires, plus bone graft will be needed to stabilize the curedtted infracted bone. Delay of surgical treatment until the bone has healed is a more traditional approach, but this can prolong a patient's disability because the hand has to recover first from the fracture and then from subsequent surgery. Furthermore, delay in treating the lesion delays the diagnosis, should the osteolytic tumor prove to be other than an enchondroma (12,73,116). Start postoperative hand therapy as soon as practical, considering the skeletal stability following trauma and treatment, in order to minimize tendon adhesions and joint stiffness.

**Multiple Enchondromatosis**

Multiple enchondromatosis (Ollier's disease) is far less common than solitary lesions, but these multiple tumors have a tendency to be larger and unilateral, and they are associated with skeletal deformities (Fig. 74.14) (16,51). Ollier's disease is probably not hereditary. Maffucci's syndrome is Ollier's disease with associated angiommas of skin or soft tissue. The hand is most commonly involved, with tumors generally beginning in the metaphysis but gradually extending distally into the diaphysis, or proximally to the former epiphysis in adults. These lesions require curettage and en bloc excision; often the bone deformity will need osteotomy for finger realignment.
The risk of sarcomatous degeneration is considerably higher with multiple growing lesions and should be suspected if tumors become painful, begin to enlarge, or are associated with progressive deformity. Do an incisional biopsy to rule out malignancy.

**Chondrosarcoma**

Chondrosarcomas in the hand are very rare but not unknown. Findings of histologic atypia in a cartilaginous lesion should not be regarded as a necessarily clinically worrisome issue. Consider the clinical presentation and histologic situation together—especially in the older or at-risk patient. Most malignancies are low grade. (See Chapter 128.)

**Osteocartilaginous Exostoses or Osteochondroma**

Exostoses, both solitary and multiple, often originate as a hereditary problem that may cause significant and generalized skeletal deformities. Although the tubular bones of the hands are less commonly affected than the radius and ulna, they may be involved. Symptoms are generally caused by the presence of a bony mass, and complaints may include deformity (in the growing skeleton) and progressively diminished mobility because of bony block-to-joint motion. Treatment should include removal of the space-occupying lesion while preserving skeletal integrity and nearby soft tissues. The risk of malignant transformation of lesions in the hand is extremely low. The significant problem associated with these tumors is the need for reconstructive surgery to restore functional alignment of the (small and large) bones in the forearm, wrist, and hand (20-24,25,153).

Surgical treatment and reconstruction (as multiplanar osteotomy) require great care to avoid injury to the growing physis when the osteochondroma is found, because they typically are close to the physis plate. Bowing of the radius or ulna, shortening of the forearm, and limitation of forearm rotation can be a reconstructive challenge necessitating tumor treatment and lengthening of any involved bones. Removal of the mass will not, per se, correct the deformity or necessarily restore lost joint motion, which may be accompanied by secondary fibrosis (see Chapter 127).

**BONE TUMORS**

**Giant Cell Tumor of Bone**

A giant cell tumor (GCT) of bone is relatively uncommon in the hand and wrist. It is usually a tumor of younger adults and may be associated with multicentric foci when found in the upper limb. The behavior of multicentric GCTs is different from that of solitary lesions. Those of the small tubular bones should always be considered more aggressive than those presenting in the larger bones (10,26,62,55,56,104,120,132,134,136,151,161). Small multicentric foci are not easily diagnosed on routine radiographs; do a bone scan when a GCT of bone is suspected to avoid missing the multicentric variant. Patients complain of pain and enlargement of the part, and localized tenderness. Pain may be due to an impending or pathologic fracture.

Curettage—with or without bone graft—and bone substitutes, bone cement, and other techniques have been used for GCT for various locations. When in the distal portion of the upper extremity, these tumors are likely to recur, however (Fig. 74.15). It is our opinion that GCTs of tubular bones in the hand and of the distal radius and ulna should be treated by en bloc excision or by ray resection with simultaneous replacement and reconstruction with bone graft, vascularized graft, or osteoarticular allograft, appropriate to the specific case. The precise surgical technique and approach depend on the particular lesion and patient. Tailor postoperative rehabilitation to the particular reconstructive procedure. See Chapter 127 for a more extensive discussion.

**Aneurysmal Bone Cyst**

Aneurysmal bone cyst (ABC) is a benign hemorrhagic and cystic tumor of bone with a propensity for local recurrence (Fig. 74.3E, Fig. 74.3F, Fig. 74.3G, Fig. 74.3H and Fig. 74.3I). It is relatively uncommon in the hand. Most often it is a solitary, expansive lesion originating in the metaphysis of a long bone that has a "blown-out" appearance on the radiograph. ABC tends to be more common in the second and third decades, with a slight predominance for women. En bloc excision is the most dependable treatment. Radiographically, this tumor may be confused with GCT of bone, or with bone cyst, osteosarcoma, or Ewing's sarcoma. ABC, however, has a much lower recurrence rate than GCT of bone.

**Osteoid Osteoma or Osteoblastoma**

Osteoid osteomas and osteoblastomas are benign, bone-forming tumors that often present as painful but otherwise radiographically obscure lesions in young patients. The propensity for a locus in the hand is not high, but it has to be considered in patients with localized pain and apparent enlargement of a small bone in the hand with periosteal an endosteal new bone formation (Fig. 74.16).
Figure 74.16. A: Swelling and pain of 2 years’ duration in a 17-year-old boy whose radiographs show retrocondylar bone formation surrounding a central, lucent nidus. B: At surgery, the diagnosis of osteoid osteoma was confirmed and the lesion was successfully treated by curettage.

The most difficult challenge in treatment is making the diagnosis. If plain films are nonspecific, a CT scan of the lesion using fine cuts is most likely to identify the nidus, which is diagnostic. Excision without recurrence is typical if the tumor nidus is excised (5,13,37,38,71,75,91,110).

Osteosarcoma

High-grade intramedullary osteosarcoma is extremely uncommon in the hand and wrist (14,27,40,57,63,92,127,150). Of the various subtypes, the parosteal, periosteal, and low-grade central osteosarcomas have a lower incidence of metastasis and a higher overall survival than osteoblastic, chondroblastic, fibroblastic, and telangiectatic osteosarcomas.

Evolution and advancement in staging and multidisciplinary therapies have improved survival to nearly 70% in some series. Frequently, preoperative (neoadjuvant) chemotherapy is combined with other methods, including surgery. Pulmonary metastasis is the primary cause of death; however, limb salvage following regional or systemic neoadjuvants, combined with simultaneous (and most often complex microvascular) reconstruction, can salvage a useful hand without increased morbidity and mortality (see Chapter 128 and Chapter 129).

AUTHORS’ PERSPECTIVE

We emphasize here the principles of diagnosis and treatment for hand tumors rather than making an attempt to review every tumor or related condition that may present in the hand. Certain specific neoplasms have been described because they are common or could lead to death.

We strongly believe that surgeons treating tumors of the hand must be part of an oncology team. This team must be experienced and prepared to diagnose, biopsy, and excise these tumors, and simultaneously reconstruct the hand. Such a team includes musculoskeletal oncologists, medical oncologists, reconstructive surgeons, and radiation therapists, as well as experienced musculoskeletal pathologists. Treatment should achieve a cure, and function should be preserved whenever possible. Balancing these considerations may not be easy, but it is important to the patient’s daily function, and ultimately to their survival.

Kenji Takagi described the first successful arthroscopy in 1920 (55). His primitive arthroscope had only limited utility, but over the next several decades he continued to improve the quality of arthroscopic equipment. In the late 1970s, an arthroscope suitable for use in small joints was developed, leading to Chen’s description of wrist arthroscopy in 1979 (9). Over the last 20 years, wrist arthroscopy has advanced from a diagnostic to a therapeutic procedure as the principles of open surgical procedures have been adapted to the arthroscope (1, 14, 15, 23, 35, 33, 36, 38, 46, 49, 50, 63, 66). As in larger joints, this less invasive method may have decreased morbidity and shortened recovery time. Only time and careful evaluation of treatment outcomes will determine the ultimate benefit of each specific procedure.

**INDICATIONS**

Wrist arthroscopy has both diagnostic and therapeutic indications. It can be used to confirm findings suggested by other diagnostic studies as well as for the diagnosis of wrist pain of unknown etiology. Indications for wrist arthroscopy are listed in Table 75.1.

**EQUIPMENT**

**Setup**

- Position the patient supine on the operating table with the upper extremity supported on a hand table. Place a padded pneumatic tourniquet on the upper arm. In our experience, inflation of the tourniquet is required in approximately 90% of cases.
- Because of the small joint volume and the tightness of the wrist capsule, visualization requires distraction. Obtain distraction through suspension of the extremity from overhead. We prefer a distraction tower placed on the hand table (Fig. 75.1), as this allows conversion to open procedures without the need for redraping.

**Instrumentation**

Arthroscopic instruments fall into four general categories: Scopes, probes, grasping instruments, and cutting instruments. Wrist arthroscopes are generally 2.5–3.0 mm...
in diameter. An oblique viewing angle of 30° provides excellent visualization (Fig. 75.2).

**Figure 75.2.** Top to bottom: A 2.5 mm arthroscope, cannula, and camera. A 30° viewing angle provides the best perspective.

An angled probe is an extremely useful arthroscopic instrument (Fig. 75.3). Palpation with a blunt probe can help the arthroscopist define normal anatomy as well as identify pathology such as a triangular fibrocartilage complex (TFCC) injury.

**Figure 75.3.** Arthroscopic instruments.

Cutting instruments are both manual or powered. An 18-gauge needle is a versatile arthroscopic instrument. The needle is commonly used to localize the joint prior to creation of a portal. It can also be used to spear or manipulate loose bodies, and to resect the edges of a central TFCC tear. More sophisticated manual instruments include basket forceps and suction punches (Fig. 75.3).

The most commonly used powered instruments include full-radius resectors and arthroscopic burrs. Full-radius resectors are used for soft-tissue excision such as synovectomy and debridement of ligament tears. They are not well designed for work with firmer tissues such as articular cartilage. These instruments function most efficiently at lower speeds in the range of 400 rev/min (64). At higher speeds, there is insufficient time for tissue to enter the aperture of the tip. Arthroscopic burrs are useful for treatment of osseous lesions as well as for salvage procedures. These instruments work most efficiently at speeds greater than 1,200 r/min (64).

**ANATOMY AND PORTALS**

Wrist arthroscopy is performed via portals established on the dorsal aspect of the wrist. The radiocarpal portals are numbered according to their relation to the extensor compartments of the wrist. For example, the 3-4 portal is situated between the third and fourth extensor compartments (Fig. 75.4). There are also two mid-carpal portals, as well as portals for the distal radioulnar joint. Portals are established in the following manner.

**Figure 75.4.** The mid-carpal ulnar (MCU) portal is best located under arthroscopic view after the MCR portal is established. A gap between the proximal and distal carpal rows can be palpated along the midline of the fourth metacarpal. The 4-5 portal is most commonly used for radiocarpal arthroscopy. The portal is established directly distal to Lister's tubercle (approximately 1 cm) in the radiocarpal joint. It lies between the third and fourth extensor compartments. The 4-5 portal provides access to the ulnar wrist. It is located just ulnar to the fourth compartment and approximately 1 cm distal to Lister's tubercle. This portal should be established with arthroscopic visualization. The 6U portal can be used as an inflow or outflow portal. It is located ulnar to the extensor carpi ulnaris. Under arthroscopic visualization, the needle is inserted just distal to the ulnar styloid. The mid-carpal radial (MCR) portal is established 1 cm distal to the 3-4 portal, along a line bordering the radial edge of the third metacarpal. A soft depression between the proximal and distal carpal rows can be palpated.

- Determine the correct site by palpation of the surface anatomy.
- Confirm the portal site by inserting an 18-gauge hypodermic needle into the joint.
- Use a scalpel to make a 3 mm longitudinal incision through the skin only.
- Use a hemostat to bluntly dissect to the level of the wrist capsule.
- Introduce the arthroscopic sheath into the joint with a blunt trocar.

Note: Once the arthroscope has been introduced, establish subsequent portals under arthroscopic visualization. The portals are described in Figure 75.4.
DIAGNOSTIC ARTHROSCOPY OF THE WRIST

Historically, wrist arthrography was the gold standard for the diagnosis of soft-tissue wrist pathology. However, with the emergence of magnetic resonance imaging (MRI) and arthroscopy, the usefulness of this modality has been challenged \(^{(11,20,27,46,51)}\). Although it can be performed as a single radiocarpal injection, the triple injection arthrogram as described by Zinberg et al. \(^{(70)}\) is considered a better test. Inject the radiocarpal joint first. If no dye leakage is observed, inject the mid-carpal and distal radioulnar joints after the dye from the first injection has been cleared. Communication of dye between compartments indicates a tear.

Arthrography has a number of limitations. A high incidence of positive findings in the asymptomatic, contralateral wrist has led many investigators to question the significance of arthrographic findings \(^{(8)}\). Obstruction of perforations by synovitis, or a flap acting as a one-way valve can lead to false-negative tests. Positive tests give no indication of the size of a tear or the degree of instability \(^{(62)}\). A number of studies have revealed arthroscopy to have higher specificity and sensitivity than arthrography for the diagnosis of wrist soft-tissue injuries \(^{(Table 75.2)}\) \(^{(11,12,27,47,62)}\).

Table 75.2. Arthrography versus Diagnostic Arthroscopy

For the diagnosis of soft-tissue wrist pathology, MRI has become the most widely used imaging modality. An early study suggested that MRI is inferior to arthrography for the diagnosis of tears of the triangular fibrocartilage, but the MRI technology utilized at that time has become obsolete \(^{(20)}\). Many older studies relied on the "arthrogram effect," which occurs when fluid (high signal intensity on a T2-weighted image) courses through the perforated structure. Two recent studies comparing higher-resolution MRI scans with arthroscopic evaluation demonstrated sensitivity of 100% and specificity of 90% for MRI in the diagnoses of TFC tears \(^{(46,58)}\).

Potter et al. \(^{(46)}\) reported the ability to localize the site of a TFCc tear with 100% sensitivity and 75% specificity. In the diagnosis of scapholunate injuries, MRI has been reported to have a specificity of 40% to 90% and a sensitivity of 100% \(^{(24,71)}\). MRI is much less reliable for the diagnosis of lunotriquetral (LT) tears, demonstrating a sensitivity of 0% to 50% and specificity of 100% \(^{(24,71)}\).

Magnetic resonance (MR) arthrography, a relatively modern technology, involves intracarpal injection of dye followed by MRI of the wrist. This procedure theoretically combines the best aspects of both arthrography and MRI. Using this technology, Scheck et al. \(^{(51)}\) diagnosed scapholunate ligament injuries with a sensitivity and specificity of 90%. Further investigation of this technique will be required before an assessment of its utility can be made. Table 75.3 reviews the results of studies comparing these modalities to diagnostic arthroscopy.

Table 75.3. MRI versus Diagnostic Arthroscopy

Therapeutic arthroscopy has become the gold standard for the diagnosis and classification of intercarpal wrist pathology. It enables the surgeon to assess the size and stability of a tear and identify the presence of associated synovitis or chondral defects.

THERAPEUTIC ARTHROSCOPY OF THE WRIST

TRIANGULAR FIBROCARTILAGE COMPLEX LESIONS

Anatomy

The TFCC is a ligamentous, cartilaginous structure composed of dorsal and volar radioulnar ligaments, the ulnar collateral ligament, the articular disc, the sheath of the extensor carpi ulnaris (ECU) tendon, and the ulnolunate and LT ligaments (Fig. 75.5) \(^{(43)}\). The complex arises from the articular cartilage on the corner of the sigmoid notch of the radius and inserts into the base of the ulnar styloid as well as the ulnolunate and lunotriquetral ligaments. The dorsal and volar radioulnar ligaments are fibrous thickenings within the dorsal and volar edges of the triangular fibrocartilage. The central disc is the thinnest portion of the complex \(^{(10)}\). The vascularity of the TFCC has been well studied \(^{(6,58)}\). Like the knee's meniscus, only the peripheral 25% of the TFCC is vascularized; therefore, only peripheral tears are considered reparable.

Figure 75.5. The triangular fibrocartilage complex (TFCC) is a ligamentous, cartilaginous structure composed of the following components: dorsal and volar radioulnar ligaments, the ulnar collateral ligament, the articular disc, the sheath of the extensor carpi ulnaris tendon, and the ulnolunate and lunotriquetral ligaments.
Biomechanics

The TFCC has two important biomechanical functions. In ulnar-neutral individuals, the complex transmits 20% of axially applied loads from the ulnar carpus to the distal ulna (43). The percentage of the load transmitted is directly proportional to the ulnar variance. The TFCC is also the major stabilizer of the distal radioulnar joint (42,43 and 44).

Classification

Palmer's classification (41) of TFCC tears (Table 75.4) (Fig. 75.6) is the most commonly used. It divides injuries into two basic categories, traumatic (class I) and degenerative (class II).

Table 75.4. Palmer's Classification of TFCC Lesions

Radiologic Evaluation

Take plain radiographs with neutral rotation posteroanterior (PA) and lateral views. Carpal alignment, ulnar styloid morphology, and ulnar variance can be assessed through these views. Clenched-fist radiographs in full ulnar deviation may show evidence of dynamic variance changes. The role of more advanced imaging studies such as arthrography, triple-phase bone scan, and MRI remains controversial.

Treatment

If not associated with significant instability of the distal radioulnar joint, the majority of TFCC injuries can be treated with 4 weeks of immobilization (Fig. 75.7) (37). A peripheral tear would be expected to heal because of its excellent vascular supply. In some patients, a local injection of corticosteroid to relieve inflammation, as well as a short course of wrist therapy, may be helpful. Many central tears may become asymptomatic despite their inability to heal (37).

Debridement of Central Perforation of the TFCC

- Evaluate the radiocarpal joint through the 3-4 portal (Fig. 75.8A).
Figure 75.8. A: Class I-A central traumatic tear of the TFCC. Note that the ulnar head is deep to the radius, indicating negative ulnar variance. B: Class I-A after debridement. Note the stable TFC rim and normal distal ulnar articular surface. L, lunate; TFC, triangular fibrocartilage; U, ulna; R, radius.

- Use the 4-5 or the 6R portal for instrumentation.
- Perform a synovectomy with a full-radius resector. This important step allows proper visualization of pathology.
- Debride the central two thirds of the TFCC with a suction punch or full-radius resector (Fig. 75.8B). A banana blade can also be used to resect the unstable portion of the TFCC. Do not use the distal ulna as a cutting board. Avoid injury to the dorsal and volar radioulnar ligaments and the peripheral TFCC; such injury will lead to destabilization of the distal radioulnar joint (DRUJ).
- Postoperatively, splint the wrist intermittently and initiate a therapy program stressing range-of-motion (ROM) exercises for 3–4 weeks. Then initiate a graduated strengthening program. Results from the literature are shown in Table 75.5.

Table 75.5. Debridement of Central TFC Tears

Arthroscopic Repair of Class I-B TFCC Tears

- Evaluate the radiocarpal joint through the 3-4 portal. A key to the diagnosis of a peripheral tear is the loss of normal tension in the TFCC. A probe will sink into the lax tissue (Fig. 75.9A).
- Out-to-in repair: Needles are passed through the capsule and the TFC; wire loop suture is passed through one needle. 2-0 PDS suture is passed through the other needle and lassoed by a wire loop. Suture tied at the capsule level through a 1 cm incision radial to the extensor carpi ulnaris. Generally, one to three sutures are used.

Figure 75.9. A: Peripheral I-B tear. Note that the probe sinks into the lax TFC. L, lunate; TFC, triangular fibrocartilage. B: Out-to-in repair: Needles are passed through the capsule and the TFC; wire loop suture is passed through one needle. C: 2-0 PDS suture is passed through the other needle and lassoed by a wire loop. D: Suture tied at the capsule level through a 1 cm incision radial to the extensor carpi ulnaris. Generally, one to three sutures are used.

- Use the 4-5 or the 6R portal for instrumentation.
- Perform a synovectomy using a full-radius resector.
- Debride the edges of the tear with the full-radius resector.
- Make a 1 cm longitudinal skin incision radial to the ECU tendon. Then sharply open the radial aspect of the ECU tendon sheath.
- Retract the ECU and place two needles from the meniscal repair kit through the floor of the sheath and across the tear under arthroscopic visualization (Fig. 75.9B).
- Pass a 2-0 PDS (Meniscal MenderII, Instrument Maker, Inc., Okemos, Michigan) suture through one needle.
- Retrieve the suture with a wire loop passed through the other needle (Fig. 75.9C).
- Remove both needles, reapproximate the tear, and tie the suture over the dorsal wrist capsule. Multiple sutures may be necessary (Fig. 75.9D).
- Postoperatively, place the upper extremity in a long-arm splint with the forearm in neutral rotation and the wrist in neutral flexion and mild ulnar deviation. After suture removal, change to a long-arm cast for immobilization for a total of 6 weeks. Then splint intermittently and begin a therapy program stressing ROM initially, followed by a graduated strengthening program. Outcomes are detailed in Table 75.6.

Table 75.6. Repair of Peripheral TFC Tears

Arthroscopic Repairs of Class I-D TFCC Tears Class I-D TFCC lesions involve radial detachment of the triangular fibrocartilage from the sigmoid notch of the distal radius. Normally, the articular cartilage of the distal radius continues around the medial corner and into the sigmoid notch. The triangular fibrocartilage originates from this articular location. Given this cartilage barrier, the healing potential for the TFCC at this site should be poor. If the cartilage is disrupted manually or by fracture, however, the triangular fibrocartilage can be reattached to vascularized bone. To perform this repair arthroscopically, we use an alignment guide similar to that described by Jantea et al. (23).
Class I-D lesions often accompany distal radius fractures. In this scenario, we use either 0.35 or 0.45 Kirschner wires (K-wires) to pin the triangular fibrocartilage back to the radius. The pins are left percutaneous and removed at 4 weeks.

- Evaluate the radiocarpal joint through the 3-4 portal.
- Use the 4-5 portal for instrumentation.
- Use a burr to debride the TFC attachment site to allow healing to fresh cancellous bone.
- Temporarily fix the TFC to the radial attachment site with a K-wire directed from the ulnar wrist.
- Place an alignment guide over the K-wire.
- Make a longitudinal incision between the first and second extensor compartments. Dissect bluntly to the wrist capsule.
- Drill an 18-gauge spinal needle through the jig into the radius, exiting at the radial reattachment site and the TFC.
- Place a second 18-gauge needle parallel to the first.
- Place a 2-0 PDS suture through one needle.
- Retrieve the suture with wire loop placed through the other needle.
- Reapproximate the tear and tie the suture over the wrist capsule.
- Postoperatively, place the upper extremity in a long-arm splint with the forearm in neutral rotation and the wrist in neutral flexion and mild ulnar deviation. After suture removal, change to a long-arm cast to immobilize the wrist for a total of 6 weeks. Then splint intermittently and begin a therapy program stressing ROM initially, followed by a graduated strengthening program.

The only available data regarding TFCC repair or debridement have been reported in case series ([Table 75.5](#), [Table 75.6](#)) ([13](#), [14](#), [21](#), [22](#), [32](#), [36](#), [50](#), [59](#)), and no randomized controlled studies have been published. Because of the lack of normalized data, it is difficult to compare the results of open versus arthroscopic treatment of TFCC injuries.

The theoretical advantages of arthroscopic treatment for TFCC tears include improved visualization of the tear as well as any associated intracarpal pathology and, in the case of TFCC debridement, earlier postoperative mobilization. Although the available data indicate that arthroscopic treatment offers comparable or superior results, further investigation with longer follow-up is warranted.

### Class II: Degenerative Lesions

Degenerative tears of the TFCC occur secondary to a chronic increase in the load borne by the ulnar side of the wrist. This problem tends to be progressive once it becomes symptomatic; therefore, surgical correction is often advised. The etiology of this “ulnar impaction syndrome” may be primary or secondary ([Table 75.7](#)).

#### Table 75.7. Causes of Ulnar Impaction

<tr>
<td>Perforating injuries of radius following radial head resection</td>
<td></td>
</tr>
</tbody>
</table>

Class II degenerative lesions are seen in older patients who have ulnar-sided wrist pain and no history of recent trauma. Such patients may have had a distal radius fracture in the past. On physical exam there is distal ulnar tenderness. A TFCC compression test is positive and there may be LT instability. Take PA and lateral plain film radiographs to assess ulnar variance and DRUJ congruity. Cystic lesions may be present in the ulnar lunate or distal ulna. A grip view shows the presence of dynamic ulnar impaction, and MRI reveals focal signal intensity changes in the ulnar part of the lunate and tears of the TFCC.

Arthroscopic examination should include evaluation of the chondral surfaces, the TFCC lesion, and the LT joint.

**Treatment** The primary goal of treatment is to decompress the ulnar aspect of the wrist. Treatment options include ulnar shortening osteotomy, partial ulnar-head resection, ulnar salvage procedures, including the modified Darrach procedure and hemiresection arthroplasty of the distal radial ulnar joint ([Fig. 75.10](#)).

#### Figure 75.10. Treatment of degenerative tears of the TFCC.

Partial resection of the ulnar head, also known as the wafer procedure, can be performed via an open procedure or arthroscopically ([17](#), [30](#), [69](#)).

**Arthroscopic Wafer Procedure**

- Perform triangular fibrocartilage tear debridement as described previously. Note that the triangular fibrocartilage is usually fibrillated. The ulnar head has significant chondromalacia and is prominent ([Fig. 75.11](#)).
Figure 75.11. A: Degenerative TFC tear. Note the fibrillated appearance of the TFC. B: Degenerative changes of the ulnar head, which is prominent. Arthroscopic wafer resection of the ulna was performed.

- Using a 4 mm burr introduced through the 6R portal, excise the distal ulna through the perforation in the TFCC. Rotate the forearm as you do so to allow even leveling of the joint. Knowing the size of the burr will help you to assess the depth of your resection.
- Negative ulnar variance of 2 mm is acceptable.

The only available data regarding the wafer procedure have been reported in case series (Table 75.8) (17,30,52,69). No studies directly comparing the results of the open versus the arthroscopic procedure have been published. Although the available data indicate that arthroscopic treatment offers comparable or superior results, further investigation with longer follow-up is warranted.

### SCAPHOLUNATE TEARS

#### Anatomy

The interosseous scapholunate ligament is a C-shaped structure comprising dorsal, volar, and central components. The fibrous dorsal and volar components are the major stabilizers, while the membranous central component adds little to the ligament's strength (6).

Diagnosis of a scapholunate tear is made on the basis of history, physical examination, and radiography and arthroscopy. Some patients have experienced a fall on the outstretched hand with the wrist in dorsiflexion, but often there is no history of trauma.

Physical examination may reveal dorsal carpal soft-tissue swelling. There is tenderness over the dorsal scapholunate interval and over the anatomic snuff box and possibly the scaphoid tuberosity. There is decreased wrist motion and a scaphoid shift test is positive.

#### Radiologic Evaluation

Radiologic evaluation should begin with plain film radiographs including neutral rotation PA, lateral, and clenched-fist views. The key radiographic features of scapholunate dissociation are an increased scapholunate gap (PA and clenched-fist PA views), palmar flexion of the scaphoid (lateral view), and cortical ring sign, which represents an axial projection of flexed scaphoid (PA view).

#### Arthroscopy

Arthroscopy provides an excellent means of diagnosing and characterizing scapholunate injuries. The intrinsic scapholunate ligament can be easily seen from either the 3-4 or an ulnar radiocarpal portal. An ulnar portal is generally better as it allows easy access for a palpating probe through the 3-4 portal and provides excellent visualization of the volar, central, and dorsal portions of the ligament. Important information regarding ligament instability can also be obtained through mid-carpal arthroscopy. The alignment of the concave surface of the scapholunate joint is more easily assessed because the overlying interosseous ligaments are absent.

#### Classification

Watson et al. (61) have developed a classification system for scapholunate injuries. This system is based on physical and plain radiographic findings (Table 75.9). Scapholunate ligament injuries can also be classified according to their arthroscopic appearance (Table 75.10).

#### Treatment

No ideal, predictable treatment for scapholunate instability has been described. The open surgical treatment options for acute and chronic cases of scapholunate ligament lesions are described elsewhere (see Chapter 41). As mentioned previously, arthroscopy has a definite role in diagnosis but its therapeutic role...
Arthroscopic debridement of frayed ligament edges may be sufficient in cases of perforation of the central portion of the ligament without evidence of scapholunate interface instability (class II). In separate studies with short-term follow-up, Ruch and Poehling (49) and Weiss et al. (63) both demonstrated improvement in 85% of their cases.

Arthroscopic reduction and percutaneous stabilization of unstable scapholunate intervals is based on the belief that a stable ankylosis can result from immobilization and adhesion formation along pin tracks across the joint. Whipple (66) reported a series of 40 patients with scapholunate instability treated in this manner with 2- to 7-year follow-up. He determined that 85% of patients treated within 3 months of symptom initiation who had less than a 3 mm difference in the scapholunate gap as compared with the normal contralateral side maintained stability and comfort. He noted only a 53% success rate if these selection criteria were not met.

Arthroscopic Debridement, Reduction, and Percutaneous Stabilization of Scapholunate Ligament Injuries

- Arthroscopically evaluate the radiocarpal and mid-carpal joints.
- Insert the scope via the 6R portal.
- Use the 3-4 portal as an instrument portal.
- Debride the interosseous scapholunate ligament with a suction punch or full-radius resector.
- Transfer the scope to the ulnar mid-carpal portal.
- Debride the STT articulation through the radial mid-carpal portal.
- Insert 0.045-inch K-wires from the dorsal wrist into the scaphoid and lunate. These will be used as “joysticks” to manually reduce the scapholunate joint.
- Insert 0.045-inch K-wires into the proximal scaphoid via the anatomic snuff box (avoid the radial artery, dorsal radial sensory nerve, and tendons). A 14-gauge angiocatheter can be used as a soft-tissue protector.
- Reduce the scapholunate interval using dorsally placed K-wires. Extend the scaphoid and flex the lunate. Confirm the reduction arthroscopically.
- Drive the radially based K-wires across the scapholunate interval. Add one more pin for a total of three. The goal is to create enough fibrosis to provide stability.

LUNOTRIQUETRAL TEARS

Anatomy

Like the scapholunate ligament, the LT ligament is a C-shaped structure with three components. There are fibrous dorsal and volar stabilizers and a membranous central portion.

Diagnosis is made on the basis of history, physical exam, and radiologic evaluation. The patient's history may include a fall on the dorsiflexed wrist. The patient has ulnar-sided, mechanical wrist pain, frequently with clicking. Physical exam reveals point tenderness over the LT joint. An LT shock test is positive: dorsal/volar translation of the triquetrum and pisiform while the lunate is stabilized causes crepitus and pain.

Plain radiographs often appear normal. Check ulnar variance on the PA view to help rule out ulnocarpal impaction. Bone scans will reveal increased uptake over the LT interval.

Treatment Options

Traumatic LT tears must be differentiated from degenerative tears secondary to ulnocarpal impaction. Treat the latter with an ulnar carpal decompression procedure. Mild tears can be treated conservatively with nonsteroidal anti-inflammatory medications, local corticosteroid injections, and brief periods of immobilization. Treatment options for more severe injuries include ligament repair, ligament reconstruction, and intercarpal arthrodesis. Arthroscopic treatment, including ligament debridement and reduction with percutaneous pinning, is also possible. Debride ment is indicated in cases of partial, stable ligament tears (46). Complete tears with LT instability can be treated with arthroscopic reduction and percutaneous stabilization if there is no associated volar intercalated segmental instability or positive ulnar variance (69). Such cases require open procedures.

Arthroscopic Debridement, Reduction, and Percutaneous Stabilization of LT Ligament Injuries

- The LT ligament is best viewed through the 6R or the 6U portal.
- Debride LT tears with a full-radius resector introduced via the 3-4 portal. Evaluate LT stability via the radial mid-carpal portal. A stepoff or gap at this articulation, and proximal hamate chondromalacia indicate significant instability.
- Reduce the LT articulation under arthroscopic visualization from the radial mid-carpal portal.
- Insert multiple 0.045-inch K-wires across the LT interval.

Osterman and Seidman (39) reported 80% good to excellent results in 20 patients treated in this manner at 32-month follow-up. They concurred with Pin et al. (45), noting the importance of differentiating isolated LT tears from cases of ulnar impaction, as the latter group requires an additional procedure—ulnar shortening osteotomy or arthroscopic wafer—to decompress the ulnocarpal joint.

DISTAL RADIUS FRACTURES

Anatomic or near-anatomic reduction of the articular surface in cases of intraarticular distal radius fracture has become the standard of care since Knirk and Jupiter reported their findings in 1986 (25). They showed that 91% of patients with articular incongruency of 1–2 mm after reduction developed radiocarpal arthritis within 6 years. Their findings were confirmed in additional studies (7,34). Wrist arthroscopy has become a valuable tool in the treatment of a small percentage of these fractures. Arthroscopy allows visual assessment of the congruency of the articular surface as well as for the diagnosis of concomitant ligamentous injury (18). It can be used in conjunction with various fixation techniques such as percutaneous pinning, external fixation, and open reduction with internal fixation. The indications for arthroscopic assistance in the treatment of distal radius fractures include the following:

- Intraarticular fractures with more than 2 mm of intraarticular stepoff
- Any distal radius fracture with a suspected associated carpal ligamentous injury

Arthroscopy is contraindicated in cases of compartment syndrome, severe soft-tissue injury, absent median nerve function, or open joint injury.

Arthroscopic Reduction

Arthroscopic reduction should be performed between 3 and 7 days after injury (Fig. 75.13). If done more acutely, visualization might be obscured by bleeding, and after 7 days, fractures become more difficult to reduce. Palpation of extensor tendon intervals may be difficult on account of soft-tissue swelling. Other landmarks, such as the radial border of the long finger and the mid axis of the ring finger (longitudinal axes of the 3-4 and 4-5 portals, respectively) can usually be identified. Fluoroscopy may aid in placing needles and establishing portals. Traction is essential as ligamentotaxis helps with gross fracture reduction. Traction can be applied through the standard wrist tower, through finger traps and weight suspended off the end of a hand table, or, in cases where external fixation is comprehensive.
indicated, through the fixator itself.

Figure 75.13. A: Comminuted intraarticular distal radius fracture. B: Arthroscopic view showing disruption of the articular surface. L, lunate; R, radius. C: Arthroscopic reduction with use of both external and internal fixation. D: Postoperative reduction with anatomic alignment of the articular surface.

- Evaluate the radiocarpal joint via the 3-4 portal.
- Establish an outflow cannula at the 6U portal. Note: It is critical to maintain outflow to limit fluid extravasation and prevent compartment syndrome.
- Thoroughly debride the joint of fibrin clot and debris, use a full-radius resector introduced via the 6R portal.
- Reduce fractures with 0.062-inch K-wires placed percutaneously and used as joysticks.
- Stabilize the fragments with percutaneously placed 0.045- or 0.062-inch K-wires. Reduce the radial styloid fragment first and stabilize it with two 0.045-inch K-wires or a cannulated screw.
- If present, next reduce the lunate “die-punch” fragment to the radial styloid by elevating the impacted fragment with one or more K-wires. Stabilize the die-punch fragment with two transverse 0.045-inch K-wires running from the radial styloid. Note: Melone four-part fractures usually require open reduction of the volar die-punch fragment. Perform this procedure through a limited, volar incision placed between the finger flexors and the ulnar neurovascular bundle. Elevate the fragment and stabilize it with a small buttress plate.
- Bone-graft metaphyseal defects through limited incisions once the fragment fixation is completed.
- Evaluate the wrist for associated soft-tissue injuries.

In a series of 27 patients with intraarticular distal radius fractures treated by one of us (ALO), a significant number had associated soft-tissue injuries of the wrist, including scapholunate and LT ligament tears as well as injuries to the TFCC (15).

Two series (15,67) of patients with intraarticular distal radius fractures have described excellent results with the use of arthroscopically assisted reduction. At an average 27-month follow-up, Wolfe reported seven of seven patients returning to work with range of motion and maximal grip strengths averaging 92% and 98% of the uninjured side, respectively. Over the same average follow-up period, Culip and Osterman (15) reported 22 good or excellent results out of 27 cases.

SCAPHOID FRACTURES

The scaphoid is the most commonly fractured carpal bone. These fractures tend to occur in young, male laborers. Thumb spica-cast immobilization is the standard treatment for the vast majority of scaphoid fractures. Because the scaphoid has a high rate of delayed union and nonunion, prolonged immobilization (a minimum of 3 months) is required. Open reduction and internal fixation are indicated for displaced fractures, as well as in cases of nondisplaced fractures in patients for whom cast immobilization presents an undue hardship. Arthroscopic reduction and internal fixation also has a role in the treatment of patients with scaphoid fractures.

Arthroscopic Reduction

One of us (ALO) uses the equipment developed by Whipple (65) to facilitate scaphoid fixation. A standard arthroscopic setup is employed.

- Scaphoid displacement is best assessed via the mid-carpal radial (MCR) portal.
- Evacuate hematoma and debris with a full-radius resector via the mid-carpal ulnar (MUC) portal.
- If necessary, reduce the fracture through either direct manipulation of the scaphoid or the use of percutaneously placed joysticks.
- Stabilize the fracture with an 0.045-inch K-wire.
- Make a 2 cm incision radial to the flexor carpi radialis and centered over the scaphotrapezial joint. Continue dissection bluntly to the volar joint capsule. Elevate the capsule and excise the volar tubercle of trapezium.
- Place the arthroscope in the 4-5 portal and introduce the target hook of a Whipple compression jig through the 1-2 portal. Seat the hook on the dorsal aspect of the scaphoid 1–2 mm radial to the scapholunate ligament. Slide the guide barrel down to exposed articular surface of scaphoid and compress the jig. Use the guide pin to confirm correct placement.
- Place an accessory pin to control rotation.
- Place an appropriate-length Herbert–Whipple screw.
- Immobilize the extremity in a thumb spica splint for 10 days.
- Initiate protected wrist mobilization at 2 weeks.

Whipple (65) has reported his series of 20 cases of scaphoid fracture treated with arthroscopically assisted reduction and internal fixation. All fractures healed by the 12-month follow-up. The period of cast immobilization ranged from 3–4 weeks.

SYNOVECTOMY

The possible etiologies of carpal synovitis include traumatic disorders, rheumatoid arthritis, pigmented villonodular synovitis, infections, and crystal deposition disorders such as gout and pseudogout. The differential diagnosis can often be narrowed by determining the location of hypertrophied synovium as well as the extent of its inflammation. The most common reason to perform arthroscopic synovectomy is debridement of tissue that is obscuring visualization. For example, symptomatic ligament tears are often associated with a localized synovitis; to diagnose and treat the injury, the synovial tissue must be removed. Removal of tissue is best accomplished with either a full-radius resector or a more aggressive side-cutting blade. Synovectomy is most efficiently performed with shaving speeds less than 600 rpm and oscillation of the cutting blade (64).

Complete carpal synovectomy may be indicated in cases of rheumatoid or septic arthritis. In patients with rheumatoid arthritis, whose symptomatic wrists are resistant to medical management but who have preserved joint spaces, open or arthroscopic synovectomy may provide symptomatic relief. The arthroscopic technique offers superior visualization and easier access to the synovium of all the wrist compartments than does open synovectomy. Usually, a complete synovectomy can be performed by alternating the arthroscope and full-radius resector between the 3-4 and 6U portals. Occasionally, the 1-2 or 6U portals may be required. Arthroscopy of the mid-carpal joint and the DRUJ is also performed. To examine the DRUJ, distract the wrist while it is in supination. Establish the viewing portal proximally and place the working portal just proximal to the TFCC.

Arthroscopic synovectomy is contraindicated in cases of associated dorsal tenosynovitis. This tenosynovium can be removed only through an open procedure.

Adolfsson and Nylander (1) described the treatment by arthroscopic carpal synovectomy of a series of 18 patients with rheumatoid arthritis. All patients noted a decrease in their pain and significant improvements in range of motion. Overall, morbidity and complications for arthroscopic synovectomy, particularly in terms of postoperative wrist stiffness and length of rehabilitation time, have been shown to be less severe than those incurred by open synovectomy (54).

Septic arthritis of the wrist requires prompt debridement. Arthroscopic management of sepsis has been shown to be effective in larger joints such as the knee and shoulder. Although no studies have addressed the role of arthroscopy in the treatment of wrist sepsis, its use is a logical consideration. In a series by one of us (ALO), six patients with septic arthritis were treated with arthroscopic drainage and appropriate antimicrobial therapy, and all had a successful outcome. Until the efficacy of
this approach is fully established, it should be employed with caution.

DORSAL WRIST GANGLIA

Ganglia are mucin-filled cysts that are closely associated with either joints or tendon sheaths. They represent the majority of all soft-tissue tumors of the hand and wrist. The dorsal wrist ganglion is the most common of these cysts. Patients generally request treatment for their ganglia for cosmesis or because of discomfort or functional disturbances. Current treatment options include no treatment, aspiration with or without cortisone injection, and surgical excision. No treatment is not an unreasonable course of action in light of the spontaneous resolution rates of 28% to 58% that have been reported (18). Aspiration, with or without cortisone injection, has a reported success rate of 35% to 50%, whereas recurrence rates after surgical excision have been as high as 40%.

The key to successful surgical treatment is excision of the ganglion stalk and a small portion of the dorsal wrist capsule. Since the majority of dorsal wrist ganglia arise from the scapholunate interval, arthroscopic identification and excision of the stalk are possible in many cases. The advantages of arthroscopic excision over open excision are believed to be decreased wrist stiffness and an earlier return to function. Additionally, the arthroscope allows the identification of any additional carpal pathology that might be present.

Arthroscopic Ganglion Excision

- Circle the ganglion with a marker (Fig. 75.14A).
- Approach the radiocarpal joint via the 6R portal to give best access to the stalk.
- Look for the stalk of ganglion arising from the dorsum of the scapholunate interval (Fig. 75.14B).
- If the stalk is not visualized (and it is not visualized one third of the time) resect 1 cm of dorsal capsule at the dorsal scapholunate angle with a suction punch or motorized shaver.
- If the stalk can be visualized, debride it with a suction punch or motorized shaver via a portal placed through the ganglion (usually the 3-4 portal).
- Resect 1 cm of the dorsal capsule with a suction punch or motorized shaver.
- Complete your arthroscopic evaluation of the wrist (including the mid-carpal joint).
- Ensure that the extrarticular sac has ruptured.
- Immobilize the wrist in a volar splint for 1 week.
- Use a Futuro splint as needed for comfort for up to 3 weeks with early active ROM exercises for the wrist.
- Avoid strenuous use of the hand until 6 weeks after surgery.

One of us (ALO) has reported a series of 18 dorsal wrist ganglia treated with arthroscopic excision (38). The ganglion stalk was visualized in 61% of cases. At an average follow-up of 16 months, there were no recurrences. Five patients developed increased grip strength and range of motion postoperatively, whereas two experienced losses in both categories. The remainder were unchanged. Additional intraarticular pathology was identified in half the cases. The average return to work time was 3.5 weeks.

CHONDRAI DEFECTS AND LOOSE BODIES

Chondral defects are believed to be a common cause of wrist pain (3,26). There are a variety of causes of cartilage damage. Most often these lesions occur secondarily because of an existing wrist problem such as ligamentous instability, fracture, or inflammatory arthritis. Chondral defects can occur primarily as well. For example, the presence of a medial facet on the lunate is associated with an increased incidence of chondromalacia at the proximal pole of the hamate.

These defects are difficult to detect because the majority of them are not identifiable radiographically. In cases where the wrist pain is refractory to conservative treatment, arthroscopy can have a diagnostic and therapeutic role. Chondral lesions can be categorized with the system devised by Outerbridge (Table 75.11) (40).

The usefulness of debriding of chondral lesions continues to be debated. The majority of the data published on this topic comes from studies performed on arthritic knees. While several authors have reported a significant decrease in pain after arthroscopic lavage and/or debridement, these studies have been limited by follow-up periods of a year or less (4,16,28). The work of Mosely et al. (35) suggests that the benefit of arthroscopic treatment in these patients is no more efficacious than a placebo.

With these concerns in mind, the accepted arthroscopic treatment of Outerbridge lesions grades I–III involves debridement of the accompanying synovitis and fibrillation. Chondral lesions are smoothed to reduce mechanical symptoms and to minimize the production of intraarticular debris. Thick chondral flaps can be debrided with a suction punch, whereas thin flaps are best debrided with a motorized shaver.

The treatment of grade IV injuries remains controversial. While no treatment has been shown to cause repair or regeneration of hyaline cartilage, chondral abrasion appears to stimulate fibrocartilage repair. This fibrocartilage patch probably cannot hold up under physiologic loads over time but it may bind to adjacent hyaline cartilage protecting against extension of the injury.

Loose bodies are commonly caused by chondral defects and degenerative arthritis. These bodies may produce mechanical symptoms such as pain, locking, and catching. Whereas large loose bodies can often be visualized on plain radiographs, small ones often cannot. Arthroscopy provides a minimally invasive means of removing loose bodies. When performing this surgery, it is best to obtain radiographs on the day of the procedure to help confirm the location of radiopaque bodies. Use the portal closest to the loose body for the arthroscope. A separate inflow portal helps to force the body toward the arthroscope. A percutaneously placed

hypodermic needle can act as a skewer if necessary. Small loose bodies can be retrieved with a basket forceps. Larger ones may require morcellization with a motorized shaver.

**ARTHROSCOPIC RADIAL STYLOIDECTOMY**

Radial styloidectomy is an early salvage procedure that may provide symptomatic relief to patients with early radiocarpal arthritis. It is particularly useful in the treatment of patients in the first stage of scapholunate or scaphoid nonunion advanced collapse. It is often only a temporizing measure (81). The procedure can be performed either arthroscopically or in open fashion.

- Perform a standard arthroscopic evaluation, synovectomy, and debridement as necessary.
- Insert the arthroscope via the 3-4 portal and identify the radioscaphocapitate and long radiolunate ligaments. **Note: These ligaments must be preserved.**
- Introduce a 3 or 4 mm burr through the 1-2 portal and excise the styloid under arthroscopic visualization.
- Fluoroscopically confirm the amount of styloid removed.
- Arthroscopically confirm the decompression of radial impingement by radially deviating the wrist.
- Split the wrist intermittently for 3 weeks.
- Initiate active ROM exercises at 1 week and begin a strengthening program at 4 weeks.

**ARTHROSCOPIC PROXIMAL ROW CARPECTOMY**

Proximal row carpectomy is a salvage procedure for preserving motion in patients with later stages of scapholunate or scaphoid nonunion advanced collapse (57,68). Its success is based on the preservation of the articular surfaces of the proximal capitate and the lunate fossa of the radius. Arthroscopy can allow for evaluation of these surfaces as well as the performance of the procedure itself.

- Perform a standard arthroscopic evaluation, synovectomy, and debridement as necessary.
- Confirm that the proximal pole of the capitate and lunate fossae have acceptable articular surfaces.
- Establish a 4-5 viewing portal.
- Introduce a 4 mm burr via the 3-4 portal.
- Remove the proximal scaphoid.
- Initiate excision of the lunate from its radial side. **Note: Take care to avoid injuring the lunate fossa and proximal capitale.**
- Protect the proximal capitale with a Freer elevator introduced via a mid-carpal portal.
- Small osteotomes help to morcelize the bones.
- Remove large fragments with pituitary rongeurs.
- Confirm decompression of radial impingement arthroscopically by radially deviating the wrist. Perform radial styloidectomy as necessary.
- Immobilize the wrist for 4 weeks, then split intermittently while initiating ROM exercises. Introduce strengthening exercises at 8 weeks.

Proximal row carpectomy is a widely accepted salvage option for the arthritic wrist (57,68). To date, no data regarding the arthroscopic procedure have been presented.

**PITFALLS AND COMPLICATIONS**

The complication rate associated with arthroscopy of any joint is low. Small (53) observed a 0.59% rate of complications in his review of 395,000 cases. Assad et al. (2) identified 17 complications in 214 cases of diagnostic wrist arthroscopy. Reflex sympathetic dystrophy was most common (3.7%), followed by dorsal radial sensory nerve neuropaxia (2.3%) and tendon problems (0.9%). All complications resolved with nonoperative treatment.

One of us (ALO) reviewed 463 therapeutic arthroscopies he performed and noted a complication rate of less than 3%. The majority of these complications were related more to percutaneous pin fixation than to the arthroscopy. The morbidity was directly related to the technical difficulty of the procedure.

Warhold and Ruth (50) divided complications into four categories: (a) complications related to traction, (b) complications related to establishment of portals and insertion of instruments, (c) procedure-specific complications, and (d) miscellaneous complications. A list of these complications and the means of avoiding them appears in Table 75.12.

**Table 75.12. Complications of Wrist Arthroscopy**

When performed by an experienced surgeon, wrist arthroscopy is a relatively safe procedure that offers excellent visualization of the wrist with minimal soft-tissue dissection. Its diagnostic value is unquestionable. Its therapeutic usefulness continues to expand.

Chapter References

The shoulder is a complex of joints and controlling muscles that links the arm to the trunk. Large arcs of motion in all three planes allow the shoulder to perform a multitude of functions that include reaching, lifting, carrying, pushing, propelling, and placing the hand. Intricate synergy among the controlling muscles provides the necessary functional precision. Shoulder function, however, is determined not only by joint structure but also by the mode of dynamic control.

Fibrous tissue bands provide passive stability of the shoulder complex, rims and discs that Codman grouped under the gross classification of ligaments (9). These structures limit motion by the lack of tissue elasticity in the line of their collagen fibers (3% to 5% stretch). On the other hand, they allow motion in all other directions according to the characteristics of the ground substance. The bands, having a gel-like proteoglycan ground substance binding the linearly aligned collagen fibers, are the most flexible. Stiffness of dense fibrous tissue or fibrocartilaginous stroma of the discs and labral rim limits their mobility to mild bending. Each joint has a unique system of ligaments.

Mobility at the shoulder is greater than at any other joint. Three skeletal segments are used: the humerus, the scapula, and the clavicle. The most prominent patterns of motion are arm elevation and rotation. Lesser actions are depression, horizontal motion, and support of the hanging arm. Each has specific biomechanical requirements of the passive structures and selected patterns of muscle action.

PASSIVE ELEMENTS OF FUNCTION

The shoulder complex comprises four joints (Fig. 76.1). Of these, the glenohumeral joint is dominant both by its extensive range of motion and by clinical concerns. The second most important functional site is the scapulothoracic articulation. Mobility of the scapula on the thorax depends on the quality of the sternoclavicular and acromioclavicular joints. These provide the skeletal link between the scapula and the trunk.

Figure 76.1. The four critical areas of motion within the shoulder complex: (1) glenohumeral, (2) scapulothoracic, (3) acromioclavicular, and (5) sternoclavicular. Clavicular rotation (4) is the result of motion at 3 and 5.

GLENOHUMERAL JOINT

BONES

Structurally, the ball-and-socket glenohumeral joint favors mobility over stability. The ball-shaped humeral head is approximately one third of a sphere (6), with an average radius of 26.9 mm in men (women's radii are 13% smaller) (64). Opposing it is a shallow bony socket formed by the glenoid fossa of the scapula. The bony surface of the glenoid fossa opposes only the central 35% of the humeral head, but a dense fibrous glenoid labrum enlarges the socket contact area to 75% (4,65). The flexibility of this dense fibrous rim lessens the shock of impact during aggressive motion.

The glenoid socket depth is approximately 9 mm in its vertical plane and 5 mm along its anteroposterior axis. In the superoinferior direction, the labrum increases the total socket depth 50%; horizontally it adds 60%.

Early measurements of the bony surfaces indicated incongruity between the humeral and glenoid curvatures (6). Recent measurements of the cartilaginous surfaces, however, have found that both surfaces accurately approximate a sphere, with the glenoid contour not differing significantly from the humeral shape (64). Further study has identified the peripheral cartilage of the glenoid to be thicker than the center. Humeral articular cartilage thickness is quite uniform.

Alignment of the glenohumeral joint is oblique to all three basic planes. Relative to the transverse axis of the elbow, the humeral head is retroverted 20° to 35° (61). It also makes a 45° vertical angle with the longitudinal axis of the humerus. These angulations align the central axis of the humeral head with the center of the glenoid fossa of the scapula as it rests on the posterior, lateral aspect of the chest wall (55). Scapular alignment defined in the quiet standing position is approximately 30° anterior to the body’s transverse plane (33).
Anatomically, the glenoid fossa is tilted slightly upward relative to the scapular blade (2). In the quiet standing position, however, the glenoid has a 5° downward tilt (20). Horizontal alignment most commonly has 7° of retroversion (in 75% of specimens) but may reach 10° of anteversion (25%) (60).

LIGAMENTOUS STRUCTURES

Passive stability of the glenohumeral joint is provided by the glenoid labrum, which deepens the socket, a capsule that encloses the joint, and several critically aligned linear bands (commonly called ligaments). The function of each structure is to prevent displacement of the humeral head beyond the margins of the glenoid socket.

Glenoid Labrum

The glenoid labrum is a soft-tissue flap that extends peripherally from the rim of the fossa to deepen the glenoid socket (Fig. 76.2). Minor differences in labral depth have been found among the areas (varying from 3.0 to 3.8 mm), with the anterior and inferior being slightly greater than others (27). Average socket depth is doubled by the labrum. No correlation has been found between the size of the labrum and that of the glenoid (27). There is no consistency between right and left labra (44). The shape of the labrum also has been found to differ with the state of humeral head rotation (39). This latter fact supports the greater detail found by arthroscopy (11).

Investigators have described the structure of the labrum as either fibrocortilage (6,9,14) or dense fibrous tissue (11,39). Recent detailed histology has shown that the dominant composition is dense fibrous tissue without chondrocytes. Fibrocortilage is present only at the base of the more inferior portion of the labrum. Structural differences are most marked between the superior and inferior portions of the labrum (11,44). Proximally, the labrum resembles a meniscus, with a roughly triangular cross section, which is loosely attached to the glenoid rim by thin connective tissue that stretches easily [mimicking a superior labral tear from anterior to posterior (a SLAP lesion)]. The superior area (12 o'clock) of the labrum inserts directly into the biceps tendon, and some of its collagen fibers extend over the rim to the tubercle. The interval between the biceps tendon insertion site (the supraglenoid tubercle) and the glenoid rim is a small (5 mm) recess.

In contrast, the lower portion of the labrum (4 to 6 or 8 o'clock) appears as a rounded, dense, fibrous tissue extension of the articular cartilage, which is firmly attached to the glenoid rim. In this area, there is a narrow fibrocorticallaginous transitional zone joining the labrum to the hyaline cartilage margin (11,39). Mechanically, glenohumeral stability is enhanced by the joint's concave contour and the labrum. In the presence of a compressive force, the joint resists passive translation (34). Passive stability in the superior and inferior directions is approximately twice that available against anterior and posterior forces. This difference correlates with the relative depth of the glenoid fossa. Excision of the labrum reduces the joint's resistance to translation by about 20% (35).

Translation has been found during active motion in the horizontal plane only at the extremes of external rotation and extension (the cocking position) (28). Then there is a 4 mm posterior displacement, corrected by either flexion or derotation. During all other arcs of motion, the humerus remains centered on the glenoid.

Capsule

A continuous fibrous sac encloses the glenohumeral joint. Its attachment on the scapula most often is about 1 cm beyond the labrum, but approximately 20% of the capsule is contiguous with the base of the labrum. On the humerus, the capsule inserts primarily into the anatomic neck. Inferiorly, the capsule attachment drops down to the surgical neck of the humerus (7). Preservation of glenohumeral stability by an intraarticular vacuum appears to be an important function of the capsule (25,35).

With the capsule intact, researchers have found normal glenohumeral contact. Ventrimg the capsule allows easy distraction and reduces the forces required for joint translation (6,23). A cadaver study of the dependent arm with an intact capsule found no subluxation even with sectioning of all the supporting muscles (35). Puncture of the capsule, however, allowed the humeral head to drop half the height of the glenoid, whether the muscles were intact or released.

Glenohumeral Ligaments

Thickening within the anterior wall of the capsule provides structural reinforcement of the glenohumeral ligaments (GHL) to preserve passive joint stability (Fig. 76.3) (7). By their point of attachment on the humerus, these otherwise thin tissues have been designated as the superior, middle, and inferior glenohumeral ligaments (7). Initially, investigators considered these structures inconsistent (14), but recent investigations have found that they vary in size rather than presence or absence (7,18,39,45,66).

Figure 76.2. The glenoid labrum. Its peripheral margin is attached to the rim of the glenoid fossa. While both the tendon of the long head of the biceps muscle (B) and the superior glenohumeral ligament (SGHL) appear to arise from the superior margin of the labrum, the biceps tendon also has a bony attachment. (Adapted from Harryman DT et al. The Role of the Rotator Interval in Passive Motion and Stability of the Shoulder. J Bone Joint Surg Am 1992;74:53, with permission.)

Superior Glenohumeral Ligament The most superior capsular thickening arises from the labrum just anterior to the tendon of the long head of the biceps brachii at the level of the coracoid base (Fig. 76.2, Fig. 76.3, and Fig. 76.4) (7,39,66). It passes under the supraspinatus muscle and inserts on the anatomic neck of the humerus, medial to the anterosuperior base of the lesser tuberosity.

The clavicle, a mobile strut, adds some stability to the junction between the scapula and the thorax. It is expendable, however, if excised cautiously (without a clavicle (congenitally or by surgical resection) have markedly increased scapular protraction and slightly reduced (10%) strength of arm elevation but no...

The coracohumeral ligament, in combination with the superior GHL, also limits maximal forward flexion (by obligatory translation) and external rotation (28). Abduction to 90° increases IGHL tautness and its coverage of the lower half of the joint (Fig. 76.5). The major strain is in the superior (anterior) band (46). There is little measurable tension in the MGHL and visibly it appears slack.

Mechanical testing has shown that the glenohumeral ligaments restrain selective arcs of abduction and external rotation (66). With the arm dependent (abduction zero), all three ligaments are visibly slack. Strain measurements, however, register tension in the superior and middle GHLs (46). The addition of external rotation introduces tension (visible on radiographic examination of tissue markers) in the middle GHL and the superior band of the IGHL (66). Placing the arm in 45° of abduction further tightens the superior band of the IGHL. External rotation moves the superior band across the middle third of the joint and the inferior margin tightly under the humeral head. Abduction to 90° increases IGHL tautness and its coverage of the lower half of the joint (Fig. 76.5). The major strain is in the superior (anterior) band (46).

The coracohumeral ligament has been identified as the most consistent of the capsular ligaments (17). It forms a “bridge-like anterior leading edge” over the rotator interval between the supraspinatus and subscapularis muscles (17). Arising from the lateral base of the coracoid process, it joins the capsule on its exterior surface and extends to both the greater and lesser tuberosities, forming part of the roof of the bicipital tendon sheath (Fig. 76.3). 8,17,18.

Passively, the coracohumeral ligament resists inferior and posterior translation (17). During quiet standing, however, the humeral head drops about 3 mm below the center of the glenoid (65). The coracohumeral ligament, in combination with the superior GHL, also limits maximal forward flexion (by obligatory translation) and external rotation (28).

The trapezoidal coracoacromial ligament is a fibrous ribbon that forms the central portion of the coracoacromial arch (Fig. 76.4). Its greater base inserts on the underside of the acromion beyond the tip, creating a mass that varies considerably in thickness (2.0–5.6 mm). The coracoid insertion is on the apophysis (22). Studies of the skeletal arch have shown degenerative changes limited to the anterior third of the acromion. The frequency of degenerative findings is related to the slope and length of the acromion and the height of the arch (17). Acromial thickness and breadth are unrelated. The finding of an eburnated facet on the underside of the acromion is consistent with a recent mechanical study that showed the coracoacromial ligament passively restrains humeral subluxation in the shoulder with a deficient rotator cuff (17,39).
and inferiorly to the cartilage of the first rib.

The upward alignment of the clavicle with its acromial end approximately 5 cm above the sternum is maintained by a dense thickening of the superior and posterior portion of the capsule (3). Simulation of arm weight (4.5 kg) suspended from the acromial end of the clavicle has been shown to depress the clavicle 50%, but twice that load caused little additional displacement. Depression of the clavicle was accompanied by a forward movement. Conversely, the sternal end of the clavicle moved upward and backward against the dense posteroinferior part of the capsule. Avulsion of the ligament from the sternum occurred with an 18 kg weight. Gray's Anatomy emphasizes the mass of the anterior sternoclavicular ligament without a reference to Beam (3,69).

Elevation and rotation of the clavicle are limited by the costoclavicular ligaments, reinforced by a dense anterior sternoclavicular ligament and a thin posterior ligament. On the inferior surface, there is a dense, complex costoclavicular ligament spanning the first rib and clavicle. This arrangement provides good stability during the significant range of motion that occurs in all three planes (29).

### ACROMIOCLAVICULAR JOINT

The articulation between the scapula and the clavicle (Fig. 76.1) is unique because its major stabilizing ligaments are remote (coracoacromial) despite there being a discrete local ligament lying on the superior surface of the joint (acromioclavicular ligament) (23). Restraint of posterior displacement of the clavicle and posterior axial rotation have been identified as the primary function of the acromioclavicular ligaments.

Both clinical experience and mechanical testing have demonstrated that joint stability is gained mainly from the bipartite coracoclavicular ligament, which is about 2 cm medial to the acromioclavicular joint. The conoid component of the coracoclavicular ligament complex is the primary restraint to anterior and superior rotation, and to anterior and superior displacement of the clavicle. The trapezoid ligament (vertical or horizontal) provides a much lower level of clavicular restraint. The relative contributions of these ligaments change with the direction and magnitude of loading and displacement.

### MOTIONS OF THE SHOULDER JOINTS

Arm elevation is classified by its planes of action (Fig. 76.6). Flexion occurs in the sagittal plane. Abduction is performed in the coronal (or frontal) plane. Scaption (a new term) refers to elevation of the arm in the plane of the scapula (30° to 40° anterior to the coronal plane).

**Figure 76.6.** The basic planes of arm elevation: flexion (sagittal plane), scaption (plane of the scapula on the thorax), and abduction (coronal plane).

No significant differences have been found in the maximal ranges of the types of arm elevation. Theoretically, the maximum is 180°, but few people have such mobility: Men average 168°, women 176° (16). Within the full range of arm elevation, humeral displacement contributes about 120° and the scapula 60°.

The two bones do not move in synchrony (Fig. 76.7) (1). Inman et al. identified a 30° delay in the onset of scapular rotation (scapular lag) (39). Doody et al. found a similar predominance of humeral motion at the end of arm elevation (16).

**Figure 76.7.** Glenohumeral rhythm during scaption. The gross ratio of humeral to scapular motion is 2:1. During the first and last 30° of arm elevation, however, the humerus moves with minimal scapular participation.

### GLENOHUMERAL JOINT MOBILITY

Both flexion and abduction cause the inferior segment of the capsule to be slightly twisted (33); scaption does not. Also, inasmuch as there is more symmetry of muscle action with scaption (50,60), it represents the plane of neutral arm elevation.

The range of internal and external rotation varies with arm elevation (80). With the arm adjacent to the trunk, the range is greatest (180°), with external rotation being the larger arc (108° versus 71°) (5). Raising the arm to 90° reduces the total range to 120° and limits external rotation to 90° (forearm vertical). With full flexion or abduction, only a jog of rotation is possible. The relative contributions of humeral and scapular motion to arm rotation have not been determined.

### SCAPULOTHORACIC MOBILITY

Movement of the scapula on the thorax follows six major paths, with the direction being defined by the motion of the acromion. Upward rotation is the largest arc (60°). An undefined degree of downward rotation accompanies humeral extension behind the body line. Planar displacement of the scapula may be vertical or horizontal.

In the vertical plane, the motions are called elevation and depression. Horizontal scapular displacement is described by two terms. Moving away from the vertebral spine is either scapular abduction or protraction; conversely, movement toward the spine is scapular adduction or retraction. The second term for each motion is preferred to avoid confusion with the descriptions of total arm motion.

### CLAVICULAR JOINTS

Selected arcs of sternoclavicular and acromioclavicular motion combined with clavicular rotation provide the scapular mobility used in arm elevation (Fig. 76.8). The same motion patterns occur in flexion and abduction.
At the sternoclavicular joint, there is a slow, steady rise of the clavicle, reaching 30° during the first 90° of arm elevation, with little gain thereafter. Clavicular protraction and rotation also take place at the sternoclavicular joint. By the end of full-arm elevation (180°), the clavicle has rotated 50°.

The acromioclavicular joint provides two small arcs of motion (15°) during the first and last 40° of arm elevation with no significant action in between. Clavicular rotation is essential for the terminal arc of acromioclavicular mobility. The sigmoid contour of the clavicle relatively lengthens the coracoclavicular ligaments as the bone rotates; this lengthening permits the scapular rotation needed to complete the last 60° of arm elevation.

MUSCULAR CONTROL

The muscles controlling the shoulder perform two functions: movement of the arm and dynamic stabilization of the glenohumeral joint. The 14 muscles contributing to these functions fall into four functional groups:

1. Three heads of the deltoid (anterior, middle, posterior)
2. Four rotator cuff muscles (supraspinatus, subscapularis, infraspinatus, teres minor) plus the biceps as an optional supplement
3. Two axiohumeral muscles (pectoralis major and latissimus dorsi) plus the teres major
4. Scapular muscle group (serratus anterior, trapezius, rhomboid, and levator scapulae)

The relative significance of these muscle groups depends on the mode of arm motion being used.

ELEVATION

As the arm is elevated from a hanging position, the increasing moment resulting from the arm's weight must be overcome by increasing muscle force. Consequently, the torque that muscles must provide at 90° is twice that needed at 30°. Arm elevation combined with preservation of glenohumeral stability involves three muscle groups: the deltoids, the rotator cuff, and the scapular rotators.

Deltoids

The anterior, middle, and posterior deltoid muscles are the primary source of arm elevation. Their relative participation varies with the plane of motion. Middle deltoid action is strong in all three planes of arm elevation. Anterior deltoid involvement is greatest in flexion and scaption. The posterior deltoid has a minor role except during abduction.

Rotator Cuff Muscles

Four muscles extend from the scapula to the perimeter of the humerus. While each provides an arc of motion, they also function in synergy to stabilize the glenohumeral joint.

The supraspinatus muscle, by crossing the joint on its superior surfaces, is primarily an abductor. It also stabilizes the glenohumeral joint by compression.
The subscapularis muscle, which crosses the glenohumeral joint anteriorly, has a distribution of its fibers that fans out from horizontal to vertical. The fibers’ common function is internal rotation. The larger vertical mass provides a downward (humeral depression) force (Fig. 76.10) (30). The subscapularis is an essential component of the dynamic anterior wall that preserves joint stability during arm abduction and external rotation. With the arm dependent, the subscapularis tendon lies across the anterior surface of the glenohumeral joint. As the arm is elevated or externally rotated, the tendon moves upward, leaving the lower portion of the humeral head uncovered (68).

The infraspinatus muscle, on the posterior surface of the shoulder joint, also has a fan-shaped dispersion of its fibers. Its actions are external rotation and humeral depression. The smaller, adjacent teres minor is a second external rotator and is most active with the arm above horizontal (54).

The biceps brachii muscle, by inserting on the scapula, has a potential for influencing shoulder as well as elbow motion. The long head is more intimately involved than the short head, however, as the tendon closely contacts the humeral head. During normal function, the biceps brachii long head primarily serves the elbow independently of shoulder action (41).

The axiohumeral muscles—the pectoralis major and latissimus dorsi—extend from the chest wall to the proximal end of the humerus. They contribute to shoulder joint stability by two very different roles. With the arm dependent, these two large muscles provide a depressor force, which protects the glenohumeral joint from upward shear when the hand is being used to support the body weight. Conversely, during arm elevation and external rotation, these muscles oppose anterior shear. As it crosses the front of the joint, the pectoralis major contributes directly to the dynamic anterior wall in synergy with the subscapularis, while the latissimus acts indirectly by retracting the humerus toward the muscle’s origin. The teres major supplements the latissimus.

**Scapular Muscles**

Upward rotation of the scapula during arm elevation is accomplished by synergistic action of the two largest scapular muscles (the serratus anterior and trapezius) (Fig. 76.11). In addition, these muscles also displace the scapula across the chest wall. Two other muscles, the rhomboids and levator scapulae, act as supplementary stabilizers.

![Figure 76.11. Scapular muscles: lateral view with arm abducted and externally rotated (cocked). SA, serratus anterior; UT, upper trapezius; MT, middle trapezius; LT, lower trapezius; R, rhomboids; LS, levator scapulae. (Adapted from Pink MM, Perry J. Biomechanics. In: Operative Techniques in Upper Extremity Sports Injuries. St. Louis: Mosby, 1996:113, with permission.)](image)

The serratus anterior, acting as a whole muscle, draws the vertebral border of the scapula toward the lateral rib cage, creating scapular protraction. The lower four segments, by their insertion on the inferior angle of the scapula, induce upward rotation.

The trapezius, as it covers the posterior chest wall from the vertebral spinous processes to the upper border of the scapular spine, provides scapular retraction. Upward rotation is accomplished by synergistic action of the upper and lower portions of the trapezius.

The rhomboids provide scapular stability as they retract the scapula toward the vertebral spines. The levator scapulae, lying between the neck and its insertion on the superior medial corner of the scapula, serves as a stabilizing pivot by resisting depression.

**BIOMECHANICS OF ARM ELEVATION**

Muscles, while creating motion, also produce forces within the joint. Their impact on stability relates to the angle that the muscle’s line of pull makes with the plane of the glenohumeral joint. Also involved is the displacement of the action line from the center of rotation of the joint. A force perpendicular to the face of the glenoid creates compression and augments joint stability. In dynamic cadaver studies, muscle compression has proved to significantly increase the joint’s resistance to translatory displacement (8). Conversely, forces parallel with the glenoid induce shear and lead to joint instability (Fig. 76.12) (56).

![Figure 76.12. Joint forces (dark arrows) resulting from the muscle’s line of pull (light arrow). Perpendicular line to glenoid (horizontal line) represents compression. Parallel line (vertical) indicates shear. Note that at this arm position, the shear force of the deltoid is greater than its compression force.](image)

The deltoids, which arise from the overhanging acromion, clavicle, and scapular spine and extend distally to the mid-humeral shaft, have a vertical alignment when the arm is down. As the arm is raised, the muscles become increasingly horizontal, which markedly changes their alignment with respect to the plane of the glenohumeral joint (48,49,56).

At 30° of arm elevation, the low angle of the deltoids results in a shear force 1.73 times greater than the compression force. Consequently, there is a tendency for upward displacement of the humerus on the glenoid that threatens joint stability and impingement of the rotator cuff against the acromion. Inspection of 200 scapulae showed a 22% incidence of an eburnated facet on the underside of the acromion (17).

Synergistic action of the supraspinatus reduces the intensity of the deltoid effort by providing part of the abduction force (70). In addition, the dominant joint force of the horizontally aligned supraspinatus is compression (2.73 times shear) (68). The subscapularis, infraspinatus, and teres minor muscles’ activity provides downward force to counteract the deltoid’s upward glenohumeral shear and reduce the necessary abduction force by 41% (63).

As the arm approaches 90° of elevation, the alignment of the deltoid becomes more horizontal and the muscle’s shear-to-compression force ratio is reversed (S/C =
Electromyographic (EMG) studies during both free and fast arm elevation in all three planes confirm this synergy between the rotator cuff and the deltoid (30,50,51). In all positions of arm elevation (flexion, scaption, and abduction), the supraspinatus is a strong synergist of the deltoids (Fig. 76.13). During flexion, the stronger action of the anterior deltoid induces a posteriorly directed horizontal shear, which is opposed by greater infraspinatus muscle action (Fig. 76.13A). Similarly, in abduction the posterior head of the deltoid is more active. This creates a forward-directed shear that is resisted by the subscapularis (Fig. 76.13C). When these muscle synergies fail to occur, dynamic instability results (37).

The long head of the biceps brachii muscle may contribute to superior glenohumeral stability. During abduction, patients with isolated proximal biceps detachment were found to have increased superior displacement of the humeral head (65). Experimentally, the presence of a biceps force added torsional rigidity (67). Hence, the biceps brachii long head can be considered an accessory joint stabilizer, to be used when needed.

The concept of Inman et al. (30) of an obligatory deltoid/rotator cuff force couple is contradicted by the finding that the arm can be raised overhead with complete paralysis of either the deltoid or the supraspinatus (65). Selected anesthetic blocks of the axillary nerve innervating the deltoid, or of the supraspinacular nerve innervating the supraspinatus and infraspinatus, have confirmed this clinical observation (10,87). Each nerve block reduced arm elevation strength approximately 50% but did not prevent a full range of motion.

Both muscle groups have accessory muscles that can provide partial substitution. For the deltoid, there is the long head of the biceps, the clavicular head of the pectoralis major, and the coracobrachialis. Supplements to the supraspinatus are the subscapularis and teres minor. Thus, inability to elevate the arm fully is not an essential sign of either a rotator cuff tear or deltoid paralysis.

Scapular muscle action increases the range of arm elevation by upwardly rotating the glenoid fossa. This action also preserves muscle length of the glenohumeral muscles. In addition, upward displacement of the acromion reduces the threat of humeral impingement. The relative intensity of contraction of the serratus anterior and the different divisions of the trapezius varies with arm position (13,38). The basic synergy was found by EMG to be between the lower serratus anterior and upper trapezius (Fig. 76.14) (13,38). During flexion, the need for scapular protraction as well as upward rotation made the serratus anterior the dominant muscle.

Upper trapezius action also was strong (38), but only minimal EMG activity was recorded in the middle head (30). Conversely, abducting the arm in the body's coronal plane includes scapular retraction. The serratus anterior was less intense, while both the upper and middle heads of the trapezius showed strong EMG (30,38).

Scaption, as a neutral position between scapular abduction and adduction, displays a balanced synergy between the two rotator systems (serratus anterior and trapezius) (51). Lower trapezius activity was slightly increased in scaption but otherwise was of just moderate intensity.

Consequently, testing for paralysis of the serratus or trapezius is highly dependent on the plane of arm elevation used. Clinical experience with cases of isolated paralysis of either the serratus or the trapezius has shown that the patient may still raise the arm to approximately 90° but that full overhead reach cannot be accomplished (unpublished data).

A low level of activity by the rhomboid was found in all three planes of arm elevation (38). Inman et al. postulated participation of the levator scapulae as a component of the serratus force couple, but this finding was not supported by EMG (30). A recent study of the levator scapulae during arm elevation, however, showed a moderate level of activity, which increased as the arm moved higher (Pink M, unpublished data, 1996). The findings of incomplete scapular mobility in a recent case of levator scapulae tendon strain support the concept of this muscle's being a central stabilizer.

**ROTAION**

Sports that involve pitching and throwing and the tennis serve rely on humeral rotation as the terminal propulsive force (31,32,59). This rotation changes the coordination between the deltoid and rotator cuff from a synergy to a sequence. The mechanics of a baseball pitch provides one example: Cocking of the shoulder begins with elevation and horizontal extension, which are quickly augmented by aggressive external rotation to tense the propulsive muscles maximally. The rapid reversal of shoulder motion into accelerated internal rotation enables the propelling forces to throw the ball at high speed (Fig. 76.15).
The EMG patterns during an average fastball pitch reflect this sequence of motions (Fig. 76.16). Early cocking relies on moderately intense deltoid (anterior, middle, and posterior) and supraspinatus activity to raise and retract the arm (15,31). Further cocking of the arm by maximal external rotation shifts the dominant muscle control to the rotator muscles (infraspinatus, teres minor, subscapularis), while the deltoids’ role is reduced. Rapid reversal of dominant muscle control to the shoulder internal rotators (upper subscapularis, latissimus dorsi, teres major, and pectoralis major) first protects the anterior joint from strain at the end of cocking. Then, as the external rotators relax, these anterior muscles whip the arm forward with a strong propelling force, which throws the ball at high speed (Fig. 76.15) (15).

Vigorous action of the serratus anterior during late cocking adds upward rotation of the scapula to increase the range of arm motion (53). There also is vigorous levator scapulae activity (15). The fact that trapezius participation in early cocking and follow-through is much less than that of the serratus (24) suggests that the scapular retraction function of the trapezius is useful as a stabilizer but is not a dominant source of motion.

Thus, pitching and the other throwing sports emphasize rotation as a primary driving force, but they also rely on timely input of all the other shoulder muscles at their appropriate intensities. The threats to anterior and posterior joint stability are enhanced by the momentum imparted to the arm by the forward drive of the trunk and legs and the forearm inertia created by the flexed elbow, which creates a significant torque against the tissues of the glenohumeral joint.

DEPRESSION

Many circumstances call for the forceful downward push of the arm, such as hammering, swimming, and using the hand to raise the body from a sitting position or to propel a wheelchair.

During the freestyle swim stroke, the body is propelled forward by the hand pushing against the water (Fig. 76.17). The forces driving the arm are the pectoralis major, latissimus, and subscapularis (Fig. 76.18) (54,62). The simultaneous action of the teres minor counterbalances the internal rotation action of the propelling muscles. Serratus anterior synergy adds the scapula to the length of the pulling extremity. Peak effort occurs as the arm is perpendicular in the water (approximately 90° of shoulder flexion).

Vigorous action of the serratus anterior during late cocking adds upward rotation of the scapula to increase the range of arm motion (53). There also is vigorous levator scapulae activity (15). The fact that trapezius participation in early cocking and follow-through is much less than that of the serratus (24) suggests that the scapular retraction function of the trapezius is useful as a stabilizer but is not a dominant source of motion.

Thus, pitching and the other throwing sports emphasize rotation as a primary driving force, but they also rely on timely input of all the other shoulder muscles at their appropriate intensities. The threats to anterior and posterior joint stability are enhanced by the momentum imparted to the arm by the forward drive of the trunk and legs and the forearm inertia created by the flexed elbow, which creates a significant torque against the tissues of the glenohumeral joint.

DEPRESSION

Many circumstances call for the forceful downward push of the arm, such as hammering, swimming, and using the hand to raise the body from a sitting position or to propel a wheelchair.

During the freestyle swim stroke, the body is propelled forward by the hand pushing against the water (Fig. 76.17). The forces driving the arm are the pectoralis major, latissimus, and subscapularis (Fig. 76.18) (54,62). The simultaneous action of the teres minor counterbalances the internal rotation action of the propelling muscles. Serratus anterior synergy adds the scapula to the length of the pulling extremity. Peak effort occurs as the arm is perpendicular in the water (approximately 90° of shoulder flexion).
hand exit.

After the hand enters the water, the shoulder continues to reach overhead (arm elevation mechanics) for a brief period. Arm depression then is initiated to propel the body. Soon after the arm has passed its peak propulsive alignment, the rhomboid, trapezius, and posterior deltoid muscles lift the arm from the water, and the mechanics of reach begin. Now the middle and anterior deltoids, supraspinatus, and subscapularis advance the arm in this recovery phase.

Pushing the body up from a seat with one's arms is a critical function for patients with spinal cord injury who rely on manual transfer (Fig. 76.19) (42, 52). An EMG study of this maneuver found that the latissimus dorsi, lower trapezius, and sternal pectoralis major are the major lifting forces. The serratus anterior, while not significant in the vertical rise, shows strong activity when the body weight is shifted from one arm to the other in the depression phase (53). A study of the prone push-up exercise shows the serratus anterior to be a major force when the trunk is elevated on the arms (40). Seldom does any head of the deltoid participate during the raise, but it is active in body positioning. Propelling a wheelchair relies on a downward forward force against the wheel rim. The muscles most active during the propulsion phase are the pectoralis major and the anterior deltoid (43).

**Figure 76.19.** Body raise: manual transfer of the body from a sitting position. Left side: raise muscles [latissimus dorsi, trapezius, pectoralis major (not shown), and triceps]. Right side: positioning muscles (deltoid, rotator cuff).

**ARM SUSPENSION**

Supporting the hanging arm and carrying a heavy object use the same mechanics. The upper trapezius and levator scapulae muscles stabilize the scapula. Glenohumeral stabilization is more indirect. Experimentally, a strong downward tug on the arm fails to elicit any response by the longitudinal muscles (triceps, biceps, and anterior and middle deltoids) (2). Instead, the supraspinatus and to a lesser degree the posterior deltoid respond. The fact that both of these latter muscles have a horizontal alignment identifies compression, rather than lift, as the primary force needed to hold the humeral head into the glenoid fossa. This finding has been confirmed by studies of passive translation (38).

**HORIZONTAL RANGES**

Movement of the elevated arm toward and away from the anterior midline may be called horizontal flexion/extension or horizontal adduction/abduction. The former term is preferred, as there is less chance for confusion with scapular motion. The pectoralis major, pectoralis minor, and serratus anterior bring about horizontal flexion.

Often, the levator scapulae also participates (13).

Among the glenohumeral muscles, the most active during horizontal flexion are the clavicular head of the pectoralis major and the subscapularis (47). During the arm-retraction phases of pitching (late cocking) and swimming (early recovery), there is prominent action by the rhomboid, trapezius, posterior deltoid, and infraspinatus (24, 47, 62). A study of horizontal circumduction confirmed the posterior deltoid and added the infraspinatus as the dominant horizontal extensor muscles of the glenohumeral joint (27).

**CONCLUSIONS**

Stability of the glenohumeral joint depends on central contact between the humeral head and the glenoid fossa. Mobility is enhanced by the flexibility of the glenoid labrum, limited glenohumeral ligamentous restraint, and the small contact areas of the clavicular articulations. The selective exchange among the various muscle groups must simultaneously provide dynamic stability as well as the wide versatility of motion that characterizes arm function. To meet these objectives, a continual balancing is necessary among the external glenohumeral muscles, the rotator cuff musculature, and the muscles controlling the scapula.

CHAPTER 77

SHOULDER ARTHROSCOPY

John P. Meehan

J. P. Meehan: Department of Orthopaedic Surgery, University of California, Davis, Medical Center, Sacramento, California, 95817.

HISTORY

Shoulder arthroscopy as a diagnostic and therapeutic modality continues to evolve as our understanding of the anatomy and pathophysiology of the disease processes, as well as new technologies, allow us to treat a broader variety of shoulder ailments. Although there are reports in the literature regarding the use of the arthroscope in the 1930s and 1940s, it was Watanabe's work in the 1950s in developing more practical arthroscopic instrumentation that ultimately led to the development of routine knee arthroscopy in the 1970s (4). The routine use of the arthroscope in the shoulder lagged behind its use in the knee, but by the early 1980s its benefits as a less invasive surgery for the shoulder were clearly established. It was during the late 1970s and early 1980s that shoulder arthroscopy expanded its applications from that of diagnosis to that of treatment (2). Many procedures such as subacromial decompression, distal clavicle excision, and instability and rotator cuff repairs, which previously required open surgical incisions, could now be treated effectively with the use of shoulder arthroscopy.

EQUIPMENT

The operating room should be equipped with a standard operating room table that allows adjustments for height; flexion/extension of the head, torso, and legs; and tilt in the long and short planes of the table. Typically, the video monitor, recorder, and printer are stored in a cabinet that allows easy viewing by all operating room personnel.

Shoulder arthroscopy is aided by continuous distention with a fluid medium. Normal saline is the fluid most commonly used, as it has demonstrated no harmful effects on articular cartilage or from systemic absorption. Both static (i.e., gravity-assisted) and arthroscopic pump systems are available and can be used according to the surgeon's preference (3).

The effectiveness of shoulder arthroscopy is augmented by the large variety of mechanical instrumentation available today. Mechanical shavers, burners, and resectors can all assist the surgeon in treating the intraarticular as well as extraarticular conditions. The ability to use electrocoagulation and cautery in a fluid medium was an important advance for shoulder arthroscopy. While capillary coozing is readily controlled by the hemostatic pressure within the glenohumeral joint from either a pump or gravity system, the surgical electrode is extremely valuable for procedures within the subacromial space, where excessive bleeding from the coracocromial artery is sometimes encountered.

A plethora of hand instruments, similar to the hand instruments in knee arthroscopy, have also been developed for the shoulder. Basket forceps, grasping forceps, curets, and probes are but a few of those available.

SURGICAL TECHNIQUES

POSITION

The two common positions for shoulder arthroscopy are the lateral decubitus position and the beach-chair position. Each position has advantages and disadvantages, and most surgeons choose the one they are most comfortable with, which is frequently the one they trained with. Proponents of the lateral position feel the continuous traction allows easier glenohumeral and subacromial arthroscopy. Proponents of the beach-chair position argue that it is more convenient for regional anesthesia and when converting to open procedures. I prefer the lateral decubitus position for most shoulder cases but occasionally utilize a beach-chair position if the possibility of an open capsular repair exists. The alternative is to reprep and redrape after the arthroscopy is performed in the lateral position.

- For the lateral decubitus position, place the patient on a standard operating table that is equipped with a bean bag. Kidney rests, adhesive tape, and thorax-positioning devices can be utilized to further stabilize patients after they are turned onto their side and after placing a padded roll to protect the neurovascular structures of the axilla.
- Flex the down-side leg at the hip and the knee, and tape over the pelvis, securing it to the operating room table to further stabilize the patient. Place a pillow between the legs. Protect the peroneal nerve and malleoli of the down-side leg. Flex the dependent arm forward.
- Flex the elbow, supporting it on a padded arm board. Support the cervical spine to prevent hyperextension that might cause a cervicobrachial radiculopathy. Tilt the torso 30° posteriorly to bring the glenohumeral joint horizontal with the floor.
- Place a plastic adhesive U-drape proximally, from a line just medial to the vertebral border of the scapula posteriorly, over the medial third of the clavicle superiorly and medial to the coracoid process anteriorly. Then place another smaller plastic adhesive drape across the ends of the U-drape at the mid-thorax level.
- Traction may be applied to the arm with various commercial devices. Secure the traction apparatus to the operating table in a position that allows abduction and forward flexion. Then various forms of skin traction can be applied to the forearm and hand. I prefer to wrap the hand and forearm with cotton cast padding (Webril), followed by reusable adhesive strips on the volar and dorsal forearm, with a loop around the hand to allow subsequent placement of a Z-hook and an S-hook, which can be attached to the traction apparatus.
- Secure the adhesive strips with elastic adhesive wrap (Coban) around the forearm. Place the remaining roll of Webril in the patient's palm to support the fingers. Do not exceed 10–15 lbs longitudinal traction, and adjust the traction weight downward depending on the individual patient. I most commonly use 7½ lbs.

The position of the arm varies slightly from surgeon to surgeon when the patient is in the lateral decubitus position, but it generally ranges from 20° to 70° of abduction and from 10° to 20° of forward flexion. In addition, a stack of towels or an assistant's hand can help provide a perpendicular translation force when placed between the chest wall and the proximal humerus.

While many surgeons feel the lateral position allows for easier diagnostic and arthroscopic procedures, many feel it is more difficult when converting to open procedures, especially open anterior capsular shifts and large rotator cuff tears. These surgeons employ a beach-chair position if conversion to an open procedure is anticipated. I have found that a capsular shift procedure can be performed without a reprep and redrape if the bean bag is deflated, the patient is allowed to fall back to a semisupine position, and the arm is rewrapped with a sterile cover. Only rarely is a complete reprep and redrape required. In addition, most open rotator cuff repairs can be performed simply by releasing traction, covering the hand and forearm with a sterile wrap, and either keeping the patient in the lateral position or deflating the bean bag and allowing her to fall back to a semisupine position.
PORTALS

A variety of portals have been described for accessing the glenohumeral joint, the subacromial space, and the acromioclavicular (AC) joint.

Glenohumeral Joint

For the glenohumeral joint, two portals are commonly used: a posterior portal and an anterior portal. Multiple variations of the anterior portal have been described.

- Before making skin incisions, be sure to outline the anatomic landmarks. Begin with the posterior angle of the acromion, which is subcutaneous and can be easily palpated in most patients. From this point, draw a line along the posterior acromion extending medially for a short distance, and anteriorly for a short distance along the lateral edge of the acromion. The angle formed is usually slightly obtuse rather than 90°.
- Identify the supraclavicular fossa by placing a thumb in the quadrangular space formed by the clavicle anteriorly, and the acromion laterally and posterolaterally.
- Outline the posterior edge of the clavicle and the medial margin of the acromion. Next, outline the anterior border of the clavicle, and the lateral border of the acromion, connecting with the previously drawn line.
- Place a circle over the coracoid process anteriorly, and draw in the coracoacromial ligament.
- Finally, estimate the position of the AC joint, which can be difficult in patients with arthritic changes (Fig. 77.1).

Figure 77.1. Setup for glenohumeral portal.

- The entry portal is posterior, which provides adequate visualization of the glenohumeral joint and also allows placement of the other portals under direct arthroscopic visualization. Place the posterior portal in what has been described as the soft spot, or the posterior glenohumeral joint line, which typically is 2 cm inferior and 1 cm medial to the posterolateral corner of the acromion. Locate the soft spot by grabbing the humeral head with your hand, using the thumb to palpate the posterior glenohumeral joint line and the long finger to palpate the anterior glenohumeral joint line. Typically, one can translate the humeral head back and forth to confirm the position of the joint line.
- Make a 3–5 mm incision along Langer’s lines through skin and subcutaneous tissues, being careful not to penetrate the deltoid muscle. With a blunt trocar in the arthroscopic cannula, advance in the direction of the coracoid through the deltoid muscle, through the infraspinatus and teres minor interval, to the posterior joint line. The blunt tip of the trocar can be used to palpate the curve of the humeral head and the stepoff of the posterior glenoid, and the interval of the joint line in between.
- The joint capsule will be soft with some elasticity, as opposed to the hard surfaces of the humeral head and the glenoid. With the nondominant hand around the cannula at skin level, use your dominant hand to advance the trocar through the capsule, which will be accompanied by a slight pop. Use the nondominant hand to prevent overpenetration, and also for more precise control of the trocar as it enters the joint. Some surgeons prefer to use a spinal needle first to access the joint. They can then confirm intrarticular placement of the needle by injecting 30–40 ml of saline through a syringe, and noting the resistance to injection and backflow from the needle after removal of the syringe. In the intact joint, the resistance slowly increases as fluid is injected, and the syringe can be removed after 15–20 ml have been inserted.
- After entering the joint, perform a diagnostic arthroscopy. Some surgeons create an anterior portal at this point to create an outflow and to allow the insertion of instrumentation to assist with the diagnostic portion of the procedure.

As the ability to perform more procedures with the arthroscope increased, so did the number of anterior portals described by various authors. The most frequently used anterior portal allows anterior instrumentation and visualization of the posterior portion of the joint. There are multiple techniques for creating this anterior portal. Most are performed under direct arthroscopic visualization with either an outside-in or an inside-out technique. While viewing with the arthroscope from the posterior portal, the interval in which the anterior portal will be established is a triangle formed by the long head of the biceps, the superior border of the subscapularis tendon, and the glenoid (3).

An outside-in technique frequently used is to make a skin incision directly in line with the arthroscope, which, if it is looking at the interval above, will be just lateral and slightly superior to the tip of the coracoid process. Some surgeons use a spinal needle to enter the joint prior to making the skin incision. An incision should never be made inferior or medial to the tip of the coracoid as this could potentially injure the neurovascular structures in the axillary sheath (4).

- Make a 3–5 mm skin incision. While looking at the shoulder from the outside, insert a 5.5 mm plastic cannula with a blunt trocar through the incision, through the anterior deltoid to the level of the joint. In most cases, the plastic cannula will be 180° opposite the arthroscopic cannula.
- At this point, shift your view to the video camera screen, which is still looking at the triangle formed by the superior border of the subscapularis tendon, the long head of the biceps tendon, and the glenoid.
- Advance the plastic cannula slightly to see an indentation of the anterior capsule in or near the superior aspect of the triangle above and make minute adjustments in the position or angle of the plastic cannula before advancing it under direct visualization into the joint. Alternatively, use an inside-out technique with the arthroscope and a Wissinger rod.
- Advance the arthroscope into the superior aspect of the previously mentioned triangle, and maintain the cannula in this position.
- Remove the scope from the cannula and place a Wissinger rod through the cannula, the joint, and the anterior deltoid; tent the skin. Now make the skin incision, and further advance the rod. Place the plastic cannula over the Wissinger rod and retrograde it into the joint. Remove the Wissinger rod and reintroduce the arthroscope to the posterior portal.

A third portal described for the glenohumeral joint is the superior portal. This portal is used must less frequently than the anterior and posterior portals. It is created in the supraaclavicular fossa, bounded by the distal clavicle and the AC joint anteriorly, the acromion laterally, and the base of the spine of the scapula posteriorly (4). This portal can be used for inflow, as well as to view the posterior glenoid labrum, the posterior portion of the humeral head, and, with a limited view, the rotator cuff. It is a relatively safe portal; the only structure at risk is the suprascapular nerve, which is about 3 cm inferior to the intended course of the instrumentation.

- Make a small skin incision and pass a blunt trocar through the teres major, the muscular portion of the supraspinatus, and the superior joint capsule into the glenohumeral joint.
- With the posterior portal, the nerves at risk for injury are the suprascapular nerve medially and the axillary nerve inferiorly. The suprascapular nerve lies approximately 2 cm medial to the postero-lateral glenoid, travelling in the spinoglenoid notch. The axillary nerve travels through the quadrangular space at the inferior border of the teres minor, which is approximately 2–4 cm inferior to the portal placement as described.
- With the classic anterior portal, as long as you stay lateral to the coracoid process, the chances of a severe neurovascular injury are minimized. The cephalic vein is located anterior and lateral to the anterolateral acromion and is rarely injured with these techniques.

Subacromial Space

The lateral and subacromial portals allow examination of the superior surface of the rotator cuff, the undersurface of the acromion (particularly the anterior inferior surface), and the coracoacromial ligament, and they allow access to the AC joint.

Multiple portals have been described for approaching the subacromial space from the lateral aspect of the shoulder. They can range anywhere from the anterior edge to the posterior edge, but they all must be at least 2 cm lateral to the lateral edge of the acromion to allow access to its entire undersurface. They should not be more than 3 cm from the lateral edge of the acromion, as the risk of injuring the axillary nerve increases. Anterolateral, mid-lateral, and posterolateral portals can be used,
depending on whether you need access to the AC joint (anterolateral) for distal clavicle excisions and subacromial decompressions, or the superior surface of the rotator cuff (mid-lateral) for rotator cuff repairs, or even accessory portals (posterolateral) if additional outflow is needed.

- To introduce a blunt trocar and scope cannula into the subacromial space, use the skin incision and the deltoid perforation from the primary posterior portal as described for the glenohumeral arthroscopy. Aim the scope cannula and blunt trocar slightly superior and toward the central aspect of the undersurface of the acromion.
- Use the blunt trocar to palpate the undersurface of the acromion, and distend the space with fluid through the cannula. Alternatively, using a syringe, inject 30 cc from a lateral approach prior to advancing the scope cannula. Fluid egress when the blunt trocar is removed provides confirmation.
- Under direct visualization, establish a lateral portal with a 5.5 mm plastic cannula through which instrumentation can be passed.
- Not uncommonly, the subacromial space is severely scarred and inflamed so that visualization is obscured. When this occurs, place a shaver or synovial resector through the lateral portal, with its teeth facing upward against bone, and begin shaving with an anterior to posterior sweeping motion until landmarks come into view. Similarly, the hypertrophied bursal tissue can be removed from the superior surface of the rotator cuff with gentle sweeping motions in an anterior to posterior direction.
- Considerable bleeding can be encountered, especially from the inflamed bursal tissues, so be prepared with electrocautery to assist with hemostasis. Once the bursal space is cleared, you should be able to visualize the superior surface of the rotator cuff from the AC joint to a point distal and lateral to the greater tuberosity.

The undersurface of the acromion is usually covered with a thick periosteal layer, and the anterior third is covered by the fibers of the coracoclavicular ligament, which attach under the anterior edge of the acromion, thereby forming the anterior roof of the acromial arch. The ligament is 2–3 cm wide at its acromial insertion.

**DIAGNOSTIC ARTHROSCOPY**

**Glenohumeral Joint**

- Begin the diagnostic arthroscopy with the patient in a lateral decubitus position, after entering the glenohumeral joint through the posterior portal and establishing an anterior portal for outflow and instrumentation. A nerve hook can be placed through the anterior cannula to assist with the procedure. Institute a systematic approach for reviewing the intraarticular anatomy of the shoulder, to avoid missing any abnormalities. Keep the orientation of the glenoid surface, as viewed on the video monitor, parallel to the floor, with the humeral head superior, the glenoid inferior, and the biceps tendon perpendicular and between the two. The initial view will allow inspection of the biceps tendon from the passage through the rotator cuff interval to its attachment to the superior labrum at the supraglenoid tubercle.
- Inspect the humeral head for articular surface defects, such as that seen with a Hill-Sachs lesion on the posterior superior humeral head. Do not confuse the Hill-Sachs lesion with the normal intracapsular portion of the humeral neck that is devoid of cartilage, the so-called anatomic bare patch. Also inspect the articular surface of the glenoid, remembering that a pitted area, less than 10 mm and with smooth chondral margins, is a normal finding in many older individuals. At this point, you may continue the arthroscopy in a posterior to anterior direction, or, as I prefer, in an anterior to posterior direction.
- Inspect the superior and anterior glenoid labrum. There is considerable anatomic variation in both the size and the attachments to the labrum. Inspect the insertion of the biceps tendon into the glenoid labrum for fraying or detachments, especially superior labral tears from anterior to posterior (SLAP lesions). (Fig. 77.2; see also Color Fig. 77.2)

![Figure 77.2](https://example.com/fig77_2.png)

*Figure 77.2. (See Color Fig. 77.2.) Superior labral tear from anterior to posterior (SLAP lesion).*

- Next, inspect the anterior glenoid labrum for fraying, and probe for possible detachments from the anterior glenoid neck, which, when associated with a history of dislocation, is called a Bankart lesion. When viewing the anterior superior labrum, make a mental note of a normal anatomic variant, in which the middle glenohumeral ligament forms a cordlike structure that is contiguous with the anterosuperior labrum, forming a foramen of variable size between the ligament and the labrum. (5)
- Inspect the anterior glenohumeral ligaments, which are thickened portions of the anterior capsule and can be quite variable. The superior glenohumeral ligament is the most difficult to visualize arthroscopically. It appears as a confluence of the capsule at the inferior edge of the rotator cuff interval, and it is frequently obscured by the biceps tendon.

The middle glenohumeral ligament can vary in width, but it typically passes the superior border of the subscapularis in an obliquely vertical manner (at approximately 45°) to insert on the superior glenoid. It can vary from being very discrete to absent, with a range of variations between (3). The inferior glenohumeral ligament is the most constant and clinically significant of the glenohumeral ligaments. It has been described as a suspensory sling that stabilizes the joint. It originates along the anterior and inferior labrum and attaches along the anteroinferior portion of the humeral neck. Its origin has been called a labrocapsular complex, which describes the confluence of the inferior glenohumeral ligament, the anterior inferior glenoid labrum, and the peristeum of the anteroinferior glenoid. The axillary recess, or inferior recess, is a loss of the covering of the capsule and synovium inferior to the humeral head. It is a lax portion of the inferior glenohumeral ligament between the antero- and posterosuperior bands.

- Visualize the posterior labrum by turning the lens of the camera and following the posterior glenoid from inferior to superior. If the shoulder is tight or if you have difficulty visualizing the posterior glenoid labrum in this manner, insert the arthroscope into the anterior portal.

The final structure to be inspected is the intraarticular or undersurface of the rotator cuff. The rotator cuff is made up of the tendons of the subscapularis, the supraspinatus, the infraspinatus, and the teres minor. The tendon of the subscapularis, located anteriorly, has already been inspected. The tendon of the supraspinatus is located adjacent and slightly posterior to the long head of the biceps.

- Inspect the insertion of the supraspinatus by following the long head of the biceps laterally. The insertions of the infraspinatus and teres minor are located posterior to the insertion of the supraspinatus. Abnormalities of the rotator cuff can range from fraying, or partial-thickness tears seen only on the undersurface (glenohumeral side), to full-thickness tears seen both on the undersurface and on the superior surface when viewed from the subacromial space.

**Subacromial Space**

- Upon completion of the glenohumeral arthroscopy, withdraw the arthroscope after allowing the outflow to drain the shoulder joint. Insert a blunt trocar into the cannula and, using the same posterior portal skin incision, insert the arthroscope into the subacromial space as previously described, again aiming superior and for the midpoint of the acromion. It is sometimes useful to use a sweeping motion of the cannula on the undersurface of the acromion to break up any adhesions that might be there.
- Remove the blunt trocar and insert the arthroscope with inflow attached. Orient the camera with the acromion at the top and the rotator cuff at the bottom of the screen. In some patients, there will be a distinct subacromial space and viewing will be easy. A normal subacromial space will have a thin, smooth bursal layer on the superior surface of the rotator cuff. The undersurface of the acromion will have a thin periosteal layer.
In patients with chronic impingement syndrome, the subacromial space can be difficult to visualize and may have a cobweb appearance from adhesions. In this situation, establish an anterolateral portal using the 5.5 mm plastic cannula with the orange-colored trocar, aiming perpendicular to the arthroscopic cannula and slightly in front of it. When the orange trocar comes into view, insert a shaver under direct visualization. With the blades positioned toward the undersurface of the acromion, remove the scarred tissues in a controlled and safe manner.

- Identify the anterior inferior surface of the acromion, the coracoacromial ligament, the AC joint medially, the superior surface of the rotator cuff as far lateral as possible, and especially the supraspinatus tendon near its musculotendinous junction. Frequently, a probe can be used from the anterolateral portal to help
- Close the portals with simple nonabsorbable sutures or subcuticular sutures, depending on your preference.
- After diagnostic procedures, encourage the patient to begin range-of-motion exercises of the shoulder, elbow, wrist, and hand on the first postoperative day; the patient should also discard the sling when comfortable, typically within a week or by the first postoperative visit. Slowly reintroduce functional and recreational activities once motion and strength are regained.

**ACROMIOCLAVICULAR JOINT**

- The AC joint is most commonly approached from the same portals as used for subacromial procedures, although separate transcutaneous portals specifically for the AC joint have been described. Place lumbar puncture needles either in the AC joint itself, or use to outline the anterior and posterior border of the joint (Fig. 77.4; see also Color Fig. 77.4). To aid in visualization of the distal clavicle, remove fibrosis or hypertrophied bursal tissue in the subacromial space.

**SUBACROMIAL DECOMPRESSION**

As surgeons have become experienced with shoulder arthroscopy, they have realized the benefits of avoidance of detioloid detachment as well as early return of function associated with arthroscopic acromioplasty. Typically, this procedure is performed after a thorough glenohumeral joint and subacromial space arthroscopy, and after the diagnosis of impingement syndrome has been confirmed.

- Use the same portals as for the subacromial space arthroscopy, specifically the posterior and the anterolateral or mid lateral. I prefer to view the procedure with the arthroscope in the posterior portal and instrumentation inserted through the anterolateral or mid lateral portal.
- Insert a blunt instrument through the lateral portal and confirm the bone outlines of the anterior, anterolateral, and lateral acromion. Then insert an electrocautery device and incise the thickened periosteal tissues on the undersurface of the anterior acromion, as well as the hypertrophied coracoacromial ligament.
- When incising the coracoacromial ligament, a vessel is frequently encountered that can cause bleeding, which makes visualization difficult. At this point, advance the arthroscope with the inflow attached as close to the vessel as possible, providing a tamponade effect, and coagulate it with the electrocautery.
- Insert an arthroscopic shaver, typically a full-radius resector, through the lateral portal and remove the previously incised soft tissue. Expose the entire bone undersurface of the anterior acromion. Follow with a 5.0 mm arthroscopic oval burr. The goal is to remove enough bone to prevent further impingement, although surgeons differ as to what the actual amount is. I strive to remove at least a burr's width (5.0 mm) of bone from the projected undersurface of the acromion and the cut surface of the distal clavicle.

**AUTHOR’S PERSPECTIVE**

Detailed explanations and techniques for treating a variety of other common shoulder disorders are covered in chapter 78, chapter 79, and chapter 80. As the experience of surgeons and the development of instruments have improved, so has the ability to use the arthroscope to treat these conditions. Shoulder instability, glenoid labrum injuries, and many rotator cuff tears can now be approached with an arthroscope and/or limited incision techniques. Laser and radiofrequency devices are being applied with encouraging short to midterm results.

Additional applications include removal of loose bodies, synovectomy, biopsy, irrigation and debridement for infection, and treatment of refractory adhesive capsulitis.

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

The acromioclavicular (AC) joint is a diarthrodial joint located between the lateral end of the clavicle and the medial margin of the acromion process of the scapula (Fig. 78.1). DePalma (56) showed marked variability in the plane of the joint. Viewed from the front, the inclination of the joint may be almost vertical, or it may be inclined from downward medially, with the clavicle overriding the acromion by an angle as large as 50° (Fig. 78.2) (23,181).

### THE ACROMIOCLAVICULAR JOINT

The acromioclavicular (AC) joint is a diarthrodial joint located between the lateral end of the clavicle and the medial margin of the acromion process of the scapula (Figs. 78.1, 78.2). DePalma (56) showed marked variability in the plane of the joint. Viewed from the front, the inclination of the joint may be almost vertical, or it may be inclined from downward medially, with the clavicle overriding the acromion by an angle as large as 50° (Fig. 78.2) (23,181).

**Figure 78.1.** Anteroposterior view of the normal shoulder. Note the AC joint, the coracoid process, and the CC interspace.

**Figure 78.2.** Variations of the inclination of the AC and the SC joints. (Redrawn from DePalma AF. Surgery of the Shoulder. Philadelphia: JB Lippincott.)

The AC joint is stabilized by capsular (AC) and extracapsular [coracoclavicular (CC)] ligaments. The importance of the muscles that cross the joint (deltoid and trapezius) in providing the dynamic stability of the AC articulation cannot be overemphasized. A portion of the anterior deltoid provides dynamic suspensory support of the arm from the clavicle. The upper portion of the trapezius also contributes support. It is important to repair the deltoid or trapezius fascia in management of AC dislocation (110).

The AC joint is surrounded by a thin capsule reinforced by the superior, inferior, anterior, and posterior AC ligaments (Fig. 78.3). The fibers of the superior AC ligament (the strongest of the capsular ligaments) blend with those of the deltoid and trapezius muscles, which are attached to superior aspect of the clavicle and the acromion process, adding to the stability of the joint.
The CC ligament is very strong and heavy; its fibers run from the outer, inferior surface of the clavicular to the base of the coracoid process of the scapula (Fig. 78.3). It has two components: the conoid and the trapezoid ligaments.

The CC ligament is the prime suspensory ligament of the upper extremity and helps to couple glenohumeral abduction and flexion to scapular rotation on the thorax. Full overhead elevation cannot be accomplished without combined and synchronous glenohumeral and scapulothoracic motion (44, 89, 96). The clavicle rotates about its longitudinal axis through an arc of 40° to 50° during full abduction (89). Beam (16) stressed the importance of the sternoclavicular (SC) ligaments in supporting the proximal end of the clavicle by preventing downward displacement of the distal end of the clavicle. Urist (181) showed that complete dislocation of the AC joint can occur horizontally without rupture of the CC ligament.

MECHANISMS OF INJURY

A direct force produced by the patient's falling onto the point of the shoulder with the arm at the side in an adducted position (Fig. 78.4) drives the acromion downward and medially and is the most common cause of AC injury (16). If no fracture occurs, the force first sprains the AC ligaments, then tears the AC ligaments and stresses the CC ligaments, and finally tears the deltoit and trapezius muscle attachments from the clavicle and ruptures the CC ligament, resulting in drooping of the shoulder (Fig. 78.5). The mechanism for inferior dislocation of the clavicle under the coracoid is thought to be a very severe direct force onto the superior surface of the distal clavicle, along with abduction of the arm and retraction of the scapula (52, 143).

Indirect injury results from a fall on the outstretched hand, which transmits a force up the arm, through the humeral head, and into the acromion process, producing mild, moderate, or severe AC joint injury. Forces can also be indirectly applied to the AC joint by a pull through the upper extremity, which can forcibly draw the shoulder downward and anteriorly (107).

CLASSIFICATION OF AC INJURIES

Originally, AC injuries were classified into only two or three grades (2, 39, 79). One of us (C.A.R.), however, has identified type IV, V, and VI dislocations, which are more likely to require surgery (186; Fig. 78.6; Table 78.1 and Table 78.2).

Indirect injuries are those that result from a fall on the outstretched hand, which transmits a force up the arm, through the humeral head, and into the acromion process, producing mild, moderate, or severe AC joint injuries. Forces can also be indirectly applied to the AC joint by a pull through the upper extremity, which can forcibly draw the shoulder downward and anteriorly (107).

CLASSIFICATION OF AC INJURIES

Originally, AC injuries were classified into only two or three grades (2, 39, 79). One of us (C.A.R.), however, has identified type IV, V, and VI dislocations, which are more likely to require surgery (186; Fig. 78.6; Table 78.1 and Table 78.2).
separation between the clavicle and the acromion. Bottom right: This is an inferior dislocation of the distal clavicle in which the clavicle is inferior to the coracoid process and posterior to the biceps and coracobrachialis tendons. The AC and CC ligaments are also disrupted.

Table 78.2. Frequency of AC Injuries by Type

Type I. A mild force to the point of the shoulder produces a minor strain of the fibers of the AC ligaments. The ligaments remain intact, and the AC joint remains stable.

Type II. A moderate force to the point of the shoulder is severe enough to rupture the ligaments of the AC joint. The distal end of the clavicle is unstable in the horizontal plane (i.e., anteroposterior), but vertical (i.e., superoinferior) stability is preserved by virtue of the intact CC ligament.

Type III. When a severe force is applied to the point of the shoulder, "complete" AC dislocation occurs, and the AC and CC ligaments are disrupted (see Fig. 78.6).

Type III Variants. Most often, complete separation of the articular surfaces of the distal clavicle and acromion is accompanied by complete disruption of the AC and CC ligaments. Children and adolescents occasionally sustain Salter-Harris type I or II injuries in which the epiphysis and intact AC joint remain in their anatomic locations while the distal clavicular metaphysis is displaced superiority through a dorsal longitudinal rent in the periosteal sleeve (21,50,61,83,93). The importance of recognizing this injury is that the intact CC ligaments remain attached to the periosteal sleeve. Nonoperative management most often results in healing of the clavicular fracture and reestablishment of the integrity of the CC ligaments. A second uncommon variation of the type III injury involves complete separation of the AC joint combined with a fracture of the coracoid process (10,16,42,78,102,118,129,184,186).

Type IV. Posterior dislocation of the distal end of the clavicle, into or through the trapezius muscle, is relatively rare and can be so severe that the skin on the posterior aspect of the shoulder is tented (9,81,117,135,166).

Type V. A type V AC dislocation is a markedly severe version of the type III injury in which the distal clavicle is stripped of all its soft-tissue attachments and lies subcutaneously near the base of the neck.

Type VI. Inferior dislocation of the distal clavicle is an exceedingly rare injury (67,122,133,157,159) that is often the result of severe trauma and is frequently accompanied by multiple injuries.

CLINICAL ASSESSMENT

Examine patients, whenever possible, in the standing or sitting position, as the weight of the arm makes deformity more apparent.

In a type I injury, there is minimal to moderate tenderness and swelling over the AC joint without palpable displacement of the joint, only minimal pain with arm movements, and no tenderness in the CC interspace.

In a type II injury with subluxation of the AC joint, moderate to severe pain is present, the outer end of the clavicle may be noted to be slightly superior to the acromion, motion of the shoulder produces pain in the AC joint, and the outer end of the clavicle may appear to be unstable and free-floating.

In type III injuries with complete dislocation of the AC joint, the arm is held adducted close to the body and supported in an elevated position, the shoulder is depressed, the clavicle may be prominent enough to tent the skin (Fig. 78.7), and moderate pain is the rule. Any motion of the arm, particularly abduction, increases the pain. Look for an associated clavicular shaft fracture (193,190).

Figure 78.7. This patient has a complete type III dislocation of the left AC joint. The left shoulder is drooping and there is prominence of the left distal clavicle. (From Rockwood CA, Young DC. Disorders of the AC Joint. In: Rockwood CA, Matsen F III, eds. The Shoulder. Philadelphia: WB Saunders.)
In a type IV injury, the clinical findings are those of a type III injury, but the end of the clavicle is displaced posteriorly.

The type V injury is a severe exaggeration of the type III in which the distal end of the clavicle appears to be grossly superiorly displaced toward the base of the neck. The patient has more pain than with type III injury, secondary to extensive muscle and soft-tissue disruption. The patient may have symptoms of traction on the brachial plexus.

In a type VI injury, the superior aspect of the shoulder has a flat appearance, as opposed to the rounded contour of the normal shoulder. With palpation, the acromion is prominent, and there is a definite inferior stepdown to the superior surface of the coracoid process. There may be associated fractures of the clavicle and upper ribs or injury to the upper roots of the brachial plexus.

**RADIOGRAPHIC FINDINGS**

Take routine anteroposterior views with the patient standing or sitting, with the back against the x-ray cassette and the arms hanging unsupported at the side, imaging both shoulders simultaneously on one large (14 × 17-in.) cassette.

A Zanca (192) view reflects the AC joint off the scapula by tilting the central beam 10° to 15° cephalad.

Take an axillary lateral view of the injured and normal shoulders, including the lateral third of the clavicle if possible. This view will reveal any posterior displacement of the clavicle as well as any small fractures that may have been missed on the anteroposterior view.

For stressed radiographic studies, take an anteroposterior radiograph with 10- to 15-lb weights suspended from each arm with wrist straps. The weights should be hanging from the wrists rather than held by the patient to encourage complete muscle relaxation.

Occasionally a complete AC dislocation will not be apparent on routine radiographs because the patient has supported the injured shoulder with the opposite arm and reduced the AC joint. In addition, some type II injuries can be difficult to differentiate from type III injuries.

In a type I injury, the radiographs of the AC joint are normal, except for mild soft-tissue swelling, as compared with the uninjured shoulder. There is no widening, no separation, and no deformity. In a type II injury, the lateral end of the clavicle may be slightly elevated, and the AC joint may appear to be widened. Stress films reveal that the CC space is the same as that of the normal shoulder.

In type III injuries, the joint is totally displaced with the lateral end of the clavicle displaced completely above the superior border of the acromion. The CC interspace is significantly greater than that in the normal shoulder.

![Figure 78.8.](image)

**Figure 78.8.** Radiograph appearance of a grade III injury to the right shoulder. Stress radiograph films were made to compare the right shoulder with the left. Not only is the right AC joint displaced compared with the left, but, more significantly, notice the great increase in CC interspace on the injured right shoulder compared with the normal left shoulder.

Rarely, complete AC dislocation will be accompanied by a fracture of the coracoid process rather than by disruption of the CC ligaments. Although the fracture of the coracoid process is difficult to visualize on routine radiographs, its presence should be suspected because of the presence of complete AC separation and a normal CC distance as compared with the uninjured shoulder.

In type IV injuries, the most striking feature is the posterior displacement of the distal clavicle, as seen on the axillary lateral radiograph.

![Figure 78.9.](image)

**Figure 78.9.** Axillary view of type IV posterior dislocation with the distal clavicle and acromion outlined.

The characteristic radiograph feature of type V injuries is a marked increase (i.e., two to three times normal) in the CC interspace. The clavicle appears to be grossly displaced superiorly away from the acromion.

In type VI injuries, the dislocation of the distal clavicle can be subacromial or subcoracoid. In the subacromial type, radiographs reveal a decreased CC distance (i.e., less than the normal side), and the distal clavicle is in a subacromial location. The subcoracoid dislocation is characterized by a reversed CC distance, with the clavicle displaced inferior to the coracoid process.

**TREATMENT**

For type I injuries, apply ice bags to ease the discomfort and protect the shoulder from further injury until there is a painless full range of motion. Usually, the symptoms subside after 7 to 10 days of rest.

For a type II injury, apply a sling for 10 to 14 days or until the symptoms subside, followed by a gradual rehabilitation program. Advise the patient to avoid heavy lifting or contact sports for 8 to 12 weeks to allow complete ligament healing.

Surgery may be required for persistent pain after a type II AC injury. Pain can be caused by posttraumatic osteolysis of the clavicle, torn capsular ligaments trapped within the joint, loose pieces of articular cartilage, or a detached intra-articular meniscus that becomes displaced in and out of the joint like a torn meniscus in
Indicated.

the knee. An AC joint arthroplasty may be required. If the articular surface of the clavicle is degenerative, then perform an excision of the distal 2 cm of the clavicle in addition to joint debridement and meniscectomy.

Many authors recommend nonoperative management for type III AC dislocation. Banister and co-workers (8), in a randomized, prospective study, showed there was no difference between the operatively and nonoperatively treated patients except in those with severe separations (2 cm or greater), where operative fixation provided better results. No difference in strength and endurance has been found in those treated nonoperatively, comparing the injured with the noninjured side (69,116,162,188).

Convenience, shorter rehabilitation times, dissatisfaction with the results of surgical repairs, and reports of good functional outcomes have led many authors to favor “skillful neglect” over operative treatment (20,69,84,160,164). Ninety percent to 100% satisfactory results with 5- to 7-year follow-up in patients with type III AC dislocations can be expected. The types of nonoperative treatment available are described in Chapter 10.

Operative Techniques

Four types of procedures have been described: AC joint fixation, CC ligament repair, distal clavicle excision, and dynamic muscle transfers.

Direct Fixation of the AC Joint

- Place the patient on a radiolucent table under general anesthesia. Prep and drape the shoulder with the upper extremity free.
- If closed technique is to be used, insert a ½-in. or larger smooth Steinmann pin antegrade from the lateral edge of the acromion to the joint. Then reduce the joint closed and, under fluoroscopic guidance, insert the pin across the joint into the clavicle.
- Some authors prefer to open the joint for debridement and reduction. Use a “safer cut” incision 5 cm or so in length directly over the AC joint. Insert the pins retrograde from the joint into the acromion and then into the clavicle after reduction of the joint. Always bend the portion of the pin that protrudes through the lateral acromion process to lessen the possibility of medial migration (Fig. 78.10).

![Figure 78.10.](image)

**Figure 78.10.** Open reduction of the AC joint and stabilization of the joint with two pins effectively reduced the fractured coracoid. Note that the distal ends of the pins have been bent to prevent medial migration.

- Repair the ligaments as close to anatomic as possible and then do a layered closure of the wound with a subcuticular skin closure.

Postoperative Care

Encourage patients to move the hand and elbow, avoiding excessive abduction of the shoulder to prevent breakage or migration of the pins. Rowe (155) recommends that abduction motion be limited to no more than 40°. Remove the pins after 6 to 8 weeks and begin range-of-motion and strengthening exercises.

Extra-articular CC Repairs

The technique of placing a specialized screw between the clavicle and the base of the coracoid was described by Bosworth (24,25,28) and West (27) in 1941. The screw was placed percutaneously without repair of the CC ligaments or exploration of the AC joint. Good results using various modifications of Bosworth's original technique have been reported (81,86,112, Fig. 78.11).

![Figure 78.11.](image)

**Figure 78.11.** Postoperative anteroposterior radiograph of the shoulder with Bosworth screw in place. Note that the AC joint has been reduced and the coarse lag threads of the screw are well seated into the coracoid process.

Coracoclavicular fixation can be obtained by looping various materials such as stainless steel wire (1,15), dacron arterial graft, velour dacron graft (92,134,141,175), or fascia lata (122,436) over the top of the clavicle and through or beneath the coracoid process.

These techniques have been associated with erosion of material through the distal clavicle and coracoid fracture (52,53,70,128).

The recommendations concerning removal of fixation devices after healing vary considerably. Neither Bosworth (24) nor Kennedy (97) recommended removal of the CC lag screw. Weitzman (185), however, recommended CC screw removal under local anesthesia at 8 weeks.

Excision of the Distal Clavicle

Mumford (132) described simple excision of the distal clavicle, which is usually done for an old, symptomatic type II injury. In symptomatic type III injuries, in addition to the excision of the distal clavicle, there must be a reconstruction of the CC ligaments.

Although excision of the distal clavicle is usually indicated in a symptomatic, chronic, incomplete AC dislocation—and possibly in an acute injury with severe joint damage—we do not recommend excision of a normal clavicle for an acute AC dislocation.

Type IV and V Injuries

Because of the severe posterior displacement of the distal clavicle in a type IV injury and the gross superior displacement in the type V, most authors recommend surgical repair (81,117,135,166). In a type IV injury, the patient is quite symptomatic when the distal end of the clavicle penetrates the trapezius muscle. In an inactive patient in whom the clavicle can be manipulated out of the trapezius muscle, a nonoperative approach is possible. If the clavicle cannot be manipulated out of the trapezius muscle, however, one of the previously described surgical procedures is indicated. In a type V injury, the deformity is so gross that surgical repair is usually indicated.
**Type VI Injury**

All type VI injuries described in the literature (67,122,142,157) have been treated with surgery, as initial attempts at closed reduction failed. Gerber and Rockwood (67) reported using the extra-articular technique with the Rockwood CC lag screw, with repair of the ligaments and imbrication of the deltotrapezius fascia over the top of the clavicle.

**Authors’ Preferred Methods of Treatment**

Our treatment algorithm for traumatic AC injuries is shown in Fig. 78.12.

**Operative Technique**

- Place a 10 × 12-in. x-ray cassette under the patient’s shoulder, and place the patient in the beach-chair position on the operating table. A special head rest is used so the top of the patient’s shoulder is completely free at the top of the corner of the table. Deviate the head slightly toward the normal shoulder and secure it to the head rest so there is complete access to the superior aspect of the shoulder. Place the anesthesiologist and equipment at the opposite shoulder so the surgeon can stand at the top of the table. Preparation and draping must provide access from the top of the shoulder to the base of the neck.
- Make a strap-like incision in Langer’s lines approximately 3 in. long (Fig. 78.13). Begin 1 in. posterior to the clavicle, then cross the clavicle 1 in. medial to the AC joint. Extend the incision downward to a point medial to the tip of the coracoid process. Undermine the incision so the AC joint, the distal 2 in. of the clavicle, and the anterior deltoid can be visualized.

**Type I Injury**

For symptomatic treatment we apply an ice pack for the first 12 hours, followed by moist heat, and provide a sling to support the arm. We encourage the patient to rest the shoulder but to maintain a gentle, normal range of motion. The symptoms usually subside within 7 days. Advise patients to avoid heavy stresses, lifting, and contact sports until there is a full range of motion and no pain to joint palpation, which usually takes 2 to 3 weeks.

**Type II Injury**

Treat as described above for a type I injury. The patient can use the arm for dressing, eating, and necessary everyday living activities when symptoms permit, usually about the seventh day. We advise patients to avoid heavy lifting, pushing, or contact sports for at least 6 weeks.

**Type III Injury**

We either restore the anatomy through an operative procedure or put the arm into a sling for a few days and gradually allow functional use of the shoulder. We do not use braces or strappings, which tend to irritate or ulcerate the tender skin on top of the shoulder.

For people who do heavy labor, and in those younger than 25 years of age who have not yet established their future occupation or sports, we proceed with surgical repair. A exception is a young athlete who regularly subjects the shoulder to violent, unprotected trauma (e.g., in soccer, rugby, and hockey). There is no sense in repairing an injury only to have it recur when the patient falls on the point of the shoulder. American football players with a grade III injury treated nonoperatively can perform well with special shoulder pads. Throwners can usually return to their sports with a grade III injury after 4 to 8 weeks. In patients doing heavy labor, however, operative repair yields a shoulder with more endurance that will stand up to repetitive stresses and heavy loads.

**Type IV, V, and VI Injuries**

In type IV and VI injuries seen early, we recommend closed reduction to dislodge the clavicle from the trapezius muscle or from under the coracoid process. If it is successful, we then apply the same indications as above for a type III problem. If the reduction fails, then an operative reduction and repair are necessary. Type IV, V, and VI injuries require operative repair.

**Operative Technique**

- In some instances, the deltoid and trapezius muscle fascia may have been torn from the distal 2 to 3 in. of the clavicle. If not, open this interval so the clavicle can be grasped with a clamp and lifted upward while the deltoid muscle is retracted distally to visualize the torn ends of the CC ligament and the base of the coracoid process. If the deltoid has been stripped off the clavicle with an intact periosteal tube, then split the deltoid distally 2 in. in line with its fibers, and detach the distal 2 in. from its insertion into the clavicle. This technique will allow exposure of the CC ligaments and the base of the coracoid process (Fig. 78.13).
- Grasp the distal end of the clavicle and lift it upward and debride the joint of the torn intraarticular disc and any loose tags of the AC ligament. Identify the torn ends of the CC ligament and tag them with two or three #1 cottony dacron sutures. Do not tie the sutures at this time.

**Figure 78.12** University of Texas at San Antonio treatment algorithm for traumatic disorders of the AC joint.

**Figure 78.13** The authors’ repair for a complete AC dislocation. A: The skin incision is about 3 in. long and extends from the posterior edge of the clavicle, 1 in. medial to the AC joint, then down in Langer’s lines to a point just medial to the tip of the coracoid process. B: The deltoid secondary to the injury is usually subperiosteally stripped away from the distal clavicle. It may have to be surgically detached to aid in identification and reapproximation to the CC ligaments and the base of the coracoid process. The distal end of the clavicle can be lifted up with a towel clip or a bone hook to aid in the placement of the sutures in the CC ligament. The AC joint is thoroughly debrided of the meniscus. If the AC ligaments are amenable to repair, they are preserved and later repaired. C: The distal end of the clavicle is held reduced adjacent to the acromion with a towel clip. A 3/16-in. drill bit is used to make a hole in the clavicle directly above the base of the coracoid. D: Through the 3/16-in. hole in the clavicle, a 3/16-in. drill bit is used to create a hole through both cortices of the base of the coracoid. E: The specially designed lag screw of appropriate length is then placed through the clavicle until the smooth shank of the screw is in the clavicle. The nongeared nipple end of the screw is then passed into the hole of the coracoid, and the screw is tightened home to depress the clavicle down to the level of the acromion. F: The stay sutures in the CC ligaments are then tied, and the screw is tightened another half turn to take any tension off the reapproximated ligaments. G: The muscle attachments of the deltoid and trapezius are carefully repaired and, if possible, are imbricated over the top of the clavicle and the AC joint. Note: In measuring the length of the screw, it must be remembered to add 6 mm to the measurement of the depth gauge so that the heavy threads will purchase both cortices of the coracoid.
and then the proximal part of the pin is free to migrate. For that reason, most surgeons avoid the use of pins across the AC joint. In most instances, pin migration can be prevented by bending a hook on the portion of the pin that protrudes from the acromion process. However, the pins can break, spinal cord (Pins and longitudinal wires across the AC joint tend to migrate or break because of motion in the joint. They have been reported to have migrated to the lung (Migration of Pins fixation, metal failure, and migration of the fixation device to other parts of the body). Wound infection and osteomyelitis are rare. Complications unique to repair of the AC joint can occur (i.e., a fracture through a drill hole, loss of purchase of the internal

**COMPLICATIONS OF OPERATIVE TREATMENT**

Wound infection and osteomyelitis are rare. Complications unique to repair of the AC joint can occur (i.e., a fracture through a drill hole, loss of purchase of the internal fixation, metal failure, and migration of the fixation device to other parts of the body).

**Migration of Pins**

Pins and longitudinal wires across the AC joint tend to migrate or break because of motion in the joint. They have been reported to have migrated to the lung (119), spinal cord (137), neck (108), subclavian artery (163), aorta (73), and liver (150).

In most instances, pin migration can be prevented by bending a hook on the portion of the pin that protrudes from the acromion process. However, the pins can break, and then the proximal part of the pin is free to migrate. For that reason, most surgeons avoid the use of pins across the AC joint.
Failure of Soft-tissue Repairs

Simple repair of the CC and AC ligaments without the additional support of internal fixation may lead to failure. This is particularly true in chronic complete injury to the AC joint when there is a major separation between the clavicle and the coracoid. Even the transfer of the acromial attachment of the CA ligament onto or into the medullary canal of the distal clavicle may fail.

Acromioclavicular Joint Arthritis

Symptomatic arthritis of the AC joint may occur after both nonoperative treatment and surgical fixation of the AC joint. If there are significant findings of degenerative changes or traumatic injury to the AC joint at the time of initial repair, then excise the distal clavicle. Use of the CA ligament to reconstruct the CC ligaments is rarely indicated in the surgical management of acute AC trauma.

When AC arthritis occurs late after type I and II injuries, and the patient does not respond to nonoperative treatment, then excision of the distal clavicle is indicated. Distal clavicle excision may be performed as an open (76,132) or arthroscopic procedure (19,86,124,165,179).

CHRONIC CONDITIONS OF THE AC JOINT

Degenerative Arthritis

Deterioration of the fibrocartilaginous disc that separates the two articular surfaces of the AC joint begins in the second decade of life (65) and can progress as part of the natural aging process, associated with progressive AC joint space narrowing. Radiographic findings of AC degeneration are seen in nearly 80% of elderly patients, with tenderness of one or both AC joints in 42% to 70% of patients (67).

Rheumatoid Arthritis

The AC joint is affected by rheumatoid arthritis in a fashion similar to that of other joints, with discomfort localized to this area in 63% of rheumatoid patients with painful shoulders (144).

Pathologic examination reveals proliferative synovial tissue, capsular swelling, and subchondral erosion, which is more marked inferiorly in the region of the coracoid process (148). Radiographic findings include joint space narrowing, osteopenia of the acromial process, inferior surface erosions of the distal clavicle, and osteolysis of the acromial end of the clavicle with tapering (2,3,129,144). These findings are progressive and are found in about 80% of rheumatoid patients with painful shoulders.

OSTEOLYSIS OF THE DISTAL CLAVICLE

Posttraumatic osteolysis of the distal clavicle may follow an acute injury, or it may occur in patients who have repeated stress on the shoulder. Most cases involve weight lifters who complain of a dull ache, weakness, and pain with flexion and abduction. A 10° cephalic tilt radiograph of the AC joint may show osteoporosis, osteolysis, tapering, or osteophyte formation of the distal clavicle. Usually, bony changes are unilateral and do not occur in the acromion (Fig. 78.16). Technetium bone scans have also been found to be quite helpful (49).

Figure 78.16. Traumatic osteolysis of the right distal clavicle in a patient who had an injury to the right shoulder and gradually developed increasing pain. Radiograph made 3 months after the injury shows an absorption of the distal clavicle and new bone formation on the dorsal aspect of the clavicle. (From Rockwood CA, Green DP, eds. Fractures, 3rd ed. Philadelphia: JB Lippincott, 1991:1236.)

With activity modification and rest, the distal clavicle may reconstitute itself (109). Should symptoms not be relieved, then excision of the distal end of the clavicle may be necessary.

Authors’ Treatment of Chronic Problems of the AC Joint

Excision of the distal clavicle for a degenerative AC joint with an old type II injury is appropriate. We recommend excision of a minimum of 2 cm of the distal clavicle. If the excision of the distal clavicle is too small, it eventually may develop a spur that will impinge against the acromion, producing symptoms and pain just as before the operation.

If the clavicle has lost its attachment to the coracoid (i.e., a chronic type III, IV, V, or VI injury), the CC ligament must be reconstructed, and distal clavicle resection surgery must be performed.

Authors’ Method to Reconstruct a Chronic, Complete AC Dislocation

1. Position, prep, and drape the patients, using the same surgical approach described for an acute repair of a type III injury. Excise the distal 2 cm of the clavicle. Remove enough clavicle so the stump of the clavicle is located just at the lateral edge of the base of the coracoid (Fig. 78.17). Then drill the medullary canal of the distal clavicle and widen it with a curet to be able to receive the transferred CA ligament.

Figure 78.17. The authors’ method to reconstruct a chronic type III, IV, V, or VI AC dislocation. A: The incision is made in Langer’s lines. B: The distal end of the clavicle is excised. C: The medullary canal is drilled out and curetted to receive the transferred CA ligament. D: Two small drill holes are made through the superior cortex of the distal clavicle. The CA ligament is carefully detached from the acromion process. E–H: With the CA ligament detached from the acromion, a heavy nonabsorbable suture is woven through the ligament. The ends of the suture are passed out through the two small drill holes in the distal end of the clavicle. The CC lag screw is inserted; and when the clavicle is reduced down to its normal position, the sutures used to pull the ligament snugly up into the canal.
Surgery on the SC joint takes place immediately adjacent to these vital structures. The view of vital structures, including the innominate artery, innominate vein, vagus nerve, phrenic nerve, internal jugular vein, trachea, and esophagus (Fig. 78.17). There is a "curtain" of muscles consisting of the sternohyoid, sternothyroid, and scaleni posterior to the SC joint and the inner third of the clavicle. This curtain blocks the body to appear and the last epiphysis to close, ossifying between the 18th and 20th year and fusing around the 23rd to 25th year (72,74). Although the clavicle is the first long bone of the body to ossify (fifth intrauterine week), the epiphysis at the medial end of the clavicle is the last of the long bones in the body to ossify (72,74). The interclavicular ligament. The intra-articular disc ligament is a very dense, fibrous structure that arises from the synchondral junction of the first rib to the sternum and above the margins of the impression on the inferior surface of the medial end of the clavicle, sometimes known as the rhomboid fossa (72,74).

LIGAMENTS OF THE SC JOINT

The integrity of this joint comes from the intra-articular disc ligament, the extra-articular costoclavicular ligament (rhomboid ligament), the capsular ligament, and the interclavicular ligament. The intra-articular disc ligament is a very dense, fibrous structure that arises from the synchondral junction of the first rib to the sternum and passes through the SC joint, which divides the joint into two separate joint spaces (Fig. 78.18) (72,74). The upper attachment is on the superior and posterior aspects of the medial clavicle. The disc acts as a checkrein against medial displacement of the inner clavicle. The costoclavicular ligament, also called the rhomboid ligament, is short and strong and consists of an anterior and a posterior fasciculus (16,43,74). The costoclavicular ligament attaches below to the upper surface of the first rib and at the adjacent part of the synchondral junction with the sternum and above the margins of the impression on the inferior surface of the medial end of the clavicle, sometimes known as the rhomboid fossa (72,74). The interclavicular ligament connects the superomedial aspects of each clavicle with the capsular ligaments and the upper sternum (Fig. 78.18). According to Grant (72), this band may be comparable to the wishbone of birds. This ligament helps the capsular ligaments hold up the shoulder. The capsular ligament covers the anterosuperior and posterior aspects of the joint and represents thickening of the joint capsule (Fig. 78.18). The anterior portion of the capsular ligament is heavier and stronger than the posterior portion. It may be the strongest ligament of the SC joint, and it is the first line of defense against the upward displacement of the inner clavicle caused by a downward force on the distal end of the shoulder (16). The SC joint is freely movable and functions almost as a ball-and-socket joint in that the joint has motion in all planes, including rotation (23,114). The clavicle, and therefore the SC joint, in normal shoulder motion is capable of 30° to 35° of upward elevation, 35° of combined forward and backward movement, and 45° to 50° of rotation around its long axis (Fig. 78.19). It is most likely the most frequently moved joint of the long bones in the body because almost any motion of the upper extremity is transferred proximally to the SC joint.

LIGAMENTS OF THE SC JOINT

The integrity of this joint comes from the intra-articular disc ligament, the extra-articular costoclavicular ligament (rhomboid ligament), the capsular ligament, and the interclavicular ligament. The intra-articular disc ligament is a very dense, fibrous structure that arises from the synchondral junction of the first rib to the sternum and passes through the SC joint, which divides the joint into two separate joint spaces (Fig. 78.18) (72,74). The upper attachment is on the superior and posterior aspects of the medial clavicle. The disc acts as a checkrein against medial displacement of the inner clavicle. The costoclavicular ligament, also called the rhomboid ligament, is short and strong and consists of an anterior and a posterior fasciculus (16,43,74). The costoclavicular ligament attaches below to the upper surface of the first rib and at the adjacent part of the synchondral junction with the sternum and above the margins of the impression on the inferior surface of the medial end of the clavicle, sometimes known as the rhomboid fossa (72,74). The interclavicular ligament connects the superomedial aspects of each clavicle with the capsular ligaments and the upper sternum (Fig. 78.18). According to Grant (72), this band may be comparable to the wishbone of birds. This ligament helps the capsular ligaments hold up the shoulder. The capsular ligament covers the anterosuperior and posterior aspects of the joint and represents thickening of the joint capsule (Fig. 78.18). The anterior portion of the capsular ligament is heavier and stronger than the posterior portion. It may be the strongest ligament of the SC joint, and it is the first line of defense against the upward displacement of the inner clavicle caused by a downward force on the distal end of the shoulder (16). The SC joint is freely movable and functions almost as a ball-and-socket joint in that the joint has motion in all planes, including rotation (23,114). The clavicle, and therefore the SC joint, in normal shoulder motion is capable of 30° to 35° of upward elevation, 35° of combined forward and backward movement, and 45° to 50° of rotation around its long axis (Fig. 78.19). It is most likely the most frequently moved joint of the long bones in the body because almost any motion of the upper extremity is transferred proximally to the SC joint.

LIGAMENTS OF THE SC JOINT

The integrity of this joint comes from the intra-articular disc ligament, the extra-articular costoclavicular ligament (rhomboid ligament), the capsular ligament, and the interclavicular ligament. The intra-articular disc ligament is a very dense, fibrous structure that arises from the synchondral junction of the first rib to the sternum and passes through the SC joint, which divides the joint into two separate joint spaces (Fig. 78.18) (72,74). The upper attachment is on the superior and posterior aspects of the medial clavicle. The disc acts as a checkrein against medial displacement of the inner clavicle. The costoclavicular ligament, also called the rhomboid ligament, is short and strong and consists of an anterior and a posterior fasciculus (16,43,74). The costoclavicular ligament attaches below to the upper surface of the first rib and at the adjacent part of the synchondral junction with the sternum and above the margins of the impression on the inferior surface of the medial end of the clavicle, sometimes known as the rhomboid fossa (72,74). The interclavicular ligament connects the superomedial aspects of each clavicle with the capsular ligaments and the upper sternum (Fig. 78.18). According to Grant (72), this band may be comparable to the wishbone of birds. This ligament helps the capsular ligaments hold up the shoulder. The capsular ligament covers the anterosuperior and posterior aspects of the joint and represents thickening of the joint capsule (Fig. 78.18). The anterior portion of the capsular ligament is heavier and stronger than the posterior portion. It may be the strongest ligament of the SC joint, and it is the first line of defense against the upward displacement of the inner clavicle caused by a downward force on the distal end of the shoulder (16). The SC joint is freely movable and functions almost as a ball-and-socket joint in that the joint has motion in all planes, including rotation (23,114). The clavicle, and therefore the SC joint, in normal shoulder motion is capable of 30° to 35° of upward elevation, 35° of combined forward and backward movement, and 45° to 50° of rotation around its long axis (Fig. 78.19). It is most likely the most frequently moved joint of the long bones in the body because almost any motion of the upper extremity is transferred proximally to the SC joint.
Richter et al. (109) reported nine patients with infection of the SC joint secondary to tuberculosis. The average time from onset of the disease until diagnosis was 1.4 years.

**CLASSIFICATION**

The SC joint dislocations may be classified according to the anatomic position the dislocation assumes or according to etiology.

Anterior dislocations are the most common. The medial end of the clavicle is displaced anteriorly or anterosuperiorly to the anterior margin of the sternum. Posterior SC dislocation is uncommon. The medial end of the clavicle is displaced posteriorly or posterosuperiorly with respect to the posterior margin of the sternum.

Acute sprains to the SC joint can be classified as mild, moderate, or severe. In a mild sprain, all the ligaments are intact, and the joint is stable. In a moderate sprain, there is subluxation of the SC joint. The capsular, intra-articular disc, and costoclavicular ligaments may be partially disrupted. The subluxation may be anterior or posterior. In a severe sprain, there is complete disruption of the SC ligaments, and the dislocation may be anterior or posterior.

If the initial acute traumatic dislocation does not heal, mild to moderate forces may produce recurrent dislocations; this is a rare occurrence.

The original dislocation may go unrecognized, it may be irreducible, or the physician may decide not to reduce certain dislocations.

For a variety of nontraumatic reasons, the SC joint may subluxate or enlarge.

One or both of the SC joints may spontaneously subluxate or dislocate anteriorly during overhead motion. The problem usually is not painful (Fig. 78-21).

**OTHER CONDITIONS AFFECTING THE SC JOINT**

**Arthritis**

Degenerative and inflammatory arthritis (79,99,100) is encountered in the SC joint and can be secondary to trauma, condensing osteitis of the medial clavicle (91-161). SC hyperostosis, rheumatoid arthritis (33,63,191), rheumatoid spondylitis (149), spondyloarthritis (99), psoriasis (170), polymyalgia rheumatica (140), secondary hyperparathyroidism (139,177), gout (68,177), leprosy (136), syringomyelia (51), tumor (51), and aseptic necrosis (106) and following radical neck resection, particularly with loss of the spinal accessory nerve (41,71,161,176). Routine degenerative arthritis in postmenopausal women has been singled out as “postmenopausal arthritis,” but it is not a unique disorder (22,28,166).

**Condensing Osteitis of the Medial Clavicle**

Condensing osteitis of the medial clavicle usually occurs in women over the age of 40 and may be secondary to chronic stress on the joint. The joint is swollen and tender, and radionuclide studies reveal an increased uptake. Routine laboratory results are within normal limits. X-ray films show sclerosis and slight expansion of the medial third of the clavicle. The inferior portion of the sternum end of the clavicle shows sclerotic changes. Some osteophytes may be present, but the joint space is preserved. The changes of the medial clavicle are best detected with a CT scan. Most patients do well with conservative treatment (i.e., anti-inflammatory medications). Kruger and associates (101) recommend incisional or excisional biopsy in refractory cases.

**Sternocostoclavicular Hyperostosis**

This condition, usually bilateral, affects adults of both sexes between 30 and 50 years of age. The process begins at the junction of the medial clavicle, the first rib, and the sternum as an ossification in the ligaments and later involves the bones. In some cases, the hyperostosis is extensive and forms a solid block of bone of the sternum, ribs, and clavicle. Patients may have peripheral arthritis. Subchondrocalval bone changes have been noted in other bones (68). The condition has been graded into three stages by Sonozaki (177,178 and 179). Stage I is mild ossification in the costoclavicular ligaments; stage II is characterized by an osseous mass between the clavicle and the first rib; in stage III, a bone mass exists between the clavicle, sternum, and first rib. As might be expected with the fusion of the SC joint, shoulder motion is severely restricted.

Pustular cutaneous lesions of the palmar and plantar surfaces of skin may be seen. There is no specific laboratory test, except for an occasional elevation of the serum alkaline phosphatase (68).

**Infection**

Spontaneous swelling with the appearance of joint subluxation may be associated with acute, subacute, or chronic bacterial arthritis. Predisposing conditions include intravenous drug addiction and the presence of the human immunodeficiency virus (HIV) (47,187). Common predisposing causes to infection in nonaddicts are bacteremia, infectious invasion from surrounding bone, rheumatoid arthritis, alcoholism, and chronic debilitating diseases. The CT scan is very helpful in making an early diagnosis of a septic SC joint (109,130,167).

Richter et al. (151) reported nine patients with infection of the SC joint secondary to tuberculosis. The average time from onset of the disease until diagnosis was 1.4 years.
MECHANISMS OF INJURY

Because the SC joint is subject to practically every motion of the upper extremity, and because the joint is so small and poorly matched, one would think it would be the most commonly dislocated joint in the body. However, the ligamentous supporting structure is so strong and so designed that it is, in fact, one of the least commonly dislocated joints in the body. A traumatic dislocation of the SC joint usually requires tremendous forces, either direct or indirect.

When a force is applied directly to the anteromedial aspect of the clavicle, the clavicle is pushed posteriorly behind the sternum and into the mediastinum. A force applied indirectly to the SC joint from the anterolateral or posterolateral aspects of the shoulder is the most common mechanism of injury to the SC joint (85,123). If the shoulder is compressed and rolled forward, an ipsilateral posterior dislocation results; if the shoulder is compressed and rolled backward, an ipsilateral anterior dislocation results (Fig. 78.22).

Figure 78.22. Mechanisms that produce anterior or posterior dislocations of the SC joint. A: If the patient is lying on the ground, and a compression force is applied to the posterolateral aspect of the shoulder, the medial end of the clavicle will be displaced posteriorly. B: When the lateral compression force is directed from the anterior position, the medial ends of the clavicle are dislocated anteriorly.

CLINICAL ASSESSMENT

In a mild sprain, the ligaments of the joint are intact. The patient complains of a mild to moderate amount of pain, particularly with movement of the upper extremity. The joint may be slightly swollen and tender to palpation, but instability is not noted.

A moderate sprain results in a subluxation of the SC joint. The ligaments are either partially disrupted or severely stretched. Swelling is noted, and pain is marked, particularly with any movement of the arm. Anterior or posterior subluxation may be obvious to the examiner when the injured joint is compared with the normal SC joint.

A severe sprain is analogous to a joint dislocation. The dislocation may be anterior or posterior. The capsular ligaments and the intra-articular disc ligament are ruptured. The patient with a SC dislocation has severe pain that is increased with any movement of the arm, particularly when the shoulders are pressed together. The patient usually supports the injured arm across the trunk with the normal arm. The affected shoulder appears to be shortened and thrust forward when compared with the normal shoulder. The head may be tilted toward the side of the dislocated joint. Discomfort increases when the patient is placed in the supine position, at which time it will be noted that the involved shoulder will not lie back flat on the table.

With an anterior dislocation, the medial end of the clavicle is prominent anterior to the sternum (Fig. 78.23) and can be palpated anterior to the sternum. It may be fixed anteriorly or be quite mobile.

Figure 78.23. A: With the patient supine, view the clavicles from around the level of the patient’s knees. It is apparent that the right clavicle is dislocated anteriorly. B: Clinically, an anterior dislocation of the right SC joint is evident (arrow).

The patient with a posterior dislocation has more pain than a patient with an anterior dislocation. The anterosuperior fullness of the chest produced by the clavicle is less prominent. The medial end of the clavicle is displaced posteriorly. The corner of the sternum is easily palpated, as compared with the normal SC joint. Venous congestion may be present in the neck or in the upper extremity (172). Breathing difficulties, shortness of breath, or a choking sensation may be noted. Circulation to the ipsilateral arm may be decreased. The patient may complain of difficulty in swallowing or a tight feeling in the throat or may be in a state of complete shock or possibly have pneumothorax.

Because of swelling, it can be difficult to distinguish between anterior and posterior dislocations.

RADIOGRAPHIC FINDINGS

The routine anteroposterior or posteroanterior radiographs of the chest or SC joint may suggest that something is wrong with one of the clavicles, because it appears to be displaced as compared with the normal side (Fig. 78.24). It would be ideal to take a view at right angles to the anteroposterior plane, but because of human anatomy, it is impossible to take a true 90° cephalic-to-caudal lateral view.
Figure 78.24. Anteroposterior radiograph of the SC joints with anterosuperior displacement of the left medial clavicle. The displacement is quite noticeable when the clavicles are outlined.

Heinig View

With the patient supine, place the x-ray tube approximately 30 in. from the involved SC joint and direct the central ray tangential to the joint and parallel to the opposite clavicle (Fig. 78.25). Place the cassette against the opposite shoulder and centered on the manubrium.

Figure 78.25. A: Positioning of the patient for radiograph evaluation of the SC joint, as described by Heinig. B: Heinig view demonstrating a normal relationship between the medial end of the clavicle (C) and the manubrium (M).

Hobbs View

For the Hobbs view, seat the patient at the x-ray table, high enough to lean forward over the table. Place the cassette on the table, and position the lower anterior rib cage against the cassette (Fig. 78.26). Have the patient lean forward so that the nape of the flexed neck is almost parallel to the table. The flexed elbows straddle the cassette and support the head and neck. Place the x-ray source above the nape of the neck, and direct the central beam through the cervical spine to project the SC joints onto the cassette.

Figure 78.26. Positioning of the patient for radiograph evaluation of the SC joint, as recommended by Hobbs. (Redrawn from Hobbs DW. The SC Joint: A New Axial Radiographic View. Radiology 1968;90:801.)

Serendipity View

Rockwood described the “serendipity” view of the SC joint, which is a 40° cephalic tilt view (Fig. 78.27). On this view the medial end of the clavicle will be displaced more anteriorly for an anterior dislocation and posteriorly for a posterior dislocation compared with the normal side.

Figure 78.27. Positioning of the patient to take the “serendipity” view of the SC joints. The x-ray tube is tilted 40° from the vertical position and aimed directly at the manubrium. The nongrid cassette should be large enough to receive the projected images of the medial halves of both clavicles. In children, the tube distance from the patient should be about 45 in.; in thicker-chested adults, the distance should be 60 in.

Figure 78.28. Interpretation of the cephalic tilt x-ray films of the SC joints. A: In the normal person, both clavicles appear on the same imaginary line drawn horizontally across the film. B: In a patient with anterior dislocation of the right SC joint, the medial half of the right clavicle is projected above the imaginary line drawn through the
General anesthesia is usually required for reduction of a posterior dislocation of the SC joint, although reduction with conscious sedation is possible. The treatment of posterior dislocation is complex and requires careful consideration. Consultation with a thoracic or vascular surgeon may be indicated before reduction. Posterior dislocation of the clavicle into the right pulmonary artery has been reported (189). Complications and associated injuries are common with posterior dislocation of the SC joint; prompt diagnosis and treatment are important.

TREATMENT

Nonoperative Treatment

For the mildly sprained SC joint, apply ice for the first 12 to 24 hours, followed by heat. Place the upper extremity in a sling for 3 to 4 days, then allow the patient gradually to use the arm in everyday activities.

For subluxation of the SC joint, treat symptomatically in the first 48 hours as above. Whether the joint is subluxated anteriorly or posteriorly, reduce it by drawing the shoulders backward as if reducing and holding a fracture of the clavicle. Use a figure-of-eight clavicle strap to hold the reduction. Also apply a sling and swath to hold up the shoulder and to prevent motion of the arm. Protect the shoulder for 4 to 6 weeks.

In anterior dislocations, closed reduction of the SC joint may be accomplished with local or general anesthesia or, in stoic patients, with conscious sedation or without anesthesia. Position the patient supine on a table, lying on a 3- to 4-in.-thick pad between the shoulders. In this position, the clavicle may reduce the joint. Sometimes, both shoulders must be pushed back to the table while an assistant applies pressure to the anteriorly displaced clavicle. When the pressure is released, the clavicle usually dislocates again, but occasionally the clavicle will remain reduced.

Postreduction Care

If, with the shoulders held back, the SC joint remains reduced, stabilize the shoulders with a soft figure-of-eight dressing, a commercial clavicle strap harness, or a plaster figure-of-eight cast (see Chapter 10) combined with a sling. Continue immobilization for 6 weeks and then have the patient avoid strenuous activities for another 2 weeks. If the SC joint again dislocates when the reduction pressure is released, as it usually does, use a figure-of-eight dressing or a sling for symptomatic treatment. Although some authors have recommended operative repair of anterior dislocations of the SC joint, we believe that the operative complications are too great, and the end results are too unsatisfactory, to consider an open reduction.

Complications and associated injuries are common with posterior dislocation of the SC joint; prompt diagnosis and treatment are important.

Rule out damage to the pulmonary and vascular systems. A CT scan is indicated occasionally, combined with an aortogram. If vascular injury is suspected, consultation with a thoracic or vascular surgeon may be indicated before reduction. Posterior dislocation of the clavicle into the right pulmonary artery has been reported (189).

General anesthesia is usually required for reduction of a posterior dislocation of the SC joint, although reduction with conscious sedation is possible. The treatment of choice for posterior SC dislocation is closed reduction (38, 45, 46, 65, 75, 85, 120, 121, 127, 143, 158, 173).

Methods of Closed Reduction

Many different techniques have been described for closed reduction of the posterior dislocation of the SC joint.

- For the abduction traction technique (65, 127, 152, 158), position the patient supine with the dislocated shoulder near the edge of the table. Place a 3- to 4-in.-thick sandbag between the shoulders (Fig. 78.30).
- Apply lateral traction to the abducted arm and gradually extend the shoulder. This procedure may be all that is necessary to accomplish the reduction. The clavicle usually reduces with an audible snap or pop, and it is almost always stable. Too much extension can bind the anterior surface of the dislocated medial clavicle on the back of the manubrium. Occasionally, it may be necessary to grasp the medial clavicle with your fingers to dislodge it from behind the sternum. If this maneuver fails, prep the skin, and use a sterile towel clip to grasp the medial clavicle to apply lateral and anterior traction to reduce it.
- In the adduction traction technique, position the patient supine with a 3- to 4-in. bolster between the shoulders. Apply traction to the arm in adduction while downward pressure is exerted on the shoulders. The pressure leveres the clavicle over the first rib into its normal position. This technique may succeed when the abduction traction technique has failed (34).
- Alternative techniques include placing the patient supine on the table with three or four folded towels between the shoulders and applying forward pressure on both shoulders, or placing a knee between the shoulders of the seated patient and pulling back on both shoulders (65, 85). Closed reduction usually becomes...
*Postreduction Care* After reduction, immobilize the shoulders in extension for 4 to 6 weeks with a figure-of-eight dressing or similar dressing.

**Operative Treatment**

In an open reduction, try not to disturb the anterior ligaments, if possible. If anterior ligaments remain intact, then, with the shoulders held back in a figure-of-eight dressing, the reduction may be stable. If all the ligaments are disrupted, then stabilization of the SC joint or resection of the medial 1 to 1.5 in. of the medial clavicle and stabilization of the remaining clavicle to the first rib may be necessary.

Procedures to stabilize the unstable, recurrent, or unreduced SC dislocation include the following:

- Local ligament repair and pin or wire stabilization (30,32,54,56,62).
- Circumferential wires across the joint (7,60,77,80,95,138,145,173,174).
- Figure-of-eight carbon fiber (36).
- Reconstruction of the SC ligaments with tendons or fascia of the sternocleidomastoid, subclavian, or pectoralis major muscles (11,37,72,74,82,115).
- Loops of fascia lata between the clavicle and sternum or first rib (7,98,113,125,171).
- Arthrodesis (150) is to be avoided.

Most adults cannot tolerate posterior displacement of the clavicle into the mediastinum and late complications involving underlying vascular structures, so an operative procedure to correct the situation is nearly always required. These include open reduction and one of the reconstructions mentioned above or resection of the medial end of the clavicle (described under *Authors' Preferred Method of Treatment*; 13,14,28,125,129,147). Because children usually have an epiphyseal slip, remodeling will often correct the deformity, and surgery is rarely required (154).

**Authors' Preferred Method of Treatment**

**Anterior Dislocations** In most instances, knowing that the anterior dislocation will be unstable, we try to reduce the anterior displacement, using the technique previously described.

Most of the anterior injuries that we have treated in patients up to 25 years of age are not dislocations of the SC joint but type I or II physeal injuries, which heal and remodel without operative treatment. Patients older than 23 to 25 years with anterior dislocations of the SC joint do have persistent prominence of the anterior clavicle. It does not, however, seem to interfere with usual activities and, in some cases, has not even interfered with heavy manual labor.

We wish to reemphasize that we do not recommend open reduction of the joint and would never recommend transfixed pins across the SC joint.

We do not usually operate on acute posterior SC joint dislocations. Furthermore, once the joint has been reduced closed, it is usually stable. For closed reduction, we use the traction–abduction method previously described.

If the traction in abduction and extension is not successful, grasp or push down on the clavicle to dislodge it from behind the sternum. If unsuccessful, use the sterile towel clip method described previously. With the towel clip, grasp completely around the shaft of the clavicle, as the dense cortical bone prevents the purchase of the towel clip tines into the clavicle. Following the reduction, the SC joint is normally stable, but we always hold the shoulders back in a well-padded figure-of-eight clavicle dressing, the reduction may be stable. If all the ligaments are disrupted, then stabilization of the SC joint or resection of the medial 1 to 1.5 in. of the medial clavicle and stabilization of the remaining clavicle to the first rib may be necessary.

Operative Technique When operating on the SC joint, take care to evaluate the residual stability of the medial clavicle. If the costoclavicular ligaments are intact, the clavicle medial to the ligaments can be resected and beveled smooth (*Fig. 78.31*). If the ligaments are gone, the clavicle must be stabilized to the first rib. If too much clavicle is resected, or if the clavicle is not stabilized to the first rib, an increase in symptoms can occur.

![Figure 78.31. Technique for resecting the medial clavicle for degenerative arthritis. A: Care must be taken to remove only that part of the clavicle medial to the costoclavicular (rhomboid) ligaments. There must be adequate protection for the vital structures that lie posterior to the medial end of the clavicle. B,C: An air drill with a side-cutting bur can be used to perform the osteotomy. D: When the fragment of bone has been removed, the dorsal and anterior borders of the clavicle should be smoothed to give a better cosmetic appearance.](image)

![Figure 78.32. Proposed skin incision for open reduction of a posterior SC dislocation.](image)
Synchondral junction of the first rib to the sternum and passes through the SC joint, dividing the joint into two separate spaces. The capsular ligament covers the anterosuperior and posterior aspects of the joint and represents thickenings of the joint capsule. This ligament is primarily attached to the epiphysis of the medial clavicle and is usually avulsed from this structure with posterior SC dislocations. Similarly, the intra-articular disc ligament is usually intact where it arises from the synchondral junction of the first rib and sternum and avulsed from its attachment site on the medial clavicle.

- If the sternal attachment site of these structures is intact, weave a nonabsorbable #1 cottony Dacron suture back and forth through the ligaments so that the ends of the suture exit through the avulsed free end of the tissue.
- Resect the medial end of the clavicle, being careful to protect the underlying structures. Do not damage the costoclavicular (rhomboid) ligament or the vascular structures that are located posterior to the medial clavicle and SC joint. Protect these vital structures by passing a curved crego or ribbon retractor around the posterior aspect of the medial clavicle. Drill holes through both cortices of the clavicle at the intended site of clavicular osteotomy, and then use an air drill with a side-cutting burr or an osteotome to complete the osteotomy. Bevel the anterior and superior corners of the clavicle with an air burr.
- Next, enlarge the medullary canal of the medial clavicle with drills and curets to receive the transferred intra-articular disc ligament (Fig. 78.33). Drill two small holes in the superior cortex of the medial clavicle, approximately 1 cm lateral to the site of resection (Fig. 78.34). Pass the free ends of the suture into the medullary canal of the clavicle and out the two holes in the superior cortex (Fig. 78.35). While the clavicle is held in a reduced position, pull the ligament tightly into the medullary canal of the clavicle and tie the sutures, thus securing the transferred ligament into the clavicle (Fig. 78.36). Complete the stabilization procedure by passing several 1-mm cottony Dacron sutures around the medial end of the remaining clavicle and securing the periosteal sleeve of the clavicle to the costoclavicular ligament.

Figure 78.33. The medullary canal of the medial clavicle is curetted in preparation for receiving the transferred intra-articular ligament.

Figure 78.34. Drill holes are placed in the superior cortex of the clavicle, approximately 1 cm lateral to the osteotomy site.

Figure 78.35. The free ends of the suture are passed into the medullary canal and out the two holes in the superior cortex.

Figure 78.36. Closure of the periosteal sleeve around the medial clavicle and secure fixation of these structures to the costoclavicular ligament.

- Postoperatively, keep the patient in a figure-of-eight dressing for 4 to 6 weeks to allow for healing.

Chronic Traumatic Dislocation of the SC Joint

As previously described, most patients with an unreduced and permanent anterior dislocation of the SC joint are not very symptomatic, have almost a complete range of motion, and can work and even perform manual labor without many problems. In patients who have had a previous failed SC surgery, we perform a repeat arthroplasty with a resection of the medial clavicle, as described above.

If the patient has persistent symptoms of traumatic arthritis for 6 to 12 months following a dislocation, and if the symptoms can be completely relieved by injection of local anesthetic into the SC joint region, we perform an arthroplasty similar to that described earlier in this chapter.

Posterior Dislocation

In the adult, because of the potential problems that can be associated with the clavicle remaining displaced posteriorly into the mediastinum, an open reduction is...
usually indicated. This requires excision of the medial 1 in. of the clavicle and stabilization to the first rib as described above.

**Spontaneous Subluxation or Dislocation**

We have seen 39 patients with spontaneous subluxation or dislocation of the SC joint. About the only symptoms they have is that the medial end of the clavicle subluxates or dislocates anteriorly when they raise their arms overhead (153). This occurs spontaneously and without any significant trauma. Many of these patients have generalized ligamentous laxity. This problem might be considered voluntary or involuntary because it occurs whenever the patient raises the arms to the overhead position. We explain to patients that surgery is of little benefit, that they should discontinue the voluntary aspect of the dislocation, and that in time either the symptoms will disappear or they will completely forget that the dislocation is a problem.

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Since the first report of a torn rotator cuff in 1834 (59), disorders of the rotator cuff have become universally recognized as the predominant cause of shoulder pain and impairment in athletes and the general population as well. Pathologic conditions include tendinitis, partial- and full-thickness tears of the supraspinatus and other rotator cuff muscles, calcific tendinitis, and degeneration of the long head of the biceps tendon. Recent advances in the management of these disorders include increased recognition of the role of dynamic causes of rotator cuff tendinopathy, an expanded role of arthroscopic evaluation and treatment, and improved fixation methods of tendon repair facilitating rehabilitation. Other conditions of the shoulder discussed in this chapter include rupture of the pectoralis major and adhesive capsulitis.

ETIOLOGY AND PATHOPHYSIOLOGY

Myriad factors have been implicated in the development of rotator cuff tendinopathy. Patient age can be a clue to etiology. In the younger patient, especially the athlete, repetitive overuse, muscle imbalance and weakness, capsular contractures, and coexistent glenohumeral instability are potential causes (24,27,30). Abnormality of scapular rotation, because of the functional interdependency of the shoulder complex, can cause secondatory rotator cuff dysfunction and pain (30,31). In middle-aged and older patients, primary tendon degeneration as well as morphologic alteration of the coracocromial arch including degeneration of the acromioclavicular joint are the principal causes of symptomatic rotator cuff tendinopathy (6,12,38,39,40).

Compression or impingement of the superior surface of the rotator cuff tendons, especially the supraspinatus, against the undersurface of the anterior acromion and the coracoacromial ligament is a major mechanism for the production of rotator cuff pain (40). Progressive, unchecked mechanical impingement against the anterior-inferior acromion and coracoacromial (CA) ligament initiates a cycle of tendon degeneration, for which Neer (40) identified three stages, starting with edema and hemorrhage in the tendon, progressing to fibrosis and tendinits, and culminating in spurs and eventual tendon rupture.

Neer (40) and others have postulated that primary alteration of the coracoacromial arch reduces the space for excursion of the rotator cuff tendons during humeral elevation, precipitating tendon degeneration. An increased incidence of tendinopathy has been noted in patients with a type II or III acromial configuration (Fig. 79.1), as well as in those with ununited acromial ossification centers (38,39). It appears, however, that in a number of cases, hypertrophic changes in the coracoacromial arch develop after primary degeneration of the rotator cuff has occurred (44,45). Further attrition can then occur as the degenerated rotator cuff tendons are compressed against a thickened acromion and CA ligament.

![Figure 79.1. Acromial morphology: I, flat; II, curved; and III, hooked.](image)

Codman (12) was one of the first to recognize that tendon degeneration could occur on the undersurface (articular), superior surface (bursal), or within the substance of the supraspinatus tendon (mid-substance), creating partial-thickness lesions in these locations. Some lesions produce symptoms, and an unknown percentage progress to full-thickness tears. Most complete tears become manifest as the result of minor trauma superimposed on longstanding degeneration. Due to its intraarticular course, the long head of the biceps tendon is subjected to the same degenerative processes as the adjacent supraspinatus tendon.

In some instances, abnormal superior translation of the humeral head during overhead motion leads to compression of the supraspinatus against an unyielding but normal-shaped acromion and coracoacromial ligament. Weakness and imbalance of the rotator cuff muscles or the scapular muscles, glenohumeral subluxation, and tightness of the posterior shoulder capsule all produce rotator cuff pain as a result of dynamic compression (24,30,31).
Other mechanisms may account for the development of shoulder pain. Particularly in the throwing athlete, tensile failure from repetitive, eccentric overload occurs because the supraspinatus and posterior cuff muscles resist the forces of internal rotation, adduction, and distraction during the deceleration phase of throwing. Typically, undersurface partial tears occur in the posterior part of the supraspinatus as well as the infraspinatus (1). Acute overload of a healthy tendon contracting against excessive resistance occurs infrequently, resulting in massive rotator cuff avulsion, or in isolated rupture of the pectoralis major or long head of the biceps.

Recognition of the etiology and mechanism responsible for symptoms is important because treatment regimens differ. Whereas rotator cuff compression or impingement due to static abnormalities (abnormal subacromial outlet) may not resolve without surgical intervention, dynamic causes of rotator cuff compression most often respond to appropriate nonsurgical measures or to surgical correction of coexistent instability. Furthermore, rotator cuff tendinopathy that is not associated with an abnormal subacromial outlet may not respond to subacromial decompression (6).

**CLASSIFICATION**

A classification scheme is helpful to formulate treatment, considering the various etiologies and the spectrum of rotator cuff injuries (Table 79.1). Using a scheme prevents the tendency to generalize all cases of rotator cuff pain as impingement syndrome. That sort of generalization leads to automatic subacromial decompression for refractory cases.

**HISTORY**

Except in cases of an acute traumatic injury, patients with rotator cuff tendinitis usually describe an insidious onset of shoulder pain located over the anterior superior aspect of the shoulder. Pain occurs during or following overhead activity and is relieved by rest. Like patients with acromioclavicular (AC) joint pathology, some individuals with rotator cuff injury may experience pain with cross-arm adduction. With progression, pain may occur at rest, although usually it is less severe than that associated with activity, and it may awaken the patient at night. Rotator cuff pain can radiate laterally to the area of the deltoid attachment but not more distal. Pain radiating below the elbow suggests radicular pain from cervical or thoracic outlet disease.

In addition to shoulder pain, a complaint of weakness or stiffness of the shoulder may be elicited. A history of catching or popping can occur in partial rotator cuff tears but more likely indicates an internal derangement such as a labral tear, a superior labral tear from anterior to posterior (a SLAP lesion) (60), or loose body. Acute onset of pain in the absence of significant trauma, coupled with marked pain on attempted motion, raises the possibility of acute calcific tendinitis, infection, or acute brachial neuritis.

**PHYSICAL EXAMINATION**

Carefully examine the cervical spine, especially in older patients, to rule out degenerative disc disease with radicular symptoms. In longstanding rotator cuff cuff disease, inspection may reveal atrophy of the supraspinatus, infraspinatus, and deltoid muscles, as well as limited or asymmetric scapular rotation. Active and passive forward flexion and abstraction, as well as internal and external rotation, may be reduced, compared with the unaffected side. Loss of internal rotation identifies posterior capsular tightness. Throwers often have increased external and decreased internal rotation of the shoulder. Look for pain or weakness with manual muscle testing of external rotation, abduction, and isolated supraspinatus. Elicit the impingement sign by passive elevation of the arm against the supraspinatus outlet, which is fixed by your hand to limit rotation. Perform the maneuver in overhead elevation (60) as well as in abduction with forced internal rotation of the humerus (60).

It can be difficult to diagnose anterior glenohumeral instability, especially when there is pain with maximum abduction and external rotation but no measurable laxity. Testing in the supine position can relax the patient sufficiently to allow detection of laxity. The relocation test may be of some benefit in distinguishing anterior laxity from rotator cuff disease (61): Apply a posterior force along the anterior aspect of the humeral head, which has been subluxated by abduction and external rotation of the arm. Accurate diagnosis may not be possible until examination is performed under anesthesia and arthroscopy shows a Hill Sachs lesion or a positive “drive-through” sign (60). Inferior laxity reproducing symptoms should alert you to the possibility of multidirectional instability.

Inability to initiate or maintain abduction suggests a large tear of the rotator cuff (Fig. 79.2). A smaller tear confined to the supraspinatus may cause weakness only with isolation of the supraspinatus (elevation of the arm, internally rotated in the scapular plane). Marked weakness in external rotation suggests a tear with posterior extension to include the infraspinatus. Perform isolated testing of the external rotators of the rotator cuff (infraspinatus and teres minor) in the lateral decubitus position with the elbow aligned with the thorax. To test subscapularis function, have the patient extend her arm and rotate it internally as much as possible, which positions the hand on the lumbar spine region. Inability to lift the hand posteriorly from the lumbar spine indicates weakness of the subscapularis and has been termed the lift-off test (21).

![Figure 79.2. Inability to maintain humeral abduction.](image)

Palpate the AC joint to identify those patients with AC joint pathology. Although cross-arm adduction usually reproduces the pain of AC joint degeneration, it may be positive in patients with impingement syndrome as well. Selective injections and specific imaging as described below may be necessary to differentiate disorders of the
AC joint from those of the rotator cuff.

**ADJUNCTIVE CLINICAL TESTING**

The most helpful diagnostic test is the injection of local anesthetic into the subacromial bursa as described by Neer (40). Use of a posterior or lateral subacromial approach is less painful than anterior injection; because the entry angle of the needle is directed upward toward the acromion, inadvertent laceration of the rotator cuff is less likely. After injection of approximately 10 ml of 1% lidocaine, repeat the examination. If rotator cuff tendinitis or a partial tear of the bursal surface is present, the injection will provide a minimum of 50% and often nearly 100% relief of symptoms. If no relief is obtained, the diagnosis is incorrect or the injection has not been delivered into the bursa. If there is a full-thickness rotator cuff tear, pain will be significantly relieved, but some weakness usually persists despite injection. Continued pain and tenderness at the AC joint may warrant an injection of 1–2 ml of lidocaine into this joint. If indicated in selected cases, a steroid may be combined with the local anesthetic.

**IMAGING**

*Radiographs*

Planar radiographs are frequently helpful in the diagnosis of rotator cuff pathology. Obtain at least two perpendicular views for every patient, consisting of an anteroposterior (AP) view of the glenohumeral joint and a supraspinatus outlet view. The supraspinatus outlet view is a lateral radiograph made in the plane of the scapula with the x-ray beam directed 10° inferiorly. On the AP view, nonspecific changes such as sclerosis and cysts in the area of the greater tuberosity and anatomic neck can be seen, as well as a decreased interval (normal, 7–15 mm) between the humeral head and the acromion, which suggests a full-thickness tear of the cuff.

Calcium deposits are usually apparent on a standard AP view (Fig. 79.3), but an AP view in external rotation may better define the lesion. Although advanced degeneration of the glenohumeral joint is usually characterized by joint narrowing, effacement of the humeral head, and spurring, especially inferiorly on the humeral head, early degenerative joint disease (DJD) may not be recognized even using a true AP radiograph of the glenohumeral joint. The outlet view defines any anterior acromial spurs, CA ligament ossification, or abnormal morphology of the acromion.

*Figure 79.3. Anteroposterior radiograph of calcium deposits in a supraspinatus tendon located well medial to its insertion.*

Another view that may be helpful is an AP view with a 30° inferior tilt to identify any anterior prominence (spurring) of the acromion (52). If AC joint pathology is suspected, obtain a 10° inferiorly directed AP radiograph of that joint with reduced voltage. An axillary view is often useful to identify an os acromiale or a bony Bankart lesion. A computed tomography (CT) scan, however, may be necessary for optimal definition of an os acromiale.

*Magnetic Resonance Imaging, Ultrasound, and Arthrography*

Use magnetic resonance imaging (MRI), ultrasound, and arthrography on a case-by-case basis. Ultrasound has been shown to be helpful in identifying full-thickness tears, but it is less accurate than arthrography or MRI and remains operator dependent (49). MRI has largely replaced arthrography for the diagnosis of rotator cuff disorders as it is noninvasive. It is very accurate in the diagnosis of full-thickness tears (Fig. 79.4) but less helpful for tendinitis and partial-thickness tears (28). In as many as 50% of asymptomatic individuals, MRI can demonstrate signal changes within the supraspinatus tendon consistent with partial-thickness and complete tears (58). Because incidental MRI-documented changes increase with patient age, clinical symptoms and signs are more important than MRI findings in determining treatment in older patients.

*Figure 79.4. MRI demonstrating full-thickness tear of the supraspinatus with wide retraction.*

**DIAGNOSIS**

A number of diagnoses must be excluded in the evaluation of the painful shoulder (Table 79.2). In older patients particularly, DJD of the glenohumeral joint and cervical radiculopathy must be considered. When mild, DJD may be not be evident radiographically but can cause tendinitis-like symptoms (17,55). Often, these patients have slight but detectable limitation of shoulder motion. In younger patients, glenohumeral instability and degenerative changes of the AC joint can be associated with symptoms and signs suggestive of rotator cuff tendinopathy. Although preoperative laxity testing may not reveal instability, it should be apparent with examination under anesthesia and confirmed by arthroscopic findings. AC joint tenderness, pain with cross-arm adduction, radiographic changes, and a positive technetium-99 bone scan will confirm AC joint degeneration. These conditions should be strongly suspected whenever nonsurgical or previous surgical treatment for rotator cuff tendinitis has been unsuccessful.
Anterior-inferior acromioplasty with resection of the CA ligament is the standard treatment for patients with rotator cuff tendinitis due to mechanical impingement. Neer as many as two thirds of patients can expect relief of symptoms, allowing continuation of activity. Surgical treatment is warranted for patients who do not demonstrate any improvement after nonoperative treatment, or if you suspect a rotator cuff tear. If the patient performance of activity to ensure that proper mechanics are being used and the patient remains pain free. motion recovers, reintroduce the patient to functional activity. For a swimmer, gymnast, or tennis player, for instance, have a coach, therapist, or trainer monitor

For active patients, once a torn rotator cuff is diagnosed, surgical repair is recommended. In less-active patients who do not rely on the shoulder for work or sports, compensation can be explained on the basis of the synergistic effects of the other rotator cuff muscles (subscapularis, teres minor, and infraspinatus) together with the supraspinatus and deltoid in effecting humeral elevation (46-57). Because the other cuff muscles together can contribute to the power of elevation in magnitude similar to the supraspinatus, individuals who have adequate strength in these muscles may be able to function without significant problems following a tear of the supraspinatus.

The second question is more difficult to answer. Patients with a significant anterior acromial hook (type III acromion) are known to have a higher incidence of full-thickness tears (38). It is also apparent that repair of smaller tears produces better functional results than repair of larger tears. Assuming that an increase in tear size can occur over time due to further tearing as well as retraction, it would seem prudent to repair known tears earlier rather than later, especially in the active patient, regardless of age.

INDICATIONS AND MANAGEMENT

Nonsurgical treatment remains the standard initial care for tendinitis. Surgery is indicated for those patients who fail to respond to nonoperative measures. Although some have attempted to define a specific period of time to try treatment without surgery, it seems more reasonable to rely on the patient's response to nonoperative management and the functional demands of the shoulder as the basis for determining future treatment. In this era of managed care, many patients have had several months of nonsurgical care before they are seen by an orthopaedist. In such cases, especially if there has been no improvement, an additional lengthy period of nonoperative treatment is unnecessary before surgery.

For tendinitis due to mechanical impingement, start a nonsurgical treatment program and reexamine the patient within 2 months. If there is minimal or no improvement, offer a subacromial steroid injection. If there continues to be minimal improvement over the next 2 months, then recommend subacromial decompression in cases associated with a type II or III acromion.

If a flat acromion (type I) exists, continue nonoperative treatment for a minimum of 3 months. Failure to improve with this regimen warrants arthroscopy. Many such patients will have readily apparent articular or bursal surface, partial-thickness tears. Others will have areas of thinning consistent with mid-substance tears discernible only by probing. In these cases, articular and bursal partial-thickness tears are debrided, or, if thickness is greater than 50%, repaired by open methods; mid-substance tears usually are excised and repaired. The question of whether to perform acromioplasty to treat tendinitis-like symptoms in the patient with a normal-shaped acromion is unsettled at present because of the unpredictable response.

For tendinitis secondary to overuse, glenohumeral instability, posterior capsular contacure, and muscle imbalance, direct nonoperative treatment toward correction of the primary diagnosis. With the exception of glenohumeral instability, nonoperative measures are nearly uniformly successful.

Throwers with articular (undersurface) partial-thickness tears of the supraspinatus or infraspinatus tendons may not respond to nonoperative measures directed at eliminating capsular contacures, muscle strengthening, and alteration of throwing mechanics. Except in the high-performance athlete, where nonoperative treatment is often abandoned earlier because of nonmedical considerations, nonoperative measures should be tried before arthroscopic debridement.

For active patients, once a torn rotator cuff is diagnosed, surgical repair is recommended. In less-active patients who do not rely on the shoulder for work or sports, employ a trial of nonoperative measures similar to the program used for impingement. If there is no significant improvement in pain and function within 2 to 3 months, I recommend surgical repair. If the patient shows initial improvement and maintains a satisfactory level of function, continue additional nonoperative therapy or self-exercise and follow the patient at regular intervals.

NONOPERATIVE MANAGEMENT

A nonoperative regimen includes modalities directed at decreasing pain, stretching and range-of-motion (ROM) exercises, and a rotator-cuff-specific strengthening program consisting of isometric and isotonic exercises. Especially in cases of acute onset associated with overuse, rest may be the single most beneficial modality. Determine any specific ROM or strength deficits and then prescribe physical therapy using ice, heat, ultrasound, electrical stimulation, and transcutaneous nerve stimulation (based on patient response) to reduce pain in conjunction with posterior capsule stretching, scapulothoracic mobilization, and scapular strengthening exercises. Keeping within the pain-free ROM, start a light resistive exercise program emphasizing external rotator as well as supraspinatus strengthening.

Failure to improve from the initial use of an antiinflammatory and a supervised treatment program is reason to offer the patient a subacromial steroid injection. Give 40 mg of methylprednisolone and 7–8 cc of 1% lidocaine, followed by rest for a 1-week period before the resumption of resistance exercises. As symptoms subside and motion recovers, reintroduce the patient to functional activity. For a swimmer, gymnast, or tennis player, for instance, have a coach, therapist, or trainer monitor performance of activity to ensure that proper mechanics are being used and the patient remains pain free.

Surgical treatment is warranted for patients who do not demonstrate any improvement after nonoperative treatment, or if you suspect a rotator cuff tear. If the patient demonstrates improvement with the program but pain returns with activity, try activity modification. If unsuccessful, surgery is indicated. With a nonoperative program, as many as two thirds of patients can expect relief of symptoms, allowing continuation of activity.

SURGICAL TECHNIQUES

SUBACROMIAL DECOMPRESSION

Anterior-inferior acromioplasty with resection of the CA ligament is the standard treatment for patients with rotator cuff tendinitis due to mechanical impingement. Neer
ARTHROSCOPIC SUBACROMIAL DECOMPRESSION

OPEN ACROMIOPLASTY

Place the patient in the beach-chair position. Use a folded sheet to stabilize the shoulder along the medial border of the scapula. Drape the arm free for manipulation, as manual traction and rotation can facilitate exposure of the rotator cuff.

Inject the subcutaneous tissues with 10 ml of 1% lidocaine with 1:200,000 epinephrine to decrease bleeding. Make a 3 to 4 cm straplike incision parallel to and centered over the anterolateral edge of the acromion. This cut allows posterior as well as anterior extension, if necessary, to treat an associated rotator cuff tear. Incise the skin and subcutaneous layer to the level of the deltidium fascia. Obtain hemostasis with electrocautery. Insert a self-retaining retractor to increase exposure of the underlying deltoid.

Identify the deltoid attachment to the acromion, the AC joint, and the lateral and anterior edge of the acromion. Split the deltoid at the level of the AC joint, limiting its distal incision to 3 cm to avoid injury to the axillary nerve innervating the anterior head of the deltoid. It is usually necessary to detach a short segment of the deltidium beginning at the AC joint and extending laterally for about 1 cm. Use electrocautery to incise the deltidium subperiosteally, and elevate its fibers from the anterior edge of the acromion. This technique preserves a satisfactory cuff of tissue for deltidium reattachment.

Identify the coracoacromial ligament running obliquely from the medial border of the anterior acromion to the coracoid. Do not detach the ligament yet. Carefully open the bursa, which may be adherent to the undersurface of the acromion; introduce a fingertip to palpate the contour of the undersurface of the acromion. If necessary, repair any full- or partial-thickness tears of the rotator cuff, use care, as excessive force can cause fracture.

Protect the rotator cuff with a mallable retractor while performing the acromioplasty. Excise any portion of the acromion extending anterior to the distal clavicle. Next, starting at the superior cortex of the anterior acromion direct a 1/4-inch osteotome or small oscillating saw to remove the anteroinferior prominence of the acromion, tapering to exit about 1.5 cm posteriorly on the undersurface of the acromion. A flat acromion is the goal. The lateral deltidium will retain some connections to the osteotomized piece. Incise along the deltidium margin with electrocautery to mobilize the fragment anteriorly in one piece, pulling on it with a rongeur or Kocher clamp.

Next, detach a 1 cm segment of coracoacromial ligament and remove the osteotomized fragment and ligament stump.

Palpate the undersurface of the acromion. File rough areas with a rasp and remove any spurs along the inferior AC joint. Excise any residual bursal tissue to allow complete inspection of the rotator cuff while rotating the humerus. If necessary, repair any full- or partial-thickness tears of the rotator cuff. Repair the detached deltidium to its origin using horizontal mattress stitches with #1 nonabsorbable suture, or place small drill holes in the acromion for direct deltidium-to-bone reattachment if the soft-tissue repair is tenuous. Repair the longitudinal deltidium split with #0 absorbable sutures. Irrigate and check for bleeding. Close the subcutaneous tissue loosely with inverted 3-0 absorbable suture and the skin with a subcuticular suture. Apply a sterile dressing and place the arm in an immobilizer or commercial pillow splint, either of which provides better support than a simple sling.

ARTHROSCOPIC SUBACROMIAL DECOMPRESSION

Place the patient in either the beach-chair or lateral decubitus position. Mark the outlines of the acromion, AC joint, posterior and lateral portals, and, if needed, anterior portal. Using gravity inflow or a mechanical pump, perform diagnostic arthroscopy of the glenohumeral joint. If gravity inflow is selected, it is helpful to add one ampule of 1:1,000 epinephrine per 3-liter container of irrigating solution to reduce bleeding. The supraspinatus outlet should be readily visible during the procedure in order to assess the amount of acromion to be removed.

Replace the arthroscope, which is in the posterior portal, with a dull trocar, and then withdraw the arthroscope from the capsule and posterior deltidium. The trocar should move easily in the subcutaneous tissue. Palpate the lateral border of the acromion and advance the arthroscope sheath along this path toward the anterior limit of the acromion. Reinsert the arthroscope. If the bursal space is well visualized, proceed; if not, reinsert the trocar and advance the arthroscope sheath in a slightly more medial direction until the bursal space is entered. Taking the time to get adequate visualization at this point is the key to a well-performed, quick arthroscopic procedure.

Insert an 18-gauge spinal needle through the lateral portal (2–3 cm distal to the lateral acromion and parallel with the posterior border of the clavicle). Palpate the CA ligament, the undersurface of the AC joint, and the acromion. If acceptable, make the portal incision, and if you see vessels on the soft tissue around the necessary, apply gentle longitudinal traction electrocautery them prior to debridement. Place a nonconducing canula through the lateral portal (Fig. 79.5). Next, insert a 4.5 mm aggressive motorized shaver to begin stripping the peristeme and soft tissue covering the anterior acromion. Using the shaver or electrocautery, remove the peristeme and fibrous tissue from the lateral margin of the acromion as well, up to the point at which the deltidium fibers attach. Medially, the AC joint may not be apparent until externally balled. The medial aspect of the acromion must be identified, as it can be a cause of recurrent symptoms if not adequately resected as well. Identify the coracoacromial ligament and divide it from the anterior and medial acromion, taking care not to injure the deltidium fibers immediately underneath (Fig. 79.6; see also Color Fig. 79.6).

Figure 79.5. Arthroscopic set-up for subacromial decompression. Shaver is inserted in the lateral portal created in line with the posterior axis of the distal clavicle 2–3 cm distal to the lateral edge of acromion.

Figure 79.6. (See Color Figure 79.6) Coracoacromial ligament prior to division with electrocautery (undersurface of acromion is exposed for better visualization).

Now that the anterior tip of the acromion, both medial and lateral borders, are well seen, introduce a round or elliptical burr from the lateral portal to begin the acromioplasty. Resect the leading edge of the acromion flush with the anterior edge of the distal clavicle (Fig. 79.7). Next, by referencing the posterior margin of the distal clavicle, mark the posterior extent of the acromioplasty by creating a shallow trough, no deeper than 5 mm, medial to lateral. Now, switch the arthroscope to the lateral portal and insert the burr posteriorly.

The main disadvantage of arthroscopic decompression is that the procedure requires technical proficiency and can be difficult to learn.

OPEN ACROMIOPLASTY

- It enables the surgeon to evaluate the glenohumeral joint (for undersurface tears, for example, and SLAP lesions, DJD, and loose bodies).
- It can be done on an outpatient basis.
- It entails decreased perioperative morbidity and faster relief of pain.

The main disadvantage of arthroscopic decompression is that the procedure requires technical proficiency and can be difficult to learn.
Beginning at the level of the trough, continue the acromioplasty by sweeping the burr from medial to lateral and advancing it from posterior to anterior. Keeping the shaft of the burr in contact with the undersurface of the acromion posteriorly will result in an upward-sloping acromioplasty, protecting against either inadequate or excessive bone resection (54).

Reinsert the arthroscope into the posterior portal to inspect the acromioplasty. The acromion should be flat when viewed from both posterior and lateral (Fig. 79.8; see also Color Fig. 79.8). Often, resecting from only one portal will result in a cup-shaped configuration of the acromion, with prominent spurs anterolaterally and anteromedially. Using these two portals both for viewing and for planing the acromion will eliminate this possibility (Fig. 79.9). At this point, if there are no spurs on the undersurface of distal clavicle, debride the remainder of the coracoacromial ligament, using the shaver. If possible, remove 1 cm to eliminate any possibility of reattachment. Using the shaver in this manner will protect from accidental deltoid detachment. Remove inferior spurs from the distal clavicle without disrupting the AC joint itself.

Close the skin portals and apply a nonbulky dressing incorporating a cryotherapy pad, if desired. Use a sling or immobilizer for support.

Postoperatively, if arthroscopic decompression has been performed, start immediate active and passive ROM exercises. Pendulum exercises and motion performed supine are best tolerated in the immediate postoperative period. Advise the patient to avoid active abduction beyond 60° while standing or sitting for the first 3–4 weeks; such activity may result in painful impingement due to postsurgical dysfunction of the cuff. Initiate isometrics as early as 1–2 weeks.

Electrical stimulation is helpful in minimizing atrophy. Once ROM has been restored (in 4–6 weeks), start resistive exercises, but advise the patient to avoid heavy resistance and contact for a minimum of 3–4 months to prevent acromial fracture or reexacerbation of symptoms. Usually, high-demand activities (tennis, swimming, throwing) can be resumed within 4–6 months’ time.

If open acromioplasty has been performed, especially if the deltoid has been elevated or detached, then rehabilitation will proceed more slowly. Do not allow the patient to perform significant active flexion or abduction for approximately 4 weeks. Rehabilitation then proceeds as above with return to activity requiring 1–2 additional months on average.

**OS ACROMIALE**

When os acromiale is associated with rotator cuff tendinitis, intraoperative assessment of motion of the fragment directs treatment. If the fibrous union between the fragments is secure, perform routine acromioplasty. If the nonunion is mobile, perform excision for small fragments (os acromiale), and open reduction and internal fixation for larger fragments (meta- or mesoacromion). Center a 4 cm incision over the anterior acromion and parallel to the acromial border to expose the nonunion, which is debrided of fibrous tissue, bone-grafted, and internally fixed with one or more small fragment screws. Rehabilitation is similar to that for open acromioplasty with active abduction delayed for 6 weeks.

**PARTIAL-THICKNESS TEARS OF THE ROTATOR CUFF**

Although recognized previously, arthroscopy has been key in the recognition and treatment of partial-thickness tears to the rotator cuff. The major issue in treating a partial-thickness tear is deciding whether to perform debridement alone, debridement with subacromial decompression, or excision and repair. This can prove to be a considerable dilemma, particularly in the young, active patient.

Even during arthroscopic examination of both the bursal and the articular side of the rotator cuff, it may prove difficult to determine the exact depth of the lesion. Moreover, midsubstance lesions may be extremely difficult to detect and measure because of the relatively normal appearance of surfaces in such lesions. Careful probing, use of a marking suture passing through both surfaces of the lesion, and injection of methylene blue dye to observe penetration, facilitate inspection and enable determination of the extent of a partial-thickness lesion.

Currently, lesions involving less than 50% thickness of the tendon are treated by debridement (Fig. 79.10), whereas those deeper than 50% are excised and repaired. Treat bursal-sided lesions with an accompanying type II or III acromion with decompression as well. If symptoms recur after debridement of a lesion, perform excision and repair. For postoperative management, follow the procedure outlined for subacromial decompression or repair, as relevant.
FULL-THICKNESS TEARS OF THE ROTATOR CUFF

Techniques to repair the majority of full-thickness rotator cuff tears include direct repair of tendon to tendon, advancement of tendon to bone, local tissue releases and advancement to effect tendon-to-bone repair, and slight medialization of the repair site. Exposure through a deltoid-splitting (mini-open) incision rather than by detachment of the deltoid is ideal to minimize perioperative morbidity and reduce the risk of deltoid avulsion postoperatively, but the ultimate goal is a well-done repair. Deltoid detachment to expose and repair a tear of the rotator cuff is preferable to a deltoid-splitting incision with a compromised repair of the cuff. Depending on the surgeon’s preference, open repair without arthroscopy remains an acceptable option (for incision and initial steps, see the section on Open Acromioplasty).

Advances in repair include the use of suture anchors to achieve direct tendon-to-bone healing. Suture anchors have been shown to have superior mechanical properties over transosseous suture fixation when loaded cyclically (10). Suture anchors perform best when inserted at 45° angles to the bony surface (in the manner of a tent stake). Transosseous fixation is improved by using 10-mm-long bony bridges, exiting the tunnels 10 mm distal to the tuberosity, and use of a plastic button to tie over in osteopenic bone (11). Using both suture anchor and transosseous fixation with suture provides optimum fixation, allowing early motion of the shoulder after rotator cuff repair.

MINI–OPEN REPAIR OF THE ROTATOR CUFF

- Place the patient in the lateral decubitus or beach-chair position and perform arthroscopy in the routine fashion. Arthroscopy is often helpful to identify the extent and reparability of a tear (Fig. 79.11 and Fig. 79.12). If the tear appears reparable with or without mobilization of the cuff, proceed with arthroscopic repair. (See below for the management of irreparable tears.) After decompression, perform arthroscopic mobilization of the cuff if desired, or proceed with open surgery.

- With the patient in the same position, make a strap incision paralleling the lateral edge of the acromion (Fig. 79.12). Such an incision is preferable to a straight lateral incision, which can result in scarring to the underlying deltoid raphe with painful dimpling of the skin.

- Split the deltoid in line with its fibers at the anterolateral corner of the acromion (junction of the anterior and middle one third of the deltoid) (Fig. 79.13). Insert a smooth, self-retaining retractor to inspect the rotator cuff (Fig. 79.14). Gentle traction on the humerus often improves visualization.
Excise adherent bursal tissue to see the actual rotator cuff. Inspect the articular surface for any delamination in a horizontal plane.

Retracted tears require mobilization. These tears are usually triangular or ovoid in shape, principally involving the supraspinatus tendon near its insertion. If mobilization is needed, apply stay sutures (#2 nonabsorbable) to the edges of the tear for traction. Start mobilizing with a blunt elevator or a finger along the superior surface, working medially. Gain additional excursion on the articular side by sharply incising the junction of the upper one half of the capsule and the cuff, staying peripheral to the labrum. Do not dissect more than 1 cm medial to the glenoid along the undersurface of the supraspinatus in order to avoid injury to the suprascapular nerve. Additional excursion can be gained by releasing the coracohumeral ligament, which can retract the anterior portion of the supraspinatus.

Advance the mobilized cuff toward the tuberosity. Observe whether the leading edge can be directly advanced to bone (crescentic tear pattern). If the tear is V-shaped, partial side-to-side repair near the apex may be necessary, with the edge of the tear then advanced to the bony trough. In some cases, the defect can be closed and secured to bone only by local transposition of tissue. Alternatively, use a partial side-to-side closure and medial repair within 10 mm of the normal insertion (McLaughlin type V-Y repair).

Prepare the area for bony attachment by lightly burring the cortical margin, leaving a shallow trough (5–7 mm) with intact lateral cortical bone to minimize the risk of suture pull-out. Insert interrupted horizontal mattress sutures with the sutures exiting the bursal surface to help force the tendon against the cancellous surface after repair. Using a small drill or awl of a diameter slightly larger than the suture, place multiple holes exiting lateral to the trough. For additional support, insert one or two suture anchors (#2 nonabsorbable) just medial to the trough, inclined at a 45° angle, as one would use to drive in a tent stake. Suture anchors provide a “belt-and-suspenders” repair. Pass the sutures in the cuff edges using a suture passer or needle through the drill holes laterally. With the lateral sutures tensioned to achieve reduction, pass the sutures from the anchors at appropriate spots through the cuff.

Perform repair with the arm as close to neutral rotation as possible. Repair a longitudinal (side-to-side) tear with interrupted #0 absorbable sutures. For tendon tears from bone, apply traction through the sutures, passing laterally through the tuberosity, and tie the anchor sutures. Tie the lateral sutures individually, leaving only a small tag to minimize formation of bursal adhesions.

Check the integrity of the repair with passive motion. Irrigate and remove any additional bursal tissue. Close the deltoide split with interrupted #0 absorbable sutures. Close the subcutaneous layer with deep sutures, and perform a subcuticular skin closure. Apply a nonbulky dressing incorporating a cryotherapy pad. Use an immobilizer for support or a commercial pillow splint for added comfort.

In designing the postoperative plan, it is important to consider the size of the tear, the type of repair (side-to-side versus tendon-to-bone), how easy it was to achieve repair (degree of retraction), intraoperative motion limits, and the age of the patient (quality of bone and tendon). Other factors include use of an abduction pillow versus a sling, the timing and extent of ROM exercises, and the rate of progression to resistive exercises and eventual return to activity. Patients typically do not progress in a straight-line fashion but rather can be expected to experience minor setbacks or temporary plateaus with regard to both postoperative pain and ROM. Patients do not experience maximal recovery for up to 1 year after surgery in many cases. Preoperative counseling is important to educate the patient about individual variability and length of recovery.
It is important to promote early motion of the shoulder without compromising the repair. If a longitudinal tendon split has been repaired without detachment of the deltoid, immediate passive ROM is acceptable, followed by active ROM exercise at 2–3 weeks. If the patient is elderly with osteopenic bone and a large, retracted tear, use of an abduction pillow for 4–6 weeks with only limited passive motion is appropriate. If the tear involves a significant portion of the infraspinatus, internal rotation may be light and may pose a danger to the repair. Use of an abduction splint in such cases may avoid the extreme internal rotation imposed by a standard sling.

In general, have the patient perform passive motion using pendulum exercises and supine ROM for 4–6 weeks within an arc of motion of up to 75% of the limit that was observed at surgery. These restrictions are necessary before allowing active assisted motion in order not to threaten the repair. Overhead pulley exercises involve active muscle contraction and should be delayed until 4–6 weeks in most cases. Part-time use of the sling may be needed for up to 6–8 weeks. Once active control of the arm is achieved at 6–8 weeks, allow isometric exercises. At 10–12 weeks, initiate light resistive exercises. If pain develops, reduce exercises while maintaining motion. Modalities such as ice and interferential stimulation are useful.

If necessary, manipulation to gain motion can be performed at 12 weeks without risk of tearing the tendon from its repair site. In most cases, functional and progressive resistive exercises can be initiated by 4 months. Most activities can be resumed between 6 and 12 months.

**IRREPARABLE TEARS**

Some large and massive tears cannot be fully repaired despite extensive mobilization. The surgical options are then to mobilize the repair as much as 10 mm along the lateral articular cartilage; perform a partial repair of the cuff; transpose the subscapularis tendon superiorly; fill the defect with allograft tissue, autograft tissue, or synthetic material; or transfer the latissimus dorsi.

Medialization of the supraspinatus insertion 10 mm or less maintains its mechanical advantage. Biomechanical and clinical evidence of the force-couple relationship of the intact subscapularis and infraspinatus to functionally substitute for the torn supraspinatus lends support to the concept of partial repair. It eliminates the unstable edges of a torn cuff, which may be the real cause of pain.

Among proponents of obtaining “coverage” of the humeral head, Cofield has reported success with transposition of the upper one half of the subscapularis tendon to fill the defect in the supraspinatus (53) (Fig. 79.19). This procedure disrupts the important force-couple between the subscapularis and infraspinatus–teres minor, which has been observed clinically and experimentally to effectively substitute for a torn supraspinatus. Because a transferred muscle loses approximately one grade of power, both subscapularis and latissimus dorsi transfers may be weakened.

**Figure 79.18.** Subscapularis transposition to cover a supraspinatus defect. A. Cross section of the shoulder showing release of the subscapularis tendon. B. Defect in the supraspinatus tendon. C. Transposition of the subscapularis tendon into the defect. (From Poppen NK. Soft-tissue Lesions of the Shoulder. In: MW Chapman, ed. Operative Orthopaedics, 2nd ed. Philadelphia: JB Lippincott, 1993:1651, with permission.)

Rockwood and others have advocated debridement alone for irreparable tears (8, 52), which can be successful in relieving pain when followed by a program to strengthen the other cuff muscles, deltoid, and scapular rotators. If a tear is found to be irreparable, then traditional acromioplasty should be modified to prevent superior migration of the humeral head postoperatively. Removal of the CA ligament in the presence of a full-thickness tear can destabilize the glenohumeral joint leading to superior dislocation (68). In these instances, perform flattening, and even slight concave hollowing, of the acromion to achieve decompression, while preserving the CA ligament attachment to its anterior edge.

**BICEPS TENDON RUPTURE**

Impending or acute rupture of the long head of the biceps can be managed by extrarticular tenodesis. In the case of rupture, the deformity is obvious with distal migration of the muscle (Fig. 79.19). Weakness is usually confined to supination activities (e.g., use of a screwdriver), unlike distal biceps rupture, which causes elbow flexion weakness. Isolated rupture is seen in young athletes and laborers, but coexistent supraspinatus tendinopathy should be suspected in middle- and older-aged patients.

**Figure 79.19.** Biceps rupture with distal migration of the muscle belly.

Impending and partial ruptures may be difficult to detect. Pain similar to rotator cuff tendinopathy is present, and tenderness anteriorly about the shoulder is common. Speed’s test (resisted elevation of the supinated arm with the elbow extended) (22) and Yeargerson’s test (resisted supination with elbow flexed) (70) may be positive. Tenodesis for bicipital tendinitis, however, is unsuccessful in as many as 50% of patients (4), and nonsurgical measures like those used in rotator cuff tendinitis are used to manage this condition.

If repair is elected for isolated rupture, use a combined arthroscopic and open approach. Do an arthroscopic inspection of the joint and rotator cuff, and resect the intraarticular portion of the torn long head of the biceps. Two short incisions may be needed for tenodesis: a 3 cm incision over the deltobicipital groove at the mid-arm to locate the often distally retracted and entrapped long head tendon, and a second 3–4 cm incision just anterior and distal to the acromion to expose the intertubercular groove. This proximal incision corresponds to the anterior portion of the saber-type incision used to expose the rotator cuff. A suture passer is helpful to deliver a retracted tendon into the proximal incision. Tenodesis is necessary because direct repair is usually not feasible, except in the rare instance of a tear at the musculotendinous junction (mid-arm level).

Although a keyhole recession can be used, a simpler method is to place two suture anchors in the middle of the groove, which has been lightly decontaminated with a burr, and secure the tendon with horizontal #2 nonabsorbable mattress sutures. Have the patient wear a sling for 10–14 days, then allow active shoulder motion. Avoid...
RESULTS OF ROTATOR CUFF SURGERY

The results of open or arthroscopic subacromial decompression are essentially equivalent, with approximately 75% to 90% of patients having a good or excellent result. Advantages of the arthroscopic approach include diminished perioperative pain, faster return of motion, and earlier return to activity. The arthroscopic procedure is technically demanding and, other than error in diagnosis, an inadequate or poorly performed acromioplasty is the major reason for failure of the procedure. Assuming a correct initial diagnosis, factors associated with a poor result include the following:

- Worker's compensation cases (25)
- Inadequate or excessive bone resection from the acromion
- Failure to remove inferior distal clavicle spurs compromising the supraspinatus outlet (50)
- Surgery performed in throwing athletes, some of whom possibly had coexistent glenohumeral instability (53,62,63)

Following direct tendon repair, satisfactory results can be expected in 75% to 90% of patients. Relief of pain rates highest, followed by lower scores for ROM and return of function. The following are useful guidelines to predict success when treating patients with rotator cuff tear:

- In general, small and moderate tears have better overall results (pain relief, motion, and function) than large and massive tears (16,27).
- Duration of symptoms and preoperative weakness correlate with the size of the cuff tear (2,16).
- Cuff integrity at follow-up correlates with improved strength, motion, and function but does not affect pain scores; large tears with involvement of the supraspinatus and infraspinatus have a retear rate greater than 50% (23).
- Return to previous activity level for the high-level competitive athlete is approximately 50% (62), whereas more than 80% of recreational athletes can return to activity (6).
- Rehabilitation time is prolonged by 25% when distal clavicle excision for AC joint DJD is performed concomitantly with rotator cuff repair (14).
- Persistent mechanical impingement and large or massive tears of the cuff are the two major reasons for surgical failure (5).
- Although a good outcome for pain relief, motion, and strength can be obtained in full-thickness tears treated by decompression only (9), improvement in pain only is most likely (15,33), and repair offers the best results (57).

COMPLICATIONS OF ROTATOR CUFF SURGERY

Complications from arthroscopic and open surgery for rotator cuff disorders include retear or failure of cuff repair, infection, stiffness, acromial fracture, deltoid injury, and reflex sympathetic dystrophy. While technical factors may be involved to some degree, many of these complications are different from those associated with other procedures. The patient's final outcome is frequently dependent on how early a complication is recognized and treated.

While a successful cuff repair can relieve pain in nearly 80% of such patients, although function is not likely to be improved significantly.

Infection is less likely in the shoulder due to its abundant vascularity, but recognition may be difficult. The traditional signs of heat, swelling, and redness are often not present initially. Diagnosis depends on suspicion of continuing or increasing pain at rest and with movement of the shoulder. Infection is more likely to develop following open surgery. If diagnosed early, infection can respond to arthroscopic debridement and irrigation, followed by appropriate antibiotic therapy. Established infection with necrotic tissue and copious granulation tissue usually requires open debridement. Preserve as possible any repair of the rotator cuff, even if repeat debridement may be needed.

Adhesions can develop quickly in the subacromial bursa even after arthroscopic debridement. Early motion is the key to prevention. If motion is slow to return during the first few weeks, increase formal therapy sessions to ensure compliance with motion exercises. Posterior capsule tightness can be a contributing factor in regaining motion by causing impingement pain with exercises. If the patient has achieved less than 60% of expected ROM by 6–8 weeks, then repeat arthroscopy with lysis of subacromial adhesions is indicated. After cuff repair, 12 weeks is required before the tendon is adequately healed for manipulation to be performed.

Fracture of the acromion has been described as a result of excessive acromioplasty (39). Rapid advancement of resistive exercises in the postoperative period may be a contributing factor. Fracture usually is not evident for several months after the index procedure. Radiographs with new onset of pain in the postoperative period. Treat large fragments by fixation; small fragments can be arthroscopically excised.

Denervation of the deltoid as well as detachment from the acromion can occur. Denervation results from distal extension of an incision transecting the axillary nerve as it courses posterior to anterior along the undersurface of the deltoid approximately 5 cm below the acromion. Weakness results in the denervated portion of the deltoid. Rarely, detachment of the deltoid occurs from inadvertent arthroscopic release during decompression of the subacromial bursa and by avulsion from its repair site following reflection during open surgery. Excessive retraction can produce a defect inferior to the acromion and a nonfunctioning segment of muscle. Early treatment by reattachment through drill holes in the acromion can be successful if performed within 6 weeks. After repair, maintain the shoulder in abduction for 3–4 weeks.

CALCIFIC TENDINITIS

Calcific tendinitis is a common condition that affects middle-aged individuals predominantly. Calcification of a portion of the supraspinatus tendon is usually followed by resorption of the deposit and by reconstitution of the tendon. The clinical expression of this degenerative process is highly variable. Incidental asymptomatic calcification is common.

In its chronic form, patients can experience symptoms similar to tendinitis. Acute calcific tendinitis is quite dramatic, with sudden onset of severe pain, exquisite tenderness, and pain that increases with attempted shoulder motion. Differential diagnosis includes trauma, acute infection, and acute brachial neuropathy.

The etiology of calcific tendinitis remains unresolved. The condition is not caused by mechanical impingement, but tendon degeneration may be important (12). It appears that calcific tendinitis is preceded by fibrocortilaginous metaplasia of the involved portion of the tendon (64).

Radiographically, calcific deposits either appear as dense, well-defined opacities or are fluffy with irregular outlines. The calcific deposition usually appears within the substance of the supraspinatus tendon distinct from its bony insertion (Fig. 79.3). Initially dense and well bordered, the deposit becomes irregular and fluffy as the resorptive phase begins with rupture of calcium particles into the subacromial bursa, which is usually associated with acute pain.

Clinically, the patient who presents with acute calcific pain is likely to respond to temporary immobilization, nonsteroidal anti-inflammatory drugs (NSAIDs), or subacromial injection of a steroid such as dexamethasone directly into the deposit. Lavage using two separate needles, one to inject lidocaine and sterile saline and the other for suction, may be helpful. Most patients begin to improve regardless of treatment during the resorptive phase. In the asymptomatic patient, treatment is not necessary. Some patients with dense deposits develop symptoms of tendinitis, which are treated with a nonsurgical program similar to that for noncalcific tendinitis. Failure to improve with this regimen is an indication for surgery.

ARTHROSCOPIC DEBRIDEMENT OF CALCIFIC TENDINITIS

- Use the same set-up as previously described for shoulder arthroscopy. After genoumenular visualization, move the arthroscope into the bursa using the posterior portal initially.
- Visualize an area of increased vascularity on the bursal surface of the tendon (Fig. 79.20; see also Color Fig. 79.20). Insert a probe or needle from the lateral portal to confirm the deposit by palpation. Uncover the deposit using a shaver (Fig. 79.20B). Note the chalklike flakes and nuggets (Fig. 79.20C). Continue debridement until the base is clean of calcium particles (Fig. 79.20D). A curet can be helpful in scraping out all remaining particles.
subscapularis and long head of the biceps tendon. Chronic tears are associated with pain and weakness with activity. On examination, there is a palpable defect in the

Partial tears are less dramatic in presentation. In the acute setting, differential diagnosis includes fracture, dislocation, rotator cuff tear, and ruptures of the

Clinically, acute injury results in sudden, dramatic pain and weakness of the shoulder. Examination shows ecchymosis along the arm and upper chest wall, associated

Male sex and steroid use.

shorter sternal fibers most often involved. Rupture is the result of eccentric loads applied to the muscle while the humerus is extended (17,60). Rupture of the pectoralis major is an infrequent event, usually the result of weightlifting or other sporting activity. Complete and partial tears are recognized, with the shorter sternal fibers most often involved. Rupture is the result of eccentric loads applied to the muscle while the humerus is extended (18,60). Risk factors include male sex and steroid use.

Contradictory pathologic changes have been described in the literature, ranging from no synovial changes, to vascular synovitis and presence of intraarticular adhesions and capsular fibrosis, to no such changes (67). More recently, it has been suggested that contracture of the rotator cuff interval is the responsible mechanism (48). Regardless, reduction in volume of the capsule is the result of the pathologic process.

Clinically, the primary form can be categorized into three phases: freezing, frozen, and thawing, each representing approximately a 6-month period. The initial process can be painful, although in some patients loss of motion is the major complaint. Once established, pain usually tapers off and restricted motion remains the concern. Unfortunately, the condition can occur bilaterally, either simultaneously or sequentially.

Diagnosis of the idiopathic condition requires exclusion of secondary causes. Plain radiographs are unremarkable unless a secondary cause is identified. A saline-contrast MRI or traditional arthrogram will demonstrate decreased capsular volume with obliteration of the inferior capsular fold, and it will exclude abnormality of the rotator cuff. Perform these studies on a case-by-case basis.

Treatment is primarily nonsurgical. NSAIDs are useful for pain and may be indicated early in the disease because of the inflammatory changes described. Similarly, an intraarticular steroid injection (40 mg methylprednisolone) may be helpful. ROM exercises are the centerpiece of treatment. Passive exercises, especially external rotation and flexion stretching, use of a pulley, and distraction techniques employed by therapists, are especially beneficial. Ultrasound may be beneficial to increase capsular compliance.

Surgical treatment is indicated when exercise and the passage of time do not improve ROM. Although arthroscopy has been used with limited success, the risk of incidental scuffing of the joint surfaces does not warrant it, in my opinion. The preferred treatment is manipulation.

MANIPULATION

Exercise care to minimize the risk of humeral fracture or dislocation.

If the defect is more than 50% the thickness of the tendon, do a repair; if it is less than 50% of that thickness, nothing further is necessary. Do not perform acromioplasty in either instance.

Close the arthroscopic portals and place the arm in a supportive sling.

Postoperatively, follow the rehabilitation schedule for repair if appropriate. Otherwise, start early ROM allowing resistive exercises by 3 weeks and return to activity at 4–6 weeks.

ADHESIVE CAPSULITIS

The clinical syndrome of shoulder pain and progressive loss of motion unassociated with trauma, followed by partial if not complete resolution over a prolonged time course, is commonly referred to as adhesive capsulitis or frozen shoulder (12,41). Adhesive capsulitis has been further classified as (a) primary or idiopathic and (b) secondary, on the basis of a precipitating condition or injury (35). Risk factors for the development of primary adhesive capsulitis include female sex, middle and older age, and diabetes. In fact, the first presentation of diabetes can be adhesive capsulitis. Secondary frozen shoulder can develop after trauma or surgery to the shoulder, cervical and intrathoracic disease including malignancy, and as a consequence of distant upper-extremity trauma (shoulder–hand syndrome).

Contradictory pathologic changes have been described in the literature, ranging from no synovial changes, to vascular synovitis and presence of intraarticular adhesions and capsular fibrosis, to no such changes (67). More recently, it has been suggested that contracture of the rotator cuff interval is the responsible mechanism (48). Regardless, reduction in volume of the capsule is the result of the pathologic process.

Clinically, the primary form can be categorized into three phases: freezing, frozen, and thawing, each representing approximately a 6-month period. The initial process can be painful, although in some patients loss of motion is the major complaint. Once established, pain usually tapers off and restricted motion remains the concern. Unfortunately, the condition can occur bilaterally, either simultaneously or sequentially.

Diagnosis of the idiopathic condition requires exclusion of secondary causes. Plain radiographs are unremarkable unless a secondary cause is identified. A saline-contrast MRI or traditional arthrogram will demonstrate decreased capsular volume with obliteration of the inferior capsular fold, and it will exclude abnormality of the rotator cuff. Perform these studies on a case-by-case basis.

Treatment is primarily nonsurgical. NSAIDs are useful for pain and may be indicated early in the disease because of the inflammatory changes described. Similarly, an intraarticular steroid injection (40 mg methylprednisolone) may be helpful. ROM exercises are the centerpiece of treatment. Passive exercises, especially external rotation and flexion stretching, use of a pulley, and distraction techniques employed by therapists, are especially beneficial. Ultrasound may be beneficial to increase capsular compliance.

Surgical treatment is indicated when exercise and the passage of time do not improve ROM. Although arthroscopy has been used with limited success, the risk of incidental scuffing of the joint surfaces does not warrant it, in my opinion. The preferred treatment is manipulation.

MANIPULATION

Exercise care to minimize the risk of humeral fracture or dislocation.

- Have the anesthetist administer propofol or a similar short-acting agent while monitoring the patient. Position the patient supine and have an assistant stand at the head of the table to apply downward force on the scapula while you perform manipulation.
- Grasp the arm near the shoulder joint, not at the elbow, to reduce the moment arm. Slowly but firmly begin flexing the humerus, overcoming adhesions. Usually, at least 90° or more will be easily obtained without excessive force.
- Grasp the arm at the elbow and begin to rotate externally with less force than used for flexion. As resistance increases, switch to flexion of the humerus until more motion is gained, then return to external rotation. Alternate this pattern until at least 80% of the normal ROM is gained.
- To reduce pain postoperatively and to encourage active ROM by the patient, inject 20 ml of 0.5% Marcaine into the glenohumeral joint. If possible, have the therapist begin working with the patient in the recovery area.

PECTORALIS MAJOR RUPTURE

Rupture of the pectoralis major is an infrequent event, usually the result of weightlifting or other sporting activity. Complete and partial tears are recognized, with the shorter sternal fibers most often involved. Rupture is the result of eccentric loads applied to the muscle while the humerus is extended (18,60). Risk factors include male sex and steroid use.

Clinically, acute injury results in sudden, dramatic pain and weakness of the shoulder. Examination shows ecchymosis along the arm and upper chest wall, associated with pain and weakness with attempted resisted adduction of the arm (Fig. 79.21). Because of swelling, no defect is usually palpable in the anterior axillary fold.

Figure 79.21. Ecchymosis associated with pectoralis major rupture.
anterior axillary fold.

Plain radiographs are unremarkable. Ultrasound can be used to identify complete tears, but MRI is more accurate, differentiating complete from partial tears.

Repair is indicated for acute, complete tears in the active patient. Successful repair of chronic tears has been reported as well, however (32).

REPAIR OF PECTORALIS MAJOR

- Under general anesthesia or interscalene block, place the patient in the beach-chair position with the arm draped free.
- Make an incision along the deltopectoral groove extending distal to the anterior axillary fold. Retract the cephalic vein laterally with the deltoid, and in the lower incision identify the avulsed pectoralis tendon (Fig. 79.22).

![Figure 79.22. Avulsed pectoralis tendon retracted medially.](image)

- Clear off the attachment area along the lateral lip of the bicipital groove, protecting the biceps tendon. Create a trough with a burr to maximize tendon-to-bone healing.
- Insert three #2 nonabsorbable suture anchors in this area and pass the ends through the tendon in a horizontal configuration. Alternatively, use drill holes exiting the trough laterally. With the arm in adduction and slight internal rotation, tie the sutures (Fig. 79.23).

![Figure 79.23. Repair of the pectoralis tendon to its bony bed.](image)

- Close the subcutaneous layer and skin in a routine manner. Apply an immobilizer for postoperative support.

Postoperatively, maintain the arm in the immobilizer for 4 weeks. Then allow forward flexion with the arm internally rotated. At 6 weeks, allow external rotation to neutral. Between 8 and 10 weeks, start additional external rotation. Do not start resistive exercises for internal rotation and adduction until 12 weeks. Return to activity usually takes 4–6 months.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Historically, treatment of shoulder instability has focused on constraining the joint through soft-tissue reconstruction, which often has distorted anatomy instead of anatomically repairing the primary lesion of an injured capsule or labrum. Foremost examples of these reconstructive techniques include transfer of the subscapularis (Magnuson-Stack), imbrication of the subscapularis and capsule (Putti-Platt), and transfer of the coracoid process and conjoined tendon (Bristow-Latarjet). As surgeons have developed a better understanding of the functional anatomy of the shoulder, treatment of shoulder instability has relied on anatomic restoration.

ANATOMY AND PATHOPHYSIOLOGY

Despite an articular mismatch resulting in only 25% to 30% glenohumeral contact at any one angle, stereophotogrammetric studies show close congruency between the articular surfaces of the glenoid cavity and the humeral head (148). Notwithstanding a flat radiographic appearance of the glenoid, the varying cartilage thickness on its surface allows a close concavity–convexity match to the humeral head, which provides stability through dynamic contraction of the rotator cuff. It has been termed the concavity-compression mechanism of stability and is described in further detail below (88,89).

Conditions affecting this precise relationship may clinically manifest as instability (Table 80.1). Examples include congenital dysplasia of the glenoid or humeral surfaces and glenoid fractures. These conditions disrupt the concavity-compression effect by decreasing the surface area of contact and disrupting the close congruent fit of articular surfaces (18,55,182). Similarly, large Hill–Sachs or reverse Hill–Sachs lesions, posteroslateral or anterolateral humeral head impaction fractures respectively, can affect this articular relationship (Fig. 80.2) (22,131,133,134). These fractures are created by direct contact between the humeral head and the glenoid rim during shoulder dislocations. While these lesions are present in more than 80% of anterior dislocations and 25% of anterior subluxations, they are rarely a contributing factor to instability. They become biomechanically relevant to joint stability when osteoarticular loss involves greater than 30% of the humeral head surface.
It acts as a point of attachment for the glenohumeral ligaments and the long head of the biceps brachii (102,158).

It increases the surface area and the depth of the glenoid cavity, improving the conforming fit of the humeral head within the glenoid (47).

Avulsion of the glenoid labrum (Bankart lesion) has been implicated as the primary lesion associated with traumatic anterior shoulder dislocation (186,187). Because variability in the anatomy of the labrum is considerable, it is important to distinguish between true labral detachment and a variation of normal anatomy (31,181). As a rule, the labrum is often loosely attached to the glenoid rim above the equator of the glenoid cavity, and in fact there may be little or no labrum present along the anterosuperior glenoid rim. This anatomic variant has been termed a sublabral foramen (hole) (Fig. 80.3).

Figure 80.3. Arthroscopic view through a posterior portal demonstrates an anatomic variant of the anterior glenoid labrum referred to as a sublabral hole. This should not be confused with a true Bankart lesion or a superior labrum anterior posterior (SLAP) lesion. (From Warner JJP, Warren RF. Arthroscopic Bankart Repair Using a Cannulated Absorbable Fixation Device. Oper Tech Orthop 1991;1:192, with permission.)

Below the equator of the glenoid, the labrum is securely attached to the glenoid rim and is actually a fibrocartilaginous transition zone to the glenohumeral ligaments. It functionally deepens the glenoid fossa, thus enhancing the concavity-compression mechanism of stability. Detachment of the glenoid labrum below the equator of the glenoid represents a functional disruption of the origin of the inferior glenohumeral ligament (IGHL), as well as a decrease in the concavity of the glenoid cavity.

The glenohumeral capsuloligamentous complex is characterized by collagenous thickenings of varying development in its anterior portion (Fig. 80.4) (11,13). These thick bands are called the glenohumeral ligaments due to their location along the glenoid rim. Table 80.1 shows the specific functional role of each ligament and the resulting pathology when each is injured. These ligaments and their interposed capsule are normally lax when the shoulder is positioned in the mid range of rotation. The rotator cuff muscles and long head of the biceps tendon (dynamic stabilizers) create the important concavity-compression effect (described below) that maintains stability (116,128,172).

Table 80.1. Glenohumeral Stability

As the arm is rotated toward its end range, the glenohumeral ligaments function in a reciprocal fashion, acting as checkreins to prevent excessive humeral head translation at the extremes of motion (37,113,114 and 115,166). O’Brien et al. (113,114) compared theIGHL to a hammock; its anterior and posterior bands should tighten at terminal external rotation with the arm abducted 90° (Fig. 80.5). In addition to their action as static restraints to excessive translation and rotation, the capsuloligamentous structures may also have a proprioceptive role (65,173). It has been postulated that stretch and motion receptors within the glenohumeral capsule and ligaments relay proprioceptive feedback to the dynamic muscle stabilizers, thus acting as an afferent feedback loop to modulate muscle activity about this joint during active motion.
The rotator cuff muscles are essential for maintaining dynamic stability of the glenohumeral joint. They work in concert to prevent excessive external rotation and adduction, thus maintaining the joint in a stable position. The cuff muscles are critically involved in the prevention of shoulder subluxation, which can occur with repetitive motions such as in swimming. The rotator cuff muscles provide a compressive load across the glenohumeral joint, which helps to prevent the humeral head from shifting out of the glenoid fossa.

Injury to the rotator cuff can result from a single macrotrauma that exceeds the ultimate failure strength of the tendon(s). Alternatively, injury can be the result of repetitive submaximal loads that cumulatively disrupt the tendon fibers. Each scenario can be associated with actual shoulder instability. In individuals older than 40 years, the tensile properties of the rotator cuff tendons tend to deteriorate more rapidly than those of the glenohumeral capsule and ligaments. As a result, patients in this age group have a high incidence of rotator cuff tears associated with a traumatic shoulder dislocation.

Conversely, a young athlete who throws or swims may subject the shoulder to repetitive forces that cause gradual injury to the rotator cuff. For example, subtle degrees of shoulder subluxation may occur with repetitive motions such as in swimming. The capsuloligamentous tissues may stretch, and the joint may become more lax. An overload of the rotator cuff muscles can occur. The active (eccentric) contraction of the rotator cuff, which decelerates the humeral head during the swimming stroke or throwing motion, has been associated with rotator cuff injury.

The long head of the biceps brachii dynamically stabilizes the glenohumeral joint. Contraction markedly limits anterior and superior translation of the glenohumeral joint, increases torsional rigidity of the joint, and decreases strain in the IGHL. Clinical experience based on arthroscopic observations has demonstrated a correlation between shoulder instability and the presence of the superior labral anterior posterior (SLAP) lesion. This injury pattern represents a detachment of the origin of the long head of the biceps.

**CLASSIFICATION**

We use a classification system originally proposed by the Hospital for Special Surgery. The system categorizes patients with shoulder instability on the basis of four criteria: frequency, cause, direction, and degree.

**Figure 80.5.** The IGHL controls glenohumeral instability in a manner analogous to a hammock. A: With the arm in 90° of abduction, the IGHL supports the humeral head inferiorly. B: With external rotation, the anterior band of the ligament prevents anterior translation of the humeral head. C: The posterior band functions in a similar fashion with internal rotation to prevent posterior translation of the humeral head. (From Warner JJP, Caborn DN. Overview of Shoulder Instability. Crit Rev Phys Rehabil Med 1992;4:145, with permission.)

A clear understanding of normal glenohumeral capsular anatomy is essential for surgeons who seek to reestablish anatomy in an unstable shoulder. Procedures that repair the soft tissues while the joint is positioned in the mid range of motion shorten the capsuloligamentous complex. As a result, the joint may be captured, preventing full external rotation, an outcome associated with the development of early arthritis.

Another important characteristic of the glenohumeral joint is the presence of negative (less than atmospheric) intraarticular pressure. This condition results from high osmotic pressure in the interstitial tissue, which draws water from the joint. Any force that tends to displace the humeral head away from the glenoid increases this vacuum effect resisting further humeral head displacement. This effect is clinically relevant when the arm is hanging at the side and the muscles of the shoulder are relaxed. Conditions that disrupt this vacuum effect include capsular rupture, intraarticular fracture, developmental or acquired capsular defects (i.e., rotator interval lesion or capsular rupture), or a large, capacious capsule.

The rotator interval has increasingly been associated with clinical instability. This region of the capsule is a triangular space whose base is located near the coracoid process and its apex near the biceps sulcus. The interval is bordered superiorly by the anterior margin of the supraspinatus tendon and inferiorly by the superior border of the subscapularis tendon. The area is completely bridged by capsule and supplemented by the coracohumeral and the superior glenohumeral ligaments. A deficiency of these ligaments and communication of the joint with the subdeltoid space lead to a significant sulcus sign (inferior laxity).
The instability itself may be acute or chronic, the differentiating feature being whether the event occurred within the previous 24 hours. The number of recurrences (frequency of instability) is also critical in this classification scheme, as it contributes to the level of damage to anatomic structures. This characteristic is extremely important when taken into consideration along with the degree and cause of the instability. This component of the history is critical in determining the appropriate treatment.

Etiology is subdivided into traumatic, microtraumatic, and atrophic groups but also includes congenital and neuromuscular causes. The atrophic group includes patients who exhibit a voluntary component. In this classification, these patients can be further subdivided into group I: voluntary instability, which is arm-position-dependent and usually posterior; and group II: voluntary instability exhibited by an ability to selectively contract muscles, causing a dislocation. While patients in group I can voluntarily demonstrate their instability, they choose to avoid dangerous arm positions. This condition subsequently affects activities of daily living (142). Conversely, patients in group II tend to have an underlying psychiatric problem, using their instability as a means to control their environment (130).

The degree of instability is also important in determining appropriate treatment options. Dislocation refers to complete dissociation of the articular surfaces of the humeral head and glenoid cavity. Subluxation describes increased humeral head translation within the glenoid cavity. Initial open procedures focused on the treatment of true glenohumeral dislocation. Arthroscopic evaluation has heightened the awareness of subtle labral, articular, and ligamentous damage that occurs because of unrecognized, recurrent episodes of subluxation (7,22,24,68,112).

The direction of instability has been a critical component of most classification systems. Traditionally, there was an assumption that 95% of shoulder instability was anterior (25). It has become increasingly apparent, however, that many athletes with ligamentous laxity have instability that is primarily posterior in nature (48, 69, 156, 178). These patients suffer recurrent posterior subluxation and have a history of posterior shoulder pain rather than complaints of frank instability. This category of patients is more prevalent than previously recognized but should be distinguished from the rare true posterior dislocation that results from an acute traumatic event (16,110).

Hawkins et al. (64) reported on a series of 40 patients with 41 locked posterior shoulder dislocations. The initial physician missed the diagnosis in the majority of cases reviewed. In this series, the causes of posterior dislocation were motor vehicle accidents, seizures, alcohol-related injuries, or electroshock therapy. Recurrent anterior subluxation may also manifest as pain rather than instability. Repetitive, high-energy, overhead activities can cause progressive attenuation of the capsular, ligamentous, and labral structures (5,78,159). As these static stabilizers fail and the dynamic stabilizers weaken, anterior subluxation occurs, leading to impingement symptoms. Recognition of the underlying problem is critical in obtaining a successful surgical outcome.

CLINICAL EVALUATION

HISTORY

The history can raise suspicion of shoulder instability. A patient's age, occupation, employment status, activity level, hand dominance, and other medical problems are helpful in classifying the nature of the instability. Certain circumstances, such as work-related injuries or those with associated litigation, might affect patients' perceptions of their disabilities as well as their expectations for recovery and compliance with treatment (180).

Seek out specific complaints. For example, a patient may indicate that the arm "went dead" during a football tackle (158). This symptom is likely associated with a traumatic subluxation of the joint and the presence of a Bankart lesion. Another example is a patient who gives a history of having had a seizure and then awakening with the sensation of the joint "out of place." This situation suggests a posterior dislocation as the result of unchecked internal rotation forces overcoming the weaker external rotators of the shoulder.

If pain is a major component of a patient's complaint, which activities cause the pain? Question athletes as to the type of sport, the position played, and the duration, frequency, and level of involvement. For example, throwers, swimmers, or tennis players may develop excessive capsular laxity as a result of subjecting their shoulders to repetitive microtrauma (83,125). The result is recurrent shoulder subluxation, which can create a sense of "looseness" or "slipping" with activity. In addition, as previously stated, secondary "nonoutlet" impingement can occur as anterior instability decreases the subacromial space, causing pain with overhead activities. Further, these same subluxations can create damage to the superior labral area, creating a SLAP lesion. Posterior subluxation has also been documented in athletes who require repetitive arm motion in front of the body, such as offensive-line football players and volleyball, softball, and baseball players (48, 156, 178). Throwing sports in particular lead to complaints of posterior shoulder pain during the follow-through phase, which has been associated with posterior subluxation and resultant microtrauma to the posterior capsulolabral complex.

PHYSICAL EXAMINATION

A systematic evaluation includes observation for abnormal motion patterns and atrophy, palpation to localize painful areas, assessment of both active and passive range of motion, measurement of strength of the rotator cuff muscles, neurovascular evaluation, and finally provocative maneuvers for instability. Examine the opposite shoulder for comparison.

In evaluating shoulder motion, carefully document any scapulothoracic substitution for glenohumeral motion, scapular winging, and other abnormal motion patterns. Atrophy of the spinatus muscles may indicate a longstanding associated rotator cuff tear or injury to the supraspinacular nerve. Similarly, atrophy of the deltoid may indicate an axillary nerve injury.

Assess patients for findings of generalized ligamentous laxity, including the ability to hyperextend the elbows more than 10°, apply the thumb to the forearm, hyperextend the metacarpophalangeal joints more than 90°, or touch the palm of each hand to the floor while keeping the knees extended (Fig. 80.8). While there is no direct relationship between generalized ligamentous laxity and shoulder instability, there is some association between hyperlaxity and glenohumeral capsular development.

Figure 80.8. Systemic laxity. A: Wrist and metacarpophalangeal joint hyperextension. B: Elbow joint hyperextension. (A and B from Warner JJP. Shoulder. In: Miller
A patient with an acute, unreduced anterior dislocation holds the painful arm in slight abduction and internal rotation (Fig. 80.10). Before attempting any reduction maneuvers, perform a careful neurovascular examination to rule out bursal, axillary, and, more specifically, brachial plexus injuries. The latter condition may sometimes escape detection, as decreased sensation over the lateral deltoid is not always present with an injury to the nerve. In older (>60 years) individuals or younger ones who have sustained a severe trauma, be aware of the possibility of an associated fracture of the humerus. Proper radiographic imaging is particularly important before attempting closed reduction in such cases.

Many methods of closed reduction apply in the case of an acute shoulder dislocation. Perform all maneuvers as a gradual and gentle technique with appropriate analgesia to ensure muscle relaxation. Intravenous analgesia and intra-articular injection of a regional anesthetic are both successful, appropriate methods of anesthesia. A method of gentle traction in line with the arm using countertraction is usually successful.

Pay careful attention to a patient who has an unrecognized chronic (fixed) dislocation. The dislocation is most often posterior, although it may be anterior, and typically occurs in patients who are poor historians because of either alcohol use or dementia. In a patient with a fixed posterior subluxation, there is limitation of external rotation compared with the opposite shoulder. In addition, there is flattening of the anterior aspect of the shoulder with an associated prominence of the coracoid process and possibly some prominence and rounding of the posterior aspect of the shoulder. The application of excessive force in attempting a closed reduction in such a patient risks neurovascular injury or fracture.

Most patients who have instability are first seen by an orthopaedic surgeon in the office setting. They may have had a documented episode of instability or an injury with pain but no true sense of shoulder instability. After a careful neurovascular examination, it is important to assess active and passive range of motion. A discrepancy between active and passive motion may indicate either an associated rotator cuff tear or a nerve injury. It is particularly important to identify a subscapularis tear in the setting of shoulder instability, a condition that is frequently missed. Patients with such tears have passively increased external rotation with the arm adducted at the side, as well as associated apprehension in this position. Strength assessment is also important. Significant external rotation weakness may indicate a rotator cuff tear.

Similarly, internal rotation weakness may be due to a subscapularis tear. In this situation, the patient has an associated lift-off sign (Fig. 80.9). If the patient lacks adequate internal rotation to perform this test, perform the bellies-press maneuver instead to determine the patient’s ability to pull the forearm in a posterior direction toward the mid abdomen while maintaining the flexed elbow anterior to this point. If the elbow remains posterior to the anterior aspect of the mid abdomen, there is likely a subscapularis tendon tear.

Various provocative maneuvers and drawer tests have been described to assess symptomatic humeral head translation and the direction of this movement. Neer and Foster originally described the apprehension test for anterior instability. With the patient seated or standing, place the symptomatic shoulder into a position of 90° abduction and maximum external rotation. Then move the arm so that it is posterior to the plane of the scapula, and apply an anterior force to the humeral head. The patient’s withdrawing from the examiner or complaining about a sense of shoulder instability demonstrates apprehension (Fig. 80.10A).

The complaint of pain is not specific for instability and may in fact be present with other conditions such as arthritis or rotator cuff disease. Kvitne and Jobe proposed a modification of this maneuver to increase its specificity for anterior instability. Place the patient in a supine position, and perform the apprehension test as described above. Ask whether the patient has a sense of instability or simply pain. Place posterior pressure on the humerus, and ask whether this pressure relieves the sense of apprehension or pain (Fig. 80.10B). This “relocation maneuver” increases the specificity of the diagnosis of instability if the patient reports decreased apprehension. If this maneuver simply reduces pain, it is not diagnostic of instability and may be associated with a variety of other diagnoses, including a SLAP lesion or impingement syndrome.

One of us (JJPW) has found that an additional modification to this test increases both its sensitivity and specificity for the diagnosis of anterior shoulder subluxation. Perform the apprehension and relocation tests as described above. If the patient reports pain and not true apprehension, inject the subacromial space with 10 ml of lidocaine 1% (Xylocaine). After 10 minutes, repeat the examination. If the pain is due to rotator cuff disease, the injection will eliminate it. If, however, the pain is due to labral injury, it will persist after a subacromial injection.

Inconsistencies with the apprehension test led Gerber and Ganz to develop the anterior and posterior drawer test to assess the shoulder for excessive translation compared with the contralateral side. Others have found merit in this method of examination and have developed grading scales for the degree of shoulder laxity. These tests may offer some insight into the degree and direction of instability. If one assesses laxity of the shoulder in an office setting, it is important to...
Snyder reported pain in patients during resisted shoulder flexion with elbow extension and forearm supination (biceps tension test). Andrews reported increased pain in patients during full shoulder flexion and abduction, with noticeable catching and popping.

Since the description of superior labral pathology by Andrews et al. (49, 119) proposed a grading scale for translation of the humeral head on the glenoid. Instability is graded on a scale of 0–3+ for all three directions. For anterior and posterior drawer testing, a grade of 0 represents no humeral head translation, while movement of the humeral head up to but not over the glenoid rim represents 1+ instability. Translation of the humeral head over the glenoid rim with an associated spontaneous reduction with relief of pressure represents 2+ instability. Frank dislocation and locking of the humeral head over the glenoid rim is graded as 3+ instability.

When these drawer tests are performed either in the office or in the operative setting, it is important to bear in mind that the position of the arm determines the degree of tension in the glenohumeral ligaments. With the arm at the side in adduction, the IGHL is relatively lax, and anterior and posterior drawer testing may be of limited value. In abduction, the IGHL comes underneath the humeral head and forms a hammock that passively limits anterior, posterior, and inferior translation (113, 114). Perform anterior drawer testing with the shoulder positioned in abduction in the plane of the scapula. Maintain the arm in the neutral rotation while using one hand to place an axial load along the humerus and the other hand to apply an anterior or posterior force to the humerus (Fig. 80.11). Often you can feel the humeral head move back into the glenoid rather than out of the glenoid during this maneuver. The patient may note a painful click with such a maneuver. In our experience, this test is particularly helpful in identifying posterior instability.

![Figure 80.11](image)

A modification of the posterior drawer test allows the examiner to elicit posterior apprehension. Perform this modification by placing the patient’s arm in 90° of forward flexion and adduction while applying an axial load down the shaft of the humerus. Pain and a palpable shift and click suggest posterior labral injury and instability.

A modification of this test, termed the jerk test, has been described for posterior instability (12, 86). With the patient seated, load the abducted shoulder axially into the glenoid with one hand, and with your other hand, palpate the posterior aspect of the shoulder. Then bring the arm into horizontal adduction anterior to the plane of the scapula; the humeral head may sublux posteriorly. Then bring the humerus posterior to the plane of the scapula; the humeral head may suddenly reduce into the glenoid. A palpable shift and pain accompany a positive test.

The sulcus sign is basically an inferior drawer test (Fig. 80.12). Neer and Foster (107) originally described it as the hallmark of inferior and multidirectional instability (MDI). Unfortunately, a common misconception has been that a large sulcus sign that is asymptomatic, thus indicating inherent joint laxity, is a positive finding. The key point is that this maneuver should be associated with pain and should reproduce the patient’s symptoms to be clinically relevant as a finding of inferior instability.

![Figure 80.12](image)

Perform this test with the patient seated and the arm adducted at the side. Rotation of the shoulder is very important in assessing the degree of inferior instability. First, with the arm in the neutral rotation, pull the humerus inferiorly, and estimate the amount of separation between the acromion and the humeral head. Grade it on a 0–3+ scale (3). A separation of 1 cm is a 1+ sulcus sign, 2 cm is a 2+ sulcus sign, and 3 cm is a 3+ sulcus sign. Anatomically, a sulcus sign greater than 2+ indicates a capsular tear and specific laxity of the anteroulnar capsular region (rotator interval).

As previously discussed, externally rotate the arm, and repeat the sulcus sign test. If the sulcus sign remains greater than 2+ with the arm in external rotation, there is a marked deficiency of the superior capsule, and a large rotator interval defect in the capsule is likely. This is the result of damage to the superior and middle glenohumeral ligaments, as well as the coracohumeral ligament. With this information before surgical repair, you then know that surgical reconstruction of this region with a capsular shift must be a component of the operation (60).

Four different types of MDI patterns have been described (119):

- **Type I:** Global instability
- **Type II:** Predominantly anterior and inferior instability
- **Type III:** Predominantly posterior and inferior instability
- **Type IV:** Anterior and posterior instability with no inferior component

The true existence of the last type has been questioned.

Since the description of superior labral pathology by Andrews et al. (5) in 1985 and of the SLAP lesion by Snyder et al. (145) in 1990, several examination techniques have evolved to diagnose this pathology. Andrews reported increased pain in patients during full shoulder flexion and abduction, with noticeable catching and popping. Snyder reported pain in patients during resisted shoulder flexion with elbow extension and forearm supination (biceps tension test).
Another useful diagnostic test is the compression–rotation test. With the patient supine, abduct the shoulder 90°, with the elbow flexed 90°. Apply a compression force to the humerus to trap the torn labrum (in the same manner as McMurray’s test for the knee is performed). O’Brien et al. (114) suggested a maneuver that they believed is accurate for determining superior labral injuries. Place the patient’s shoulder in 90° of forward flexion and then adduct it across the body. Ask the patient to flex the arm further against resistance when the shoulder is first internally rotated and then externally rotated. If pain occurs when the shoulder is rotated internally but not when it is rotated externally, the test is positive. Unfortunately, this test does not distinguish between acromioclavicular joint disease and a superior labral tear. We have found this test more useful than the other methods described above.

**RADIOGRAPHIC EVALUATION**

The minimum radiography necessary for evaluation of an acute dislocation or suspected subluxation is a true anteroposterior (AP) view and an axillary view. These images will allow accurate determination of the position of the humeral head relative to the glenoid. A true AP radiograph is obtained by angling the x-ray beam 45° relative to the sagittal plane of the body (Fig. 80.13). A scapular Y or transcapular view can also give useful information about the position of the humeral head (Figs. 80.14), but it is not as accurate as an axillary view (Fig. 80.15). If a standard axillary view cannot be obtained, a Velpeau axillary view without removing the patient’s arm from the sling will suffice (Fig. 80.16).

Figure 80.14. Transcapular or Y view of the glenohumeral joint allows assessment of the humeral head location in relation to the glenoid cavity. (From Warner JJP, Caborn DN. Overview of Shoulder Instability. Crit Rev Phys Rehabil Med 1992;4:145, with permission.)

Figure 80.15. Axillary view represents the “gold standard” in radiographic assessment of location of the humeral head relative to the glenoid cavity. (From Warner JJP, Caborn DN. Overview of Shoulder Instability. Crit Rev Phys Rehabil Med 1992;4:145, with permission.)

Figure 80.16. Two common techniques used when a standard axillary view is difficult to obtain include the trauma axillary lateral (A) and the Velpeau axillary view (B). (From Warner JJP, Caborn DN. Overview of Shoulder Instability. Crit Rev Phys Rehabil Med 1992;4:145, with permission.)

In the office setting, a true AP view of the shoulder with the arm in internal rotation may demonstrate a Hill–Sachs lesion. A Stryker notch view is a special view that will also demonstrate a Hill–Sachs lesion (Fig. 80.17) (43,121).
The West Point axillary view may prove helpful in a patient suspected of having had an episode of instability. Take the image with the patient prone so that the anterior glenoid is shown in profile without an overlying acromial shadow (Fig. 80.18).

Adjuvant imaging techniques are helpful when additional information about the three-dimensional relationship and architecture of the joint or confirmation of the presence of a Bankart lesion is required. Computed tomography (CT) demonstrates bony injuries or abnormalities including glenoid hypoplasia, congenital version anomalies, acquired version abnormalities from erosion, and glenoid rim fractures (Fig. 80.1 and Fig. 80.19). In addition, it allows measurement of the size of a humeral head defect (Hill–Sachs lesion) in cases of chronic instability (55). When combined with intraarticular dye, CT arthrography also demonstrates a Bankart lesion and articular erosion.

Magnetic resonance imaging (MRI) with or without gadolinium has gained great favor, although unfortunately it is often used as a screening tool in the evaluation of patients. Its role should instead be to confirm the presence of lesions that may need surgical management. It is accurate in the detection of labral pathology (Fig. 80.20) (27,56). Recent advances in MRI technology such as high-resolution fast-spin and gradient-echo imaging make these methods particularly appealing for detecting anterior and superior labral injuries (26).

EXAMINATION UNDER ANESTHESIA

Before arthroscopy or arthrotomy is undertaken, examination under anesthesia (EUA) can confirm or deny the preoperative impression (30,154). During EUA, muscle guarding is eliminated, and an accurate assessment of joint laxity is possible. As previously described, it is essential that laxity not be confused with instability; thus, it is important to compare the symptomatic shoulder with the asymptomatic side. Individuals who have had a previous dislocation will likely have a 2+ or 3+ anterior drawer test result (as described above) for the symptomatic shoulder compared with a 1+ – 2+ finding in the asymptomatic shoulder.

The finding of symmetric laxity, however, does not necessarily exclude instability because a Bankart lesion may be present without marked laxity on examination in a patient who has a history of subluxation (149,171). Furthermore, in very large individuals, the soft-tissue envelope of the shoulder may be so large that accurate
determination of a centimeter of translation of the humeral head on the glenoid may not be possible.

One area where we have found EUA to be helpful is in determining capsular laxity and rotator interval lesions (45), both of which are typically associated with MDI. If an individual is found to have a sulcus sign of more than 2+ and if this persists when an inferior drawer is applied with the arm in external rotation, there will be a large rotator interval defect, as well as marked anterior and inferior capsular laxity. In our hands, this is treated by a modified capsular shift, along with repair of a Bankart lesion if one is found to be present (60). Although other surgeons have used arthroscopic techniques in the treatment of this combination of problems, we generally treat only pure Bankart lesions with an arthroscopic repair technique (99,136,159).

Occasionally, EUA will identify a shoulder that can be dislocated posteriorly (3+) when anterior instability is suspected. It is usually in a patient with congenital laxity who has had a traumatic injury. We usually treat this condition with an open capsular shift method of repair.

**ARTHROSCOPY: BASIC SETUP**

Arthroscopy of the shoulder can be performed in either the seated beach-chair or the lateral decubitus position (see Chapter 77).

The lateral decubitus position allows good visualization of the anterior and inferior glenohumeral structures by virtue of the applied traction, but it does not allow the surgeon to easily manipulate the shoulder through a full range of motion. Moreover, it can limit access to the anterior glenoid with crowding of the instrumentation and cannulas on the drapes and body. In addition, if there is a need to convert to an open procedure, it is usually necessary to reposition (and therefore reprepare and redrape) the patient. As stated previously, there is a risk of transient neuropraxia due to traction (81).

The beach-chair position, our preferred position, provides unrestricted access to the entire shoulder and allows free movement of the arm in all planes. In addition, visualization is possible in a more anatomic orientation. These criteria are essential if a diagnostic arthroscopy is to be performed that inherently requires an assessment of the anatomy of the glenohumeral ligaments. Further, it permits simple conversion from an arthroscopic to an open procedure. In addition, patients tolerate the use of an interscalene block without the need for supplemental general anesthesia, in contrast to patients in the lateral decubitus position. **Table 80.3** compares the beach-chair position with the lateral decubitus position.

**Table 80.3. Advantages and Disadvantages of Lateral versus Beach-chair Arthroscopy**

**OPERATIVE TECHNIQUE**

- If general anesthesia is used, it is important to secure the endotracheal tube to the side of the mouth opposite the injured shoulder. After anesthesia has been obtained, place the patient into the seated position, and perform an EUA. There are special beach-chair attachments that can be fitted to the table (Fig. 80.21) (163). If such a device is not available, place a long beanbag beneath the patient. In this setting, the table is fully flexed, apex down, at the patient’s waist; the knees are then flexed downward approximately 45° with a footplate at the end of the table to prevent the patient from sliding down the table. Finally, the head of the table is elevated approximately 70° from the horizontal.

  ![Figure 80.21. Lateral (A) and anterior (B) views of the beach-chair attachment used for shoulder arthroscopy. (From Warner JJP. Shoulder Arthroscopy in the Beach-chair Position: Basic Setup. Oper Tech Orthop 1991;1:147, with permission.)](image)

- Then harden the beanbag, leaving the entire medial border of the scapula free posteriorly for sterile preparation and draping. Obtain this same position with the use of a beach-chair attachment (Fig. 80.22). Place the uninjured arm on a well padded arm board or a stand that is positioned at the appropriate height to avoid undue pressure on the neck and shoulder. Shave the axilla, and prepare and drape the arm from the hand to the medial border of the scapula posteriorly.

  ![Figure 80.22. Standard patient position for shoulder arthroscopy in the beach-chair position. A: The head is elevated 70° with the medial border of the scapula free and the entire shoulder free posteriorly. B: Anteriorly, the entire shoulder is free, with the uninjured forearm in a padded stand and the shoulder resting at a comfortable level. (From Warner JJP. Shoulder Arthroscopy in the Beach-chair Position: Basic Setup. Oper Tech Orthop 1991;1:147, with permission.)](image)

- Angle the table so that the feet are away from the operative side to allow better visualization of the television monitor positioned on the opposite side of the table from the surgeon. Place a padded sterile stand for instrumentation at knee level on the opposite side of the table. Pass the tubing and arthroscopic equipment underneath the arm and across the patient’s chest and then curve them forward over the shoulder. Use a clamp to secure the tubing in place; remove all instruments and tubing from beneath the arm and place them securely on the padded stand (Fig. 80.23).
Adding 1 ampule of epinephrine to each 3-l bag of irrigating solution limits bleeding. Commercially available fluid pressure pumps may be used, although we have had excellent visualization using simple gravity feed with elevation of two 3-l bags to a height of at least 7–8 ft (2 m).

PORTAL PLACEMENT AND ANATOMY

Portal placement is extremely important when an arthroscopic Bankart repair is performed.

- Place the standard posterior portal for arthroscopy 1–2 cm inferior and medial to the posterolateral tip of the acromion (Fig. 80.24) (5,6,23,79,80,172). Its location can be confirmed by grasping the humeral head and applying an anterior drawer test. We usually place an 18-gauge spinal needle at this location to confirm orientation for insertion of the arthroscope.

Then insufflate the joint with sterile saline. This step increases hydrostatic pressure in the joint and moves the humeral head away from the glenoid. It decreases the likelihood of articular cartilage damage during introduction of the arthroscope into the joint. Further, reflux of saline out of an open port confirms proper positioning in the joint.

- An anterosuperior portal is the primary working portal (Fig. 80.24 A, Fig. 80.24 C). Locate it by viewing with the arthroscope in the posterior portal and then placing an 18-gauge spinal needle into the joint just underneath the long head of the biceps tendon through the rotator interval. This portal is usually quite vertical in orientation. We make an effort to place it as superiorly as possible in the rotator interval to avoid crowding with the anteroinferior portal, which will be used for placement of the arthroscopic instruments (Fig. 80.25). We usually place a 6 mm cannula in this portal location.

Figure 80.26. A: The anterior band of the IGHL is visualized posteriorly and probed anteriorly with the arm in an adducted position. B: External rotation and abduction of the arm to 90° should increase tension in the ligament, producing a hammock-like effect. C: Probe analysis of the anterior labrum through the anterosuperior portal. (From Warner JJP. Shoulder Arthroscopy in the Beach-chair Position: Basic Setup. Oper Tech Orthop 1991;1:147, with permission.)

SLAP lesions are typically type II in nature and are amenable to repair with current arthroscopic techniques (20,44,172,184). In patients younger than 45 years, rotator cuff tears are typically partial-thickness undersurface lesions of the supraspinatus tendon and are treatable through gentle debridement and correction of the underlying instability (156). Larger tears are associated with dislocations in patients older than 40 years (109). Pay careful attention to the presence of a
subscapularis tendon injury in patients older than 40. These injuries usually require formal open repair. Significant glenoid erosion, a large Hill–Sachs lesion, or frank posttraumatic arthritis signifies longstanding instability with associated capsular laxity or, in the worst scenario, dislocation arthropathy.

- The drive-through sign is a nonspecific, though somewhat helpful, finding for capsular laxity, described by Warren and associates (118,166,178). This finding is positive if you can sweep the arthroscope with little resistance from anterior to inferior into the axillary pouch.

- A modification of the drive-through sign that we have found more specific is termed the arthroscopic drawer test (166). View through the posterior portal with the patient’s shoulder abducted. With the arm in abduction and external rotation, apply an anterior drawer. If the humeral head moves over the glenoid rim when the arm is in this position, there is significant capsular laxity (Fig. 80.27). The arthroscope may then be placed through the anterosuperior cannula, and both anterior and posterior drawer tests can be performed (Fig. 80.28).

**Figure 80.27.** Arthroscopic anterior drawer maneuver for assessing the grade of instability.

**Figure 80.28.** A: Arthroscopic visualization can be performed anteriorly and is an excellent means of evaluating the anterior glenoid rim and labrum. B: View the humeral head from an anterosuperior perspective. C: Viewing through this same portal, apply an anterior drawer test (broad arrow), and assess the degree of humeral head (HH) instability. Notice the thin, lax anterior band (thin arrows) of the IGHL and the associated Hill–Sachs lesion (posterior humeral head). (From Swenson TM, Warner JJP. Arthroscopic Shoulder Stabilization: Overview of Indications, Technique, and Efficacy. Clin Sports Med 1995;14:841, with permission.)

The examination should also focus on the quality and development of the glenohumeral ligaments (Fig. 80.29). There is typically great variation among the three glenohumeral ligaments. This development has been characterized on the basis of a 0–3+ scale (118). Zero represents absence of the ligament, while 1+ means that the ligament is thin and lax in nature or one-third the size of the biceps tendon. If the ligament is thick and robust in nature or one-half the size of the biceps tendon, it is graded as 2+, while 3+ means that the ligament is two-thirds the size of the biceps tendon or greater (168). We have found that individuals with marked laxity on drawer testing tend to have small or damaged glenohumeral ligaments compared with those who do not have marked laxity on drawer testing (Fig. 80.30) (170). We believe that thicker, more robust–appearing glenohumeral ligaments indicate a patient who is ideally suited for arthroscopic repair of a Bankart lesion. Optimal selection criteria for an arthroscopic versus an open stabilization procedure are provided in Table 80.4.

**Figure 80.29.** It is important to assess the size and quality of the IGHL. Compare its size to the biceps tendon, which has a consistent diameter and presence. A: Thin, mobile IGHL. B: An anterior view further demonstrates the laxity associated with this ligament. (From Warner JJP, Altchek DW. Arthroscopic Bankart Repair. In: Bigliani LU, ed. Shoulder Instability. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1996:47, with permission.)

**Figure 80.30.** Assess the degree of injury to the ligamentous structures, as well. A: A ruptured IGHL is visualized and probed. B: Debridement is performed for better visualization. (From Warner JJP. Arthroscopic Bankart Repair. In: Bigliani LU, ed. Shoulder Instability. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1996:47, with permission.)

If the patient is deemed to be a suitable candidate for arthroscopic Bankart repair, an anteroinferior portal will be required for the placement of anchors and for knot-tying. Locate this portal with the patient’s arm adducted at the side. Place it approximately 1 cm inferior and lateral to the coracoid process (Fig. 80.25). With the arm in this position, there is little risk of injury to the musculocutaneous nerve (5, 6, 7).

Place a spinal needle from outside into the joint; its orientation should be just over the upper border of the subscapularis tendon. Because the arm is adducted, this tendon falls inferior to the equator of the glenoid, and access to the 4- to 5-o’clock position along the glenoid rim is possible. Remove the needle, and create the portal using a #11 blade. Place an 8 mm disposable cannula with a flow-restricting diaphragm in this portal to allow room for passage of the appropriate instrumentation (Fig. 80.31).

Figure 80.31. This disposable cannula with a diaphragm maintains joint distention and contains an additional inflow–outflow portal. (From Warner JJP. Shoulder Arthroscopy in the Beach-chair Position: Basic Setup. Oper Tech Orthop 1991;1:147, with permission.)

TREATMENT OPTIONS

As seen in the algorithm in Figure 80.32, there are many errant courses that result in ineffective treatment. A patient or a physician can make these errors. A successful outcome begins with an accurate diagnosis followed by the specific treatment required for that particular patient.

Nonoperative Care

Studies on the natural history of traumatic shoulder instability demonstrate a high rate of recurrence with nonoperative treatment (21). Rowe and Sakellarides (133) reported a recurrence rate of 58% in 398 patients with 53% follow-up. They noted a strong correlation between patient age and recurrence, with an incidence of recurrence of 94% in patients younger than 20 years, 79% in patients between 20 and 40 years, and 14% in patients older than 40 years. Subsequent studies verified this trend (62, 69, 103). A large Scandinavian study suggested that recurrence was less common in young males. Hovelius et al. (70) reported on 10-year follow-up of 245 patients with 247 primary dislocations. Recurrent dislocation requiring surgery occurred in 34% of 99 shoulders in the 12–22-year age range, 28% of 57 shoulders in the 23–29-year age range, and 9% of 91 shoulders in the 30–40-year age range. Recurrence rates are even higher in the pediatric age group. Marans et al. (93) reported one or more recurrent episodes of dislocation in all of the children in their study.

Despite an initial claim by Watson-Jones (179) in 1948 that immobilization in full internal rotation for 4 weeks produced complete stability, others have not reported such successful outcomes. In fact, the success of immobilization has been variable. Rowe and Sakellarides (133) reported that immobilization for 3 weeks decreased the recurrence rate. Henry and Genung (67) reported no significant improvement with immobilization. Aronen and Regan (6b) found a reduction in the recurrence rate to 25% if first-time dislocations were treated with isometric, isotonic, and isokinetic exercises (7). Burkhead and Rockwood (21) prescribed a shoulder exercise program for patients with a traumatic or atraumatic etiology. In the traumatic subluxation group, 16% responded favorably to a rehabilitation program, while 67% of the atraumatic subluxation group without psychological problems demonstrated a good-to-excellent outcome. Hovelius et al. (70) reported that the type and duration of initial treatment had no effect on the rate of recurrence.

Thus, it is clear that the most important factors in determining recurrence of instability after a traumatic injury are age and activity level. The following discussion considers surgical options in this category of patients.

Surgical Techniques

Debridement of Labral Lesions

Detrisac and Johnson (29) originally described five variations in labral anatomy; more recently, however, Detrisac (personal communication) changed the categories to two basic types. Type A labra were attached centrally and peripherally at the inferior, posterior, and anterior regions, but superiorly they were detached centrally and...
peripherally. In contrast, type B labra were attached centrally and peripherally along the entire labrum.

Snyder et al. (146), who performed shoulder dissections, modified this description. They described an inferior labrum that consistently was triangular in shape and attached centrally and peripherally. A similar shape was demonstrated in the posterior labrum, although occasionally the undersurface of this area was not attached. The superior region once again showed consistent attachment peripherally, with a central portion that was free in varying degrees. The anterior labrum was attached at both the central and peripheral regions, appearing as a thickened band of capsule that was clearly distinguishable on histologic and gross assessment.

Several patterns of labral injury have been described. Flap tears are usually found in the anterosuperior, anteroinferior, or inferior labrum (156), associated with subluxation or frank dislocation. Other labral tears that have been described include bucket-handle and incomplete split tears, which have not necessarily been associated with instability, if located superiorly (120). Degenerative tears are labral lesions that coexist with degenerative joint disease.

Although initial reports on arthroscopic labral debridement were encouraging (4,54,122), later reports demonstrated a clear relationship between instability and labral pathology. In each study, despite early favorable results at 1- and 2-year follow-up, there was significant deterioration in clinical outcome. The authors in each article concluded that athletes whose sports involve overhead activity should be treated as if there is some underlying laxity or instability. Mere debridement of the labral pathology cannot be expected to be successful.

A study of 52 patients undergoing consecutive arthroscopic labral debridement at Columbia-Presbyterian Medical Center further strengthened these recommendations (35). The majority of these patients had SLAP lesions, while the remainder had either anteroinferior or posterior labral lesions. While no patient had a history of dislocation or clinically evident instability preoperatively, EUA revealed instability in 70% of patients with SLAP lesions and in all of the other patients.

At 1-year follow-up, 78% of the superior labral group versus 30% of the anteroinferior group had excellent results from debridement. These results deteriorated with time to 63% and 25% in each respective group at 2-year follow-up. The authors concluded that instability was frequently present in patients with labral pathology, and debridement would provide only short-term relief in this patient population. On the basis of these studies it is difficult to recommend labral debridement for most patients.

**REPAIR OF SUPERIOR LABRAL LESIONS**

In 1985, Andrews et al. (5) reported the association in athletes between throwing and injuries to the anterosuperior glenoid labrum and the insertion of the long head of the biceps brachii. These injuries were believed attributable to the large deceleration forces applied by the biceps muscle at the insertion point. Two studies further implicated the long head of the biceps in contributing to anterior and superior shoulder stability during abduction and external rotation (126,174). In 1990, Snyder et al. (145) retrospectively reviewed 700 patients who underwent shoulder arthroscopy and described four specific types of pathologic abnormalities in this area: the SLAP lesions (Fig. 80.33). A description of each type of SLAP lesion and the recommended treatment is provided in Table 80.5.

![Figure 80.33](image)

**Table 80.5. SLAP Lesion Types and Appropriate Treatments**

Anatomic and histologic studies further characterized the superior labral area (21,31,129). These studies demonstrated a relative avascularity at the superior and anterosuperior regions compared with the posterior and inferior regions, and this may be one reason for the degeneration that occurs in this area. A retrospective review by Snyder et al. (144) involving 2,375 arthroscopic shoulder procedures over 6 years found SLAP lesions in 140 (6%) patients. Most lesions were classified as either type II (55%) or type I (21%) lesions. Only 28% had isolated superior labral pathology, 22% had associated Bankart lesions, and the remainder had associated rotator cuff pathology. Another review of 712 patients revealed that 17% had type I lesions, while 11.8% had other significant labral pathology (91). The authors had difficulty classifying the remaining pathology according to the criteria described by Snyder, but once again there was a high association between labral lesions and subtle instability or laxity on EUA.

**SLAP LESION REPAIR**

The correlation between glenohumeral instability and superior-labral and biceps-insertion pathology has led to the development of several arthroscopic repair techniques. In 1991, Yoneda et al. (184) described the use of an arthroscopic staple (Instrument Makar Inc., Okemos, MI) designed by Lanny Johnson. The patient population consisted of 10 young athletes (involved in overhead sports) with type II SLAP lesions. The standard lateral decubitus position was used, and the joint was visualized through the standard posterior portal. An anterosuperior portal was used for instrumentation.

The surgery involved arthroscopic debridement, abrasion, and stapling of the SLAP area. One staple (5.5 mm diameter) was used in each case. Patients were immobilized for 2–3 weeks; range of motion was then initiated, followed by strengthening exercises at 6 weeks. Because of concerns over staple migration and irritation, all staples were removed at an average of 3.9 months. On second-look arthroscopy, complete healing had occurred in four patients, with full continuity with the glenoid surface. The remaining repairs were deemed stable despite incomplete healing. More important, 80% of patients were found to have good-to-excellent results.

Reports of loosening and irritation with the arthroscopic staple have led to the development of alternative repair techniques (36,60,124). A transglenoid approach, originally developed for Bankart lesions and popularized by Caspari, has been applied to the SLAP lesion (24,44).

- With the patient in the lateral decubitus position, use standard posterior and superior portals for visualization and inflow. Establish a third anterior portal with a spinal needle; this portal will be used for instrumentation.
- Use a Caspari suture punch (Concept Inc., Largo, FL) through the anterior portal to place four to seven 2-0 polydioxanone (PDS) sutures from posterior to anterior along the labrum-biceps tendon complex. Place an additional one to two 0-PDS sutures into the biceps tendon, as well, to reinforce the repair.
Alternative Technique

A technique designed at the Southern California Orthopedic Institute (SCOI) avoids the inherent risk of transosseous sutures (28). The standard posterior, anterosuperior, and anteroinferior portals as previously described are used with this technique. Wichman and Snyder (180) described the more inferior portal as the anterior mid-glenoid portal.

- Place disposable cannulas with flow-restricting diaphragms into each anterior portal. For type II lesions, first use a shaver to debride the fibrous membrane over the glenoid neck. Then use a 4.0 mm ball burr to decorticate and create a notch beneath the SLAP region, avoiding the articular cartilage. SCOI recommends the use of the Revo screw system (Linvatec, Inc., Largo, FL), in which nonabsorbable suture is placed through the eyelet of the screw before implantation. Insert the Revo punch through the anterosuperior cannula at a 45° angle, impact it with a mallet, and remove it. Then place the screw with the attached braided, nonabsorbable suture (Fig. 80.35A, Fig. 80.35B).

- Make a transglenoid drill hole (1-o’clock position for right shoulders or 11-o’clock position for left shoulders), using a Beath needle placed through the anterior portal approximately 3–5 mm medial to the articular surface and exiting in the infraspinatus fossa posteriorly (Fig. 80.34A, Fig. 80.34B). Then pass all previously placed sutures through the glenoid neck, using the Beath needle (Fig. 80.34C). Tie the sutures through a small posterior incision over the infraspinatus fascia (Fig. 80.34D). Immobilize the patient for 1–2 weeks, and protect the shoulder in a sling for an additional 3–4 weeks. Field and Savoie (44) reported excellent results in 80% of the patients in whom they used this technique.

- Apply tension to the suture through the cannula to assess the stability of the anchor. Then use a hook or grasper to retrieve one limb of the suture through the anteroinferior portal (Fig. 80.35C). Place a crescent-shaped suture passer through the anterosuperior portal, and use it to pass a Shuttle Relay (Linvatec, Inc., Largo, FL) through the anterior superior labrum–biceps complex (Fig. 80.35D). The Shuttle Relay contains a central loop through which suture can be placed and then pulled back through the tissue.

- Pass the Shuttle Relay through the anteroinferior portal with a grasper, and expose the loop externally. Pass the limb of nonabsorbable suture in the anteroinferior portal through the loop of the relay. Then pass the suture through the tissue by applying tension on the other end of the Shuttle Relay still exposed through the anterosuperior portal (Fig. 80.36B). Thus, the relay and attached suture are pulled back through the tissue and out the anterosuperior cannula in a retrograde fashion.

- Repeat the process for the other limb of the suture, creating a horizontal mattress repair. Place a probe through the anteroinferior portal to reduce the entire complex, and use an arthroscopic knot pusher to tie the suture in place (Fig. 80.36C, Fig. 80.36D).

- An alternative to the Shuttle Relay is a suture-transport system (Smith and Nephew, Andover, MA) (Fig. 80.37). These instruments contain a sharp tip that is passed through the anterosuperior portal and directly through the tissue (Fig. 80.38A). The surgeon deploys two small metal arms and grasps one limb of the suture, pulling it back through the tissue and out the cannula (Fig. 80.38B). The process is repeated, and the sutures are tied in horizontal fashion.

Figure 80.34. Arthroscopic repair of a SLAP lesion using a transglenoid suture technique. A: Prepare the glenoid rim. B: Drill transglenoidally with a Beath needle. C: Pass the suture that is subsequently tied over the infraspinatus fascia. (From Altchek DW, Warren RF, Skyhar MJ. Shoulder Arthroscopy. In: Rockwood CA Jr, Matsen FA III, eds. The Shoulder. Philadelphia: WB Saunders, 1990:275, with permission.)

C: Pass one limb of the suture through the anteroinferior portal. (From Cheng JC, Karzel RP. Superior Labrum Anterior Posterior Lesions of the Shoulder: Operative Techniques of Management. Oper Tech Sports Med 1997;5:249, with permission.)

Figure 80.36. SLAP lesion repair. A: Place a cannulated hook and Shuttle Relay through the SLAP lesion. Then expose the latter externally through the anteroinferior portal. Pass the suture through the eyelet portion of the Shuttle Relay. B: Pull the suture in a retrograde fashion through the SLAP lesion and the anterosuperior cannula. C: Repeat the process for the other limb. D: Tie the suture arthroscopically, creating a horizontal configuration. (From Cheng JC, Karzel RP. Superior Labrum Anterior Posterior Lesions of the Shoulder: Operative Techniques of Management. Oper Tech Sports Med 1997;5:249, with permission.)
In type IV lesions, for tears involving less than 30% of the torn biceps tendon, perform debridement and complete repair as for type II lesions. With greater involvement, perform a primary biceps tenodesis in elderly patients or a suture repair of the biceps tendon and labrum in younger patients. Good-to-excellent results with this technique have been reported in 74% of patients after long-term follow-up (153).

The numerous suture anchors on the market have different advantages and disadvantages (Fig. 80.39). Many surgeons prefer to use metal anchors for postoperative radiographic visualization in the event that an anchor dislodges from the bone, which is a potential risk with this technique. If an anchor loosens, the device must be removed because an intraarticular loose body could lead to cartilage damage. In addition, there are potentially grave complications from migration of a foreign object to the lung, subclavian artery, or spinal canal (90, 96, 98, 111, 138).

With this concern in mind, absorbable anchors have been developed. However, because they degrade, they raise concerns about the stability of the repair. Studies have focused on initial pullout strengths and degradation of the entire anchor (8, 9, 97). As most absorbable materials lose their strength in 4–6 weeks, there are also concerns over the degradation at the eyelet (20). This technique also requires secure intraarticular knot-tying with a certain level of experience before actual use in the operating room.

Warren and colleagues developed the Suretac device (Smith and Nephew, Andover, MA) to overcome some of the problems inherent in suture anchors (151, 177). This implant is an absorbable, cannulated device composed of a synthetic copolymer (polyglyconate). The tack contains ribs for increased pullout strength (3.2 mm shaft diameter). It has a wide, flat head (6.5 mm diameter) to adequately hold tissues, and undergoes hydrolysis, thereby preventing a significant inflammatory response (Fig. 80.40). The rapid, 4-week bioabsorption profile prevents the possibility of loose fragments, as might occur with slower absorption profiles, but is considered long enough for adequate tissue healing. In most descriptions of procedures employing this implant, the beach-chair position has been used (117, 172).

With this concern in mind, absorbable anchors have been developed. However, because they degrade, they raise concerns about the stability of the repair. Studies have focused on initial pullout strengths and degradation of the entire anchor (8, 9, 97). As most absorbable materials lose their strength in 4–6 weeks, there are also concerns over the degradation at the eyelet (20). This technique also requires secure intraarticular knot-tying with a certain level of experience before actual use in the operating room.

Warren and colleagues developed the Suretac device (Smith and Nephew, Andover, MA) to overcome some of the problems inherent in suture anchors (151, 177). This implant is an absorbable, cannulated device composed of a synthetic copolymer (polyglyconate). The tack contains ribs for increased pullout strength (3.2 mm shaft diameter). It has a wide, flat head (6.5 mm diameter) to adequately hold tissues, and undergoes hydrolysis, thereby preventing a significant inflammatory response (Fig. 80.40). The rapid, 4-week bioabsorption profile prevents the possibility of loose fragments, as might occur with slower absorption profiles, but is considered long enough for adequate tissue healing. In most descriptions of procedures employing this implant, the beach-chair position has been used (117, 172).
True complete superior labral detachments are a challenge to repair, but they are much more easily repaired through an arthroscopic than through an open approach because the overlying acromion makes exposure of the superior glenoid difficult through a deltopectoral approach. Furthermore, the diagnosis of a SLAP lesion is essentially an arthroscopic diagnosis.

For 6 years, one of us (JJPW) has used an arthroscopic technique that employs the Suretac device (172). In the past 2 years, a suture method has been developed. Both methods have proven efficacious. Theoretically, the suture method gives stronger immediate repair without any worry about deterioration of the strength of repair due to resorption of the polyglyconate anchor, as with the Suretac device.

Perform both techniques with the patient in a beach-chair position. Use an anterosuperior portal with a 6 mm cannula with a flow-restricting diaphragm entering the joint just underneath the biceps tendon. Use an accessory anterolateral or transcuff portal, as well (Fig. 80.41).

Place an 18-gauge spinal needle through the rotator cuff from just lateral to the acromion to identify this latter portal. Position the needle so that the most direct angle to the superior labrum is possible. Then withdraw the spinal needle and use a #11 blade to make a portal through the rotator cuff while visualizing from within the joint. Insert another 6 mm cannula into the joint through the rotator cuff. The defect made in the cuff with this approach has not led to any significant clinical problems postoperatively.

Using the anterosuperior portal, clear the superior glenoid rim of soft tissue, using a motorized shaver (Fig. 80.42), and decorticate the juxtaarticular margin with a burr (Fig. 80.43).

Repair the SLAP lesion through the transcuff portal, using either one Suretac implant placed through the labrum–biceps tendon complex or two suture anchors placed just anterior and posterior to the biceps origin. When using the Suretac implant, place a cannulated drill with protruding guidewire (3 mm) through the transcuff portal (Fig. 80.44). The wire, which is locked in position, pierces the tissue and is used to bring the complex toward the prepared glenoid neck.

Advance the drill to a depth of one external mark (approximately 1–2 cm), and unlock the wire from the bit. Tap at its free end to release it from the drill, and remove the drill. The wire should remain in place, piercing the tissue. Place the tack over the wire, and tamp it into place with a cannulated pusher.

Usually, one Suretac implant is placed (Fig. 80.45). Technical errors encountered with the Suretac device will be discussed later in the chapter. Clinical and cadaveric...
experience have demonstrated that the accessory anterolateral portal (localized with a spinal needle) can provide reliable access to the superior glenoid region (Fig. 80.46).

**Figure 80.45.** Arthroscopic stabilization of a type II SLAP lesion with a Suretac implant. (From Warner JJ, Kann S, Marks P. Arthroscopic Repair of Combined Bankart and Superior Labral Detachment Anterior and Posterior Lesions: Technique and Preliminary Results. *Arthroscopy* 1994;10:383, with permission.)

**Figure 80.46.** This cadaveric dissection demonstrates the direct localization of the superior glenoid and SLAP repair from a lateral direction. (From Warner JJ, Kann S, Marks P. Arthroscopic Repair of Combined Bankart and Superior Labral Detachment Anterior and Posterior Lesions: Technique and Preliminary Results. *Arthroscopy* 1994;10:383, with permission.)

Protect patients in a sling and swathe for 4 weeks. Initiate gentle passive range-of-motion exercises in a supervised setting 1 week postoperatively. Advise patients to avoid external rotation past neutral and forceful abduction greater than 60° for 4 weeks. With this technique, 86% satisfactory results were obtained at 2-year follow-up. Twelve of 13 athletes were able to return to full overhead function (117).

Alternatively, suture anchors can be used to repair these lesions.

- Use the anterosuperior portal for glenoid preparation and the transcuff portal for implant placement. Assess and prepare the area beneath the labrum–biceps tendon complex as described previously (Fig. 80.47A, Fig. 80.47B). Place suture anchors anterior and posterior to the complex. We have had experience with the Tag Rd II (Smith and Nephew, Andover, MA) and the ROC (Innovasive Devices, Inc., Marlborough, MA) suture anchor systems. As stated previously, there are many suture anchors on the market, each with its own advantages and disadvantages.

**Figure 80.47.** Slap lesion repair. A: Prepare the superior labral region through the lateral portal, using a shaver. B: Use an arthroscopic burr to create a bleeding surface. C: Place the arthroscopic drill through the lateral portal. D: Implant a suture anchor after drilling has been performed.

- Regardless of the system used, drill the glenoid neck at a 45° angle from the articular surface through the transcuff portal (Fig. 80.47C). Remove the drill, and then tap the preloaded (braided, nonabsorbable material) suture anchor into place (Fig. 80.47D). Apply firm tension on the suture to assess fixation. Use either a Shuttle Relay or a suture-transport system to pass one limb of the suture through the biceps tendon, as previously described, using the anterosuperior portal (Fig. 80.48A).

**Figure 80.48.** Slap lesion repair. A: One arthroscopic knot has been tied anteriorly. Use a suture-transport system to pass an additional suture through the posterior portion of the SLAP lesion, using the lateral portal.

- Using arthroscopic knot-tying technique, fix the biceps anchor to the glenoid rim with a simple (not horizontal mattress) suture configuration (Fig. 80.48B). Assess the repair for stability at this point, and, if deemed necessary, place another suture anchor either anterior or posterior to the initial suture anchor for additional fixation.
- Use the same postoperative protocol as for the Suretac repair.

Preliminary results with this technique have been satisfying, although longer follow-up will be required to determine its true clinical efficacy.
ARTHROSCOPIC BANKART REPAIR

Many of the arthroscopic techniques for SLAP lesion repairs were adapted from techniques for arthroscopic repair of Bankart lesions. Arthroscopic shoulder stabilization was initially attempted with an arthroscopic staple (79). Unfortunately, this technique was associated with a high recurrence rate and an unacceptably high rate of complications related to the implant (Table 80.6). Complications included breakage and migration of the staple, as well as articular and neurovascular injuries from the staple. This technique has largely been abandoned.

### Table 80.6. Published Complications and Instability Recurrence Rates of the Arthroscopic Staple Technique

Subsequently, Caspari and Morgan developed a transosseous suture repair technique that avoided the pitfalls of a juxtaarticular staple (24a, 104, 136). This method was based on the open technique developed by Reider and Ingles (166). In a manner similar to that previously described for SLAP lesion repairs, a Caspari suture punch is used to place PDS sutures through the IGHL. These sutures are then loaded onto a special pin with a hole at one end (Beath pin) and passed through a drill hole made at the anterior glenoid rim so that it exits out of the infraspinatus fossa (Fig. 80.34). These sutures are then separated into two limbs and tied over the infraspinatus fascia.

In the hands of the surgeons who developed this method of repair, results have been good to excellent over intermediate follow-up (157). Unfortunately, others have been unable to duplicate the success of these surgeons, and with longer follow-up, recurrence rates have been reported in the 20% to 40% range (Table 80.7) (58, 127, 140, 162, 165).

### Table 80.7. Published Instability Recurrence Rates of the Arthroscopic Suture Technique

As discussed previously, there are technical problems associated with this technique, such as placement of the drill hole too medially so that the Bankart lesion is not repaired, as well as suprascapular nerve injury from posterior exit of the pin. Finally, the need for an additional posterior incision has made this approach less desirable.

One of the first attempts to develop a reliable all intraarticular technique was made by Maki (92). He proposed drilling across the glenoid in a manner similar to the technique described above; however, a large suture (Mulberry knot) was tied in the PDS suture so that when it was pulled back it locked on the posterior cortex of the scapula. Internal knots were then tied over the anterior capsule and labrum with a special knot pusher and special knot-tying techniques. Current approaches to arthroscopic Bankart repair involve the use of suture anchors and internal knots or absorbable transfixing implants (42, 127, 183).

Regardless of which implant is used, arthroscopic methods of repair are continuing to evolve, along with an appreciation of more specific indications for their use. There are clear-cut advantages and disadvantages to arthroscopic stabilization procedures (Table 80.8). Appropriate patient selection is based on a detailed history and physical examination, imaging studies when indicated, and a careful EUA and arthroscopic inspection. In addition, other specific factors seem to be associated with a good result (Table 80.4).

### Table 80.8. Arthroscopic Bankart Repair

While some surgeons are exploring the role of arthroscopic capsulorrhaphy and thermal capsular shrinkage for patients with capsular laxity, we feel that the optimal patient for repair is one who has a discrete Bankart lesion with robust capsuloligamentous structures without significant capsular injury. In addition, it is preferable if there is no significant glenoid erosion or a bony Bankart lesion. While a small Hill–Sachs lesion is not a contraindication to arthroscopic repair, we believe that a large Hill–Sachs lesion is associated with recurrent episodes of dislocation and generally indicates significant capsular laxity. With these criteria, short-term follow-up studies have demonstrated a significant reduction to approximately 7% to 10% in postoperative failure rates (recurrences) after arthroscopic stabilization procedures (84, 175, 176).

**Authors’ Preferred Method**

- Perform arthroscopy with the patient in the beach-chair position.
- Use three portals for the arthroscopic Bankart repair: the standard posterior, anterosuperior, and anteroinferior portals (Fig. 80.49A). Accurate portal placement is...
allow active-assisted stretching and strengthening exercises. Allow swimming and throwing at 4 months and contact sports at 6 months.

As previously discussed, place the anterosuperior portal just anterior and lateral to the acromioclavicular joint, so that a 6 mm cannula enters the joint vertically just beneath the biceps tendon. Locate the anterosuperior portal 1 cm inferior and lateral to the coracoid process, entering the joint just over the subscapularis tendon. Use a spinal needle before incising the skin to ensure access to the appropriate region along the anteroinferior glenoid neck (Fig. 80.49B). It should correspond to the 4- and 5-o'clock positions for the right shoulder and to the 7- and 8-o'clock positions for the left shoulder. If this inferior portal is not placed correctly, there will be a tendency for the drill to slip either medially or inferiorly when you attempt fixation. Insert a large, 8 mm cannula through this portal to allow placement of the appropriate instruments.

As with SLAP lesions, adequately prepare the glenoid neck to ensure healing of soft tissue to bone, including the inferior glenoid rim, which usually requires enlargement of the Bankart lesion (Fig. 80.50A). Gain access to this region through the anteroinferior portal; use a motorized shaver and burr to create a bony trough along the anterior glenoid neck that prevents drill slippage during subsequent portions of the procedure (Fig. 80.50B, Fig. 80.50C and Fig. 80.50D).

Use a 30° arthroscope placed through the posterior and anterosuperior portals to assess the preparation (Fig. 80.51). Alternatively, place a 70° arthroscope through the posterior portal to gain a bird’s-eye view of the anterior glenoid region.

In chronic instability, the detached capsulolabral complex may adhere by scar medially along the scapula. Nevisier (109) termed this an anterior labral periscapal sleeve avulsion (ALPSA) injury. It is essential to mobilize this tissue so that it can be reattached at its anatomic site adjacent to the articular margin of the glenoid. Use a hooked-tip electrocautery device and a knife–rasp to subperiosteally elevate the scarred capsulolabral tissue (Fig. 80.52A).

Place an arthroscopic instrument through the anterosuperior portal and grasp the anterior band of the IGHL (H.H., humeral head; G., glenoid). B: Pull the IGHL in a posterosuperior direction, using an arthroscopic grasper. C: This cadaveric dissection demonstrates a persistent Bankart lesion after inadequate mobilization of the IGHL. (arrows). D: Appropriate superior shift of the anterior band of the IGHL avoids this problem by bringing the soft tissues firmly against the anteroinferior glenoid rim. (From Warner JJ, Miller MD, Marks P. Arthroscopic Bankart Repair with the Suretac Device. Part II. Experimental Observations. Arthroscopy 1996;11:14, with permission.)

Place an arthroscopic grasper through the anterosuperior portal, and use it to pull the tissue into the appropriate position before repair with the Suretac implant (Fig. 80.52B, Fig. 80.52C and Fig. 80.52D). Place this device, using the same technique described previously for SLAP lesion repairs.

Postoperatively, protect patients in a sling and swathe for 4 weeks. Allow them to shower, but they should avoid external rotation; advise them to maintain the arm internally rotated when it is out of the sling. Allow elbow motion, as well as activities of daily living, which generally involve limited forward flexion. After 4 weeks, allow active-assisted stretching and strengthening exercises. Allow swimming and throwing at 4 months and contact sports at 6 months.
Using many of the principals developed for the Suretac device, we recently increased our use of suture anchors along the anterior glenohumeral rim in patients with labral pathology and associated capsular laxity or stretch.

- With the patient in the beach-chair position, create posterior, anterosuperior, and anteroinferior portals as previously described. Once again, it is important to maintain adequate distance between the two anterior portals to avoid instrument crowding. A spinal needle is helpful in localizing the more inferior portal (Fig. 80.53A). The anteroinferior portal contains a large, 8.0 mm cannula to allow placement of the drill and suture hook during the procedure.

- Prepare the glenoid rim through the same anterior portals, making sure to effectively mobilize the anterior capsulolabral tissue (Fig. 80.53B). As previously described, create a trough with the摆 to prevent the drill from slipping and possibly damaging the articular cartilage (Fig. 80.53C).

- This suture anchor system requires predrilling before anchor placement. Drilling is performed through the anteroinferior portal. The system contains a drill guide, which maintains appropriate orientation and drill hole location. Remove the drill and keep the guide in place. Tap the suture anchor loaded with braided suture into place (Fig. 80.54A). Apply tension to the suture ends to test the fixation.

- Perform the remaining portion of the procedure, using a suture hook and Shuttle Relay system or a suture-transport system as previously mentioned. If the Shuttle Relay is to be used, pass one limb of the suture through the anterosuperior portal with a grasper. Pass a suture hook loaded with a Shuttle Relay through the anteroinferior portal and IGHL. Take care to avoid tearing the tissue while grasping enough tissue to adequately reduce joint volume. If using the Shuttle Relay, advance it through the suture hook and pull it through the anterosuperior cannula with a grasper (Fig. 80.54B). Remove the suture hook while maintaining tension on the Shuttle Relay; then load the eyelet of the Shuttle Relay with the previously passed suture, and pull this suture in a retrograde fashion back through the tissue and the anteroinferior cannula.

- Leave the second limb of suture free, rather than passing it through the tissue. This technique pulls the tissue to the glenoid rim, and bunches it together to recreate the "chock block" effect of the labrum. Then tie the suture with an arthroscopic knot pusher (Fig. 80.54C). In the case illustrated, a half-hitch technique was used to secure the tissue, essentially tying the suture with alternating half-knots. There are other knot-tying techniques (i.e., Tennessee slider) that allow immediate locking of the stitch by pulling the post. These knots have the benefit of being lower profile.

- Alternatively, if using a suture-transport system, pass the device through the anteroinferior portal and tissue. Grasp one limb of the suture still in the anteroinferior portal with an arthroscopic grasper. Use a cannulated hook to pass the Shuttle Relay through the IGHL, and then pull it through the anteroinferior portal through the IGHL, which is then tied arthroscopically with half-hitch knots. D: Alternatively, use a suture-transport system to pass the suture through the soft tissue.

- Bending of wire during drill placement and glenoid drilling
  - Improper drill or wire placement: Above the equator of the glenoid (Fig. 80.55)
  - Slips medially and inferiorly: Captures too little tissue x-ray tissue of poor quality (Fig. 80.56)
  - Guidewire extraction during drill removal
  - Head of Suretac buttonholes through tissue (Fig. 80.57)
  - Removal of Suretac causes bleeding
  - Drill too deeply (exiting posterior cortex of scapula) Breakage or bending of Suretac during placement (Fig. 80.58A)
  - Suretac may fall into axillary pouch (Fig. 80.58B)

- Table 80.9. Use of suture anchors along the anterior glenohumeral rim in patients with labral pathology and associated capsular laxity or stretch. As alluded to previously, there are several common technical errors to avoid with use of the Suretac device (176). Further, there are also problems that can arise with use of suture. These problems and the most appropriate methods of avoiding and solving them are presented in Table 80.9 and Table 80.10.

Figure 80.55. Arthroscopic Bankart repair. A: The Suretac implant has been placed too far medially (arrow) in this cadaveric specimen. B: This coronal dissection demonstrates a medially placed implant. Arrows demonstrate the correct location for implant placement and a persistent capsulolabral separation that results from medial Suretac placement. (From Warner JJ, Miller MD, Marks P. Arthroscopic Bankart Repair with the Suretac Device. Part II. Experimental Observations. Arthroscopy 1995;11:14, with permission.)

Figure 80.56. Arthroscopic Bankart repair. A: Arthroscopic view demonstrates a rupture in the anterior band of the IGHL while the arm is in the neutral position. B: With the arm in abduction, the degree of damage is further demonstrated. Incompetent or damaged ligamentous tissues prohibit adequate arthroscopic shoulder stabilization. (From Warner JJP. Arthroscopic Bankart Repair. In: Bigliani LU, ed. Shoulder Instability. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1996:47, with permission.)

Figure 80.57. Arthroscopic Bankart repair. A: Arthroscopic view through the anterosuperior portal demonstrates a Suretac implant that has buttonholed (arrows) through the anterior band of the IGHL. B: Viewing through the posterior portal demonstrates limited soft tissue under the head (arrows) of the device. (From Warner JJP, Altchek DW. Arthroscopic Repairs for Instability. In: Warner JJP, Iannotti JP, Gerber C, eds. Complex and Revision Problems in Shoulder Surgery. Philadelphia: Lippincott–Raven Publishers, 1997:39, with permission.)

Maintain patients in a sling and swathe for 4 weeks. Allow bathing and elbow–wrist range of motion at 1 week, but external rotation past neutral should be avoided. Allow passive and active-assisted range-of-motion exercises and pulley exercises at 4 weeks. Initiate elastic band rotator cuff strengthening exercises at 2 months and weight training at 4 months. Allow noncontact sports at 4 months and contact sports at 6–9 months, depending on the level of contact.

ARTHROSCOPIC CAPSULAR SHIFT

Since Neer and Foster’s (107) original description of MDI, many open techniques have been developed to stabilize patients with the condition (3, 10, 78, 171). While results with these methods have been good, they have not been on par with the results after treatment of traumatic unidirectional anterior instability; return to overhead athletic activities has been less certain. Moreover, there is a perception that perioperative morbidity might be improved with a “less invasive” arthroscopic technique. For this reason, several surgeons have attempted to develop arthroscopic methods of capsulorrhaphy to treat patients with MDI. While some surgeons have reported
on their initial experience with these methods (Eugene Wolf and Steven Snyder, personal communications), little has been reported in the peer-reviewed literature.

Duncan and Savoie (41) described an arthroscopic inferior capsular shift in 1993. The technique involved dividing the anterior and inferior capsule with an end-cutting shaver. This division allowed the inferior capsule to be advanced superiorly. Sutures were tied with a transglenoid suture technique. This initial report was a preliminary study of 10 patients who were all found to have a “satisfactory” shoulder according to the Neer and Foster criteria. An average Rowe score of 99 was reported, as well. Modifications of this transglenoid suture capsulorrhaphy have been developed to address posterior instability (100).

Wichman and Snyder (180) described a technique of capsular plication in a select population with MDI and no associated labral pathology. All patients underwent a prolonged course of rehabilitation before surgical intervention, which allowed serial examinations. Over the weeks, the physicians’ knowledge of the patient and the underlying disorder increased. Thus, patients with voluntary instability of a psychological nature could be identified.

This technique is performed in the lateral decubitus position, using the standard posterior and anterosuperior portals as described previously. In addition, an anterior mid-glenoid portal is used corresponding to an area approximately 3 cm distal and 2 cm lateral to the anterosuperior portal. This portal is made through an outside-in technique and enters the joint just over the subscapularis tendon in a manner similar to the anteroinferior portal previously described.

Place a large (8.4 mm) cannula into this portal to provide access for large suture hooks. For anterior plication, place the arthroscope posteriorly, and abrade the synovium along the anterior and inferior capsule with a rasp or 4.5 mm arthroscopic shaver (Fig. 80.59A). This abrasion creates bleeding, which will subsequently promote healing.

**Figure 80.59.** Arthroscopic capsular shift. A: Use an arthroscopic rasp to prepare the anterior capsule through the anteroinferior portal. B: Pass a suture hook through the inferior capsule. C: The hook allows passage of the Shuttle Relay through the inferior capsule and labrum, and the relay is then passed through the anterosuperior portal using an arthroscopic grasper. D: Use the Shuttle Relay to pass the suture in a retrograde fashion through the tissue. (From Wichman MT, Snyder SJ. Arthroscopic Capsular Plication for Multidirectional Instability of the Shoulder. Oper Tech Sports Med 1997;5:238, with permission.)

Pass a 90° suture hook with a loaded Shuttle Relay through the anteroinferior cannula and create a pinch stitch by taking anteroinferior capsule and advancing it superiorly and medially to the anteroinferior labrum (Fig. 80.59B). A 1-cm-thick fold is produced between the capsule and labrum.

Deliver the Shuttle Relay through the end of the hook, and pull it through the anterosuperior portal with a grasper (Fig. 80.59C). Lead the eyelet of the Shuttle Relay with a braided, nonabsorbable suture, and pull it in a retrograde fashion through the labrum and capsule and out the anteroinferior portal (Fig. 80.59D). Repeat this process slightly more superiorly to create a horizontal mattress stitch (Fig. 80.60A).

**Figure 80.60.** Arthroscopic capsular shift. A: Repeat the process for the second limb of the suture to create an effective horizontal stitch. B: The process can be repeated anteriorly, inferiorly, and posteriorly for the patient with MDI. C: The goal is to decrease the capsular volume and recreate the “chock block” effect of the labrum. (From Wichman MT, Snyder SJ. Arthroscopic Capsular Plication for Multidirectional Instability of the Shoulder. Oper Tech Sports Med 1997;5:238, with permission.)

If posterior plication is anticipated, it is recommended that the posterior portal be created slightly more superiorly. Of course, hook and suture placement would be performed with the arthroscope through the anterosuperior portal in this case. With this technique, external rotation was preserved to within 10° of the preoperative level in 92% of patients at a minimum 2-year follow-up. An assessment of postoperative function using the American Shoulder and Elbow Society instrument revealed an improvement from a preoperative score of 63 to a postoperative score of 86.2 The average Rowe score postoperatively was 79.6. Five patients’ conditions were rated unsatisfactory, with 19 patients having satisfactory ratings, according to Neer’s criteria. The authors noted a disproportionately high number of workers’ compensation cases in the unsatisfactory group. Interestingly, three patients underwent second-look arthroscopy (two for unrelated procedures) that revealed significant capsule formation at the site of previous plication and no adverse synovial reaction to the suture.

**LASER OR THERMAL CAPSULAR SHRINKAGE**

The use of heat to treat shoulder instability dates back to 460 BC when Hippocrates inserted a hot iron into the axilla, contracting the inferior aspect of the joint. This same concept has gained recent popularity, but laser and radiofrequency energy sources are used to produce the heat. The triple-helix structure of collagen unwinds at 65°C, undergoing a conformational change from a crystalline, extended state to a randomly coiled, contracted state (denatured) and producing shrinkage in capsular tissue properties.

The use of heat to treat shoulder instability dates back to 460 BC when Hippocrates inserted a hot iron into the axilla, contracting the inferior aspect of the joint. This same concept has gained recent popularity, but laser and radiofrequency energy sources are used to produce the heat. The triple-helix structure of collagen unwinds at 65°C, undergoing a conformational change from a crystalline, extended state to a randomly coiled, contracted state (denatured) and producing shrinkage in capsular tissue properties.

Radiofrequency thermal stimulation has been used as an alternative energy source that avoids some of the problems inherent in laser energy. Such devices are less expensive and are relatively easier to use. The ElectroThermal-Arthroscopy system (ORATEC Interventions, Inc., Menlo Park, CA) integrates a thermocouple into the arthroscopic handpiece, creating a monopolar system. The current applied to the tissue at the dull probe tip is minimally invasive while still accomplishing collagen denaturation (S.P. Amozych, personal communication). This system contrasts with the vapor system from Mitek Surgical Products, Inc. (Westwood, MA), which represents a bipolar system without a thermocouple. Both products are radiofrequency systems.

These instruments have been applied over the past several years as an experimental treatment method. Their obvious appeal is that they can be used effectively in an outpatient setting. The procedure does not require a great deal of time or the use of sutures or implants. Unfortunately, while anecdotal reports concerning these procedures are appearing, there is currently no peer-reviewed literature available regarding the effectiveness of this technique. Nevertheless, thermal capsular shrinkage remains a possible alternative treatment. Its efficacy will need to be substantiated over the next 5–10 years with well controlled follow-up studies to assess whether there is a gradual restretching of the tissues with increased use.
OPEN SURGICAL TECHNIQUES

The indications for open versus arthroscopic shoulder stabilization remain a controversial topic (164). As outlined in Table 80.4, the criteria for arthroscopic shoulder stabilization are becoming more clearly defined. As surgeons continue to improve their ability to arthroscopically shift the glenohumeral ligaments and repair labral lesions and as new technologies are developed, the number of patients who are candidates for open surgical procedures will decrease. Certainly, the presence of a large Hill–Sachs lesion or a bony Bankart lesion on radiographic examination is an indication for an open surgical approach. Likewise, patients without a significant Bankart lesion by MRI or CT may not be optimal candidates for an arthroscopic Bankart procedure. Similarly, findings consistent with significant capsular laxity or stretch, such as an atrophic medical history or MDI findings on physical examination, should direct the surgeon toward open treatment options. Significant capsular damage, rotator interval lesions, or rotator cuff tears are also currently better repaired with open surgical techniques.

Open Anterior Shoulder Stabilization Procedures

Many open procedures have been developed and popularized to treat anterior glenohumeral instability. The Magnuson-Stack and Putti-Platt procedures attempted to realign and tighten the subscapularis tendon (158,179). The anterior capsule was also tightened by the latter technique. The du Toit staple capsulorrhaphy attempted to reattatch the capsule and glenoid (15,143). The Bristow and other bone block procedures attempted to replace the injured anterior labrum and glenoid (10).

These procedures and their modifications achieved reasonable success rates in decreasing recurrent instability. Long-term follow-up studies continued to reveal low recurrence rates, but techniques that used metal staples or screws revealed high rates of hardware-related problems. Zuckerman and Matsen (188) retrospectively reviewed 37 patients who had previously been treated with a modified Bristow procedure, a staple capsulorrhaphy, or a modified Magnuson-Stack procedure. The hardware migrated or loosened in 24 shoulders and broke in three patients. Thirty-four patients required a second operation to remove the hardware. At reoperation, 41% demonstrated significant injury to the articular surface. Other studies have reported similar rates of hardware-related complications (69,185). Further, because of failure to correct the underlying anatomic problem, many patients had significant loss of external rotation or frank internal rotation contractures and subsequent glenohumeral arthritis (61).

In an attempt to avoid the use of hardware and correct the presumed anatomic abnormality, Rowe and colleagues popularized the Bankart procedure for anterior unidirectional instability (130,131,133,134).

- This technique uses a standard deltopectoral approach. Classically, the subscapularis tendon is incised vertically at its lateral insertion and sharply dissected medially from the anterior capsule (Fig. 80.61A). Several alternatives for subscapularis dissection have been developed that purportedly gave equal exposure of the anterior capsule (Fig. 80.61D, Fig. 80.61G) (77,58).

![Figure 80.61](https://example.com/image1)

**Figure 80.61.** Bankart procedure for anterior unidirectional instability. A: Perform a standard lateral subscapularis dissection 1 cm from its insertion onto the lesser tuberosity. B: An L-shaped dissection avoids the anterior circumflex humeral vessels but prevents complete access to the inferior capsule. C: Alternatively, the subscapularis muscle can be horizontally split, which avoids the need for later repair of the tendon. (From Zarins B. Bankart Repair for Anterior Shoulder Instability. Tech Orthop 1989;3:23, with permission.)

- Make a vertical capsulotomy approximately 0.5 cm lateral to the glenoid rim with the arm in complete external rotation (Fig. 80.62).

![Figure 80.62](https://example.com/image2)

**Figure 80.62.** Bankart procedure for anterior unidirectional instability. A medially based capsulotomy can be converted to a T-shaped capsulotomy that allows improved mobilization of the inferior axillary pouch in patients with increased anteroinferior instability. (From Zarins B. Bankart Repair for Anterior Shoulder Instability. Tech Orthop 1989;3:23, with permission.)

- With complete muscle relaxation, insert a humeral head retractor and inspect the glenoid for evidence of a Bankart lesion. If a Bankart lesion is present, repair the lateral capsular flap to the glenoid neck.
- Prepare this area with a curet to expose bleeding bone, and drill three holes; one at the 2-o’clock, one at the 4-o’clock, and one at the 6-o’clock positions for right shoulders (10-, 8-, and 6-o’clock positions for left shoulders) as demonstrated in Figure 80.63.

![Figure 80.63](https://example.com/image3)

**Figure 80.63.** Bankart procedure for anterior unidirectional instability. Make drill holes along the glenoid rim at the 1-, 3-, and 5-o’clock positions for right shoulders. (From Zarins B. Bankart Repair for Anterior Shoulder Instability. Tech Orthop 1989;3:23, with permission.)

- Pass sutures through the holes and the lateral capsular flap with a Mayo needle (Fig. 80.64A). Tie the flap down to the glenoid rim, and pass these same sutures through the small medial capsular flap, reinforcing the repair (Fig. 80.65).

![Figure 80.64](https://example.com/image4)

**Figure 80.64.** Bankart procedure for anterior unidirectional instability. A: The repair is performed with a standard lateral deltopectoral approach. B: An L-shaped dissection allows complete exposure of the inferior capsule. C: With the arm in neutral rotation, make a vertical capsulotomy at the 10-o’clock position. D: The capsule is incised vertically from the anterior capsule to the lesser tuberosity. E: The subscapularis tendon is incised vertically midway between the lesser tuberosity and the tendon insertion. (From Zarins B. Bankart Repair for Anterior Shoulder Instability. Tech Orthop 1989;3:23, with permission.)

**Figure 80.65.** Bankart procedure for anterior unidirectional instability. A medially based capsulotomy can be converted to a T-shaped capsulotomy that allows improved mobilization of the inferior axillary pouch in patients with increased anteroinferior instability. (From Zarins B. Bankart Repair for Anterior Shoulder Instability. Tech Orthop 1989;3:23, with permission.)
Figure 80.64. Bankart procedure for anterior unidirectional instability. **A:** Pass the suture through drill holes in the glenoid rim. **B:** Alternatively, if there is no significant Bankart lesion, the suture can be placed directly through the anterior labrum. (From Zarins B. Bankart Repair for Anterior Shoulder Instability. Tech Orthop 1989;3:23, with permission.)

If no Bankart lesion is found on inspection, merely place sutures through the labrum rather than drill holes (Fig. 80.64B).

With the production of multiple suture anchors, many surgeons have modified the procedure, using these implants along the glenoid rim (87). Despite reports of good success with these devices, there remains a risk of technical failure and resultant instability or articular cartilage damage.

Rowe et al. (131,134) reported good-to-excellent results in 96.5% of patients, with a 3.5% recurrence rate, using this procedure. A loss of terminal external rotation, however, was noted in many patients. Further, only 33% of throwing athletes with involvement of the dominant arm were able to return to their original level of competition. Rosenberg et al. (128) demonstrated a statistical relationship between late degenerative changes and restriction of external rotation in 90° of arm abduction. These reports led others to modify the operative techniques to address these problems. In addition, the increased association between repeated subluxations or dislocations and subsequent capsuloligamentous injury has shifted attention toward correction of the associated capsular laxity.

The T-plasty modification of the Bankart procedure was developed to treat underlying anteroinferior capsular laxity with an associated Bankart lesion (3).

- If a Bankart lesion is visualized, prepare the glenoid neck as previously described. If there is no lesion, pass sutures through the labrum rather than through drill holes.
- Position the arm in 40° of external rotation and 45° of abduction. Then pull the inferior flap superiorly and medially to the upper rim to allow 40° external rotation (Fig. 80.65), reduce the inferior redundancy, and simultaneously correct for a Bankart lesion, if present. Pull the superior flap inferiorly and medially to reinforce the inferior flap (Fig. 80.66).

Altchek et al. (3) reported on their experience with this procedure involving 42 shoulders in 40 athletes. Postoperatively, 20 shoulders had external rotation in adduction that was symmetric to the opposite side. The remaining22 shoulders, however, demonstrated a loss of 5° to 25° external rotation (average, 10°). Despite 95% excellent results with this procedure, throwing athletes in this study continued to report a decrease in maximum ball speed on throwing.

Jobe et al. (78) performed a similar operation but used a horizontal split in the subscapularis muscle to expose the anterior capsule. This method avoids the risk of postoperative subscapularis tendon disruption (69). Intraoperatively, they made sure no tension was present along the suture line until 90° of abduction and 45° of abduction.
external rotation was reached. Patients were then splinted in 90° of abduction, 45° of external rotation, and 30° of forward flexion. With this technique, they reported excellent results in 68% of a group of overhead athletes. Despite these efforts, six patients had a loss of 10° to 20° external rotation. An assessment of the 12 skilled pitchers in this study revealed that 50% returned to their former level of competition for at least one season.

As becomes apparent from these studies, it is difficult to obtain full terminal rotation postoperatively with this repair technique; further, full external rotation is necessary for high-level pitchers to obtain peak throwing velocity. In Neer and Foster’s (107) classic article on MDI, the inferior capsular shift was introduced. Like the modified Bankart procedures described above, this technique involved a T-shaped capsulotomy, but the vertical cut was made laterally along the humeral neck and a horizontal cut was made between the middle glenohumeral ligament (MGHL) and the IGHL. If a rotator interval defect was noted, it was repaired and then the same horizontal cut created.

This operation was designed for patients with involuntary inferior and multidirectional instability. If a patient had an associated Bankart lesion, however, it was repaired with the use of an inside-out suture technique at the glenoid rim. A shallow trough was made laterally along the humeral neck. Neer and Foster recommended holding the arm in 10° extension while suturing the inferior flap to the stump of the subscapularis tendon and to the remaining cuff of capsule along the humeral neck. The superior flap containing the MGHL was then sutured over the inferior flap to reinforce the repair. The tension on the inferior flap was selected to reduce the inferior and posterior capsular laxity. The lateral capsulotomy, as opposed to the medial approach, has a greater ability to reduce capsular volume because the capsular circumference is largest laterally.

Bigliani et al. (10) reported on a series of inferior capsular shift procedures performed in 68 shoulders in 63 athletic individuals. On the basis of Neer and Foster’s experience and the concept that anterior instability in the athlete represents a spectrum of pathology, they performed an inferior capsular shift in all cases. The inferior capsule was mobilized and shifted on the basis of the degree of inferior laxity demonstrated by EUA in each individual. Initially, the shoulders were repaired with the arm in 20° of abduction and 10° of external rotation. However, as it was noticed that only 50% of the overhead athletes involved in throwing had excellent results, abduction and external rotation were increased by 10° at the time of repair. Despite modifications in technique and postoperative mobilization, only 5 of 10 overhead athletes returned to their same level of competitiveness. Only two of six varsity or professional overhead athletes were able to return to the same level of sporting activity.

**Authors’ Preferred Method** We prefer a selective capsular shift. This technique is based on the clinical observation that a spectrum of labral and capsuloligamentous pathology exists, as well as on experimental observations concerning the role of the glenohumeral ligaments (171).

As alluded to previously, patients with traumatic instability may have a Bankart lesion, while others may have capsular injury without labral pathology. It is generally believed that some capsuloligamentous damage is created with each episode of instability. As a result, it becomes difficult to categorize patients purely on the basis of history or physical examination. An operative repair should be able to address all intraarticular pathology adequately.

In addition, cadaver studies demonstrate that the superior glenohumeral ligament and the MGHL function as a static barrier to anteroinferior humeral head translation with the arm in abduction and external rotation (37,169). Similar studies demonstrate that the IGHL serves as a static restraint to translation with progressive increases in abduction and external rotation (113,114 and 115). As a result, in the technique that follows, each capsular flap is sutured with the arm in the position that maintains greatest tension on ligamentous structures being repaired, contributing, it is hoped, to overall postoperative motion.

Examination under anesthesia is performed as described previously, and the degree of capsular laxity is used to determine the amount the inferior capsule that should be mobilized.

- Place the patient in a semisitting position resting on a long bean bag. Contour the bag along the medial scapular border, allowing the injured shoulder and arm to hang over the edge of the table. First, mold and solidify the band, and then pull the entire construct over the edge of the table. A McConnell Shoulder Holder (McConnell, Inc., Greenville, TX) allows proper positioning of the arm. Use a standard deltopectoral approach, with the incision maintained low in the axillary fold for better cosmesis. Place a self-retaining retractor into the interval. Make a small transverse incision, if needed, in the conjointed tendon just distal to the coracoid tip to increase medial exposure. Maintain manual retraction along the conjointed tendon to avoid a neuropraxic injury to the musculocutaneous nerve. Resect the coracocapitellar ligament to better expose the superior capsule and evaluate the rotator interval.

- Isolate the anterior circumflex humeral vessels, and suture-ligate them at the inferior aspect of the subscapularis muscle. Use needle-tip electrocautery to dissect the subscapularis muscle from lateral to medial off the anterior capsule. Palpate the axillary nerve; then visualize and isolate it with a vessel loop to avoid injuring it during surgery.

- If no significant rotator interval lesion is noted, create a T-shaped capsulotomy with the horizontal cut between the MGHL and the IGHL, ending at the equator of the glenoid. Make the vertical component of the capsulotomy just medial to the lateral insertion of the subscapularis muscle. Use needle-tip electrocautery to dissect the subscapularis muscle from lateral to medial off the anterior capsule in the coronal plane. Palpate the axillary nerve; then visualize and isolate it with a vessel loop to avoid injuring it during surgery.

If a Bankart lesion exists, further mobilize it from the scapular neck, and place a three-prong retractor medially along the scapular neck for exposure. Then decorticate the capsule was mobilized and shifted on the basis of the degree of inferior laxity demonstrated by EUA in each individual. Initially, the shoulders were repaired with the arm in 20° of abduction and 10° of external rotation. However, as it was noticed that only 50% of the overhead athletes involved in throwing had excellent results, abduction and external rotation were increased by 10° at the time of repair. Despite modifications in technique and postoperative mobilization, only 5 of 10 overhead athletes returned to their same level of competitiveness. Only two of six varsity or professional overhead athletes were able to return to the same level of sporting activity.

- Place the patient in a semisitting position resting on a long bean bag. Contour the bag along the medial scapular border, allowing the injured shoulder and arm to hang over the edge of the table. First, mold and solidify the band, and then pull the entire construct over the edge of the table. A McConnell Shoulder Holder (McConnell, Inc., Greenville, TX) allows proper positioning of the arm. Use a standard deltopectoral approach, with the incision maintained low in the axillary fold for better cosmesis. Place a self-retaining retractor into the interval. Make a small transverse incision, if needed, in the conjointed tendon just distal to the coracoid tip to increase medial exposure. Maintain manual retraction along the conjointed tendon to avoid a neuropraxic injury to the musculocutaneous nerve. Resect the coracocapitellar ligament to better expose the superior capsule and evaluate the rotator interval.

- Isolate the anterior circumflex humeral vessels, and suture-ligate them at the inferior aspect of the subscapularis muscle. Use needle-tip electrocautery to dissect the subscapularis muscle from lateral to medial off the anterior capsule. Palpate the axillary nerve; then visualize and isolate it with a vessel loop to avoid injuring it during surgery.

- If no significant rotator interval lesion is noted, create a T-shaped capsulotomy with the horizontal cut between the MGHL and the IGHL, ending at the equator of the glenoid. Make the vertical component of the capsulotomy just medial to the lateral insertion of the capsule into the humeral neck. At this point, consider the degree of capsular laxity demonstrated during the EUA. The position of the vertical capsulotomy may range from 6 o’clock to 8 o’clock along the humeral neck, depending on the degree of inferior laxity. If there is significant inferior laxity, choose the latter position. Carry the vertical component up to the supraspinatus tendon superiorly. With maximal muscle relaxation, place a humeral head retractor into the joint, and visualize the anterior labral region.

If a Bankart lesion exists, further mobilize it from the scapular neck, and place a three-prong retractor medially along the scapular neck for exposure. Then decorticate the glenoid surface, using a small osteotome. Place suture anchors (Acufex Microsurgical, Inc., Mansfield, MA) loaded with a #1 nonabsorbable suture into the 2-, 4-, and 6-o’clock positions for right shoulders or corresponding positions for left shoulders. Then place sutures through the capsule from the inside-out, and tie them over the capsule in a horizontal mattress fashion to repair the Bankart lesion (Fig. 80.68). Take care to repair the capsule without any shortening in a medial direction. No shifting of the capsule is performed at this point, as an anatomic repair of the Bankart lesion is the goal.

**Figure 80.68.** Open selective capsular shift. **A:** After a lateral capsulotomy, mobilize the capsule laterally from its scarred position along the glenoid rim. Place a suture anchor along the rim, and pull each limb of the suture through the capsule. **B:** Typically, three suture anchors are placed and tied in horizontal fashion. An additional horizontal capsulotomy creates superior and inferior flaps. (From Warner JJP, Johnson D, Miller MD, Caborn DN. Technique for Selecting Capsular Tightness in Repair of Anteroinferior Shoulder Instability. J Shoulder Elbow Surg 1995;3:52, with permission.)

- Remove the humeral head retractor, and place the shoulder into 60° to 80° of abduction, 45° to 60° of external rotation, and 10° of forward flexion. Pull the inferior capsular flap superiorly and laterally, and suture it to the cuff of capsular tissue at the humeral neck (Fig. 80.69A). Adjust abduction and external rotation on the basis of the individual’s needs. Thus, if the operation involves the dominant arm of a throwing athlete, position the arm in 80° of abduction and 60° of external rotation. Use lower degrees if treatment involves a nondominant arm or an athlete involved in a sport with limited overhead activity.
In 1993, Tibone and Bradley reported on their experience using a posterior staple capsulorrhaphy technique. Twenty athletes were treated for recurrent posterior subluxation, with eight of them also suffering from concomitant anterior instability. In this series, six patients suffered from recurrent posterior instability, while an additional three underwent surgery for anterior instability. However, 70% of the athletes in both groups participated in sports at a diminished level.

Following the repair of the inferior flap, reposition the arm in 0° of adduction and 45° of external rotation. The superior capsular flap is then sutured inferiorly and laterally over the other flap (Fig. 80.69). Place sutures, which were previously placed through the inferior flap, through the superior flap to create a pants-over-vest closure.

Incorporate significant rotator interval defects, which are associated with increased inferior laxity in adduction, into the capsulotomy. This method is in contrast to repairing the defect as Neer and Foster recommend. The rotator interval becomes part of the horizontal cut to create an upside-down L-shaped capsulotomy (Fig. 80.70A, Fig. 80.70B). Suture the inferior capsular flap as previously described, but apply tension to the remaining superior capsule by repairing the horizontal portion of the inferior flap over the superior flap with an arm in 0° of abduction and 45° of external rotation (Fig. 80.70C, Fig. 80.70D).

On completion of the repair, 90° of abduction should be possible in the scapular plane. Further, in this position, 60° of external rotation should be possible before tension is noted along the suture lines. With the arm in 0° of abduction, external rotation to 45° should be possible with minimal tension along the repair. Typically, an intraoperative drawer test is performed, and with the arm in 45° of abduction and neutral rotation, anterior and posterior drawer tests should not be greater than 1+. The shoulder should further stabilize with increased abduction and external rotation, with the drawer tests decreasing to zero. The inferior drawer test should be 0–1+ with the arm at the side. If so, the subscapularis tendon is repaired anatomically.

Postoperatively, immobilize the arm in a sling and swathe for 3–4 weeks, allowing the patient to perform limited abduction for axillary care and dressing. During this period, allow the patient to flex and extend the elbow. Then remove the sling and institute unlimited active-assisted range-of-motion exercises, as well as isometric strengthening for external rotation, flexion, extension, and abduction of the arm. Caution the patient to avoid internal rotation for 6 weeks to prevent stress on the subscapularis repair.

At 6 weeks, allow isotonic strengthening exercises using elastic bands, and at 4 months allow the patient to swim, throw a ball, or hit gentle ground strokes in tennis. At 6 months, release the patient to more forceful throwing or swinging. Do not allow the patient to return to contact sports until 8 months after the operative procedure.

Open Posterior Shoulder Stabilization Procedures

The incidence of true posterior dislocations is rare. Yet there is increasing evidence that a higher prevalence of posterior subluxation exists, especially in overhead athletes, than previously recognized. Operative procedures that have treated posterior instability have been less successful than anterior procedures at preventing recurrent instability.

Nonoperative Treatment Because of the lower success rates with posterior procedures, it is important in primary and revision cases to attempt an adequate course of nonoperative management. Focus rehabilitation on strengthening the dynamic muscle stabilizers to correct for the deficient posterior static stabilizers. Specifically, exercises should focus on strengthening the rotator cuff and deltoid and scapular muscles. Further, the patient and the therapist should be educated to avoid forward flexion, abduction, and internal rotation, as these positions place increased stress on the posterior structures. If this process fails to alleviate symptoms or episodes of instability, it is important to focus on patient goals, as the outcome of surgical treatment may be unsatisfactory to the patient.

Operative Techniques Initial attempts at posterior stabilization procedures used either the Nicola procedure or the posterior Bankart procedure. These initial reports involved limited numbers of patients with mixed results. Boyd and Skik used a posterior capsulorrhaphy and posterior transfer of the long head of the biceps brachii in nine shoulders and reported no recurrences. Mowery et al. reported on the use of a posterior bone block in five patients with recurrent posterior dislocations. Four of the five cases were rated as excellent at a minimum 2.5-year follow-up. However, closer evaluation revealed that one patient underwent screw removal, and one of the bone grafts was deemed osteoporotic at 3 years. Further, in the fifth case that was rated as good, the patient required a manipulation under anesthesia for limited motion and subsequently suffered from anterior instability.

These initial posterior procedures were performed on individuals with a history of dislocation. As noted by Hawkins et al., the uncommon nature of posterior instability and confusion in the literature in differentiating subluxations from dislocations led to a poor understanding of this entity. In the same article, they retrospectively reviewed 50 shoulders in 35 patients treated for recurrent posterior instability. Only 11 patients had had a primary traumatic event before the onset of instability. Forty-one of the affected shoulders demonstrated voluntary, positional instability that affected activities of daily living. Thirteen of 26 shoulders that underwent surgical reconstruction developed recurrent instability. The authors also noted that the posterior glenoid osteotomy was associated with osteoarthritis.

In 1989, Fronke et al. presented a series of 24 patients with posterior subluxation who were divided into two groups. Members of the first group, who had less severe symptoms, were treated with physical therapy and had a 63% success rate. Group II consisted of individuals who either failed physical therapy or had more severe symptoms. They were treated with a posterior capsular release with or without a posterior bone block. In this group, 91% suffered no additional episodes of instability. However, 70% of the athletes in both groups participated in sports at a diminished level.

Tibone and Ting reported on their experience using a posterior staple capsulorrhaphy technique. Twenty athletes were treated for recurrent posterior subluxation, with eight of them also suffering from concomitant anterior instability. In this series, six patients suffered from recurrent posterior instability, while an additional three patients had moderate to severe pain. Significant complications that were a direct result of the procedure developed in five patients. They concluded that this technique was not an acceptable treatment option for posterior instability.

In 1993, Tibone and Bradley reported on their experience using a posterior suture capsulorrhaphy technique that avoided the complications associated with staples or bone blocks. This technique, which was very similar to that described by Fronke et al., used a posterior saber incision starting at the acromion and terminating in the posterior axillary fold. Split the deltoideus muscle in line with its fibers approximately 2–3 cm medial to the posterosuperior corner of the acromion for 5–6 cm, with care to avoid injury to the axillary nerve, which enters the muscle distal to the teres minor muscle.
[Image 102x270 to 302x411]

- Develop the interval between the infraspinatus and teres minor muscles, and expose the underlying capsule. Make a T-shaped capsulotomy with the horizontal component at the glenoid rim.
- Transfer the inferior flap superiorty and medially. Secure it to the glenoid rim with #1 nonabsorbable suture placed through the labrum, if it is intact.
- If there is significant labral pathology, expose the glenoid rim, and prepare it as previously described for anterior repairs. Suture the capsular flap through bone holes, or secure it with suture anchors. Once again, the superior flap is sutured over the inferior flap to reinforce the repair. Position the arm in neutral rotation during the repair.

In these operations, there was no need to augment the repair with infraspinatus advancement or bone blocks. Researchers reported a 40% failure rate in 40 athletes who were followed adequately, attributing the failures to ligamentous laxity or unrecognized MDI. Importantly, they also noted worsening results as the athletes' competitive level increased and concluded that high-level athletes should be informed preoperatively of a possible poor outcome.

In 1994, Tibone and coworkers described a modification of this technique (139). A cadaveric and clinical investigation was undertaken to study an infraspinatus muscle-splitting approach to the posterior capsule. Dissection of 20 cadavers revealed that the suprascapular nerve entered the infraspinous fossa at the spinoglenoid notch as a single trunk, 22 mm medial to the glenoid rim. The infraspinatus muscle was bipennate in all specimens, with the tendinous interval an average of 14 mm inferior to the scapular spine. Limiting dissection in this interval to 1.5 cm medial to the posterior glenoid rim prevented damage to any suprascapular nerve branches. The researchers performed this approach in four patients and reported excellent exposure of the posterior capsule, labrum, and glenoid, thus avoiding tendon detachment. Electrodiagnostic testing revealed no significant denervation in these patients.

Neer and Foster (157) introduced a posterior capsular shift procedure in their classic article on the treatment of MDI. This technique has many features that are similar to their previously described anterior capsular shift.

- Make a 10 cm incision either horizontally at the level of the scapular spine or vertically just medial to the posterolateral corner of the acromion. The latter incision creates a more cosmetic postoperative scar.
- Detach the deltoid from the posterolateral aspect of the acromion and from the lateral 9.0 cm of the scapular spine.
- Split the deltoid muscle for approximately 3.0 cm inferiorly, exposing the infraspinatus muscle and tendon. This muscle–tendon unit is split obliquely, creating a superficial tendinous flap later used to reinforce the capsule. Mobilize the remaining infraspinatus muscle medially to expose the underlying capsule.
- Make a T-shaped capsulotomy with the horizontal component created laterally along the humeral neck. The authors noted that the arm should be progressively internally rotated during mobilization of the inferior capsular flap to protect the axillary nerve.
- Then place a humeral head retractor into the joint and visualize the labrum; if there is labral pathology extending beyond the inferior glenoid rim into the anterior aspect of the joint, a separate anterior incision is recommended to address the Bankart lesion. Posterior labral pathology is incorporated into the capsular shift as previously described for the anterior procedure. Once again, this is performed before advancement of the flaps.
- Position the arm in slight extension and external rotation during capsular reattachment. Then pull the superior flap inferiorly and laterally, and suture it to a shallow bony trough created at the humeral neck. Next, pull the inferior flap superiorly and laterally, and repair it over the superior flap. The superficial portion of the infraspinatus tendon is used to augment the posterior capsular repair. The deep portion of the infraspinatus muscle is then repaired to its origin to prevent postoperative weakness. Carefully reattach the deltoid muscle.

Postoperatively, keep patients in a plastic splint that extends from the wrist to the mid-arm level and around the waist. Keep the arm in neutral flexion and extension and 10° of external rotation for 6 weeks. Begin isometric deltoid and rotator cuff exercises at 8 weeks, and add progressive resistive exercises at 12 weeks. Using this technique in 25 shoulders, Bigliani et al. (11) reported good-to-excellent results in 89%. This assessment was based on stability, pain, range of motion, and activity level.

**Author’s Preferred Method** After adequate general anesthesia has been obtained, place the patient into the lateral decubitus position with the injured side up. Place an axillary roll, and pad all potential pressure points on the downside. Inflate the bean bag, and contour it anteriorly and posteriorly. Prepare and drape the injured arm and hemithorax in sterile fashion. Apply a McConnell Shoulder Holder to the table opposite the surgeon, and use it to maintain appropriate arm position during the operation.

- Create a vertical incision in line with the posterior axillary fold, and carry it over the posterior acromial edge. Employ sharp dissection through the subcutaneous tissue down to the deltoid fascia. Raise subcutaneous flaps medially and laterally.
- Detach the deltoid from the posterolateral aspect of the acromion, leaving a cuff of tissue down to the deltoid fascia. (From Rowe CR, Yee LB. A Posterior Approach to the Shoulder. J Bone Joint Surg [Am] 1944;26:580, with permission.)

**Figure 80.71.** Open posterior shoulder stabilization procedure. Make a standard split in the posterior deltoid muscle in line with the muscular fibers at the level of the glenohumeral joint. In muscular patients, decreased visualization may require perosteal elevation of the deltoid muscle from the scapular spine. (From Rowe CR, Yee LB. A Posterior Approach to the Shoulder. J Bone Joint Surg [Am] 1944;26:580, with permission.)

- Insert a self-retaining shoulder retractor, and adequately mobilize the subdeltoid plane to expose the underlying infraspinatus fascia (Fig. 80.72). Then externally rotate the arm, and split the infraspinatus at the equator of the glenoid in line with its fibers. Carefully, develop the plane between this muscle and the underlying capsule (Fig. 80.73). Take care with this step, as there are frequently adhesions, as well as a thin redundant capsule. If further visualization of the capsule along the humeral neck is required, a portion of the infraspinatus tendon insertion may have to be released. Maintain a cuff of tissue in this case to permit an anatomic repair later in the procedure.

**Figure 80.72.** Open posterior shoulder stabilization procedure. Develop the interval between the two heads of the infraspinatus muscle, which exposes the underlying capsule. Alternatively, the glenohumeral joint can be palpated, and the infraspinatus muscle can be split at this level. (From Rowe CR, Yee LB. A Posterior Approach to the Shoulder. J Bone Joint Surg [Am] 1944;26:580, with permission.)
Place long, thin manual retractors along the infraspinatus muscle to aid in visualization at this point in the procedure. Carefully, create a vertical capsulotomy just off the glenoid margin to dissect inferiorly and allow adequate correction of the capsular laxity later in the procedure. Make a horizontal cut at the equator of the glenoid to create a T-type capsulotomy (Fig. 80.74). If there has been concomitant avulsion of the capsule from the humeral insertion site, incorporate it into the procedure to create an H-type capsulotomy.

Place a spiked retractor medially along the scapula to allow adequate visualization of the posterior labrum. If a posterior Bankart lesion exists, repair it at this point. Prepare the glenoid rim with a motorized burr and rasp to create a bleeding surface. Place double-loaded (#1 nonabsorbable) suture anchors at the 2- and 4-o’clock positions for left shoulders and at the 10- and 8-o’clock positions for right shoulders. Then repair the capsulolabral tissue with these sutures placed in standard horizontal mattress fashion. Retain the suture and attached needles for lateral closure of the capsulotomy. If no Bankart lesion exists, maintain this area intact, and place sutures directly through the labral tissue during later repair of the capsule.

Then mobilize the inferior capsular flap in a superior and medial direction for a T-type capsulotomy (Fig. 80.75) to reestablish tension in the IGHL. Use the previously placed nonabsorbable sutures to secure the capsule to the glenoid surface. Pull the superior flap inferiorly and medially to supplement the thin capsular tissue. Suture this flap to the glenoid surface, using the previously placed nonabsorbable sutures, as well as to the underlying capsule (Fig. 80.76).

Place the patient into a prefabricated gunslinger brace, with immobilization for 6 weeks. Then initiate active-assisted and active range-of-motion exercise. Allow light muscle-strengthening exercises (Theraband, Hygenic Corp., Malaysia) 3 months postoperatively but no heavy contact sports or significant labor until 6 months after the operative procedure.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

While the elbow is a relatively stable hinge joint in flexion and extension, the ligament restraints and tendon insertions are subject to significant stress during the course of athletic activities. Whereas daily activities depend on the upper extremity for lifting and positioning, athletic activities require specific and precise motions for propulsive activity. Interaction between static restraints and the dynamic muscle unit allows for the versatile motion and power required in competitive performance. Most injuries to the elbow in the athletic population occur with overuse and repetitive activities, though acute traumatic injuries may occur (4,9,12,31,56). Typically, chronic repetitive stress injuries to the elbow occur during the valgus stresses imparted to the elbow in the course of athletic endeavors. The valgus forces seen during athletics produce tension overload to the medial soft-tissue restraints, compression injuries to the lateral radiocapitellar joint, and extension overload injuries within the posterior compartment (1,2,51,61). While less frequent in incidence, soft-tissue instability of the lateral capsule (lateral and posterior lateral instability) may occur (49).

Epicondylitis, whether lateral or medial, is a frequent source of elbow pain in both the athletic and the nonathletic populations (23,24,30,54,55). Although the term tennis elbow has become accepted as a descriptive and diagnostic term, it is something of a misnomer as it occurs more commonly in the nonathletic population.

Isolated disruption of the distal biceps tendon from the radial tuberosity, and avulsion of the biceps from the olecranon are relatively rare (3,6,7,11,16,40,45). Failure to diagnose and treat these two injuries may lead to significant disability, not only during athletic activity but with activities of daily living.

To best treat the various entities, a thorough understanding of the anatomy, pathophysiology, and clinical evaluation are necessary for an accurate diagnosis. While rehabilitation is usually successful in treating elbow tendon and ligament disorders, surgical alternatives now exist for those cases not responsive to an appropriate nonoperative treatment program.

ANATOMY

The ulnar collateral ligament complex consists of an anterior, a posterior, and a transverse band (Fig. 81.1) (34,41,58,61). The anterior band, which is composed of two distinct bundles, is the most important restraint to valgus stress across the elbow. The ulnar collateral ligament is uniquely configured to provide stability throughout the full range of motion (ROM) of the elbow. The weaker posterior band, which is fan shaped, provides stability primarily beyond 90° of elbow flexion. The transverse ligament does not cross the ulnohumeral joint but exists as a thickening of the inferior joint capsule. The lateral collateral ligament complex is less consistent and not as well understood as the ulnar collateral ligament (Fig. 81.2). The annular part of the lateral collateral ligament originates from the lateral epicondyle and blends with the fibers of the annular ligament. The ulnar band of the lateral collateral ligament originates from the anteroinferior portion of the lateral epicondyle, crosses the radiocapitellar joint, and inserts on the tubercle of the supinator crest of the ulna.
With repeated valgus stress over time, the ligament typically continues to attenuate, yielding clinically significant instability. With time, recurring and progressive medial dysfunction, allowing further stresses to be transmitted to the ulnar collateral ligament. When these forces are applied at a rate that exceeds tissue repair, progressive microscopic tearing and attenuation occurs within the ligament. Initially, this produces swelling and inflammation associated with pain and tenderness about the medial aspect of the joint. Further stresses from throwing may attenuate the ligament or cause further degeneration of the ligament fibers.

Most commonly, elbow injuries in the athletic population are caused by chronic repetitive overuse stress. Overhead athletic activities generate significant valgus forces that are transmitted to the stabilizing soft tissues about the medial aspect of the joint. These stresses are transmitted primarily to the ulnar collateral ligament complex, the flexor carpi ulnaris, and, to a lesser extent, the flexor–pronator muscle group. Poor throwing mechanics and/or muscle fatigue may lead to muscular dysfunction, allowing further stresses to be transmitted to the ulnar collateral ligament. When these forces are applied at a rate that exceeds tissue repair, progressive microscopic tearing and attenuation occurs within the ligament. Initially, this produces swelling and inflammation associated with pain and tenderness about the medial aspect of the joint. Further stresses from throwing may attenuate the ligament or cause further degeneration of the ligament fibers.
tension overload creates strong compressive forces over the lateral and posterior aspects of the joint. This may produce transient synovitis and osteochondral injuries, including osteochondritis dissecans and frank osteochondral fracture. Lateral compression stresses typically injure the capitellum, although radial head injuries may occur.

During the deceleration and follow-through phases of the throwing motion, extension injuries may occur within the posterior compartment (5,38). Repeated stresses may lead to a triceps muscle strain, avulsion of the tip of the olecranon process, hypertrophic olecranon spur formation, and posterior impingement.

Instability patterns of the lateral collateral ligament complex are uncommon and usually result from an acute traumatic injury such as an elbow dislocation or a hyperextension injury (49,51,57-59). Lateral collateral ligament laxity rarely occurs after isolated varus stress to the elbow. A complete elbow dislocation is by far the most common cause for chronic lateral ligamentous insufficiency. It may also develop from elbow subluxations that may or may not be associated with fractures of the radial head. Isolated lateral collateral ligament laxity may occur during release of the common extensor tendon for lateral epicondyritis or radial head excision with injury of the lateral collateral ligament complex.

Lateral epicondyritis begins as a microscopic tear within the origin of the extensor carpi radialis brevis (24,30,54). With repetitive trauma, this process results in mucoid degeneration and reactive granulation within the tendinous origin of the extensor carpi radialis brevis. It has been shown that this reactive granulation tissue contains a large number of free nerve endings and may lead to pain production with tension or compression. Nirschl and Pettrone (53) have described the histology as "angiofibroblastic hyperplasia." The normal parallel orientation of the collagen fibers is disrupted by an invasion of fibroblastic and vascular granulation tissue. The large number of free nerve endings and may lead to pain production with tension or compression. Nirschl and Pettrone (30) have described the histology as "angiofibroblastic hyperplasia." The normal parallel orientation of the collagen fibers is disrupted by an invasion of fibroblastic and vascular granulation tissue. The overall intensity and duration of arm use will influence this tendinosis and degeneration. Lateral epicondyritis is directly related to activities that increase the tension and the stresses along the course of the wrist extensors and supinator muscles.

Athletic injuries that place a valgus force across the elbow may cause inflammation of the flexor–pronator muscle mass. The pronator teres and flexor carpi radialis are the most common sites of pathologic changes that include tissue overload with resultant microscopic tearing, tendinosis, and degeneration.

Distal biceps tendon ruptures typically occur in well-developed muscular men such as laborers and body builders (7,8,47). The majority of ruptures involve the dominant extremity and usually result from a single traumatic event with an intense biceps contraction overwhelmed by an unanticipated extension force. Most injuries occur when lifting, pulling, or straining with heavy objects. Chronic degeneration of the tendon of the radial tuberosity has been seen with both partial and complete ruptures and has been postulated that chronic inflammation of the bursa at the radial tuberosity may contribute to degeneration of the biceps tendon, making the tendon more susceptible to rupture.

The mechanism of injury of triceps tendon avulsion is typically a fall on an outstretched arm (3,6,21,26,67). This occurs as a result of deceleration stresses superimposed on a contracting triceps muscle with or without a concomitant blow to the posterior aspect of the elbow. Most commonly, rupture occurs as the result of an abrupt, forceful, eccentric contraction of the triceps.

CLINICAL EVALUATION

The typical differential diagnosis of medial elbow pain in the adult athlete is the following:

- Ulnar collateral ligament tendinitis and/or insufficiency
- Medial epicondyritis with a strain of the flexor–pronator muscle mass
- Ulnar neuritis

Typically, those activities that produce medial elbow pain with overhead activities and valgus stress will affect the ulnar collateral ligament. As the ulnar collateral ligament attenuates, there may be traction on the cubital tunnel producing secondary symptoms of ulnar neuritis. Primary ulnar neuritis in the overhead athlete is rare but can occur, especially if there is a bony spur in the cubital tunnel or a subluxating ulnar nerve that causes the nerve to become scarred and irritated over time (15). Patients with medial epicondyritis tend to exhibit pain primarily over the medial epicondylar origin rather than over the ulnar collateral ligament, which will tend to be extenuated with resisted palmar flexion of the wrist and fingers and typically not affected by valgus stress to the elbow. Patients with medial epicondyritis tend to have a history of pain associated with forearm and wrist activities such as pushing a heavy object, or with overuse of the flexor–pronator muscle mass in athletic activities such as golf. While symptomatic cervical radiculitis is not confused with lateral epicondyritis, the cervical spine must also be evaluated to rule out referred radicular pain that occurs isolated to the lateral epicondylar region.

ELBOW INSTABILITY

The clinical diagnosis of elbow instability primarily depends on the patient's history and physical findings. Radiographic evaluation may provide correlative information but is not the basis by which a diagnosis is made. Patients with elbow instability typically give a history of repetitive stress to the elbow, though on occasion a single event may be causative.

The athlete who presents with medial-sided laxity of the ulnar collateral ligament will describe an insidious but progressive onset of medial elbow pain. The pain typically occurs during an athletic endeavor such as throwing a baseball, serving a tennis ball, or throwing a volleyball. Pain tends to be most noticeable during the late cocking and acceleration phases of the overhead motion but may progress over time to include pain during the entire activity, and it may even progress to include pain with activities of daily living. Athletes who have had ulnar collateral ligament insufficiency for a period of time often present with symptoms of associated ulnar neuritis secondary to traction stresses placed on the ulnar nerve during the overhead activity (33). Rest from activity will typically relieve the symptoms.

On occasion there is an acute event that occurs during an athletic activity, when the athlete senses a pop or sudden sharp pain along the medial aspect of the elbow joint. This may be the result of a valgus stress applied to a previously asymptomatic attenuated ligament. Acute injuries are typically associated with traumatic events such as falling on the outstretched elbow and may rarely present as a postreduction complication following an elbow dislocation.

Pain that originates from ulnar collateral ligament insufficiency typically occurs along the course of the ulnar collateral ligament. An athlete may complain of fatigue over time and lack of normal strength associated with athletic activities. As the inflammation along the ulnar collateral ligament progresses, athletes may notice pain and tenderness beyond the ulnar collateral ligament, extending into the cubital tunnel and flexor–pronator muscle mass. When the inflammation has progressed to include not only the ulnar collateral ligament but also the flexor–pronator muscle mass and ulnar nerve, a very careful assessment is required to help differentiate between the primary source of the pathology and the secondary problems.

Physical examination for those with ulnar collateral ligament insufficiency typically reveals tenderness along the course of the ulnar collateral ligament, especially at the mid and distal portions rather than the proximal origin at the medial epicondyle. Typically, the examiner will not note tenderness at the medial epicondyline itself unless there has been an associated inflammation of the flexor–pronator muscle mass.

The cubital tunnel is typically without tenderness unless there has been repeated ulnar neuritis secondary to traction stresses. When the ulnar nerve has been inflamed repeatedly, there may be a positive Tinel sign, and in addition there may be other focal ulnar nerve findings such as intrinsic muscular atrophy and loss of sensation in the ulnar distribution of the hand (27). Testing for valgus instability is best performed with the patient seated and his hand and wrist securely held between the examiner's elbow and trunk. The examiner firmly grasps the patient's elbow and proximal forearm while simultaneously palpating the ulnar collateral ligament at the medial joint line. Varus and valgus stress can then be applied to determine the presence of an end point and the degree of laxity (Fig. 81,4). It is important during stress testing that the elbow be flexed beyond 25° to eliminate the stabilizing effect of the olecranon within the olecranon fossa. It is also critical to compare the involved elbow with the uninvolved elbow to differentiate between normal laxity and pathologic instability. Even asymptomatic overhead athletes tend to have increased medial laxity, and therefore the physical findings of laxity must be correlated with the areas of tenderness and the characteristic of pain that occurs with activities. When ulnar collateral ligament insufficiency has been present over time, there may also be findings consistent with lateral compression injuries, including swelling, tenderness, or even crepitation around the radiocapitellar joint. Chronic ulnar collateral ligament insufficiency may cause or contribute to valgus extension overload that affects the posterior compartment, with findings of tenderness, crepitation, and even loose bodies within the posterior compartment. Decreased ROM and synovitis may result from the chronic secondary effects of ulnar collateral ligament insufficiency.
Patients with lateral collateral ligament insufficiency have symptoms that vary from frank recurrent dislocations to minor mechanical symptoms from occult subluxations. Patients may complain of pain, tenderness, catching, snapping, or frank symptoms of instability. Patients who have recurrent lateral subluxation can be mistakenly diagnosed as having a recurrent dislocation of the radial head, which may lead to unsuccessful and improper treatment. The typical patient has had an initial traumatic injury, such as a sprain, dislocation, or fracture of the elbow, or she has had surgery involving the lateral aspect of the elbow. Following this, she will have symptoms of recurring subluxation that can include clicking, catching, snapping, or even locking.

Patients with varus instability may be noted to have laxity on varus stress. O’Driscoll et al. (67) described patients with posterolateral instability and described the lateral pivot-shift test (Fig. 81.5) to identify these patients. This test involves flexion of the elbow from an extended position and supination of the forearm while the valgus stress and axial load is applied. This maneuver subluxates or dislocates the radial head posteriorly with rotatory subluxation of the ulnohumeral joint. When the lateral pivot-shift test is positive, there is a palpable and visible reduction of the radioulnar joint together with the ulnohumeral joint when the elbow is flexed beyond 45°. The pivot-shift test may fail to cause apprehension in patients or may appear falsely negative in patients with severe instability when the elbow does not reduce with flexion. Be aware that the varus stress test may be normal in the presence of a positive pivot-shift maneuver and clinically significant lateral insufficiency.

**Figure 81.5.** Pivot-shift test.

**ELBOW EPICONDYLITIS**

The pain of lateral epicondylitis is insidious and progressive, and it occurs with grasping and lifting. While the term tennis elbow is typically used for this syndrome, most patients develop the symptoms from activities such as lifting at work, carrying luggage and briefcases, and typing (39,52,55). Pain originates over the lateral epicondyle but may radiate into the proximal forearm overlying the proximal extensor musculature. As the condition progresses, even light daily activities such as shaking hands, picking up a bottle, or grasping for a carton of milk may cause symptoms. During tennis, the lateral epicondylar pain typically occurs at the point of ball contact during the ground strokes and is more often noted with backhand than forehand strokes. Differential diagnosis of lateral epicondylitis includes the supinator syndrome with entrapment of the posterior interosseous nerve. Typically, these patients have pain overlying the proximal supinator musculature exacerbated with activities that include pronation and supination of the forearm. Usually there will be absence of tenderness along the lateral epicondyle unless there is combined lateral epicondylitis and radial nerve entrapment. Differential diagnosis may be difficult because posterior interosseous nerve entrapment may coexist with lateral epicondylitis in about 5% of patients. A selected injection of lidocaine in the lateral epicondyle or the proximal supinator may help differentiate these two diagnoses. Other causes of lateral elbow pain include arthritis, osteochondral injuries to the capitellum, and lateral collateral ligament insufficiency.

Examination reveals tenderness overlying the extensor tendon origin at the lateral epicondyle. Resisted wrist and finger extension will reproduce the patient’s pain along the lateral epicondyle, and resisted long-finger extension often produces the most pain. ROM of the elbow is usually normal unless there are other conditions such as arthritis or bony elbow impingement. After repeated cortisone injections (19,20), there may be atrophy of the skin and subcutaneous tissue overlying the lateral epicondyle, causing a very prominent bony epicondyle.

Medial epicondylitis often presents as pain along the medial epicondyle, which is aggravated with resisted palmar flexion of the wrist and fingers, and pronation with the forearm. The onset of pain typically occurs in an insidious fashion, although there are cases that are traumatic in origin and present with acute onset of pain. The medial epicondyle pain is typically aggravated with activities that involve stress across the flexor–pronator muscle mass; it usually is not associated with valgus stress across the joint unless there is an associated inflammation of the ulnar collateral ligament. Pain along the cubital tunnel and ulnar nerve symptoms typically are absent unless there is an associated ulnar neuritis.

Examination will demonstrate tenderness overlying the origin of the flexor–pronator muscle mass at the medial epicondyle, and possibly radiation of tenderness into the forearm. The onset of pain typically occurs in an insidious fashion, although there are cases that are traumatic in origin and present with acute onset of pain. The medial epicondyle pain is typically aggravated with activities that involve stress across the flexor–pronator muscle mass; it usually is not associated with valgus stress across the joint unless there is an associated inflammation of the ulnar collateral ligament. Pain along the cubital tunnel and ulnar nerve symptoms typically are absent unless there is an associated ulnar neuritis.

**Figure 81.4.** Varus and valgus instability.

**A BICEPS AND TRICEPS RUPTURE**

Distal biceps rupture most often occurs with the onset of a sudden sharp tearing sensation or pop within the anterior antecubital fossa. Subsequently, antecubital swelling and ecchymosis may occur, with pain aggravated by any flexion and supination of the forearm. The intense pain will change to a persistent dull ache, and the biceps musculature will retract proximally, yielding an asymmetrical appearance compared to the opposite extremity. The patient will complain of weakness and fatigue of the arm, especially with those activities that require elbow supination (such as using a screwdriver) and repetitive elbow flexion and supination (such as hammering).

Physical examination of a distal biceps rupture can reveal deformity of the proximal biceps, but this deformity can be masked by antecubital swelling and ecchymosis. With palpation, there may be tenderness along the course of the distal biceps and a defect may be palpated. An intact lacertus fibrosus can be mistakenly interpreted as the biceps tendon, but comparison to the opposite extremity will reveal the differences between the injured arm and the normal intact biceps tendon. Elbow ROM is not affected by this condition unless there are unrelated entities such as osteoarthritis. While medial epicondylitis usually occurs as an isolated entity, associated ulnar neuritis may occur and, if it does, there will be tenderness along the cubital tunnel with a positive Tinel sign.

**BICEPS AND TRICEPS RUPTURE**

Distal biceps rupture most often occurs with the onset of a sudden sharp tearing sensation or pop within the anterior antecubital fossa. Subsequently, antecubital swelling and ecchymosis may occur, with pain aggravated by any flexion and supination of the forearm. The intense pain will change to a persistent dull ache, and the biceps musculature will retract proximally, yielding an asymmetrical appearance compared to the opposite extremity. The patient will complain of weakness and fatigue of the arm, especially with those activities that require elbow supination (such as using a screwdriver) and repetitive elbow flexion and supination (such as hammering).

Physical examination of a distal biceps rupture can reveal deformity of the proximal biceps, but this deformity can be masked by antecubital swelling and ecchymosis. With palpation, there may be tenderness along the course of the distal biceps and a defect may be palpated. An intact lacertus fibrosus can be mistakenly interpreted as the biceps tendon, but comparison to the opposite extremity will reveal the differences between the injured arm and the normal intact biceps tendon. Elbow ROM is not affected by this condition unless there are unrelated entities such as osteoarthritis. While medial epicondylitis usually occurs as an isolated entity, associated ulnar neuritis may occur and, if it does, there will be tenderness along the cubital tunnel with a positive Tinel sign.
Plain radiographs are useful to diagnose radiocapitellar joint arthrosis, posterior elbow osteophytes, or loose bodies in particular. Radiographs may identify ossification within the ulnar collateral ligament, which typically is a sign of chronic inflammation rather than of an acute injury to the ligament (Fig. 81.6). Stress radiographs may reveal excessive laxity and medial joint line opening, especially compared to the opposite elbow. In patients with ulnar collateral ligament instability, radiographic valgus stress testing may be used to document the degree of instability when the diagnosis is in question. MRI may be used as an adjunctive diagnostic tool, as it will clearly delineate pathology within the ulnar collateral ligament (Fig. 81.8) (43). Unfortunately, the magnetic resonance imaging (MRI) scan is not always capable of delineating the difference between degenerative tendinitis that is otherwise asymptomatic, and symptomatic tendinitis or a tear with associated laxity. An MRI scan revealing a normal ulnar collateral ligament (Fig. 81.7) can provide impetus to search for a different diagnosis. Arthrography is not useful because of frequent false negative findings in cases of chronic ulnar collateral ligament insufficiency with an intact capsule.

Figure 81.6. Ulnar collateral ligament calcifications.

Figure 81.7. MRI showing normal ulnar collateral ligament.

Figure 81.8. MRI showing a tear in an ulnar collateral ligament.

Radiographic evaluation for lateral collateral ligament instability is typically unrevealing except for associated and unrelated bony pathology. Varus stress to the elbow typically does not reveal insufficiency, even when present. The presence of asymmetrical joint opening under radiographic varus stress, when present, may help to confirm the findings of examination.

Radiographs of those with lateral epicondylitis typically are normal, though approximately 20% to 25% may show calcification within the soft tissues about the lateral epicondyle (17,44). The occurrence of this calcification has no prognostic implication. These and other radiographic modalities such as MRI do not appear to add further diagnostic information (Fig. 81.9).

Figure 81.9. MRI demonstrating lateral epicondylitis.

Plain elbow radiographs of those with medial epicondylitis typically are normal. Throwing athletes may have an associated ulnar traction spur and calcification within the ulnar collateral ligament.

Radiographs of a biceps tendon rupture may reveal irregularity of the biceps tuberosity, suggesting an underlying degenerative etiology. Elbow radiographs in those with a triceps avulsion may reveal a small avulsion fracture from the olecranon. It has been suggested that the "flake sign" will be present in two thirds of cases with a complete triceps rupture (48,64). When the physical examination is not revealing or is confusing due to significant swelling, an MRI scan may be valuable in differentiating between an incomplete and a complete tear of the triceps or biceps muscle tendon unit (Fig. 81.10). MRI is not necessary when complete rupture of
either the biceps or the triceps tendon is clinically obvious.

**Figure 81.10. MRI showing a torn distal biceps tendon.**

**INDICATIONS AND TREATMENT**

**ULNAR COLLATERAL LIGAMENT**

Rest from the causative etiology (overhead throwing activities), nonsteroidal anti-inflammatory drugs (NSAIDs), and other modalities (e.g., ice) are the main focus of the initial treatment. Steroid injections of the ulnar collateral ligament can decrease the biomechanical strength of the ligament as well as mask clinical symptoms allowing too early a return to activity. After swelling and pain have subsided, a flexibility and strengthening program is completed before return to throwing. While most athletes with ulnar collateral ligament tendinitis and insufficiency will respond to conservative treatment, failure to do so after 3 to 6 months of treatment necessitates surgical intervention (13,22). Avoidance of valgus stresses avoids aggravation and possible attenuation of the ligament. Bracing, while theoretically feasible, has not proved efficacious. Athletes involved in valgus stress activities such as throwing, tennis, and volleyball are the most likely to fail nonoperative treatment.

**POSTERIOR LATERAL INSTABILITY**

Although ulnar collateral insufficiency may be successfully treated nonoperatively, Morrey and O'Driscoll (53,57) have found that recurrent elbow instability due to lateral collateral ligament laxity does not improve with nonoperative treatment. As lateral collateral ligament insufficiency typically interferes with daily functional activities, early surgery is recommended in most cases. Less active patients who do not have significant instability may avoid surgery by modifying activities and using a hinge brace with an extension block.

**LATERAL AND MEDIAL EPICONDYLITIS**

Treatment of epicondylitis is typically nonoperative, with surgery reserved for the minority who do not respond to conservative treatment (14). Advise modification or avoidance of all athletic and daily activities that aggravate symptoms. Useful measures include cryotherapy, NSAIDs, and counterforce bracing to reduce tensile stress along the epicondyke (55). A counterforce brace may inhibit full musculature expansion and therefore decrease the tension developed by the inflamed tendon proximal to the brace (29,35).

If the patient does not improve with conservative measures, corticosteroid injection can be administered (42). Mix the steroid with a local anesthetic. Avoid direct injection into the tendon, and inject over the inflamed tendon. If the injection has been efficacious but symptoms recur, administer a maximum of two to three injections over a 3-month period. If the etiology results from athletics, evaluate the biomechanics and equipment used during the sport. For example, a tennis racquet should be assessed for proper grip size. Lighter racquets made of low vibration materials and strung less tightly may dampen the impact forces on the extensor origin. Upon improvement in symptoms, institute a rehabilitation program to regain strength and flexibility. As strength, endurance, and flexibility improve, prescribe progressive eccentric and concentric resisted exercises. Indications for surgery include failure of a well-managed conservative program over a period of 3 to 6 months and impairment of athletic or daily living activities.

**DISTAL BICEPS RUPTURE**

Surgical treatment remains the treatment of choice for an acute complete distal biceps rupture (8,18,46), although some recommend conservative treatment (18). Patients treated nonoperatively gain improvement in elbow flexion and supination over time, but they typically have significant loss of both elbow flexion and supination strength, as well as endurance (7,48). Isokinetic muscle testing has documented deficits in elbow flexion of 30% to 36% and supination deficits of 40% to 45% following conservative treatment (50).

In the case of delayed diagnosis, primary repair can be accomplished as late as 6 weeks following injury. Mobilization of the retracted tendon may be required. Late reconstruction has been used for those who have persistent symptoms, although it is not possible to realign the distal biceps tendon to the radial tuberosity. Options for late reconstruction include direct repair of the biceps tendon to the brachialis muscle, which helps to restore elbow flexion strength but will not change the supination strength deficit. Late reconstruction can also involve an interposition graft such as a fascial autograft (36).

Partial tears of the distal biceps tendon, while rare, do exist and are best diagnosed with an MRI scan. Provided that there is continuity of tendon to the radial tuberosity, partial tears may be treated conservatively. In the face of persistent symptoms, especially with resisted flexion and supination activities, the patient is at increased risk for eventual rupture of the tendon. Clinical judgment, with consideration of the severity of the patient's symptoms and functional status, dictates whether early surgical intervention or continued conservative treatment best suits the individual patient.

**DISTAL TRICEPS RUPTURE**

Surgical repair is the treatment of choice for complete triceps tendon ruptures. When there is complete rupture of the triceps tendon mechanism, significant disability occurs without surgical repair (6,28,63). Triceps function is also important for the elderly who require the use of ambulatory aids and transfers because of lower extremity impairment. In the presence of a partial tear, conservative treatment may be employed. An MRI scan may be helpful in evaluating the degree of a partial tear. Persistent symptoms, such as pain and weakness with attempted elbow extension, despite conservative treatment, are indications for surgical treatment.

**SURGICAL TECHNIQUES**

**ULNAR COLLATERAL LIGAMENT RECONSTRUCTION WITHOUT ULNAR NERVE TRANSPOSITION**

Prior to a 1992 review of the operative technique for ulnar collateral ligament reconstruction (23), the ulnar nerve was always transferred anteriorly in association with an ulnar collateral ligament reconstruction. It has been shown, however, that there is an increased complication rate with transposition of the ulnar nerve, and therefore I now transfer the nerve only when clinically indicated. When the patient does not have chronic ulnar nerve symptoms, leave the ulnar nerve within the cubital tunnel. This requires a change in the technique for transfixing the ulnar collateral ligament graft proximally at the medial humerus. When the patient has clinically significant ulnar neuritis, transfer the ulnar nerve anteriorly in a submuscular fashion in conjunction with the ulnar collateral ligament reconstruction.

- Make an incision just above the medial epicondyle extending proximally 3 cm and distally 5 cm (Fig. 81.11A). Carry the dissection down to the fascia overlying the flexor–pronator muscle mass and overlying the cubital tunnel.
Muscle mass origin at the medial epicondyle. Injury of this nerve will cause paresthesias or complete loss of sensation along the proximal medial forearm. In addition, there is the risk of developing an underlying neuroma, which could require further surgery. The cutaneous nerves tend to lie just above the flexor–pronator muscle fascia and to run in an oblique direction, from proximal lateral to distal medial, often parallel to the basilic vein.

Identify the cubital tunnel and, using palpation, visualize the course of the ulnar nerve along the posterior aspect of the distal intermuscular septum and through the ulnar collateral ligament. The ulnar nerve passes anterior to the flexor–pronator muscle mass. Bluntly dissect through the muscle down to the ulnar collateral ligament and surrounding capsule. Inspect the ulnar collateral ligament both by observation and palpation. There may be signs of obvious tissue degeneration, attenuation, or complete disruption of the ligament. Make a longitudinal incision in the ligament to inspect its substance. Changes may be revealed that were not apparent from the surface.

Inspect the joint and determine the degree of valgus opening. If the ligament is lax, elevate the ligament and capsule in an anterior and posterior direction in a subperiosteal fashion to gain exposure for subsequent placement of the ulnar collateral ligament graft into bony tunnels.

Harvest the palmaris longus tendon graft (Fig. 81.11B). Previous studies [22] have not demonstrated any clinical difference with respect to the graft, including ipsilateral arm, contralateral arm, or tendon graft from the leg, such as plantaris or strip of Achilles tendon. When the palmaris longus tendon graft is present, it is the graft of choice; it is typically harvested from the ipsilateral extremity unless it is considered to be significantly smaller than the palmaris longus tendon graft from the opposite extremity. To harvest the palmaris longus graft, create a 2 cm transverse skin incision within the distal flexor crease of the wrist. Protect the median nerve and palmar cutaneous branches as the tendon is isolated at its insertion into the palmar fascia. Make two additional transverse incisions overlying the palmaris longus tendon, the most proximal incision over the muscle–tendon junction and an additional incision half-way between the muscle–tendon junction and the wrist crease. Free the tendon from its origin into the palmar fascia and place a #0 nonabsorbable braided suture through the end of the free tendon graft. Retract the tendon through the middle incision and then proximally at the muscle tendon junction. Finally, place a #0 nonabsorbable braided suture through the proximal end of the tendon.

Create bone tunnels proximally and distally (Fig. 81.11C) with the tunnels having adequate size for the tendon graft. Typically, a 3.2 mm drill bit makes an adequate bony tunnel for passage of the graft. Place the converging drill holes at the proximal ulna orientated in a vertical direction and at the level of the coronoid tubercle just distal to the articular surface of the proximal ulna. Make the drill holes proximally at the medial epicondyle at the level of the anatomic origin of the anterior bundle of the ulnar collateral ligament. Begin the drill hole midway between the base and the tip of the medial epicondylar prominence. The holes are fashioned with a single entrance hole at the medial epicondyle, which then diverges into two separate anterior-superior and posterior-superior holes more proximally. Drill the posterior-superior hole to exit posterior to the first anterior-superior hole, but not in the cubital tunnel. Split the flexor–pronator muscle mass at a second location just proximal to the medial epicondyle in a longitudinal fashion to facilitate placement of the anterior-superior and posterior-superior drill holes.

Pass tendon graft through the respective proximal and distal bone tunnels (Fig. 81.11C). Pull the graft taut and move the joint through a ROM to assess isometricity and valgus stability. Excess length of the tendon graft can be routed back through a bone tunnel upon itself to provide more tissue to overlie the joint. Avoiding valgus stress, pull the graft taut and suture it to itself with #0 nonabsorbable sutures (Fig. 81.11E) at 45° of elbow flexion.

Close the incision in the subcutaneous tissue and the skin. Reattach theкрючковидная ligament in a side-to-side manner overlying the tendon graft, imbricating the overlying capsule with a #0 or #1 nonabsorbable suture.

Release the tourniquet and achieve hemostasis. Repair the flexor–pronator muscle mass in a side-to-side manner. Close the wound with careful attention to avoid injury to the cutaneous nerve. Apply a long-arm posterior plaster splint to immobilize the elbow in 90° of flexion and neutral forearm rotation avoiding any valgus stress.

ULNAR COLLATERAL RECONSTRUCTION COMBINED WITH SUBMUSCULAR ULNAR NERVE TRANSPOSITION

In patients with chronic (as opposed to transient) ulnar neuritis associated with instability, a decompression of the ulnar nerve and submuscular ulnar transposition may be performed in conjunction with the ulnar collateral ligament reconstruction. The difference in technique requires removal and subsequent repair of flexor–pronator muscle mass origin at the medial epicondyle.

Make a similar skin incision, except that 2–3 cm of proximal extension may be needed to expose the ulnar nerve and intermuscular septum. Again, protect the branches of the medial antebrachial cutaneous nerve.

Unroof the cubital tunnel and free the ulnar nerve, tracing it proximally to the arcade of Struthers, which must be released. Mobilize the ulnar nerve using a Penrose drain for retraction. Dissect the ulnar nerve from the epicondylar groove. Divide the arcuate ligament and follow the nerve to the interval between the two heads of the flexor carpi ulnaris. The articular branches will be sacrificed but preserve the motor branches to the flexor carpi ulnaris during the distal dissection. Excise the medial intermuscular septum for 5–8 cm proximal to its attachment to the medial epicondyle to ensure that the transposed nerve will not rest against its edge and cause a new site of compression or impingement. Avoid the numerous vessels that underlie the intermuscular septum and are part of the extensive collateral circulation of the elbow.

Detach the flexor–pronator muscle group 1–2 cm distal to the medial epicondyle, leaving the proximal tendon origin for later reattachment (Fig. 81.12A). Bluntly elevate the flexor–pronator muscle mass, avoiding injury to the median nerve and its branches. At this point, palpate and inspect the underlying ulnar collateral ligament.

Incise the ligament and capsule in a longitudinal fashion as previously described. Explore the joint and note the degree of valgus laxity and ligamentous pathology. Obtain a tendon graft in the manner previously described.

Make converging drill holes in the proximal ulna (as previously described) at the level of the coronoid tubercle. The bone tunnels within the medial epicondyle may be made in the manner noted previously, or they may be made to exit within the cubital tunnel (Figs. 81.12B). If the proximal holes exit within the cubital tunnel, drill the proximal entrance hole just anteriorly at the level of the anatomic origin of the anterior bundle of the ulnar collateral ligament between the base and the anterior-superior and posterior-superior holes. Make two divergent drill holes within the cubital tunnel, allowing a bone bridge within the cubital tunnel between the two posterior holes.

Pass the graft in figure-eight fashion. Apply tension and observe the graft during ROM and valgus stress. If there is extra length of the graft, it may be passed back upon itself through one of the bony tunnels. Secure the graft by suturing it to itself with a nonabsorbable suture (Fig. 81.12C). Close the overlying capsule in a side-to-side imbricating manner with a #0 or #1 nonabsorbable suture.

At this point, transpose the ulnar nerve anteriorly (Fig. 81.12D). Place the nerve anterior to the medial epicondyle and beneath the flexor–pronator muscle mass. It is important to take the elbow through a ROM to ensure that there are no areas of impingement along the new course of the ulnar nerve. Look for any...
Percutaneous release of the extensor tendon is described, but it is not recommended in the active population. LATERAL EPICONDYLITIS

While exposing the deep fascia through mobilization of subcutaneous flaps, take care to avoid any distal branches of lateral cutaneous nerves. After complete exposure of the extensor tendon and its aponeurosis (Fig. 81.16), palpate the extensor mechanism as it inserts into the lateral epicondyle.

Figure 81.16. Anatomy of extensor mechanism.

Place the patient in a supine position with the upper extremity supported by an arm board. Drape the involved extremity free to allow for control of elbow and arm position during the procedure. Begin an incision just proximal and posterior to the lateral epicondyle, extending distally to the radiocapitellar joint (Fig. 81.15).

Figure 81.15. Anatomy of extensor mechanism.

LATERAL COLLATERAL RECONSTRUCTION

Obtain a tendon graft as previously described for the ulnar collateral ligament. As with the ulnar collateral ligament reconstruction, an osseous tunnel must be created in the correct anatomic position (Fig. 81.14). Identify the insertion site of the lateral ulnar collateral ligament on the tubercle of the supinator crest of the ulna by palpation or by stressing the elbow in supination and varus. Make one hole in the ulna just posterior to this point, and another proximally near the annular ligament. Place tension on the tendon graft, typically using the palmaris longus, although other sources such as a plantaris or a medial strip of Achilles tendon may be used.

At this point, decide whether to do a ligamentous repair or a ligamentous reconstruction. When the lateral ligament is attenuated, reinforce the repair with an autogenous free tendon graft, typically using the palmaris longus, although other sources such as a plantaris or a medial strip of Achilles tendon may be used. If the lateral collateral ligament has become detached from the humerus, treat it with two #1 nonabsorbable sutures placed in Bunnell fashion in the lateral collateral ligament.

Place the sutures for reattachment of the flexor–pronator muscle mass under direct vision to avoid injury to the underlying ulnar nerve. Do not tie the sutures until all have been placed. This repair is by nonabsorbable suture to the tendinous cuff of tissue left at the medial epicondyle or through drill holes made within the medial epicondylar bone. Tie the sutures and observe that the ulnar nerve glides freely without any impingement or entrapment from the flexor–pronator muscle mass repair. Assess the integrity of the flexor–pronator repair during elbow ROM. Wound closure, postoperative immobilization, and rehabilitation are then performed as for patients without ulnar nerve transposition.

LATERAL EPICONDYLITIS

Approach the elbow through a modified lateral Kocher's incision. Expose the joint capsule by reflecting the anconeus muscle posteriorly. Make a longitudinal incision through the extensor tendon origin to the lateral epicondyle and reflect the tendon anteriorly from the lateral epicondyle to expose the origin of the radial collateral ligament.

Palpate the ulnar attachment of the lateral ulnar collateral ligament at the tubercle of the supinator crest deep to the fascia over the extensor carpi ulnaris and the supinator muscles. Reflect the triceps and anconeus from the posterior margin during reflection of the common extensor tendon origin. It is important to preserve the underlying capsule and the lateral ulnar collateral ligament.

Findings may reveal a lax ulnar band of the lateral collateral ligament proximal to the annular ligament. The lateral pivot-shift maneuver can demonstrate subluxation of the radial head and ulnohumeral joints, as well as attenuation of the capsule. Make an arthrotomy at the level of the radiocapitellar and ulnohumeral joints. Treat any associated loose bodies, synovitis, and osteochondral injuries. Place plication sutures within the anterior and posterior aspect of the joint capsule, tying the sutures at the completion of the procedure.

Determine the isometric point on the lateral epicondyle. Place a suture through the two holes in the ulna and extend it to the lateral epicondyle, holding it against the spot determined while flexing and extending the elbow to confirm isometricity.

At the chosen site, drill the hole eccentrically in a posterior and proximal direction with reference to the isometric point. Exit posterior to the supracondylar ridge and 2 cm proximally. With a bone bridge of 1–1.5 cm, create a reentry tunnel from this site back to the original entry at the epicondyle. Pass the graft through these osseous tunnels using a suture passer, and flex the elbow to 30° with full pronation. Close the joint capsule so that the tendon graft becomes extraarticular and does not rub against the lateral margin of the capitellum.

With tension placed on the tendon graft, use #0 nonabsorbable sutures to anchor the tendon to itself and to the surrounding soft tissues. Reapproximate the anconeus and extensor muscles along with the common extensor origin, and complete routine closure.

Fig. 81.14. Lateral collateral ligament repair. A: Placement of sutures for repair. B: Completion of the repair.
Incise the deep antebrachial fascia directly over the epicondyle, and subsequently divide it distally toward the radiocapitellar joint, thus exposing the fibrinous origin of the common extensor tendon and the superior and inferior margins of the lateral epicondyle (Fig. 81.17). Elevate the superficial and distal fibers of the extensor carpi radialis longus anteriorly. Continue the incision subperiosteally and distally to the extensor carpi radialis brevis.

Incise the origin of the extensor brevis tendon longitudinally and elevate anteriorly. Carry the dissection distally through the synovial membrane into the lateral compartment of the elbow. Inspect the underlying extensor tendon mechanism that has been released subperiosteally (Fig. 81.18). Note any evidence of tears, granulation tissue, or fibrinous replacement of the tendon. Inspect the radiocapitellar joint and the overlying synovium.

Tears of various degrees and magnitudes are commonly found on the underside of the extensor carpi radialis brevis and frequently may penetrate distally to the level of the lateral compartment of the elbow joint. Therefore, follow the tendon to the level of the radiocapitellar joint to be sure that the entire pathology has been observed (Fig. 81.19). If a tear, granulation tissue, or fibrinous material is not identified in the extensor carpi radialis brevis, inspect the extensor carpi radialis longus proximally and the extensor digitorum distally.

Elevate the extensor origin in a subperiosteal fashion both anteriorly and posteriorly until the entire pathologic area of tendon tear and degeneration has been exposed. It is not necessary to elevate the entire extensor origin but merely that portion of the extensor tendon involved with disease. The normal muscle length should be preserved; this is accomplished by continuing the dissection in a longitudinal subperiosteal fashion, beginning with a longitudinal incision. The degenerative portion of the tendon typically occurs along its undersurface at its insertion into the lateral epicondyle. A nerve hook can be introduced for palpation of the partial-thickness tear within the tendon. Excise the degenerative portion of the tendon, as well as any abnormal granulation tissue and fibrillated torn edges. Typically this requires removal of a portion of the undersurface of the extensor carpi radialis brevis tendon.

Using a rongeur, superficially decorticate the area of the lateral epicondyle that has been exposed (Fig. 81.20). This helps provide a cancellous bleeding surface for later reattachment of the extensor mechanism.

Figure 81.16. Exposure of extensor mechanism laterally.

Figure 81.17. Lateral approach over the lateral epicondyle and extending distally to the radial head.

Figure 81.18. Lateral exposure of the pathology in the ECRB and joint.

Figure 81.19. Excision of the degenerative portion of the ECRB tendon.

Figure 81.20. Debridement of the lateral epicondyle.
Use a $\frac{5}{64}$-inch drill bit (Fig. 81.21) to create a V-shaped tunnel in the lateral epicondyle, allowing passage of a slow-absorbing #0 suture through the bone (Fig. 81.22) for improved fixation, and eliminating any potential dead space between the tendon and the lateral epicondyle at the completion of the procedure.

**Figure 81.21.** Drilling of the lateral epicondyle.

**Figure 81.22.** Passage of suture through bone.

Finally, perform a side-to-side repair using absorbable #0 suture, replacing the extensor tendon mechanism anatomically to the lateral epicondyle.

**MEDIAL EPICONDYLITIS**

- Place the patient supine with the extremity resting on an arm board and the limb draped free. Incise anterior to the prominence of the medial epicondyle, extending distally approximately 4 cm. Identify and protect the underlying cutaneous nerves.
- Incise the common flexor at its origin on the medial epicondyle, extending the dissection through the central portion of the flexor–pronator muscle mass. Elevate the flexor–pronator muscle mass tendon origin in a longitudinal subperiosteal fashion off the medial epicondyle. Avoid inadvertent entry into the cubital tunnel.
- Inspect the underlying flexor–pronator tendon for any tear, granulation tissue, or fibrinous replacement. The degenerative portion of the tendon typically occurs along its undersurface at its insertion into the medial epicondyle. Use a nerve hook for palpation of partial thickness tears. Excise the degenerative portion of the tendon as well as any abnormal granulation tissue.
- Using a rongeur, decorticate the area of the medial epicondyle that has been exposed, creating a cancellous bleeding surface for later reattachment of the flexor tendon. Use a $\frac{5}{64}$-inch drill bit to create a V-shaped tunnel within the medial epicondyle to allow passage of a slow-absorbing suture through the bone for improved fixation and to eliminate dead space between the tendon and epicondyle postoperatively. Use caution while drilling, to avoid any entry into the cubital tunnel.
- Reapproximate the flexor tendon to itself, overlying the medial epicondyle in a side-to-side manner. Use simple interrupted #0 absorbable sutures to reapproximate the tendon. Release the tourniquet and obtain hemostasis. Close the subcutaneous tissue, and follow with a running subcuticular skin closure.

**Figure 81.23.** Closure of extensor mechanism.

**DISTAL BICEPS RUPTURE**

The biceps tendon is reinserted into the radial tuberosity through a modification of the two-incision technique described by Boyd and Anderson (16).

- Place the patient supine with the elbow extended and the forearm supinated on an arm board. Make an oblique incision beginning medially and proximally to the elbow crease, and extending distally and laterally (Fig. 81.24). The lacertus fibrosis may be intact and should be released to reveal the underlying hematoma and biceps tendon. Protect the underlying lateral antebrachial cutaneous nerve, which runs lateral to the biceps tendon. Identify the end of the tendon. Place two different-colored, nonabsorbable #2 sutures within the biceps tendon in a modified Kessler fashion (Fig. 81.25).

**Figure 81.24.** Anterior incision for repair of a bicep tendon.
Insert a curve clamp between the radius and the ulna, down the tunnel vacated by the biceps tendon (Fig. 81.26). Flex the elbow and direct the curved clamp posterolaterally, tenting the skin on the forearm. Make a second 4–6 cm incision, paralleling the radial border of the ulnar. Split the extensor muscle mass carefully, avoiding exposure of the ulna. Avoidance of the ulna and its subperiosteum minimizes the postoperative risk of radioulnar synostosis.

Identify the radial tuberosity and clear it of soft tissue. Make a $\frac{1}{8}$-inch drill hole within the radial tuberosity, enlarging it with a $\frac{1}{4}$-inch drill bit. Enlarge the cavity with a high-speed burr or curet. It is important to remove all bony debris after drilling, with copious irrigation. Drill two smaller holes through the edges of the cavity in the tuberosity using a $\frac{5}{64}$-inch drill bit.

Pass the tendon from anterior to posterior through the soft-tissue tunnel between the radius and the ulna. Using a 24-gauge wire, a commercial suture passer, or a free needle, pass the nonabsorbable sutures through the cavity in the radial tuberosity, exiting through the smaller side-drilled holes. Using the different-colored sutures, bring one limb through each of the two side-drilled holes. Pull the sutures firmly with the arm in flexion and supination, and be sure by direct palpation that the tendon is seated within the bony defect created within the radial tuberosity. Before tying the suture, release the tourniquet and thoroughly irrigate and close the anterior incision. It is critical to close the anterior incision before tying the sutures of the biceps tendon through the posterior incision, as the elbow will remain in a flexed position following closure of the biceps tendon repair.

Tie each of the sutures from the biceps tendon, and again inspect the distal tendon of the biceps to make certain that it is secured within the radial tuberosity. Tie the sutures securely with the elbow flexed 90° and the forearm supinated (Fig. 81.27). Irrigate the posterior wound thoroughly. Close the deep fascia with interrupted #0 absorbable suture, and close the subcutaneous tissue with a running subcuticular closure.

DISTAL TRICEPS TENDON RUPTURE

Use a posterior approach to the distal arm (Fig. 81.28) in either a supine lateral or prone position. Make the skin incision over the distal triceps mechanism and develop subcutaneous flaps, protecting any underlying cutaneous nerves. While the ulnar nerve does not need to be freed or transposed, it is critical to identify the course and to be aware of its position throughout the surgical repair. Isolate the avulsed triceps tendon and at this point inspect the posterior aspect of the joint. Excise any bone flecks accompanying the triceps tendon avulsion. If there has been a large fragment avulsed with the triceps tendon (often seen in the adolescent athlete), repair this fragment with either a tension band technique or screw fixation.

Place two different-colored #2 nonabsorbable sutures through the tendon in a modified Kessler fashion. Use crisscrossed bone tunnels in the olecranon as described by Morrey (48) to secure the sutures to bone (Fig. 81.29). Make sure that, as the sutures are placed through the bone and tension is placed on the tendon, the overlying fascia is not tethered, which would compromise the ulnar nerve.
Deflate the tourniquet prior to closure and obtain hemostasis. Tie the sutures and check the integrity of the repair during ROM of the elbow. After routine closure, split the elbow at 45° of flexion.

REHABILITATION

LATERAL EPICONDYLITIS

After repair for lateral epicondylitis, place the elbow in a soft dressing and allow gentle active-assisted ROM. In 7–10 days, remove the sutures. Encourage gentle passive and active flexion, extension, supination, and pronation. Initiate ROM exercises for the wrist and fingers, including squeezing a light rubber ball with the hand. Discourage activities that require lifting with the involved extremity, and avoid any resisted dorsiflexion of the wrist or fingers.

At 4 weeks, initiate light resisted isometric exercises. At 6 weeks, start a strengthening program, including isometric and isotonic exercises, that progresses on a graduated basis. Return to normal activities such as heavy lifting or athletics at 3 months.

MEDIAL EPICONDYLITIS

Apply a soft dressing and splint for comfort to the elbow after surgical treatment of medial epicondylitis. Adopt a program similar to that described for lateral epicondylitis, with a similar time frame for return to sports and heavy activity.

DISTAL BICEPS RUPTURE

After repair of a distal biceps rupture, maintain the forearm in supination with the elbow flexed 90°. Remove the sutures at 1 week while continuing to immobilize the elbow for 2 more weeks. At 3 weeks, initiate gentle active extension and passive flexion exercises, as well as gentle active pronation and passive supination exercises. At 6 weeks, continue ROM exercises and introduce isometric strengthening exercises in all planes. Initiate a progressive strengthening program that includes isometric exercises at 12 weeks, and progressively continue until full ROM strength and endurance is restored. Do not recommend full activities until full ROM strength and endurance have been achieved, which typically takes 4 months following surgical repair.

DISTAL TRICEPS REPAIR

After surgical repair of a distal triceps avulsion, immobilize the arm in a plaster splint at 45° of elbow flexion for 3 weeks. Remove sutures at 7–10 days postoperatively. Next, begin gentle passive extension and active flexion. At 6 weeks, initiate progressive resisted exercises beginning with isometric exercises, and progress to isotonic exercises with a progressive strengthening program. Unrestricted activity typically can be initiated 4 months after surgery, when full ROM, strength, and endurance have been achieved.

PITFALLS AND COMPLICATIONS

ULNAR COLLATERAL RECONSTRUCTION

In a review of ulnar collateral ligament reconstruction for medial elbow instability, all the complications except one postoperative hematoma were related to either cutaneous nerves or the ulnar nerve (22). Cutaneous nerve complications included a transient paresthesia, cutaneous neuroma, and residual pain. In the reconstruction group, 21% had ulnar nerve symptoms postoperatively. One third of this group had transient paresthesias that subsided after 4 months. The remaining two thirds required a revision procedure on the ulnar nerve, with the majority having residual paresthesias of the ulnar nerve during long-term follow-up. When performing an ulnar collateral ligament reconstruction, it is critical to be mindful of the potential iatrogenic neurogenic injuries that may occur. The cutaneous nerves off the medial antebrachial cutaneous nerve tend to be robust, and they are easily injured. Traction on the cutaneous nerves may result in transient postoperative paresthesias that typically resolve. It is the residual neuroma from an accidental transection of the nerve that results in the most difficulty in the postoperative course for these patients. Ulnar nerve problems are common, but their incidences may be reduced by separating those patients who require an ulnar nerve transfer from those who do not.

Previous reviews (22,23) of ulnar collateral ligament reconstruction from the Kerlan-Jobe Orthopaedic Clinic were limited to patients who uniformly had submuscular ulnar nerve transpositions performed as a part of their reconstructive procedure. The majority of patients with ulnar collateral ligament insufficiency do not require ulnar nerve transfer. It is critical in that group to be sure that, during the course of the surgical procedure, the cubital tunnel is not violated. For those patients who require an ulnar nerve transposition, strict attention to detail is required, as for any submuscular ulnar nerve transfer. It is imperative that any residual or new site of compression or impingement of the nerve be eliminated and that the nerve is noted to lie free underneath the flexor–pronator muscle mass following its repair at the conclusion of the procedure.

Pain during the follow-through phase of throwing may be due to impingement of the posterior medial olecranon in the olecranon fossa. Termal valgus extension overload, this may result in the development of osteophytes on the posterior-medial margin of the olecranon and loose fragments of bone within the olecranon fossa. Although in many patients, impingement may be eliminated by restoration of the ulnar collateral ligament, I believe that it is important to remove any posterior osteophytes and loose bodies at the time of surgery.

After reconstruction of the ulnar collateral ligament, athletes must rehabilitate the shoulder along with the elbow and maintain good overall physical condition to minimize the risk of injury during the early postoperative period. Proper throwing mechanics, balance, and coordination must be restored before returning to competition.

Technical pitfalls at the time of surgery also include improper placement of the osseous tunnels in a nonisometric position. Other problems include penetration of the articular surface during drilling of the osseous tunnel, and loss of the bone bridge between the two surfaces of the osseous tunnel if forceful placement of the graft occurs without having previously ensured adequate communication between the two tunnels. Salvage of a disrupted bone tunnel may require the need for a bone anchor and fixation of the tendon graft into a trough. I have had no experience with this and cannot predict the difference in fixation strength between a tendon graft fixed within a bony tunnel and one fixed into a trough secured by bone anchor and sutures.

LATERAL COLLATERAL LIGAMENT RECONSTRUCTION

The most common complication that occurs after lateral collateral ligament reconstruction is persistent instability (48,57). It is critical at the time of the procedure to determine the presence or absence of competency of the lateral ulnar collateral ligament, in addition to that of the remaining posterior and anterior lateral capsule. When a repair or reconstruction is being performed for the lateral ulnar collateral ligament, establish the isometric points proximally and distally to ensure stability in the postoperative period. In addition, at surgery, assess other pathologically lax sources for instability, such as the anterior and posterior capsule, which will require plication sutures as part of the repair. Injury to the cutaneous nerves, while less common than after a medial approach, may occur and can be a significant source of impairment for the patient. Careful attention to avoid any injury to the cutaneous nerves is imperative. In addition, be aware of the proximity of the radial nerve while...
excellent. The hallmark of an excellent outcome is an accurate diagnosis. In the athletic population, rule out underlying ulnar collateral ligament insufficiency and

MEDIAL EPICONDYLITIS

avoid any injury to the lateral collateral ligament complex.

The incidence of radial nerve injury after distal biceps tendon reattachment is significantly reduced since the development of the two-incision technique. The radial nerve was vulnerable when we previously used an extended anterior approach. However, the two-incision technique has raised the incidence of radialnualynear instability. When creating the posterior incision, a muscle-splitting approach must be performed rather than a subperiosteal dissection along the course of the ulna. It addition, the presence of the hematoma communicating with the radius and the ulna may also increase the risk of a postoperative synostosis.

It has been suggested that a bone anchor in the radial tuberosity may be used through a single anterior incision, avoiding the potential risks of radioulnar synostosis. We have no experience with this technique and do not know if this will again initiate an increase incidence of radial nerve injuries, nor do we know if the fixation strength of the biceps tendon to bone will be altered.

REPAIR OF DISTAL TRICEPS TENDON AVULSION

Injury to the ulnar nerve during vigorous dissection and mobilization of the triceps may occur, but it is not commonly reported. Careful attention of the anatomic location to the ulnar nerve and avoidance of the cubital tunnel is imperative.

AUTHOR'S PERSPECTIVE

ULNAR COLLATERAL LIGAMENT RECONSTRUCTION

Reconstruction of the ulnar collateral ligament in overhead and throwing athletes unable to compete prior to surgery has been successful in returning the majority of them to their previous level of participation. Of 71 surgical procedures with valgus instability treated at the Kerlan-Jobe Orthopaedic Clinic, 14 had a direct repair and the remainder had a reconstruction using a free tendon graft (22). These patients were followed for 6.3 years postoperatively, and 68% of the reconstruction group returned to their previous level of participation. The mean time to return to competition was 12 months. The negative prognostic factors included previous operations on the elbow and being a baseball pitcher (as opposed to other throwing positions). Postoperative complications involving the cutaneous nerves or the ulnar nerve itself accounted for the major complications following this procedure. There were no differences in results when the source of graft material was evaluated, which included the ipsilateral palmaris longus tendon, the contralateral palmaris longus tendon, and the plantaris or partial Achilles tendon graft.

The incidence of ulnar collateral ligament insufficiency is not common in the general population, but it is quite frequent in the athletic population engaged in athletic activities that place valgus stress across the medial aspect of the joint. Most athletes with ulnar collateral ligament tendinitis or instability improve with conservative treatment and do not require surgical intervention. Those athletes not responding to conservative care, and those who wish to continue to pursue athletic endeavors, are excellent candidates for a surgical reconstruction. The results of surgical repair, especially in the chronic setting, are unpredictable. When addressing the problems of ulnar collateral ligament insufficiency surgically, it is recommended that a reconstruction be performed with the use of a free tendon graft. Postoperative complications may be minimized (a) by paying meticulous attention to avoid injury to the cutaneous nerves and (b) by limiting transposition of the ulnar nerve to those cases with preoperative clinical indications.

LATERAL COLLATERAL LIGAMENT INJURY

Results of surgical treatment for lateral collateral ligament insufficiency have been reviewed at the Mayo Clinic (48-57) with 11 cases that were followed a minimum of 1 year. Six cases were rated as excellent, which indicated that the patients perceived the elbow to be normal. One case was considered to be good, which indicated no objective or subjective elements of instability, with residual mild pain or apprehension. Three patients were rated as fair, which indicated no objective instability but the patient did have subjective symptoms including an apprehension sign. Mild or moderate pain with the loss of more than 10° of motion was also present. There was one poor result with a recurrence of instability that was perceived and could be demonstrated by a positive pivot-shift maneuver.

The diagnoses of lateral collateral ligament and posterior lateral instability are not common. Keep these diagnoses in mind when evaluating any patient with lateral elbow pain. Many patients who failed treatment for lateral epicondylitis and other diagnoses for lateral elbow pain, in fact had lateral collateral ligament laxity that was not recognized. When the diagnosis is made and clinical symptoms are sufficient, the treatment is primarily surgical; there is little role for the nonoperative management.

LATERAL EPICONDYLITIS

Nirschl and Sobel (55), Coonrad (23), and Leach and Miller (44) noted that 85% to 90% of patients returned to full activity without pain after surgical treatment of lateral epicondylitis. Approximately 10% to 12% were noted to have improvement, but with some residual pain, and 2% to 3% were felt to have no appreciable improvement as a result of the surgical procedure. At the Kerlan-Jobe Orthopaedic Clinic, 1,200 patients with a diagnosis of lateral epicondylitis were treated over a 10-year period (20). Of the 1,200 patients, 60 subsequently underwent surgical treatment for persistent symptoms. Of those 60, 39 were available for long-term follow-up. Although 94% had dramatic improvement in their symptoms, this did not correlate with the objective findings, which demonstrated that 36% had residual limitations from heavy lifting. Grip-strength deficits were found in 15%, and 100% had some degree of isokinetic strength deficit. It was concluded that while the procedure provides excellent subjective postoperative relief, the subjective results do not necessary correlate with objective findings of persistent weakness.

Tennis elbow or lateral epicondylitis is one of the more common diagnoses made by musculoskeletal specialists dealing with elbow problems. The results of conservative treatment are uniformly excellent. However, those patients who have associated entrapment of the radial nerve or other causes for lateral elbow pain must be identified. For those who fail conservative treatment, lateral epicondylitis surgery is predictable and excellent, but careful attention to detail is critical at surgery to avoid any injury to the lateral collateral ligament complex.

MEDIAL EPICONDYLITIS

Vangsness and Jobe's review (66) of 35 patients with surgically treated medial epicondylitis revealed that subjective function improved from 38% to 98%. Excellent or good results were obtained in 97% and isokinetic grip-strength testing revealed no significance between the involved and uninvolved elbows.

Although the majority of patients presenting with medial epicondylitis may be treated conservatively with excellent results, the results of surgical treatment are uniformly excellent. The hallmark of an excellent outcome is an accurate diagnosis. In the athletic population, rule out underlying ulnar collateral ligament insufficiency and dissecting and immobilizing the anterior capsule.

LATERAL EPICONDYLITIS

Failure of the procedure to provide clinical improvement may be caused by improper patient selection or improper diagnosis. The differential diagnosis of a patient with lateral epicondylitis includes degenerative arthritis, forearm extensor tendinitis, lateral collateral ligament instability, and entrapment of the radial nerve. A preoperative assessment must be completed to distinguish between these various entities. An incomplete release or excision of the pathologic tissue may also cause persistent symptoms after the surgical procedure, so pay careful attention to technique.

In the course of surgical dissection, it is imperative that injury to the radial nerve be avoided when elevating the lateral epicondylar tendon anteriorly and exploring the radiocapitellar joint. During the initial dissection, when the longitudinal incision is made through the extensor tendon and carried distally to the radiocapitellar joint, is iatrogenic injury to the radial collateral ligament may occur. The dissection must be carried out in a longitudinal fashion, and the lateral capsule must not be transected with a transverse incision. It is also critical that the lateral ulnar collateral ligament not be violated during the course of the dissection and repair.

MEDIAL EPICONDYLITIS

Be sure during the initial dissection for the surgical treatment of medial epicondylitis to avoid any injury to the underlying cutaneous nerves, as noted previously. A common source of persistent postoperative pain is failure to adequately diagnose the underlying condition. Those patients with symptomatic collateral ligament insufficiency or who have persistent symptoms after their underlying disease is not recognized. When the diagnosis is made and clinical symptoms are sufficient, the treatment is primarily surgical; there is little role for the nonoperative management.

The diagnoses of lateral collateral ligament and posterior lateral instability are not common. Keep these diagnoses in mind when evaluating any patient with lateral elbow pain. Many patients who failed treatment for lateral epicondylitis and other diagnoses for lateral elbow pain, in fact had lateral collateral ligament laxity that was not recognized. DISTAL BICEPS RUPTURE

A study by D'Alessandro et al. (25) consisted of weight lifters and body builders with high functional demands. All patients in this group were satisfied with their functional and cosmetic result and returned to full, unrestricted activities. Isokinetic testing demonstrated that supination strength and endurance was normal; in flexion, the patients had normal strength but averaged 20% less endurance. Morrey et al. (50) reported on seven patients with at least 15 months follow-up after a two-incision technique. Those treated early had at least 95% restoration of strength in all planes. Those who had a late reattachment or a late insertion into the brachials had deficits in flexion and supination.

While distal biceps rupture typically occurs in the active population such as weight lifters and heavy laborers, it may occur in anyone, especially with a traumatic injury. Unlike a proximal biceps tendon rupture, a distal biceps tendon rupture left untreated will yield significant functional deficits. Except for those individuals who are otherwise inactive, an acute repair of the distal biceps tendon will yield predictable results with restoration of ROM and function. The two-incision technique is preferred because of the low incidence of radial nerve problems, but a muscle-splitting approach must be utilized to lower the incidence of postoperative radialnlar synostosis.

DISTAL TRICEPS REPAIR

Morrey (48) has reported that the results of immediate or delayed repair have been uniformly good, with restoration of normal strength and full ROM. Approximately 20% of patients will develop a loss of 5° of terminal extension.

Although a complete avulsion of the triceps mechanism is rare, the physician treating an active athlete or heavy laborer population will undoubtedly encounter the injury. In cases of complete disruption, prompt diagnosis and surgical repair result in a predictable optimal outcome with excellent functional recovery.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Arthroscopy of the elbow is a relatively recent advance in the treatment of elbow disorders. Its minimally invasive nature allows for rapid postoperative rehabilitation, which helps prevent the most common and dreaded complication of elbow surgery, arthrofibrosis. Arthroscopy permits better visualization of the elbow joint than does limited arthrotomy; arthroscopy of the elbow is difficult, however, because the joint is small and in close proximity to neurovascular structures. These reasons limit widespread use of the procedure.

CLINICAL EVALUATION AND IMAGING OF THE ELBOW

History and physical examination are critical in evaluation of disorders of the elbow. The timing of the injury, whether it was acute or insidious, is important. Acute trauma to the elbow may involve capsular injury, which is a contraindication to elbow arthroscopy.

Symptoms of locking are typical of a loose body. Loss of extension can be the first sign of elbow pathology in an adolescent, often before any complaints of pain. In older patients with degenerative changes, a loss of both flexion and extension is typical.

Additionally, the location of pain is informative. Lateral pain is seen in lateral epicondyritis and osteochondritis dissecans. Medial pain is associated with chronic valgus laxity, ulnar nerve symptoms, and medial epicondyritis. Posterior pain is typical of posterior impingement and biceps tendinitis. Anterior pain is less common and is associated with biceps tendinitis, anterior coronoid osteophytes, and arthritis.

If the symptoms are associated with throwing, it is useful to determine at which stage of the throwing motion pain occurs. Pain that occurs just before ball release when the arm is maximally cocked is associated with valgus laxity and ulnar collateral injuries. Pain after ball release is more often seen with posterior impingement injuries.

If the patient has a history of previous trauma, review the initial treatment along with the type and duration of physical therapy. Arthrofibrosis after elbow trauma is one of the most common abnormalities seen. An adequate course of physical therapy to try to restore motion and strength is necessary before surgery. Review previous surgeries with careful attention to whether the ulnar nerve has been transferred. A previous ulnar nerve transposition does not allow access to the medial portal and severely limits an arthroscopic operative procedure.

In physical examination of the elbow, include careful measurement of the preoperative range of motion using a long goniometer with the forearm in the same position for each measurement. Measurement by eye alone may not pick up flexion contracture. Compare measurements to those on the opposite side. Measure pronation and supination. Tenderness and crepitation over the radiocapitellar joint or posterior ulnahumeral articulation may indicate chondral injury in these areas. An effusion may be detected by palpation of the lateral soft spot.

Examine the elbow for signs of instability. With medial instability, valgus opening may be detected with the elbow flexed about 30° as a valgus force is applied to the forearm. This test may be easier to perform with the patient supine and the humerus maximally externally rotated, with the arm off the side of the table.

Test for posterolateral instability with a pivot-shift-type test. With the patient supine and the arm overhead and forearm in supination, apply a supination and valgus force to the elbow in an axial direction with it flexed 20° to 30°. Posterolateral subluxation will be visible and will decrease with further flexion of the elbow.

Valgus extension overload refers to the injuries associated with throwing and includes medial tension, lateral compression, and posterior impingement injuries. Perform a valgus extension overload test by extending the elbow with a valgus force applied across the joint. This procedure forces the posteromedial olecranon to contact the humerus with impingement and pain. This test is also often positive with ulnar collateral ligament injuries.

Carefully inspect the ulnar nerve with attention to its position and whether it subluxes. (The nerve can be displaced over the medical epicondylic, or, with flexion of the elbow, the nerve will slide anteriorly.) This can be easily missed on physical examination. It is easier to visualize subluxation of the nerve medialy with the patient supine.

Obtain routine radiographs, including an anteroposterior (AP), lateral, oblique, and an axial view. Radiographs alone are adequate to diagnose degenerative changes but may be completely normal in cases of osteochondritis dissecans and loose bodies. Magnetic resonance imaging (MRI) is useful to evaluate osteochondritis dissecans and ligamentous injuries. The ulnar collateral ligament is more easily visualized with either a contrast MRI or a computed tomography (CT) arthrogram. Computed tomography arthrography is also helpful to find loose bodies, but it is not foolproof. In one series of patients with known loose bodies, the preoperative radiographs were negative in 71% of the patients, and the CT-arthrogram was negative in 36%.

INDICATIONS

Elbow arthroscopy is indicated for the diagnosis and removal of loose bodies, evaluation and treatment of osteochondritis dissecans of the capitellum, and excision of osteophytes from the coronoid and posterior olecranon. It is also indicated in release of posttraumatic contractures of the elbow, synovectomy in inflammatory disorders, and debridement of degenerative changes. It is useful in evaluation of the ulnar collateral ligament and detection of valgus instability as well as evaluation of the painful elbow with uncertain intra-articular pathology.

Contraindications to elbow arthroscopy include bony ankylosis and severe fibrous capsular contracture, which can make introduction of the arthroscope into the elbow joint difficult. An acute capsular tear in the elbow is also a contraindication, as fluid extravasation may occur that can collapse the joint; this makes visualization difficult and, additionally, presents the danger of compartment syndrome.

PREOPERATIVE TREATMENT

Try to document the presence of an intraarticular derangement. If the specific disorder is not known, a preoperative intraarticular lidocaine injection can be useful to determine if pain is relieved. Undertake an adequate course of conservative treatment before surgery. Specific treatment guidelines are outlined with each diagnosis.
Surgical Techniques

- Position the patient supine or prone, depending on your preference and the portals to be used. I prefer to use a general anesthetic because it offers complete muscle relaxation and avoids intraoperative patient discomfort. In addition, it allows an immediate postoperative neurologic examination in the recovery room, which is not possible if a block is used. Apply a tourniquet around the proximal arm before positioning and draping. For both the supine and prone position, place the arthroscopy equipment on the opposite side of the table from the surgeon.

- In the supine position, a standard operating table suffices. Place the hand in a gauntlet or suspension unit that is used for shoulder arthroscopy (Fig. 82.1). Then suspend the arm overhead to hold the shoulder in neutral rotation and 90° of abduction with the elbow flexed 90°. This position provides maximal protection of the neurovascular structures in the antecubital fossa. Use 5 lb of traction initially; when extension of the elbow is needed to work in the posterior compartment, add another 3 to 5 lb. Alternatively, prep the hand and suspend it with a sterile suspension device or finger traps if you plan a later open procedure. In general, for elbow arthroscopy, suspend the hand first and then steriley prep the elbow and cover the forearm with a towel and clear sticky drape. A split drape works well for the supine position, and the arthroscopy drapes with bags attached are useful in collecting fluid. Sit on a rolling stool with the patient's elbow at a comfortable level. This arrangement allows access to both the medial and lateral sides of the elbow and rotation of the forearm.

**Figure 82.1.** Setup and patient positioning for elbow arthroscopy. The affected arm is statically suspended and positioned so that the elbow hangs freely off the side of the table.

- If the patient is prone, support the chest and abdomen to avoid compression (20) and place an arm board parallel to the operating table at the level of the patient's arm. Elevate the proximal arm and shoulder on a sandbag placed on the arm board. No traction is required; gravity alone distracts the elbow joint. The shoulder is in 90° abduction, and the elbow flexed 90°, with the forearm pointed to the floor. The surgeon then stands at the operating table with the elbow at chest level.

- There are many debates regarding the best position for elbow arthroscopy. In general, operative arthroscopy in the anterior compartment with release of the anterior capsule is easier in the supine position. Advocates of the prone position cite the greater ease of operating in the posterior compartment because the surgeon is not fighting gravity with the arm in this position. If a coupled videoarthroscope or “glass on glass” camera is not available, the prone position is preferred to avoid fogging of the camera (when the supine position is used, the fluid runs down the arthroscope and can cause fogging of the camera). I prefer the supine position and suggest that you select one position and develop proficiency with it. The elbow is a very difficult joint to examine and treat arthroscopically. It takes several cases before a reasonable level of ease with the procedure is achieved.

Instrumentation

Standard arthroscopic instruments can be used in the elbow. The 4-mm, 30° arthroscope can be used throughout the procedure. Visualization with the larger arthroscope is much better than with the smaller 2.7-mm arthroscope. The 2.7-mm arthroscope is at times useful in the tight lateral compartment. I use a standard-sized shaver handpiece with a 4.0-mm shaver tip; the smaller handpiece may be needed in the lateral compartment. Other instruments needed include a grasper for loose bodies and microfracture awls to abrade full-thickness chondral defects. An arthroscopic system that allows the camera and shaver to be placed through the same metal cannula is very helpful in preventing loss of a portal. If they are not available, use switching sticks to change the position of the cannulas. Finally, an arthroscopic fluid system is very useful in maintaining pressure in the joint when the shaver is used. Two-port arthroscopy can be used, as the debrider can be used as outflow. A pressure setting of approximately 30 to 35 mm Hg works well in the elbow joint. One ampule of epinephrine added to each 3,000-cc bag is also helpful in controlling bleeding in the joint, in addition to the use of a tourniquet.

Location of Standard Portals

- Outline the bony landmarks about the elbow with a marking pen, carefully marking the location of the ulnar nerve. With the hand covered and the elbow distended with fluid, it can be difficult to locate the standard anatomic landmarks. Identify the radial head as well as the medial and lateral epicondyles and the tip of the olecranon. The most commonly used portals are the direct lateral, anteromedial and anterolateral, posterolateral, straight posterior, and proximal medial (used in the prone position) portals.

- Locate the direct lateral portal among the lateral epicondyle, olecranon tip, and the radial head in the soft spot of the elbow (Fig. 82.2). This is a safe portal, as instrumentation introduced through this portal traverses only skin, a thin subcutaneous layer, the anconeus muscle, and joint capsule (Fig. 82.3).

**Figure 82.2.** The direct lateral portal is located amid the lateral epicondyle, olecranon tip, and radial head. (From Andrews JR, Carson WG. Arthroscopy of the Elbow. Arthroscopy 1985;1:97.)

**Figure 82.3.** Instruments placed in the direct lateral portal penetrate the anconeus muscle before entering the joint capsule.

- Locate the anterolateral portal approximately 2 to 3 cm distal and 1 cm anterior to the lateral epicondyle (Fig. 82.4). Make this portal over the radiocapitellar joint just anterior to the radial head, which is easily identified by pronating and supinating the forearm. This portal goes through the extensor carpi radialis brevis
muscle and comes within 7 mm of the radial nerve (Fig. 82.5) (12). In an anatomic study, Lynch and associates (12) found the radial nerve to be displaced 11 mm from the portal with 35 to 40 ml of fluid distention of the joint; without distention it is only 4 mm away.

**Figure 82.4.** Establish the anterolateral portal approximately 3 cm distal and 1 cm anterior to the lateral epicondyle. Arthroscopic anatomy as seen through this portal includes the distal humerus and the coronoid process of the ulna. (From Andrews JR, Carson WG. Arthroscopy of the Elbow. *Arthroscopy* 1985;1:97.)

**Figure 82.5.** Instruments placed in the anterolateral portal penetrate the extensor carpi radialis brevis muscle and pass within 7 mm of the radial nerve. (From Chapman MW, ed. *Operative Orthopaedics, 2nd ed.* Philadelphia: JB Lippincott, 1993.)

[Image of anatomical diagram]

Locate the anteromedial portal approximately 2 cm distal and 2 cm anterior to the medial epicondyle (Fig. 82.6). Instruments in this portal pass through the tendinous portion of the pronator teres and the radial aspect of the flexor digitorum superficialis (Fig. 82.7). This portal comes within 1 cm of the median nerve and the brachial artery (12). Lynch showed that the median nerve was an average of 4 mm from this portal without distention and 14 mm with joint distention. The brachial artery averaged 9 mm of displacement without and 17 mm with joint distention.

**Figure 82.6.** The anteromedial portal. Instruments enter the skin approximately 2 cm distal and 2 cm anterior to the medial epicondyle. The arthroscopic view includes the capitellum and radial head. (From Andrews JR, Carson WG. *Arthroscopy of the Elbow. Arthroscopy* 1985;1:97.)

**Figure 82.7.** Instruments passed in the anteromedial portal penetrate the tendinous portion of the pronator teres and the radial aspect of the flexor digitorum digitalis.

Establish the posterior portals with the elbow in slightly more extension, which relaxes the triceps muscle and allows the posterior joint to be distended. The posterolateral portal is approximately 3 cm proximal to the olecranon tip, just off the lateral epicondylar ridge posterior and proximal to the lateral epicondyle (Fig. 82.8 and Fig. 82.9). The second posterior portal is the straight or working portal. It is used if there is need for a second operating portal posteriorly. Place it in the middle portion of the triceps tendon, splitting the triceps in line with its fibers. Take care to avoid too medial positioning of this portal, as the ulnar nerve is close. This portal comes within 18 mm of the ulnar nerve (12). I do not incise medial to the midpoint of the triceps tendon.

**Figure 82.8.** With the elbow in 20° to 30° of flexion, (A) the posterolateral portal is established 3 cm proximal and 2 cm medial to the triceps tendon, and (B) the straight posterior portal is established 3 cm proximal to the olecranon tip and 2 cm medial to the posterolateral portal.
Figure 82.9. Instruments placed in the posterolateral portal pass just lateral to the triceps tendon. Instruments in the straight posterior portal split the triceps tendon in line with its fibers.

- Place the proximal medial or the supracondylar anteromedial portal with the patient in the prone position (Fig. 82.10). This portal is located 2 cm proximal to the medial epicondyle. Incise the skin and insert the cannula anterior to the intermuscular septum, avoiding injury to the ulnar nerve (Fig. 82.10). With the cannula directed toward the radial head, maintain contact with the anterior humerus, which protects the median nerve and the brachial artery (Fig. 82.11).

Figure 82.10. Medial view of the left elbow. The proximal medial portal is used in the prone position.

Figure 82.11. Arthroscopic view of the ulna (u) and humerus (h) in anterior compartment from the anterolateral portal.

ARTHROSCOPIC ANATOMY AND OPERATIVE TECHNIQUE

After identifying the bony landmarks, inflate the tourniquet. Insert an 18-gauge needle into the soft spot, in the area of the direct lateral portal, aimed directly at the center of the joint. Then distend the elbow with approximately 30 to 40 ml of fluid, using intravenous tubing and a 50-ml syringe. The IV tubing allows for an easier injection. Confirm entry into the joint by the visible distention of the joint and the free backflow of fluid from the needle. Leave this needle in place with pressure applied to the syringe to distend the joint. Maximal distention of the joint displaces the antecubital neurovascular structures into a more anterior position, providing a safety margin.

Place a second spinal needle for the anterolateral portal. The angle of this needle is then used as a guide for directing the cannula into the joint. Incise the skin only with a #11 blade; do not penetrate deeper to avoid damage to subcutaneous nerves. Use a straight hemostat to spread the tissues to the level of the joint capsule. Enter the joint with a blunt trocar. Because the capsule is trapped between the radial head and the capitellum, a change in angle is required toward the center of the joint once the trocar has passed over the radial head. Otherwise, the trocar has a tendency to track across the joint and enter in a more medial position, which makes visualization difficult. Direct the blunt trocar down toward the humerus. Palpate the medial epicondyle as the cannula is introduced; it stabilizes the arm and also serves as a point of reference. Once the cannula is in the joint, insert the arthroscope into the sheath without the fluid flowing in order to confirm an intrarticular location.

With the arthroscope in the anterolateral portal, visualize the coronoid, humerus, and a portion of the radial head (Fig. 82.11). With extension of the elbow, the view of the trochlea of the humerus is improved. Take care not to pull the arthroscope out of the joint when attempting visualization of the radial head. Once a portal is established, leave a cannula in the portal to prevent extravasation of fluid.

Then establish the anteromedial portal under direct arthroscopic visualization. This method is preferred to the use of an inside-out switching stick, as it allows for better control in placing the portal. Insert an 18-gauge spinal needle at a point 2 cm distal and 2 cm anterior to the medial epicondyle. When it is inside the joint, bring the needle over the humerus just above the articulation between the coronoid process and the humerus. Use the needle to test the optimal angle for the shaver. The portal needs to be made anterior enough to allow the shaver to be brought down onto the humerus if any debridement or anterior capsular release is anticipated. Make this portal in the same fashion as the anterolateral portal, with an incision in only the skin layer, and blunt dissection to the level of the joint capsule. Insert the cannula into the joint under direct visualization. With the arthroscope in the anteromedial portal, it is easy to visualize the radial head and capitellum (Fig. 82.12). Pronation and supination of the forearm provides additional visualization of the radial head. The coronoid process can also be seen if the scope is carefully withdrawn from the joint. The ulnar-radial articulation can be inspected through this portal. Small loose bodies are often found in this location. The anteromedial portal is critical for viewing the radial head, as visualization of the radial head from the anterolateral portal is very poor.

Figure 82.12. Arthroscopic view of the radial head (r) and the capitellum (c) from the anteromedial portal.

Next establish a direct lateral, or “soft spot” portal. Use a #11 blade to incise the capsule. Make the initial portal just off the center of the soft spot to help establish a second working portal in the lateral compartment. Use a straight hemostat in the portal to spread the capsule. Place a blunt trocar into the portal and direct it toward bone. Once bone is contacted, change the direction of the cannula to parallel the lateral capsule, which points the cannula toward the ceiling. This
The technique allows the edge of the cannula to enter the joint, so that when the trochar is withdrawn, the cannula will remain inside the capsule. The lateral compartment is tight, and the small 2.7-mm arthroscope may be helpful. Through the straight lateral portal, the radial head, capitellum, articular surfaces of both the trochlea and olecranon, and the ulna are visualized. The landmark of the lateral compartment is the articulation of the "three bones" (Fig. 82.13).

![Image](102x1208 to 302x1349)

**Figure 82.13.** Arthroscopic view of the lateral compartment including the capitellum (c), radial head (r), and ulna (u), as seen from the straight lateral, or soft spot, portal.

- Then establish a working portal in the lateral compartment. Introduce a spinal needle. Arthrofibrosis in a joint can be difficult to visualize. It is possible at times to place the shaver in the portal and then look for the movement in the synovium. Take care to avoid scuffing the cartilage. Once the shaver is visualized, place it slightly ahead of the arthroscope. The arthroscope can then follow the shaver down the olecranon curve to enter the posterior compartment. If the shaver is not useful to clear the synovium in this area, it can be difficult to follow the curve of the ulna into the posterior compartment.

- Once the arthroscope is at the tip of the olecranon in the posterior direction from the direct lateral portal, introduce an 18-gauge spinal needle through the posterolateral portal. With supine arthroscopy, the needle is directed almost toward the ceiling. After it is correctly positioned, use a #11 blade to make the portal, entering the capsule while visualizing the blade with the arthroscope. Use a hemostat to spread the capsule, and introduce the cannula into the portal site. The olecranon tip, the posterior olecranon fossa, and the posterior trochlea are visualized from this portal. Loose bodies are frequently encountered posteriorly in the olecranon fossa. The posteromedial olecranon osteophyte is seen, as well as chondral defects posteriorly.

- If a second operative portal is required posteriorly, make a direct posterior portal under direct visualization. Place an 18-gauge spinal needle at the level of the tip of the olecranon and pass it straight through the triceps, in the middle portion of the tendon. The needle can be used to confirm that the areas the shaver needs to reach will be accessible through this portal. Insert a #11 blade in line with the fibers of the triceps tendon. The posterior capsule can be difficult to enter, especially if there is a thickened olecranon bursa. Use a hemostat to expand the portal site. Once the portal is established, loose bodies can be removed, and debridement of posterior olecranon osteophytes can be performed as well as synovectomy of the posterior compartment. The ulnar nerve rests against the posteromedial capsule; exercise great care when shaving in the posteromedial area. Keep the back side of the shaver away from this capsule, never allowing the mouth of the shaver to work against the capsule.

**SURGICAL TREATMENT OF SPECIFIC LESIONS**

**Loose Bodies**

Removal of loose bodies from the elbow is one of the most common arthroscopic procedures. Osteocartilaginous bodies are usually the result of osteochondritic lesions of the capitellum, osteochondral fractures of the radial head, and synovial diseases, such as synovial chondromatosis. The patient usually complains of catching and locking in the elbow, and a joint effusion may develop after a painful episode. Radiographs, CT-arthrograms, and MRI all may be negative preoperatively. The procedure is usually undertaken more on the basis of clinical findings than the results of imaging studies. It is important to obtain consent for a possible arthrotomy, as it may not be possible to remove the fragment arthroscopically.

A complete inspection of the elbow joint is necessary when searching for loose bodies, as defects from the anterior and lateral compartments can frequently lodge in the posterior compartment. The loose body may be drawn into view by using the shaver with full suction. If one loose body is encountered, make a careful search for others. In the anterior compartment, loose bodies are more easily removed through the lateral portal. If a large piece is too big to pull through the portal, it can be removed in piecemeal fashion. The Schlossinger grasper is useful for breaking a loose body into pieces, or a shaver can be used to break up the large fragment.

After removing loose bodies from the elbow, inform the patient that other loose bodies may have been left behind in the joint and, in addition, that new loose bodies may form (28). This is often the case in the throwing athlete, who continues to subject the joint to repetitive microtrauma. Once the portals are healed, start the patient on range-of-motion exercises and a strengthening program. Most athletes are ready to start throwing at 6 to 8 weeks after surgery. Several studies have shown the benefits of removal of loose bodies from the elbow, especially in the joint free of degenerative changes (5,8,17,18).

**Osteochondritis Dissecans**

During the throwing motion, the valgus moment of the forearm in the elbow results in compression of the lateral joint. In the skeletally immature, osteochondritis dissecans can result, which is usually seen in throwing athletes or gymnasts (4,10,21). The patient usually has a flexion contracture, locking episodes caused by loose bodies, and pain, with decreased ability to participate in sports. At arthroscopy, visualize the lateral joint from the anteromedial portal initially. The best visualization of the typical osteochondritis lesion, however, is from the soft spot, or straight lateral portal. Once the synovial tissue is debrided, locate the chondral defect. It is usually soft, and there may be a large flap of cartilage. A small (3.5 mm) shaver is useful both to probe and to debride the lesion. Use forceps or a small knife to debride the crater, and once the cartilage flaps are removed, use awls to microfracture the subchondral bone in an attempt to heal the area with fibrocartilage. Braungaraten et al. advise against attempting to reattach the fragment (4). After debridement, younger athletes are usually able to return to full activity, but older patients have less successful results (4,19,21).

**Posterior Impingement**

In the throwing athlete, one of the most common causes of elbow pain is the formation of a posteromedial osteophyte on the olecranon, resulting in impingement and chondromalacia on the trochlea (1). The forces of throwing place a valgus force across the medial elbow, and with ball release a forced extension occurs. The combination of this valgus and extension force is referred to as "valgus extension overload syndrome" (22,29). In 72 professional baseball players requiring arthroscopy, 65% had posteromedial olecranon osteophytes requiring debridement, which was the most commonly performed procedure (3).

Patients usually complain of posteromedial joint pain during the throwing motion, especially after ball release. Physical examination typically reveals slight loss of full extension, and valgus and extension loading cause pain. Ulnar nerve symptoms may also be present. Assess the stability of the ulnar collateral ligament. Medial instability increases the valgus force across the elbow, and osteophytes may form in response to medial laxity. Routine radiographs are often normal. The osteophyte may be seen on an axial view (1) or on MRI. The diagnosis is usually based on the clinical history and the findings on physical examination.

Treatment is debridement of the osteophyte, which is best visualized on arthroscopy. Chondral defects on the posterior trochlea can be very difficult to see without the arthroscope.

- Position the patient supine and place the arthroscope in the posterolateral portal with the elbow in approximately 30° of flexion. Use a cannula in this portal because fluid extravasation can make it difficult to find the portal again. Make a second working portal and bring a shaver in through this portal.

- Initially debride the synovitis posteriorly in order to improve visualization. Then use a burr or shaver to debride the posterior olecranon osteophyte (Fig. 82.14). It is important to completely remove the posteromedial corner of the osteophyte, but the ulnar nerve is very close to this location; take care to keep the open side of the shaver away from the nerve.

- Initially debride the synovitis posteriorly in order to improve visualization. Then use a burr or shaver to debride the posterior olecranon osteophyte (Fig. 82.14). It is important to completely remove the posteromedial corner of the osteophyte, but the ulnar nerve is very close to this location; take care to keep the open side of the shaver away from the nerve.

It is important to completely remove the posteromedial corner of the osteophyte, but the ulnar nerve is very close to this location; take care to keep the open side of the shaver away from the nerve.
Figure 82.14. A: A diagram of debridement of a posteromedial olecranon osteophyte. The camera is in the posterolateral portal, with the burr in the straight posterior portal. B: Arthroscopic view of the posterior compartment with olecranon osteophyte (o) and humerus (h). C: Arthroscopic view after debridement of the olecranon osteophyte.

- The question is how much of the osteophyte should be removed. When this operation was initially developed (1), a relatively generous excision of the osteophyte was recommended. In more recent years, however, less aggressive excision has been adopted because excessive debridement increases the stress on the ulnar collateral ligament. Typically 4 to 5 mm is removed, or enough to debride the loose fragments and prevent further impingement. If there is a chondral defect on the trochlea, use a burr to debride the lesion to stimulate bleeding and fibrocartilage formation.
- Once the portals are healed, start range-of-motion exercises, followed by a strengthening program. Athletes are usually able to return to an early throwing program by 6 to 8 weeks after surgery, but it may take 4 to 6 months for complete recovery.

In professional baseball players (3), there is a high rate of reoperation because of recurrence of the posteromedial osteophyte. In addition, 25% of the athletes who initially had debridement of the posterior osteophyte required an ulnar collateral ligament reconstruction. It is important to carefully assess the integrity of the ulnar collateral ligament in the presence of a posterior osteophyte. In athletes who continue to throw, this procedure is palliative and does not solve the underlying problem of overstress.

**Instability**

During the throwing motion, the medial soft tissues are subject to large forces. The anterior bundle of the ulnar collateral ligament is the primary stabilizer against valgus stress (9, 13, 23). Injuries to this ligament are usually the result of repetitive microtrauma (27); less commonly, sudden severe trauma can result in an acute tear. Maximum valgus instability occurs at 70° of elbow flexion (23) after sectioning of the anterior bundle of the ulnar collateral ligament (UCL). This instability can be difficult to detect clinically. It may be that the high forces of throwing are required to cause the painful symptoms.

The UCL is difficult to visualize arthroscopically (28). Only the anterior 20% to 30% of the anterior bundle and the posterior 30% to 50% of the posterior bundle are visualized, using both anterior and posterior portals (Fig. 82.15). A complete tear of the anterior bundle of the UCL can be missed during arthroscopy. With a ligament injury, however, laxity will result that can then be visualized arthroscopically (27).

Figure 82.15. The portion of the ulnar collateral ligament that is visible arthroscopically. (From Timmerman LA, Andrews JR. The histologic and arthroscopic anatomy of the ulnar collateral ligament of the elbow. Am J Sports Med 1994;22(5):667.)

From the anterolateral portal, the first structures visualized are the coronoid process and the trochlea. With the humerus stabilized, apply a valgus force to the forearm and assess the resulting opening between the humerus and olecranon (Fig. 82.16; see also Color Fig. 82.16). Normally there is no, or minimal (less than 1 mm), opening in the ulnohumeral joint. With injury to the UCL an increase in opening is seen, and with a complete large tear the arthroscope itself may be placed between the ulna and humerus. Reconstruction of the UCL may be indicated when the typical history and physical findings are present, a course of conservative treatment fails, and increased valgus opening of the joint is seen on arthroscopy.

Figure 82.16. (See Color Fig. 82.16) A: An arthroscopic view from the anterolateral portal in a right elbow of the humerus (h) and the ulna (u). B: With valgus stress applied, the increase in space between the ulna and the humerus is seen.

In posterolateral instability, as described previously (16), the forearm bones subluxate as a unit on the humerus in a pivot-shift fashion. A stress examination at the time of arthroscopy is useful to see this abnormal intraarticular movement (Fig. 82.17; see also Color Fig. 82.17).
Degenerative Arthritis

Degenerative arthritis of the elbow is not common, and it is usually the result of previous trauma or longstanding overuse. Typical complaints are of pain, loss of motion, and catching and locking. Radiographs usually demonstrate degenerative changes, including loss of joint spaces and formation of osteophytes. Large coronoid osteophytes can impinge anteriorly, preventing flexion, and posterior olecranon osteophytes can impinge and prevent extension. Loose bodies can cause locking or can block motion.

The procedure for debridement of degeneration of the elbow joint is similar to that described for arthrofibrosis. More bony work is usually required with degenerative arthritis, with emphasis on removing the osteophytes that impinge. A small ¼-in. osteotome is often useful, it can be introduced through the portal to remove large pieces of bone. A burr that fits the canalula may be preferred to prevent loss of the portal site. The associated synovitis and capsular contractures can also be debrided. Caution the patient preoperatively that the procedure is palliative and that symptoms may recur.

Synovitis

Synovitis is seen frequently with inflammatory disorders of the elbow (Fig. 82.19; see also Color Fig. 82.19). Treat rheumatoid arthritis involving the elbow arthroscopically; it may be easier to enter the joint in these cases, as the capsule tends to be lax and enlarged. Perform the synovectomy using the usual portals. Occasionally a synovial band will thicken in the elbow, creating symptoms of popping and catching (7), which are usually seen laterally and are referred to as a lateral band or plica. This thickening can result in impingement on the radial-capitellar joint, resulting in persistent lateral elbow pain. Its symptoms can be confused with those of lateral epicondylitis. The lesion can be visualized and debrided arthroscopically. Take care not to excessively debride the lateral capsule, including the annular and lateral collateral ligaments, to prevent destabilizing the joint.
GENERAL REHABILITATION AND POSTOPERATIVE PRINCIPLES

After arthroscopy is completed, close the portals with suture, using a nylon in the skin or a subcutaneous absorbable suture. It can be difficult to apply Steri-Strips, as extensive soft-tissue swelling is often present. Injection of the joint with morphine helps postoperative pain. It is preferable not to inject a local anesthetic until after a neurologic examination can be completed in the recovery room; the agent can extravasate from the joint and produce a nerve palsy.

Place a bulky soft dressing with an ice pack. The compression ice dressings designed for the knee work well on the elbow, with the olecranon placed in the same area as the patella. If the patient is excessively uncomfortable in the recovery room, use an axillary block before discharge. A short course of antibiotics may be desirable if significant postoperative debridement was performed, as the posterior triceps portal can sometimes drain excessively.

Instruct the patient to start with gentle grip exercises immediately and to work on gentle range of motion with the soft dressing in place. Increase motion as tolerated, with emphasis on maintaining extension and flexion. Once inflammation and swelling have subsided, initiate strengthening exercises. Initially use 1-lb weights, increasing gradually to a 5-lb weight; subsequently increase repetitions rather than increasing the weight.

PITFALLS AND COMPLICATIONS

It is at times difficult to gain access to the joint, but familiarly with the procedure and careful patient selection improve the surgeon’s ability.

Infection and neurovascular injury are complications common to all surgical procedures. They do not appear to occur at an increased rate in elbow arthroscopy. Occasionally persistent draining from a portal occurs, usually the posterior portal. Considerable soft-tissue swelling occurs posteriorly when both posterior portals are used, and the fluid can collect in the olecranon bursa. Treat this condition with immobilization and oral antibiotics.

Neurovascular damage has been reported (19-24), including injury to the posterior interosseous nerve with an anterolateral portal (24).

With excessive fluid extravasation, a forearm compartment syndrome can occur. Once the use of the portal is completed, insert a blunt trocar into the portal to prevent fluid from leaking out. Placement of the trocar also allows return to these portal sites later if needed.

With the supine position, severe fogging of the arthroscope will occur unless a coupled videoarthroscope is used.

AUTHOR’S PERSPECTIVE

I prefer to position the patient supine because I am familiar with use of this position. I find it easier to work in the anterior compartment with the patient supine, and it is not different to do posterior debridement and inspection of the radiocapitellar articulator in the supine position. If I plan an open procedure, I use the supine position to avoid having to reposition the patient.

Compared with the knee, ankle, shoulder, and wrist, the elbow is the most difficult joint to arthroscope, but skills improve considerably with experience. Among the most satisfied patients I have treated are those with arthrofibrosis of the elbow. They report improvement of both pain and function (25). A close second in patient satisfaction—although the procedure is less common—is the group of adolescents treated by debridement of osteochondritis dissecans. These patients typically regain range of motion quickly and are throwing at approximately 3 months. Removal of a loose body is the easiest operative procedure to perform, although an isolated loose body is not often present without another associated disorder, such as a posteromedial osteophyte or arthrofibrosis. The most difficult procedures to perform are debridement of extensive arthrofibrosis and debridement of a posteromedial olecranon osteophyte.

Elbow arthroscopy is becoming more common now and is probably the treatment of choice for several disorders discussed above. The major advantages of improved visualization and more rapid rehabilitation are tempered by the difficulty of the procedure and the remote risk of significant neurologic damage. Meticulous technique as outlined above gives the best assurance of a satisfactory outcome.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

The knee joint is the largest and probably the most complex joint within the human body. Its position between the two longest lever arms of the skeleton makes it vulnerable to injury by the tremendous moments that can be transmitted to it from loads applied at great distance to the ligaments and capsular structures that provide the structural integrity of the joint. Thus, it is not surprising that the knee joint is one of the most frequently injured joints. Because of its vital importance in support and locomotion of our bipedal existence, damage to its major components results in much discomfort and disability. An understanding of fundamental anatomy and biomechanics provides the basis for appropriate treatment of injury and disease processes involving the knee.

ANATOMY AND KINETICS AND FEMORAL–TIBIAL ARTICULATIONS

The knee joint does not conform to any of the standard classifications of joints because it has some features of a ginglymus or hinge joint and some of an arthrodial joint, which by definition allows only gliding movement along opposing plane surfaces. The knee consists of three more or less independent articulations: one between each sphere-like condyle of the femur and a corresponding but more planar condylar surface of the tibia, with interposed menisci, and a third between the patella and the patellar or trochlear groove of the femur. None of the pairs of bearing surfaces is exactly congruent, which results in a combination of rolling and gliding motions determined by the restraints of a complex network of ligaments, capsular structures, and the contours of the bones themselves. This intricate arrangement of anatomic interrelationships allows the knee six degrees of freedom of motion: three rotations and three translations. The translations are anteroposterior (5 to 10 mm), compression–distraction (2 to 5 mm), and mediolateral (1 to 2 mm). These motions are limited by the ligaments, capsule, and to some degree the intracondylar eminences of the tibia and are of small magnitude in the normal knee. The rotations are flexion–extension, varus–valgus, and internal–external rotation, and in general they are much more extensive than the translations. Normal flexion and extension of the knee is variable, ranging from 0° to 15° of hyperextension to 130° to 150° of flexion. Internal and external rotation ranges from little or no motion in full extension to 20° to 30° with the knee flexed. Tightening of the capsular and ligamentous structures, which is greatest in full extension, accounts for this variation. The mean values for rotations during level walking, as determined by Kettelkamp et al. using an electrogoniometer, provide insight into the complexity of motion during function of the knee (Table 83.1) (46).

A reproducible pattern of all of these motions exists during gait for each person, with minor variations observed between individuals. They found that none of the knees tested extended fully during normal walking but extended slightly farther than in resting stance just before or at heel strike. The most common motion pattern observed revealed that maximum extension and external rotation occurred just before heel strike; maximum abduction occurred at heel strike, and maximum adduction during swing phase; and flexion and internal rotation, which began just before heel strike, continued to increase between heel strike and foot flat (Fig. 83.1). Similar patterns were observed by Marans et al., who used a more sophisticated electrogoniometric system (54). They measured not only the rotational degrees of freedom (flexion–extension, varus–valgus, and internal–external rotation) but also the translational degrees of freedom (anteroposterior, mediolateral, and superior–inferior). Only with evaluation of anteroposterior translation measurements during level walking were they able to distinguish between a group of normal knees and a group that were anterior-cruciate deficient. The knees with no anterior cruciate ligament (ACL) demonstrated greater anterior translation of the tibia relative to the femur during the swing phase of gait but not during the stance phase.

Figure 83.1. Electrogoniometric patterns of knee motion of a normal knee. The 0° line represents the position in neutral stance (H.S., heel strike; F.F., foot flat; H.O., heel off; T.O., toe off). (From Kettelkamp DB, Johnson RJ, Smidt GL, et al. An Electrogoniometric Study of Knee Motion in Normal Gait. J Bone Joint Surg 1970;52-A:775.)
The axes of the rotations of the knee are not fixed in a single plane; thus, combinations of rotations and translations (coupled motions) are seen through the normal range of motion. The flexion-extension axis provides the most obvious example. This axis varies because the radii of the lateral and medial femoral condyles are dissimilar, and the patellar plateau topography varies from side to side as well. Viewed from the side, the medial femoral condyle has a more constant radius of curvature than does the lateral. Posteriorly, both condyles have similar radii, but anteriorly the lateral condyle rapidly attains a longer radius and appears to flatten out to a greater degree than the medial condyle. Often, near the midpoint of the lateral condyle, a lateral groove passing diagonally, anteriorly, and laterally from the anterior aspect of the intracondylar notch produces a distinct indentation. This differentiates the lateral from the medial condyle as observed on a lateral roentgenogram. This lateral groove demarcates the extent of the articular surface of the femur, which articulates with the tibia (Fig. 83.2) (43). All articular surfaces anterior to this area contact only the patella. As viewed from its distal end, the medial femoral condyle extends anteriorly and inclines toward the lateral side, so it is somewhat longer than the lateral condyle. A small V-shaped indentation (medial groove) delineates the anterior extremity of the articular surface of the medial condyle that contacts the tibia (Fig. 83.2). This medial groove is well forward of its counterpart on the lateral femoral condyle and is probably often mistaken to be a pathologic process caused by a hypertrrophic medical plica. It is, in fact, the area where the anterior horn of the medial meniscus abuts the femur when the knee is fully extended.

![Figure 83.2](image)

**Figure 83.2.** Distal end of femur showing lateral (A) and medial (B) grooves in the articular surfaces of the medial and lateral femoral condyles and the patellar or trochlear surface (C) and intercondylar fossa or notch (D). (From Jackson JP. Surgery of the Knee Joint. In: Jackson JP, Waugh W, eds. Surgical Anatomy. Philadelphia: JB Lippincott, 1984:5.)

The patellar plateau possesses two articular facets. The medial is a good deal longer in the sagittal plane than the lateral. Both facets appear to be slightly concave in the coronal plane, but the lateral facet demonstrates a convexity in the sagittal plane, producing a saddle shape (44,56,60). Thus, in the lateral compartment of the knee, the rounded femoral condyle rests on a convex surface of the tibia, which contributes to the complexity of stabilization of this joint. This stabilization is controlled by the interposed meniscus, the surrounding capsular and ligamentous structures, and the muscles crossing the knee joint.

In part because of the asymmetry of the contact areas of the tibia on the two femoral condyles, the tibia is obligated to externally rotate significantly during the last few degrees of full extension as the tibia rolls farther forward on the medial femoral condyle than on the lateral condyle. This screw home mechanism is also guided by the alignment and tension in the ligaments and capsular structures. In the fully extended position of the knee, the majority of the ligaments and capsular structures are under tension, thus allowing no further extension or external rotation. With active or passive flexion from full extension, the rotation process is reversed, with the tibia internally rotating relative to the femur during the first 10° to 20°. The motion of the femur relative to the tibial plateau during flexion is initially a pure rolling motion, but by 10° to 15° on the medial tibial and by 20° on the lateral side, sliding of the femur begins relative to the tibia and becomes progressively more important until flexion is complete (Fig. 83.3) (43). Thus, the contact area between the tibia and femur moves rapidly backward during the first 10° to 20° of flexion and then gradually progresses posteriorly to eventually ride entirely on the posterior horns of both menisci at the extreme of flexion. Because the lateral condyle rolls more than the medial over the corresponding tibial plateau, another manifestation of the screw home mechanism is explained. Kapandji observed that the 15° to 20° of initial rolling corresponds to normal range of movements required in flexion and extension during the stance phase of ordinary walking (43).

![Figure 83.3](image)

**Figure 83.3.** Medial (A) and lateral (B) compartments of the knee demonstrating the amount of rolling and sliding of the femoral and tibial surfaces occurring during flexion. Starting from full extension, the femoral condyles roll without sliding. Sliding movement then becomes progressively more important, so that by the end of flexion, the condyles slide without rolling. For the medial condyle, pure rolling occurs only during the first 10° to 15° of flexion. For the lateral condyle, the rolling continues until 20° of flexion. (From Kapandji A. The Physiology of the Joints, Vol. 2. Lower Limb. Edinburgh: Churchill Livingstone, 1970.)

**PATELLOFEMORAL ARTICULATION**

The patellofemoral articulation provides an isolated articular surface for the control of the extensor mechanism of the knee as it glides over the anterior aspect of the joint. The extensor mechanism stabilizes the joint against gravity when the knee is flexed and assists in the forward propulsion of the mass of the body as the knee extends during gait. The patella contacts the patellar or trochlear surface of the femur during these activities (Fig. 83.2). Anteriorly, the condyles of the distal femur are separated from one another by this shallow articular depression, which averages 5 to 6 mm in depth. Inferiorly and posteriorly, the trochlear surface is continuous with the intercondylar fossa or notch (Fig. 83.2). The lateral wall of the trochlear surface of the femur is more prominent than the medial and projects farther anteriorly. The patella has a multifaceted dorsal surface, which articulates with the trochlear groove. A median ridge divides the patella into two large facets. Most frequently, the lateral facet demonstrates a convexity in the sagittal plane, producing a saddle shape (Fig. 83.2) (43). The range of motion. The patellar tendon (A) is supported by the force (W) generated within the quadriceps mechanism. Figure 83.4 presents a static representation of this in simplified terms. On the left diagram, the superincumbent mass (W) of the body is supported by the force (M) generated within the quadriceps. The line from the center of mass from the body falls well behind the flexion axis of the knee. The moment arm (c) in this situation is relatively small, and thus the quadriceps force (M) and the PFJR force (R) are relatively small. When the figure depicted flexes further (right diagram), decreasing the angle (b), the moment arm (c) increases. To allow this system to remain static, the new force (M') generated within the quadriceps must significantly increase, which in turn increases the PFJR force (R'). The PFJR force estimated...
for various activities is presented in Table 83.2.

**Figure 83.4.** Static representation of the patellofemoral joint reaction forces ($R$ and $R'$) at two positions of flexion (see text).

Table 83.2. Patellofemoral Joint Reaction Force

The patellofemoral contact area in the normal knee increases in response to the increased loads that develop as the knee flexion angle ($\theta$) decreases during most activities (Fig. 83.5) (40). For this reason, stress (force per area) increases less rapidly than the total force across the patellofemoral joint. However, if a weight is applied to the ankle, as in most weight-training programs, and the knee is extended against gravity plus the additional weight, the opposite effect is noted. In this situation, the area of contact decreases as the PFJR force increases. Thus, the PFJR stress becomes excessively high even for light weights applied at the ankle, as depicted in Figure 83.6 (76). For this reason, isometric or isokinetic exercises through a full range of motion are not advised in the treatment of patellar pain syndromes. Quadriceps exercises that extend the knee through only the last 15° to 20° of extension are much more likely to be tolerated, as can be seen in Figure 83.6. Abnormal tracking of the patella, which allows lateral subluxation of only a few millimeters, confounds this principle. Under these circumstances, the larger load is borne on a relatively small contact area, greatly increasing the local stress (Fig. 83.7) (63). This undoubtedly contributes in many instances to the production of patellofemoral pain and, if severe, degeneration of patellar articular cartilage (chondromalacia). Many anatomic conditions can and do contribute to this common problem. These include hypoplasia of the trochlear groove, abnormal patellar articular configuration, underdevelopment of the vastus medialis, rotational malalignment of the proximal tibia relative to the distal femur, and an abnormally high valgus angle of the distal quadriceps mechanism (Q angle).

**Figure 83.6.** Patellofemoral joint reaction force (PFJR) produced during extension of the knee from 90° of flexion to 0° while lifting a 0.9-kg weight. (After Reilly DT, Martens M. Experimental Analysis of the Quadriceps Muscle Force and Patellofemoral Joint Reaction Force for Various Activities. Acta Orthop Scand 1972;43:126.)

**Figure 83.7.** Quadriceps muscle force and patellofemoral joint reaction force during eccentric knee extension with a 3-kg weight.
The patella also increases the distance of the quadriceps muscles from the axis of knee flexion. In so doing, it decreases the force (M) that is necessary to maintain static equilibrium, as depicted in Figure 83.4. Kaufel has shown that patellectomy decreases this effective moment arm by 31% at 0° flexion, 22% at 30°, 13% at 60°, 12% at 90°, and 10% at 120° (45). Maquet has shown that by increasing the quadriceps mechanism's moment arm, a 2-cm elevation of the tibial tubercle produces a 50% reduction in the PPJR force when the knee is flexed 45° (62-53). Thus, patellectomy is not advised, and tibial tubercle elevation procedures are effective in the treatment of patellar pain syndromes.

Hubert et al. simulated the squatting activity in human cadaveric specimens while measuring quadriceps force with a tensile load sensor and patella tendon force with an ultrasonic transducer. They demonstrated that for knee flexion between 0° and 45°, the force developed in the patellar tendon was greater than that in the quadriceps mechanism. With continued knee flexion to 120°, the patellar tendon force was consistently less in comparison to the quadriceps force. The authors suggested that the patella not only functions as a pulley that changes the magnitude and direction of forces in the quadriceps and patellar tendon but, in addition, has two distinct mechanical functions. In the first, more classically described function, the anteroposterior (AP) thickness of the patella can be attributed to increasing the effective moment arm of the quadriceps muscles and patellar tendon, whereas in the second, the patella acts as a lever. Therefore, the parameters that define the proximal and distal lever arms of the patella have a direct effect on the balance of forces in the quadriceps and patellar tendon. The authors reasoned that these parameters were the length of the patella, the location of the patellar femoral contact area, and the angle between the quadriceps and patellar tendon.

THE MENISCI

BIOMECHANICAL FUNCTION

The fibrocartilaginous C-shaped menisci that are interposed between the tibia and femur were long thought to be vestigial devices that had no significant function. Fairbank, in 1948, proposed that the menisci serve a load-transmission function and suggested that the joint space narrowing, osteophyte formation, and flattening of the femoral condyles frequently observed following meniscectomy most likely resulted from the loss of this function (24). Several investigators in the late 1960s (35,87) and early 1970s (42) reported less than satisfactory results in long-term follow-up investigations in a high proportion of patients undergoing meniscectomy, thus adding credence to Fairbank's observations (24). It was not until the mid-1970s that several reports confirmed the load transmission function of the menisci (48,81,53,90).

Although some variation was reported, these investigations all estimated that 30% to 60% of the load transmitted across the joint passes through the menisci during weight-bearing activities. In 1979, Seedhom and Hargreaves reported that 70% to 99% of the total load acting on an intact joint is passed through normal menisci and that all of the load is transmitted through the posterior horns of the menisci if the joint is flexed beyond 75° (82). In several of these investigations, it was clearly shown that the ability of the joint to transmit a load was significantly reduced by removal of all or part of the menisci and that these structures assist in reducing stress across the joint (64,48,62,82,90). Seedhom and Hargreaves also showed that removal of part of the meniscus reduced the weight-transmitting function less than removing the entire structure as long as the circumferential continuity of the meniscus remains intact (82). Thus, the rationale for partial meniscectomy, made possible by arthroscopic techniques, was at least partially verified.

The ability of meniscus to heal following operative repair has been well documented (23,29,77,79). However, it is probably too early to be certain that normal meniscal function is restored by these procedures in humans. Recent studies in animals suggested that the repair of peripheral longitudinal lesions produced compressive force displacement behavior indistinguishable from normal (6,61). However, repairs of radial tears are less successful in restoring normal biomechanics (61).

Meniscal allografts are being used to replace native menisci destroyed by trauma or removed surgically. Early follow-up studies with small numbers of cases suggest that meniscal function may be restored, but no evidence confirms that normal biomechanical behavior is established or that transplanted menisci are capable of protecting articular cartilage (15,49,91). In a human cadaver study, size-matched meniscal allografts resulted in improved load transition profiles compared to the meniscectomized state, but only by 55% to 65% (71). Further clinical animal and cadaveric studies are necessary to prove the efficacy of meniscal allografts.

The menisci also contribute to the stability of the knee. However, Markoff et al. (55) observed that although removal of meniscus made the unloaded knee more lax, stability of the loaded knee was little affected. In unloaded human cadaver knees at 25° of flexion, Wang and Walker (53) evaluated the effect of rotatory laxity before and after removal of the menisci. They defined two types of rotatory laxity: primary and secondary. The former occurred at torques up to 0.5 nm and represented the looseness of the joint before significant resistance was encountered. The latter occurred at torques between 0.5 and 5 nm and represented significant resistance before plastic failure of soft-tissue structures. In their study this failure occurred at approximately 12.5 nm. Under such loads the ligaments were stretched but not totally disrupted, and, as might be expected, they found greater rotational instability after such ligamentous failure. They determined primary and secondary rotatory laxity of eight human knees before and after removal of both menisci. A 14% increase in primary rotatory laxity and a 2% increase in secondary laxity were observed. Although they thought that the increase in secondary laxity was not significant, they concluded that the menisci serve to restrict primary rotatory laxity, perhaps by acting as space-filling buffers.

Several investigators have found that meniscectomy had little effect on laxity in the anteroposterior plane in the otherwise intact knee (7,36,51). However, when the cruciate ligaments were severed, and these same anteroposterior loads were repeated before and after removal of the menisci, there were large differences in the anteroposterior stability. The investigators concluded that the menisci apparently play an important role in preventing this instability when cruciate function has been lost. This may account for the frequent development of a torn meniscus after apparently isolated disruption of the ACL.

Many other functions have been attributed to the menisci, including shock absorption, increasing joint congruity, assisting with lubrication, preventing synovial impingement, and limiting extremes of flexion and extension. However, these functions are difficult to prove.

MENISCAL ANATOMY

The meniscus is somewhat more C-shaped than the circular lateral meniscus (Fig. 83.6). This is because the posterior and anterior horns of the lateral meniscus attach to the nonarticular area of the tibial plateau, whereas those of the medial meniscus are well off the plateau. The anterior horn of the medial meniscus attaches well forward on the anterior surface of the proximal tibia, and the posterior horn is fixed within the groove on the posterior tibial surface just above the posterior cruciate attachment. The anterior horn of the lateral meniscus blends into the attachment of the anterior cruciate; the posterior horn attaches just behind the intercondylar eminence, often blending into the posterior aspect of the ACL.
Wrisberg's ligament passes posteriorly to the posterior cruciate, and Humphrey's ligament passes anteriorly. Usually only one of these structures is present, and they vary quite markedly in size.

The lateral meniscus is consistent in width throughout its course, whereas the medial meniscus is wide posteriorly and narrows significantly anteriorly. Both menisci are attached to the femur and tibia on their periphery by capsular sheets called meniscofemoral and meniscotibial ligaments. These attachments are continuous to the meniscus but are interrupted by the popliteus tendon as it passes between the lateral collateral ligament and the posterolateral aspect of the lateral meniscus (Fig. 83.9) (66). The posterior third of the lateral meniscus receives a strong insertion from the popliteus muscle into its posterior horn, which allows the meniscus to be pulled posteriorly as the knee flexes. The medial meniscus has no direct attachment from any of the muscles, but indirect capsular connections from the semimembranosus, at least in theory, may provide some ability to retract the posterior horn (69).

Collagen fibers within the menisci are primarily oriented in a circumferential fashion, thus resisting the loads applied to them from the femur. In this manner they are suitably aligned to resist elongation, much as hoops prevent the expansion of a barrel.

**SYNOVIAL CAVITY OF THE KNEE**

This largest joint cavity in the human body is lined by a smooth synovial surface that has a varying number of villous fronds and folds. Three of these folds are present consistently enough to have been given specific names (Fig. 83.10) (30). Most knees have a fold of synovium called the ligamentum mucosum or infrapatellar plica, extending from the midportion of the posterior surface of the infrapatellar fat pad to the apex of the intracondylar notch. If small, this structure is nothing more than a small fasciculus band, but if well developed, it forms a septum from the anterior cruciate to the fat pad and divides the knee into distinct medial and lateral compartments. A small artery often courses through it from the apex of the intercondylar notch to the fat pad. Thus, if it is ruptured, it may contribute to hemarthrosis.

The suprapatellar pouch usually extends to 5 to 7 cm above the superior pole of the patella. In the embryo, the true suprapatellar pouch is separated from the rest of the knee joint by a fold of synovium perpendicular to the long axis of the femur just above the superior pole of the patella. This septum usually becomes perforated, but a portion of it often remains as a partial septum. Its medial side is most likely to persist as a crescentic fold. On occasion only a small perforation occurs through its central portion, or more rarely it may remain intact into adult life. Inflammation and thickening of this structure may produce pain and crepitus.

The medial synovial plica (also termed the medial shelf, medipatellar plica, plica alaris elongata, medial interarticular band, or Lino's band) extends perpendicularly to the medial aspect of the suprapatellar plica to the medial superior aspect of the infrapatellar fat pad. It is present in 15% to 60% of normal knees. This variation in incidence probably results from interpretation of how much of a synovial fold has to be present before the investigator judges it to be identifiable as a specific entity. Much emphasis has been given to pathology observed in this structure since knee arthroscopy has become common. Thickening and inflammation of this structure to the point of producing symptoms is rare, and its frequent excision must be observed with skepticism. The biomechanical function of all the plica structures is probably of minimal importance because function of the knee does not seem to be disturbed in their absence.

**LIGAMENTS**

The ligaments of the knee function primarily to stabilize the joint by guiding and limiting motion; they are the most important static stabilizers. They consist of large, clearly identifiable structures, such as the collateral and cruciate ligaments, and less obvious capsular structures. Ligaments are a dense connective tissue primarily composed of collagen with lesser and varying amounts of elastin and reticulin fibers. Cellular elements, ground substance, vascular channels, and nerves also are present. Collagen fibers and their orientation within the tissue are responsible for the primary biomechanical behavior of each of these structures. The fibers of the large distinct ligaments are almost all arranged in parallel bundles, suiting them to withstand tensile loads, whereas capsular structures have a less consistent orientation, making them more flexible and not as strong in resisting uniaxial forces.

Although tendons and ligaments have many morphologic and histologic similarities, they also have many differences (1). Ligaments in general are more metabolically active than tendons, as demonstrated by increased plump cellular nuclei, higher DNA content, and more reducible cross-links and glycosaminoglycans. Collagen constitutes between 70% and 80% of the ligament's dry weight (25). The collagen within a normal ligament is more than 90% fibrillar type I with less than 10% type III (25). Minor variations in composition among the various ligaments of rabbit knees have been reported (1).

The insertion site of ligaments makes them able to distribute the stresses of loading at the bone–ligament interface in a gradual fashion, thus reducing the chance of failure. This is accomplished by collagen fibers passing from the ligament into the bone through four distinct zones: usual ligament morphology, a fibrocartilaginous matrix, mineralized fibrocartilage, and the bone itself (21). In spite of this transition, it has been shown in the anterior and posterior cruciates, the medial and lateral collateral ligaments, and the patellar tendon that some strain concentration occurs near the insertion sites (64).

The ability of a ligament to resist loading can best be understood by examining the load–elongation curve produced in the laboratory when bone–ligament–bone specimens are tested to failure (Fig. 83.11) (19). As load is applied, the ligament elongates. The stiffer the ligament, the steeper is the curve. In the resting position the ligament fibers are under minimal tension, and the collagen fibers within the ligament are wavy. As loading begins, little force is necessary to elongate the ligament, and thus, the curve is flat. During this phase the collagen fibers become aligned. The "toe" portion of the load deformation curve is variable in width, depending on the...
relative normal laxity of the particular ligament.

![Image](72x621 to 272x763)

**Figure 83.11.** Load–elongation curve of a bone–ligament–bone specimen tested to failure. A: Yield point. B: Maximum load. (After Cabaud HE. Biomechanics of the Anterior Cruciate Ligament. Clin Orthop 1983;172:26.)

As is well known from stress testing, ligamentous laxity varies widely from individual to individual. The transition from the toe to the linear portion of the curve represents the change in stiffness that an examiner perceives during a clinical stress test when the ligament's endpoint or “check rein” is reached. When all the collagen fibers are straightened, stiffness increases, and the curve becomes nearly linear. This portion of the curve is characterized by elastic deformation until near its upper end, at which point plastic failure begins. When the yield point is reached, the curve becomes irregular. After the maximum load is reached, the curve drops as the last few fibers are destroyed, and the curve returns almost straight down to baseline after all fibers fail.

Normal activities result in deformation along the linear portion of the curve approximately one fourth of the way to the yield point (64). The area under the load–deformation curve is equivalent to the amount of energy absorbed by the ligament during testing.

Variables such as age and strain rate dramatically affect the characteristics of the load–elongation curve. Young adults have a yield point as much as three times greater than older people, and people who have been immobilized for even short periods have greatly reduced ligament strength (63,69). The rate at which the ligament is loaded greatly affects its elongation behavior. Noyes et al. (65) demonstrated that human bone–ligament–bone ACL specimens that failed rapidly (0.6 seconds) show a 20% increase in load to failure over those that failed at a slower speed (60 seconds). In their experiments, the energy stored before failure was 30% greater in the group tested rapidly than in those that failed at the slower speed. At slow strain rates, avulsion of ligaments from bone is often seen, but at higher strain rates intrasubstance failures occur more frequently. Although both ligament and bone strength are favorably affected by increased strain rate, these observations suggest that this strain rate effect has a greater influence on bone than on ligament.

**MEDIAL SIDE OF THE KNEE**

The medial aspect of the knee can be divided into three layers of tissue (Fig. 83.12) (16,94). Within these layers are the muscles and tendons that pass by the joint as well as the medial collateral ligament, the deep medial ligament, and capsular structures. The superficial (first) layer is composed of the deep or crural fascia; the middle (second) layer is the medial collateral ligament, and the deep (third) layer is the capsule of the knee joint and the deep medial ligament. Only in an area roughly overlying the parallel fibers of the medial collateral ligament can all three layers be identified as separate entities.

![Image](72x1205 to 272x1346)

**Figure 83.12.** Transverse section through the distal femur. A: The retinacular fibers, which are the conjoined layers I and II. B: The conjoined layer-II and -III fibers posterior to the medial collateral ligament. (Redrawn from Warren LF, Marshall JL. The Supporting Structures of the Medial Side of the Knee. J Bone Joint Surg 1979;61-A:56.)

The first layer is defined by the fascia that invests the sartorius muscle and tendon. It extends from the patella to the fascia of the popliteal space. Anteriorly, it blends with fibers of the second layer along a line 1 to 2 cm in front of the anterior margin of the medial collateral ligament (Fig. 83.12). From this point to the patella, the two layers are blended in an indistinguishable sheet of tissue, which in part becomes the patellar retinaculum. Posterior to the parallel fibers of the medial collateral ligament, the fibers of the first layer are distinct from the underlying structures, and between them and the second layer pass the gracilis, semitendinosus, and semimembranosus tendons (Fig. 83.12). Anteriorly and distally, the first layer blends into the periosteum at the tibial attachment of the sartorius. Anteriorly, it blends into the fascia overlying the quadriceps, and inferiorly, it blends into the deep fascia of the leg.

The most prominent structure in the second layer is the medial collateral ligament, in which parallel fibers extend from the medial epicenter to blend with the periosteum along the medial border of the tibia beneath the pes anserinus tendons. Among the names assigned to this ligament are the tibial collateral, superficial medial collateral, and the internal lateral ligament. Probably the name most commonly used is the previously mentioned medial collateral ligament. The medial collateral ligament (parallel-fibered superficial portion) is the primary medial stabilizer of the knee, providing 57% to 78% of the restraining moment resisting valgus stress to the intact knee (28).

The parallel fibers of the medial collateral ligament in an average-sized knee are approximately 1.5 cm wide and 11 cm long. The femoral attachment of the parallel fibers is arranged around the varying flexion axis of the knee so that some portion of these fibers remains under tension throughout the range of knee motion. In full extension, the posteriormost fibers are taut, whereas in flexion, the more anterior fibers are under the greatest tension. Strain in the anterior fibers varies significantly during flexion (2). The fibers near the anterior border proximal to the joint were strained 4% above their normal resting length at full extension when the knee was passively flexed to 110°. At the joint line the anterior fibers strained 2%, and below the joint line only 1.5% during the same motion. Thus, a variable strain pattern is observed not only between the anterior and posterior portions of the superficial medial ligament but also along the course of the anterior or posterior fibers of this ligament.

Along the course of the parallel fibers of the medial collateral ligament, the three layers of the medial aspect of the knee can easily be distinguished (Fig. 83.12). Anterior to the medial collateral ligament, the fibers of the second layer often are divided vertically, but they eventually blend with the first layer to form the patellar retinaculum. Posterior to the medial collateral ligament, the fibers within the second layer above the joint line become obliquely oriented and appear to fan out from their attachment to the adductor tubercle, passing posteriorly and inferiorly (posterior oblique ligament) (16). These fibers form a sheet of tissue indistinguishable from the third layer beneath. Below the joint line, the fibers of the second layer also are obliquely oriented, flowing from the posterior margin of the parallel fibers of the superficial medial ligament toward the posteromedial aspect of the joint line. Warren and Marshall (84) suggest that all oblique fibers behind the parallel portion of the medial collateral ligament should be termed the oblique portion of the superficial medial ligament, but more commonly the portion above the joint line is called the posterior oblique ligament (16,39). An extension of the second layer passes from the anterior aspect of the medial femoral epicondylo at the patella deep to the vastus medialis (Fig. 83.13). This structure is the patellofemoral ligament (84). Thus, the second layer extends from the level of the medial femoral epicondyle to the tibial attachment of the medial collateral ligament in its midpoint. Posteriorly, this layer does not extend proximal to the capsular attachments superiorly, nor does it...
extend inferior to the oblique portion of the medial collateral ligament.

The third layer is composed of the medial capsule and its thickened midportion, which forms the deep medial collateral ligament (also termed the deep layer of the medial ligament, short internal lateral ligament, or the middle capsular ligament). Its attachments to the tibia and femur delimit the margins of the articular cartilage. Anteriorly, it is distinct from the overlying retinaculum but quite thin and weak. Posteriorly, it blends with the second layer to envelop the posteromedial corner of the joint. The deep medial ligament is made up of short parallel fibers running from an attachment point on the femur approximately 0.5 cm distal to the medial epicondyle to the tibia and femur just above the attachment of the anterior slip of the semimembranosus tendon. It is approximately as wide as the overlying medial collateral ligament and is clearly separated from it by a bursa. Posteriorly, the margins of the deep and superficial ligaments blend as the second and third layers fuse together (Fig. 83.12).

Warren and Marshall (64) observed that the semimembranosus tendon attaches directly to the posterior tubercle of the knee and to the tibia medially in a groove distal to the attachment of the third layer and beneath the medial collateral ligament. The semimembranosus tendon sheath contributes extensions blending with structures in the second layer (Fig. 83.14). The most distinct of these is a large contribution across the back of the joint to the lateral femoral condyle, the oblique popliteal ligament. Other frequently observed slips extend into the inferior and superior oblique portions of the medial collateral ligament and the fascia of the calf. No direct continuation of semimembranosus fibers passes directly into the posterior horn of the medial meniscus, as has sometimes been suggested (69). The complex insertion of the semimembranosus tendon indicates that besides being a strong knee flexor, it also serves to internally rotate the tibia on the femur and to tense the posteromedial capsular structures, which become lax as the knee is flexed. It also probably acts to protect the ACL from excessive stress by helping to prevent anterior subluxation of the tibia on the femur.

The semitendinosus, gracilis, and sartorius tendons pass the posteromedial aspect of the knee to form a conjoined tendon (pes anserinus) that passes superficially to the distal end of the medial collateral ligament and inserts into the anteromedial crest of the tibia several centimeters distal to the joint line. These muscles are primarily knee flexors, but they also act as internal rotators. They serve in conjunction with the quadriceps to reduce loads within the medial collateral ligament and assist in preventing anterior subluxation of theibia on the femur at knee flexion angles from 0° to approximately 70° (22). Beyond 70° of flexion, the quadriceps acts synergistically with the ACL. Transplantation of the pes anserinus reduces the flexion power of this group of muscles by 30% in all positions of knee flexion between 0° and 90° while increasing internal rotation power by as much as 50% at positions between 30° and 60° of flexion (67).

ANTERIOR ASPECT OF THE KNEE

The fascia lata of the thigh invests the superficial surface of the quadriceps, the patella, and the patellar tendon. Its medial and lateral extensions contribute to the patellar retinaculum along with aponeurotic fibers from the vastus medialis and lateralis. Laterally, the fascia lata thickens into the iliotibial tract and the iliopatellar band. The former inserts into the tubercle of Gerdy, and the latter inserts into the patella. Decussation of the superficial fibers of these two specialized portions of the fascia lata can be seen just above the level of the lateral epicondyle. Deeper portions of these complex structures are discussed in the section describing the lateral aspect of the knee. The patellofemoral ligaments are variably present; when present they range in width from 3 to 12 mm (75). They are thickenings of the joint capsule and pass from the epicondyles to their respective borders of the patella. Of 20 specimens dissected specifically to identify these structures, Reider et al. reported them to be present laterally in seven instances, medially once, and both medially and laterally in six specimens (75).

The patellofemoral mechanism has already been described, but some details of the relationships of the quadriceps merit comment here. The four large quadriceps muscles form a tendon of insertion into the superior aspect of the patella, which has classically been described as consisting of three separate layers: a deep portion...
arising from the vastus intermedius, a middle layer consisting of the two vasti, and a superficial layer from the rectus femoris. The actual insertion is variable, but most often a deep layer extending from the vastus intermedius can be separated from a more superficial portion from the other three muscles (75). The rectus femoris tendon is the longest (8 to 10 cm) and is roughly triangular; its base is 3 to 5 cm wide at the superior pole of the patella. It is the only tendon that consistently sends a significant number of its fibers anterior to the patella to be continuous with those of the patellar tendon. The inferior terminus of the vastus medialis obliquus is at the superior border of the patella in most knees, allowing a tendon of only a few millimeters in length to insert into the superior medial border of that bone. The muscle fibers of the inferior aspect of the vastus medialis are oriented at angles of 55° to 70° in relation to the sagittal plane near this insertion (75). The muscle fibers of the distal vastus lateralis also are oblique, ranging from 22° to 45°; they terminate well above the superior border of the patella, allowing a tendon averaging 2.8 cm in length to insert into the superior lateral aspect of the patella. Variable numbers of fibers from the distal vastus medialis and lateralis tendons insert into their respective retinacula (72).

The primary function of the quadriceps mechanism is to extend the knee, but just as important, it also controls flexion of the knee by antagonizing gravity and the hamstring muscles. Its insertion into the tibial tubercle and orientation anterior to the transverse axis of rotation of the distal femur allow it to assist in the prevention of posterior subluxation of the tibia on the femur if the knee is flexed less than approximately 70° (22). The quadriceps thus functions synergistically with the posterior cruciate ligament (PCL). In positions of knee flexion greater than 70°, it actually reverses this role and becomes a weak synergist of the ACL by tending to prevent anterior subluxation of the tibia on the femur. It also assists in stabilizing the patella within the patellofemoral groove by means of vertically and obliquely oriented fibers. Through the retinaculum, the quadriceps tenses the underlying anterior medial and anterior lateral joint capsule. Coupled with the muscles of the pes anserinus group, it reduces stresses within the medial collateral ligament when valgus moments are applied to the knee (73). It also has been proposed that via capsular attachments to the anterior horns of the menisci, the quadriceps functions to pull these structures anteriorly as the knee extends (44).

The patellar tendon extends from the entire inferior aspect of the patella (closer to its superficial surface than to the articular surface) to the periosteum overlying the tibial tubercle. The majority of its fibers blend into the periosteum rather than inserting directly into bone. The length of the infrapatellar tendon is variable, but it is usually approximately equal to that of the patella.

LATERAL ASPECT OF THE KNEE

As with the medial side, the lateral aspect of the knee can be divided into three separate layers (80). The most superficial (layer 1) contains the iliotibial tract and its ramifications anteriorly and the biceps and its expansion posteriorly (Fig. 83.16). The second layer is formed by the retinaculum of the quadriceps anteriorly. Posteriorly, it is not complete and is composed of the two patellofemoral ligaments and their various attachments to other structures (Fig. 83.16 and Fig. 83.17). The patellofemoral ligaments extend from the retinaculum and split into a superior limb that inserts into the distal end of the intermuscular septum and an inferior expansion that fans out to insert into numerous lateral structures. These structures include the fabella when present, the lateral head of the gastrocnemius, and the iliotibial tract just below the termination of the lateral intermuscular septum. Terry et al. describe five different layers of the iliotibial tract and band, which differ somewhat in interpretation from what is presented here (88). Of note is the deepest layer of this structure, which Terry et al. term the capsuloosseous layer, and acts as an anterolateral ligament of the knee (68).

Figure 83.17. Lateral aspect of the knee with layer 1 incised and peeled back from the lateral margin of the patella, showing layer 2. (From Seebacher JF, Inglis AE, Marshall JL, et al. The Structure of the Posterolateral Aspect of the Knee. J Bone Joint Surg 1982;64-A:536.)

The third layer is the lateral portion of the joint capsule, which is attached to the tibia and femur at the margins of the articular space (Fig. 83.16). This layer attaches to the margins of the lateral meniscus and is called the meniscocapsular capsule above and the meniscotibial capsule below that structure. It was formerly termed the coronary ligament. At the postero-lateral aspect of the knee, the popliteus tendon passes through a hiatus in the capsule, thus rendering the capsule incomplete in its attachment to the meniscus (Fig. 83.9). As one moves posteriorly at approximately the midlateral position, the capsule (third layer) splits into two laminae (Fig. 83.16). The more superficial includes the lateral collateral ligament and ends posteriorly at the fabelloligamellar ligament (short external ligament). The deeper layer of the posterolateral capsule forms the meniscotibial and meniscocapsular portions of the posterior capsule and encompasses the arcuate ligament. The inferior lateral geniculate artery passes between the lateral collateral ligament and fabelloligamellar ligament and the underlying arcuate ligament at the level of the meniscus.

The lateral collateral ligament extends from the lateral epicondyle of the femur downward and slightly posterior to near the midportion of the superior surface of the fibula. It is a discrete cord-like structure that is under maximum tension in extension and becomes lax as the knee is flexed (4). Its lower end is nearly surrounded by the middle layer of the biceps insertion (58). In theory, this allows the biceps to maintain some tension within this structure, even when the knee is flexed. Such an effect has been demonstrated within the lateral collateral ligament during simulated contraction of the biceps in human cadaver knees (4). The lateral collateral ligament is the primary restraint preventing varus deformity of the knee (28).

The fabelloligamellar ligament and the arcuate ligaments insert on the tip (posterior aspect) of the styloid of the fibula just posterior to the lateral collateral ligament, with the former being the most superficial (Fig. 83.16). They extend superiorly and slightly posteriorly to blend with the origin of the lateral head of the gastrocnemius and the termination of the oblique popliteal Winslow’s ligament. The arcuate ligament arches over the musculotendinous junction of the popliteus muscle as it passes upward toward its capsular hiatus. There is great variation in the size of the contribution of the arcuate and fabelloligamellar ligaments (50). In 13% of the dissections done by Seebacher and associates, the arcuate ligament alone was present; in 20% only the fabelloligamellar ligament was present; and in 67% both of these ligaments were present (80). In general, when a fabella is present, the fabelloligamellar ligament is large, and when even its cartilaginous remnant is not present, the ligament is very small or absent.
The anterior cruciate ligament (ACL) resides completely within the notch of the femur and thus has no capsular attachments. It is surrounded by loose areolar tissue, from which it obtains its blood supply, primarily from the middle geniculate artery. Its areas of insertion on the tibia and femur are large, resulting in fibers of various length as they pass from the tibia posteriorly, laterally, and cephalad to the femur. In full extension all the fibers are under tension; as flexion occurs, all fibers relax, but those most posterior and lateral relax the most (5). Over 90° of flexion, the ligament rotates approximately 180° (Fig. 83.19) (24). During this maneuver, the fibers that originally were most anterior at their attachment site on the femur become most posterior, and vice versa.

The popliteus muscle originates from the attachment of its tendon just anterior and inferior to the superior attachment of the lateral collateral ligament and the posterior aspect of the lateral meniscus. The contributions of these two sites are variable. Basmajian and Lovejoy proposed that a portion of it also arises from the arcuate ligament, thus giving it a fibular as well as femoral origin (8). It courses inferiorly and medially across the posterolateral aspect of the joint and inserts through its fleshy attachment to the posterior aspect of the tibia. The intricate relationship of the popliteus tendon to the superior and inferior popliteomeniscal fascicles as it passes by the lateral meniscus is demonstrated in Fig. 83.9 (86). The anteroinferior and posterosuperior meniscal fascicles are important stabilizers of the lateral meniscus. Sectioning of these structures increased anterior displacement of the lateral meniscus 18% when one fasciculus was sectioned and 78% when both fasciculi were sectioned (89). These displacements did not result in locking of the menisci but clearly could result in painful dysfunction clinically. The popliteus muscle functions synergistically with the PCL through Wrisberg's and Humphrey's ligaments when they are present. It internally rotates the tibia on the femur, especially during the first 10° to 20° of flexion. It acts as a weak flexor of the knee and draws the lateral meniscus posteriorly as the knee is flexed.

In a recent article, Maynard et al. point out that there has been much confusion about terminology and anatomic detail concerning those structures that attach to the fibular head (58). They propose the term popliteal fibular ligament for a consistent structure that passes from the popliteus tendon downward to the fibular head. They identified its presence in 20 of 20 cadaver dissections but state that most anatomy texts of the 20th century have not reported this structure. Biomechanical investigations performed by Maynard et al. revealed that this structure is nearly as large and about 56% as strong as the lateral collateral ligament. This anatomic observation has important ramifications for reconstruction of the complex lateral structures following damage to the lateral side of the knee. In contrast to the above findings, Kim et al. reported in a cadaver study correlating anatomic to magnetic resonance imaging (MRI) findings that a popliteofibular ligament was present in only 37.5% of 50 adult knees evaluated (47).

The biceps femoris tendon inserts into the posterolateral aspect of the knee in a multipart arrangement similar to that of the semimembranosus posteromedially (58,89). Its insertion can be divided into three distinct layers with attachments into the fibular head, proximal tibia, fascia around the leg, and posterior capsule of the knee joint, as well as an indirect attachment to the lateral collateral ligament. Thus, the biceps serves to flex the knee, antagonistically control extension of the joint, externally rotate the tibia on the femur, tense the lateral and posterior capsule, and dynamically control anterior displacement of the tibia on the femur. Its ability to tension the lateral collateral ligament was discussed previously.

THE CRUCIATE LIGAMENTS

Anterior Cruciate Ligament

The anterior cruciate ligament (ACL) resides completely within the notch of the femur and thus has no capsular attachments. It is surrounded by loose areolar tissue, from which it obtains its blood supply, primarily from the middle geniculate artery. Its areas of insertion on the tibia and femur are large, resulting in fibers of various length as they pass from the tibia posteriorly, laterally, and cephalad to the femur. In full extension all the fibers are under tension; as flexion occurs, all fibers relax, but those most posterior and lateral relax the most (5). Over 90° of flexion, the ligament rotates approximately 180° (Fig. 83.19) (24). During this maneuver, the fibers that originally were most anterior at their attachment site on the femur become most posterior, and vice versa.

The attachment on the tibia occurs on the nonarticular surface, extending from just behind the medial and lateral spines forward for approximately 3 cm (Fig. 83.20) (24). The ACL insertions on the tibia and femur are both nearly planar, with the femoral attachment being circular and the tibial attachment more oval (31). The attachment areas are nearly three times the ACL cross-sectional area at the midpoint of the ligament. The femoral attachment of the ACL is far posterior on the lateral wall of the intracondylar notch (Fig. 83.21) (25). No fibers of the ACL are totally isometric, with the least variation in length (approximately 1.5 mm) occurring along fibers coursing through the anteromedial aspect of the structure (27,78,84).

The anterior cruciate ligament (ACL) resides completely within the notch of the femur and thus has no capsular attachments. It is surrounded by loose areolar tissue, from which it obtains its blood supply, primarily from the middle geniculate artery. Its areas of insertion on the tibia and femur are large, resulting in fibers of various length as they pass from the tibia posteriorly, laterally, and cephalad to the femur. In full extension all the fibers are under tension; as flexion occurs, all fibers relax, but those most posterior and lateral relax the most (5). Over 90° of flexion, the ligament rotates approximately 180° (Fig. 83.19) (24). During this maneuver, the fibers that originally were most anterior at their attachment site on the femur become most posterior, and vice versa.

The attachment on the tibia occurs on the nonarticular surface, extending from just behind the medial and lateral spines forward for approximately 3 cm (Fig. 83.20) (24). The ACL insertions on the tibia and femur are both nearly planar, with the femoral attachment being circular and the tibial attachment more oval (31). The attachment areas are nearly three times the ACL cross-sectional area at the midpoint of the ligament. The femoral attachment of the ACL is far posterior on the lateral wall of the intracondylar notch (Fig. 83.21) (25). No fibers of the ACL are totally isometric, with the least variation in length (approximately 1.5 mm) occurring along fibers coursing through the anteromedial aspect of the structure (27,78,84).

The anterior cruciate ligament (ACL) resides completely within the notch of the femur and thus has no capsular attachments. It is surrounded by loose areolar tissue, from which it obtains its blood supply, primarily from the middle geniculate artery. Its areas of insertion on the tibia and femur are large, resulting in fibers of various length as they pass from the tibia posteriorly, laterally, and cephalad to the femur. In full extension all the fibers are under tension; as flexion occurs, all fibers relax, but those most posterior and lateral relax the most (5). Over 90° of flexion, the ligament rotates approximately 180° (Fig. 83.19) (24). During this maneuver, the fibers that originally were most anterior at their attachment site on the femur become most posterior, and vice versa.

Disruption of the anterior cruciate ligament may result not only in abnormal knee kinematics but also in changes to the neuromuscular system. Even low-demand activities such as walking may be performed in an abnormal manner. For example, subjects with an anterior-cruciate-deficient knee have been shown to reduce the flexion moment about their knee in an effort to reduce contraction of the antagonistic quadriceps muscles (9). This has been coined the quadriceps-avoidance gait.

The strain distribution of the cruciate ligaments varies along their length (i.e., the strains in the midsubstance portion of the ligament are different in comparison to those at the insertions (and about its cross section) (15). This has been investigated by Woo et al., who used a robot combined with a six-degree-of-freedom force transducer to apply load to the knee (96). They have shown that the restraint forces in the anteromedial and posterolateral aspects of the anterior cruciate ligament differ, and they change relative to knee flexion. A similar behavior occurs during passive flexion–extension of the knee (96).

Our approach was to measure the strain in the anteromedial aspect of the ACL in humans, the region of the ligament to which we have access with the arthroscope and our current differential variable-reluctance transducer (DVRT; MicroStrain, Burlington, VT). The study participants were patients who underwent a diagnostic arthroscopic surgery, typically for meniscectomy, and volunteered to participate under a protocol approved by our institutional human subjects review board. The surgical and experimental procedures were performed under local anesthesia, allowing study subjects full control of their musculature. The subjects had normal cruciate ligaments as documented by arthroscopic and clinical exam, normal range of joint motion, no history of previous ligament injury, and normal gait. After the surgical procedure was finished, the DVRT was implanted into the anteromedial aspect of the ACL to characterize its displacement pattern and calculate its strain behavior.

Movement of the knee from a flexed to an extended position, either passively or through contraction of the leg muscles, consistently produced an increase in ACL strain values (19). Rehabilitation exercises that produce low ACL strain values involve contraction of the dominant quadriceps muscle group with the knee flexed at 60° or greater (simultaneous quadriceps and hamstrings contraction, isometric contraction of the quadriceps) or were dominated by the hamstrings muscle group (isometric hamstrings muscle contraction; Fig. 83.23). Extension of the knee produced by contraction of the dominant quadriceps muscle group produced a substantial increase in ACL strain values, a finding that has been observed by Markoff et al. (56). The peak ACL strain values that were produced by squatting (a closed-kinetic-chain activity that induces a substantial compressive load across the tibiofemoral joint because of body weight as well as cocontraction of the leg musculature) were similar to those produced during open-kinetic-chain active flexion/extension of the knee (an activity that does not involve the compressive load produced by body weight) (12) (Fig. 83.24 and Fig. 83.25). The ACL strain values that were created by squatting were unaltered with the addition of an elastic resistance (the SportCord) that increased activity of the musculature spanning the knee. Thus, increasing resistance with the SportCord (producing a moderate increase in muscle activity) in an effort to strengthen the leg muscles during the squat exercise does not necessarily produce a significant increase in ACL strain magnitude (19). Currently, the limit of ACL graft strain during healing that is safe or unsafe is unknown. Therefore, we are unable to recommend what rehabilitation exercises should be performed based on whether they are safe or harmful. However, we feel it is important to point out the peak strain values that are produced during the quadriceps-dominated exercises (Table 83.3) may damage a healing ACL graft if they are used too early during rehabilitation, or if they are advanced to include more challenging levels of muscle contraction.

of these structures coexist, but in some instances they are quite large. Clancy et al. (20) stated that when one of these structures is robust, it may mask the clinical laxity (posterior drawer sign in internal rotation) observed when the PCL has been destroyed.

The PCL functions primarily to prevent posterior displacement of the tibia relative to the femur. With posterior displacements of more than 3 mm in the intact human knee, more than 90% of the restraining force (11) resides in this ligament (17). It secondarily assists in restraining varus and valgus moments to the knee and resists internal rotation of the tibia relative to the femur.

In a recent detailed anatomic comparison of the ACL and PCL, Harner et al. showed that the cross-sectional areas of both ligaments changed along their course from proximal to distal, whereas the PCL shows exactly the opposite trend. This implies different exposure to strain along various portions of these ligaments. The complex nature of the cruciate ligaments needs to be considered when these structures are being replaced following injury.

**AUTHORS' PERSPECTIVE**

The complexities of the anatomy and biomechanics of the human knee can be introduced only briefly in this short chapter. Many topics are only superficially discussed or totally ignored. Yet a thorough understanding of this information and the unexpressed details is mandatory if appropriate treatment is to be rendered to patients suffering disease and injury to their knees. We are experiencing an explosion of new research and literature concerning many subjects involving the biomechanics and anatomy of the knee. In many areas, our understanding of the intricate details of knee function is so superficial that at best our efforts to prescribe the appropriate surgical procedures and therapeutic regimens is marginal and, in some cases, inadequate. No area better exemplifies this point than the treatment of the ACL-deficient knee with the myriad therapeutic options present today. No single treatment method can be considered superior, simply because our knowledge is too limited. We are undoubtedly in a period when significant breakthroughs are likely at any time. It is the responsibility of us all to keep abreast of this information and apply it to our own practices.

CLINICAL EVALUATION AND IMAGING

A thorough history and physical examination are imperative to the diagnosis and treatment of a knee disorder: magnetic resonance imaging (MRI) or arthroscopy

HISTORY

Some knee problems and injuries are more commonly seen in specific age groups. Patellofemoral disorders, osteochondritis dissecans (OCD), Osgood-Schlatter
disease, and rarely, tumors are seen in adolescents who complain of knee pain with no history of trauma. In patients between 20 and 50 years of age, trauma often
leads to meniscal tears or ligament injuries. In patients over age 50 years, it is typical to see degenerative meniscus tears or degenerative arthritis in the absence of a
specific history of trauma. Awareness of these age-related problems permits better focus in taking the history.

- Determine the mechanism of history. Was the injury due to a twisting or turning mechanism or a direct blow?
- Did the pain come on gradually or immediately following an injury?
- Was the patient able to continue the activity or forced to stop because of the injury?
- Tears of the anterior cruciate ligament are frequently due to a noncontact, twisting or turning injury, which is often associated with immediate severe pain lasting
approximately 5 to 10 minutes. A pop is often heard as the injury occurs, and the patient cannot continue with the activity. Swelling occurs within 24 hours,
accompanied by the loss of full knee extension (19).
- Cumulative minor trauma can lead to a degenerative meniscus tear and articular cartilage injury with no specific history of trauma.
- Is the pain diffuse or localized? Can the patient point with one finger to the locus of the pain? Such specificity may not be possible, because often the entire knee
may injured. Patients with medial meniscus tears, in the absence of degenerative joint disease (DJD) often point to the medial joint line as the site of the problem.
- A history of activities that aggravate or alleviate the symptoms aids in diagnosis.
- Patellofemoral disorders are typically aggravated by bent-knee activities such as ascending or descending stairs, squatting, kneeling, riding in a car, or sitting in a
theater.
- Meniscus tears are aggravated by twisting and turning maneuvers.
- Determine what activity limitations are present because of the knee problem.
- The presence of knee effusion reflects an intra-articular problem in the knee.
- Patients with a true knee effusion often feel that the knee is tight or stiff. When they are asked where the knee swelling occurs, these patients will sense their
travelling to be in the lateral parapatellar or suprapatellar regions.
- With a communicating popliteal cyst, there is a sense of fullness in the posterior aspect of the knee as well as discomfort.
- Patients without a significant intra-articular knee effusion localize their sense of swelling in the inferior parapatellar region.
- Locking of the knee can occur when the normal movement of the knee is impaired; locking is associated with meniscus tears in the younger patient and loose
bodies in the older patient.
- Beware of the acutely injured knee that feels “locked” and will not extend fully. Frequently, with acute ligament injuries, there is concomitant splitting or spasm of
the hamstring musculature that impedes full extension of the knee and can be mistaken for mechanical locking. It is important to differentiale mechanical locking from
pseudolocking.
- Complaints of buckling, giving way, and feelings of instability may be caused by quadriceps muscle weakness or inhibition, in which the knee can flex
uncontrollably at times. This type of buckling is rarely disabling.
- A feeling that “the kneecap is going out” may be associated with patellofemoral instability.
- With anterior cruciate ligament instability, the individual may say, “The knee is going out of joint.”
- Some degree of disability is often associated with episodes of instability due to patellofemoral or anterior cruciate ligament disorders.
- Patients may describe snapping, grinding, popping, or clicking.
- In patellofemoral disorders, the patient frequently notes a grinding sensation, especially when walking up stairs.
- Establish whether the knee noise is associated with pain; many knees have nonpainful popping or clicking noises that are not pathologic. Painful pops or clicks
are of more concern. Meniscus tears or plicae may be associated with painful popping or clicking.
- Has there been a previous problem with the knee? If so, has that problem been similar to or different from the present knee complaints?
- Has there been any previous attempt at treatment (nonsteroidal anti-inflammatory drugs, physical therapy, injections), and if so, what has been the response?
Are there any other joints involved with a similar or different problem?
Is there a family member with a history of orthopaedic problems?

A thorough, focused history often points to a diagnosis, which, in turn, allows for a more directed physical examination.

PHYSICAL EXAMINATION

- A reproducible, systematic approach to the physical examination of the knee is important for accurate diagnosis.
- Examine the ipsilateral hip and ankle, because some knee complaints are due to referred pain or reflect a disorder of the hip or ankle.
- Always compare the examination to the normal knee (if possible).
- Observe the patient standing and assess alignment, noting excess varus or valgus (Fig. 84.1).

Figure 84.1. While the patient is standing, evaluate varus or valgus alignment. Note the increased varus alignment in the left lower extremity.

- Have the patient walk, and note any abnormality such as a limp or a varus or valgus thrust (Fig. 84.2).

Figure 84.2. A medial or lateral thrust is noted during the stance phase in gait. (Redrawn from Tria AJ, Klein KS. An Illustrated Guide to the Knee. New York: Churchill Livingstone, 1992, with permission.)

- Observe younger patients attempting to squat.
- Observe older patients getting into and out of a chair.
- Inspect the knee and lower extremity for previous incisions, scars, swelling, or ecchymosis.
- Place the patient in the supine position on an examination table (Fig. 84.3). Place a pillow beneath the knee to allow some flexion, because many knee disorders are painful in full extension. The extended position can cause the patient to splint and make the examination difficult.

Figure 84.3. Examine the patient with a pillow under the injured knee to allow the knee to flex slightly. The fully extended position is often uncomfortable and may cause the patient to splint, making the examination difficult.

- Examine the uninvolved knee first for comparison (right-to-left knee variability is minimal). In the general population, there is a significant variability between different individuals.
- Assess the knee for quadriceps atrophy and tone by grasping the anterior aspects of both thighs and asking the patient to tighten up the muscles in both lower extremities simultaneously. Compare the two sides for tone and size differences.
- Measure the thigh circumference at a standard position above the patella (i.e., 10 cm) with the thigh muscles tensed. Measuring allows for comparison to past and future examinations.
- Ask the patient to perform a straight leg raise and watch for quadriceps lag. Inability to perform a straight-leg raise (SLR) can be associated with injury to the patellar tendon or quadriceps tendon.
- With the knee in near-full extension, estimate the quadriceps angle (Q angle) by drawing a line from the anterior superior iliac spine to the patella, and from the tibial tubercle to the patella (Fig. 84.4) (22). The acute angle formed by these two lines is the Q angle. In men, the Q angle is approximately 10°, and in women, it is 15°. Alternatively, the Q angle can be measured with the knee flexed to 90° (tuberico–tubercle angle). In this position, the normal Q angle is up to 8° (Fig. 84.5). An increase in the Q angle by either measurement is associated with patellofemoral disorders.
Document the range of motion in degrees, using a goniometer. There is significant variability among individuals.

To demonstrate loss of extension reproducibly, examine the knee with the patient prone and estimate the heel height difference in cm (Fig. 84.6). Each 1 cm of heel height difference represents 1° loss of extension.

To document differences in flexion, measure the distance from the heel to the thigh in cm with the patient supine (Fig. 84.7).

Prone heel height difference and supine heel-to-thigh distance are measurements that are reproducible and more accurately reflect loss of extension or flexion.

With the hip flexed to 90°, have the patient actively flex and extend the knee (Fig. 84.8). Note patellofemoral crepitus and other knee noise (90–90 testing). Attempt to palpate the anatomic location of the crepitus. Patellofemoral joint crepitus usually reflects articular cartilage damage on the patella or in the trochlear groove of the femur. Determine whether the patella is tracking centrally or laterally.

With the knee in full extension, document patellar mobility and tilt.

With the knee in full extension, document patellar mobility and tilt. The diagnosis is enhanced if the pain can be reproduced; inability to reproduce the symptoms is an inconclusive finding.

A systematic examination for ligament laxity of the knee permits diagnosis of most knee ligament injuries. Compare the examination with that of the normal knee. Test for varus or valgus laxity at 0° and 30° of knee flexion (Fig. 84.9).
In full extension, varus or valgus stress can be used to assess the collateral ligaments as well as the posteromedial and posterolateral capsular structures, posterior cruciate ligament, and anterior cruciate ligament. Examination at 30° of knee flexion isolates the collateral ligaments; increased laxity only at 30° suggests an isolated collateral ligament injury. Increased laxity at both 0° and 30° of flexion represents an injury to the collateral ligament as well as to the posterior ligament restraints and, less commonly, the anterior cruciate ligament.

Estimate in millimeters (mm) the ligament laxity of the injured knee compared with that of the normal knee (27). Rate varus or valgus laxity as follows:

<table>
<thead>

</table>

- Examine the anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL) at 30° and 90° of flexion.
- Perform the Lachman test at approximately 30° of knee flexion. It is the most sensitive for detecting a tear of the ACL (Fig. 84.10). Check for the “end point”—a sensation analogous to a rope being pulled taut. In comparison to the normal knee, note the quality of the end point (same, soft, or absent). Document the change in the anterior excursion of the tibia. If the right and left difference is greater than 3 mm, it is likely (95% confidence level) that the ACL has been disrupted (19).

Several clinical tests have been developed to document ACL instability, including the pivot shift and flexion rotation drawer tests (Fig. 84.11) (10). These tests reduplicate clinical instability if it is due to the ACL.

- The PCL can be tested at 30° of flexion but is easiest to test at 90° of flexion (18). With the hip flexed 45° and the knee at 90°, perform a posterior drawer test. Palpate the stepoff between the medial and lateral femoral condyles and tibial plateau (Fig. 84.12). Normally, the tibia sits 5 mm anterior to the femoral condyles, producing a stepoff. Loss of this normal stepoff is due to posterior displacement of the tibia on the femur, which is caused by laxity in the posterior ligamentous restraints. Estimate the tibial stepoff as follows:

<table>
<thead>
<tr>
<th>Grade</th>
<th>Decrease in Tibial Stepoff</th>
</tr>
</thead>
<tbody>
<tr>
<td>I</td>
<td>0 to 5 mm</td>
</tr>
<tr>
<td>II</td>
<td>5 to 10 mm</td>
</tr>
<tr>
<td>III</td>
<td>&gt; than 10 mm</td>
</tr>
</tbody>
</table>
I 0–5 mm (tibial stepoff is still palpable)
II 6–10 mm (tibia is equal to the femoral condyle)
III >10 mm (tibia is posterior to the femoral condyle)

- If the Lachman test is normal, an increase in the side-to-side anterior or posterior laxity at 90° of flexion represents an injury to the posterior ligamentous restraints.
- There are numerous specific tests that have been described to examine the knee ligaments. Try to isolate and assess the integrity of the four major ligaments of the knee. Recognize that most knee ligament injuries are not truly isolated but are more complex.

**ASPIRATION OF THE KNEE**

Aspiration of the knee is indicated to diagnose or remove a hemarthrosis, to look for fat droplets (lipohemarthrosis) that might suggest a fracture or osteochondral injury, or to perform synovial fluid analysis (Fig. 84.13). Aspiration aids in diagnosis and has therapeutic benefit as well.

**Figure 84.13.** With the patient supine and pillow under the knee, aspirate knee effusions through a superolateral approach.

- Observe the fluid aspirated and determine if it is clear, cloudy, or bloody. Note the viscosity of the fluid.
- Clear fluid can be discarded. Send cloudy or bloody fluid for a cell count and differential, crystal analysis, and culture.
- Patients with crystal deposition disorders can have meniscus-like symptoms. Look for crystals on a polarized light microscope.
- Intra-articular disorders such as a meniscus tear or a loose body typically cause overproduction of normal clear synovial fluid.
- Gout or other crystal deposition disorders causes an inflammatory synovial fluid with a white blood cell count (WBC) of 5,000 to 20,000.
- Intra-articular infections typically have a WBC greater than 50,000.
- The presence of a hemarthrosis in a “stable” knee suggests an anterior cruciate injury or peripheral meniscus tear (11,47).
- Fat present in the hemarthrosis represents an osteochondral injury or fracture.
- A large effusion restricts knee range of motion. Aspiration improves motion and facilitates rehabilitation.
- Intra-articular injections with lidocaine help differentiate intra-articular from extra-articular knee disorders. An intra-articular injection with lidocaine temporarily relieves knee pain due to intra-articular knee disorders. Although this test is not 100% accurate, it appears in clinical practice to be at least 95% specific and sensitive.
- In patients with DJD, failure to relieve pain with an injection suggests that in addition to arthritis, there may be an extra-articular component of the knee pain that requires diagnosis.

**IMAGING OF THE KNEE**

Standard radiographs of the knee include anteroposterior (AP), lateral, notch, and patellofemoral views. The posteroanterior (PA) weight-bearing view of both knees at 45° of flexion is substituted for the notch view in individuals over age 40 years, those with previous knee surgery, or those with systemic arthritis. Evaluate the radiographs for abnormalities of the soft tissues, as well as for bone density. Extension weight-bearing views of both knees are useful in documenting degenerative changes (17); however, joint space narrowing is best noted on the PA 45° flexion weight-bearing view (Fig. 84.14) (56). A true lateral view taken at 30° of knee flexion allows for assessment of patellar height as well as osteophytes and loose bodies. The notch view and 45° flexion weight-bearing view are useful for demonstration of loose bodies, OCD, and narrowing of the intercondylar notch. The Merchant view (40) at 45° of flexion or Lauren view (36) at 20° of flexion demonstrates abnormalities of the patellofemoral joint, including joint space narrowing, patellar tilt, and patellar subluxation (Fig. 84.15).

**Figure 84.14.** A: Technique for the 45° PA flexion weight-bearing x-ray study of the knee. B: Demonstrating medial compartment joint space loss in flexion. C: Demonstrating lateral compartment joint space loss in flexion.

**Figure 84.15.** A: Patient position for the Merchant view. B: Merchant view of both patellofemoral joints.
A 51-inch standing weight-bearing AP of the entire limb is useful for assessing the mechanical axis of the limb. The mechanical axis normally falls through the medial tibial spine (Fig. 84.16). Shift of the weight-bearing axis into either compartment leads to relative joint overload, as well as a change in the tension relationship of the collateral ligaments (Fig. 84.17). This view is essential for preoperative planning in patients undergoing total knee replacement, osteotomy, ligament reconstruction, meniscus reconstruction with an allograft, or chondrocyte autograft. Without proper attention to the mechanical axis before surgery, the outcome of these procedures may be compromised.

Figure 84.16. The mechanical axis measured on a 51-inch weight-bearing AP is sensitive to demonstrating shift of the weight-bearing axis into the medial or lateral compartment.

Figure 84.17. Fifty-one-inch standing AP weight-bearing view demonstrating shift of the weight-bearing axis into the medial compartment.

Arthrography is performed by injecting contrast material intra-articularly, and then obtaining radiographs in multiple projections, both with and without stress applied to the knee (Fig. 84.18). Although arthrography has been largely replaced by MRI, the former technique may be indicated in patients with contraindications to MRI. The primary reason for obtaining a knee arthrogram is for assessment of the menisci (2).

Figure 84.18. Arthrogram demonstrating a tear of the posterior horn of the medial meniscus.

Arthrography may also be used to diagnose cruciate and collateral ligament injuries, OCD, chondral defects, plica, and popliteal cysts. The accuracy of arthrograms for the diagnosis of meniscal tears has been reported to be between 76% and 96% (13,28). In comparison to MRI, there are more false-negative results associated with the use of arthrography.

Radionuclide imaging is most frequently performed with technetium 99m/methylene diphosphonate, a compound that is readily absorbed by metabolically active bone (Fig. 84.19). The primary advantages of bone scanning are its high sensitivity in detecting early osseous disease and the ease of surveying the entire skeleton. Bone scans have been used in the diagnosis of primary and metastatic neoplasms, implant loosening, infection, reflex sympathetic dystrophy, osteonecrosis, occult fractures, stress fractures, and arthritis (16). When considering a valgus-producing osteotomy of the knee for genu varum, a bone scan is a more sensitive indicator of arthritis in the lateral compartment than plain radiographs (6). The disadvantages of bone scintigraphy are the radiation exposure, the length of time to perform the exam, and most important, the lack of diagnostic specificity. Despite the high sensitivity of bone scans, false-negative results may occur with certain neoplasms (multiple myeloma) and in elderly patients within 3 days after sustaining radiographically occult fractures.

Figure 84.19. Technetium 99m bone scan of the lower extremities demonstrating increased uptake in the medial compartment of the left knee.

The use of tomography and computerized tomography (CT) has declined with the advent of MRI, but it remains useful in the diagnosis of osteonecrosis, OCD, tibial...
plateau fractures, and tumors, as well as for evaluation of patellar tracking, patellar tilt, and patellar subluxation (Fig. 84.20).

Figure 84.20. CT image of the patellofemoral joint at 30° (A) with quad tightening and (B) without quad tightening.

Diagnostic imaging of the knee has been revolutionized by the development of MRI (23). After plain radiography, MRI is the imaging test of choice for evaluating internal derangements of the knee. The frequency with which this test should be used, however, is the subject of substantial controversy.

The scientific principles of MRI have been well described (55). MRI routinely generates high-resolution images in 3 mm to 5 mm sections of the knee in multiple anatomic planes. The advantages of MRI are that it is noninvasive and safe. However, the most significant advantage of MRI is the capability of generating high-contrast soft-tissue imaging that is not possible with other imaging techniques (Fig. 84.21).

Figure 84.21. MRI of the knee. A: A vertical tear of the posterior horn of the medial meniscus. B: A tear of the medial meniscus with displacement into the intercondylar notch.

The disadvantages of MRI include the relatively high cost and the fact that not all patients can fit into the scanner because of a weight and size limitation with standard closed MRI. There is also a subset of patients who cannot tolerate MRI because they are claustrophobic. MRI is contraindicated in patients with pacemakers, ferromagnetic intracranial aneurysm clips, cochlear implants, and intracocular metal fragments. Pregnancy is a relative contraindication. Open MRI can accommodate patients with claustrophobia or a size limitation. There is, however, an associated loss of image contrast owing to the need for a smaller magnet.

The interpretation of knee MRI is difficult when there has been previous injury or surgery. Retained ferromagnetic hardware creates artifacts, which may obscure adjacent abnormalities. After partial meniscectomy or meniscus repair, the accuracy of conventional MRI for detecting new meniscal abnormality decreases significantly. In order to optimize the imaging of patients suspected of having recurrent meniscal tears, MR arthrography is useful (2).

If the cost and utilization were not a concern, MRI would be useful in nearly all patients with knee problems. The cost and the time involved in performing the procedure prohibit its widespread use (23). MRI needs to be used selectively as a diagnostic tool for evaluating disorders of the knee. Before ordering MRI, it should be clear that the information obtained would impact or change the treatment program. Indications for MRI are determined individually. MRI of the knee may be used to diagnose the presence of meniscus tears, ligaments and tendon injuries, and osteoarthritis, chondral and chondral lesions.

MRI is highly accurate for the evaluation of the ACL, PCL, and menisci (7, 44). When comparing the accuracy rates of MRI versus knee arthroscopy, meniscus tears are identified with a 90% to 95% accuracy with MRI. ACL and PCL tears are identified with over 95% accuracy. Bone contusions, radiographically occult fractures, and spontaneous osteonecrosis of the knee are diagnosed with almost 100% accuracy on MRI. Equally important, negative findings on MRI of the knee is 95% accurate for the prediction of normal intra-articular structures. With an experienced evaluator, there are relatively few false-positive and false-negative results. MRI has rapidly evolved into a comprehensive and versatile tool for the evaluation of knee disorders.

INDICATIONS FOR KNEE ARTHROSCOPY

Knee arthroscopy is indicated for the purposes of diagnosis or therapeutic treatment. Always take a complete history, do a physical examination, and obtain radiographs before proceeding with an arthroscopic evaluation of the knee. Other diagnostic studies are used as necessary for purposes of establishing a diagnosis. Arthroscopy is not meant to be used for every patient with knee pain. The Arthroscopy Association of North America has suggested the following guidelines for arthroscopy (64):

1. The arthroscopist should perform an adequate history and physical examination, as well as obtain radiographs or other pertinent laboratory evaluations of the patient if they have not already been performed.
2. The risks, benefits, alternatives of treatment, and potential complications should be carefully explained to each patient before an arthroscopic evaluation is performed.
3. The arthroscopist should exercise due consideration in selecting the correct arthroscopic procedure for a particular condition.
4. A detailed report of the procedure should be prepared, including the arthroscopic findings and description of the operation.

Institute initial conservative management for most disorders of the knee with few exceptions such as intra-articular fractures, intra-articular infections, and true mechanical locking. Conservative measures for the management of knee disorders include a range-of-motion and muscle-strengthening program.

Shelbourne’s studies (59) on ACL injuries and timing of surgery have similar application to most other knee disorders. Under ideal circumstances, range of motion and muscle strengthening should be optimized before surgery. Postoperative rehabilitation is facilitated by a preoperative program of exercise. If surgery is undertaken before the patient regains range of motion, there is an increased risk of postoperative stiffness (23).

Activity modification plays a major role in the management of knee disorders. Minimizing or avoiding the activities that aggravate the knee will often reduce knee symptoms. Crutches or other ambulatory aids are recommended for individuals who have an antalgic gait following injury or onset of symptoms. Ice, elevation, and a compression dressing may aid in controlling intra-articular and extra-articular swelling. Immobilization may be useful to control pain and allow some injuries to heal, but its use should be carefully weighed against the joint stiffness that can occur with immobilization. Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used to help reduce swelling and inflammation, but their use must be carefully balanced against the risk of gastrointestinal irritation and bleeding.

Intra-articular injections of lidocaine and a corticosteroid can be beneficial for both diagnosis and treatment. Suspected intra-articular disorders should have at least temporary improvement with an intra-articular lidocaine injection. Concomitant use of corticosteroids may provide a long-term therapeutic benefit for the individual. The use of intra-articular injections must be carefully individualized. A 70-year-old patient with DJD may be injected multiple times. An 18-year-old with an ACL injury and...
A meniscus tear will not benefit by intra-articular injections. After conservative modalities have proven ineffective over a reasonable period of time and the individual remains disabled, consideration for an arthroscopic evaluation of the knee is warranted for purposes of diagnosis and treatment (52). A thorough preoperative medical evaluation is necessary to minimize operative complications.

Patient education plays a critical role in the outcome of arthroscopic surgery. Preoperatively, have a thorough discussion with the patient of the risks, benefits, alternatives of treatment, and postoperative rehabilitation. It is imperative to define clearly for the patient what to expect from surgery. The importance of postoperative rehabilitation for the success of the procedure should be emphasized. Written guidelines, illustrations, and videotapes facilitate the education process.

**ANESTHESIA**

Perform arthroscopy under local, regional, or general anesthesia. The choice of anesthetic is determined by the patient's medical history and the procedure being performed, as well as the preference of the patient, surgeon, and anesthesiologist. Local anesthesia has gained popularity with the advent of office arthroscopy.

- Procedures that require less time and are not dependent on joint exposure (such as diagnostic arthroscopy, loose body removal, and lateral release) can be performed with local anesthesia and intravenous (IV) sedation.
- Regional anesthesia is not adequate in procedures requiring use of a tourniquet for more than 20 minutes or in procedures requiring significant exposure of the joint such as meniscectomy or meniscus repair and procedures requiring bone drilling (59).
- General anesthesia is indicated in patients in whom general anesthesia is believed to be medically contraindicated. Additionally, there are patients who prefer regional anesthetics, including those with the desire to watch the procedure on the video monitor.
- General anesthesia is the preferred anesthesia for most arthroscopic procedures of the knee. It allows for complete muscle relaxation and facilitates adequate joint exposure.

**SURGICAL TECHNIQUES**

- Position the patient supine. Place the operative knee in full extension or at 90° of flexion with the end of the table flexed. Position a tourniquet on the proximal thigh. It can be used at the discretion of the surgeon. Adequate exposure is facilitated by use of a leg-holding device or post. The nonoperative leg needs to be well padded and supported (Fig. 84.22).

![Figure 84.22. Patient positioning for knee arthroscopy. A thigh holder is secured over or distal to the tourniquet. The nonoperative limb is placed in a well-padded leg support. This leg position insures easy access to the posteromedial compartment.](image)

- Diagnostic arthroscopy is the initial phase of all procedures. Use a standardized and systematic approach to achieve a thorough and efficient evaluation of the entire knee joint before performing any type of surgical treatment. Avoid the temptation to focus on a specific problem and not complete the diagnostic arthroscopy. The only exceptions to this would be if a loose body were encountered or the knee was mechanically locked (due to a loose body or displaced meniscus fragment). Rather than lose the loose body within the joint, remove it first and then complete the diagnostic arthroscopy. A displaced meniscus tear should be reduced into its normal anatomic position before resuming the diagnostic arthroscopy.

**ARTHROSCOPIC PORTALS**

Proper placement of arthroscopic portals is critical for the success of the procedure. The standard arthroscopic portals are anterolateral, anteromedial, superolateral, superomedial, posterolateral, and posteromedial (Fig. 84.23). The accessory portals include the midpatellar, transpatellar, accessory medial and lateral, and accessory posteromedial and posterolateral portals (Fig. 84.24). Knowledge of the surface and deep anatomy of the knee is a prerequisite for establishing portals safely and effectively. An accurately placed portal will allow instruments to be used effectively. An improperly placed portal can cause damage to the knee as well as hamper the surgical procedure.

![Figure 84.23. Anatomic location of arthroscopic portals.](image)

![Figure 84.24. Accessory arthroscopic portals. (Redrawn from Scott, WN, Insall JN, Kelly MA. Arthroscopy and Meniscectomy: Surgical Approaches, Anatomy and Techniques. In: Insall JN, ed. Surgery of the Knee. 2nd ed. New York, Churchill Livingstone, 1993, with permission.)](image)
ANTEROLATERAL PORTAL

The anterolateral portal is the primary viewing portal for knee arthroscopy. Establish it with the knee in 90° of flexion and distended with fluid. The landmarks for portal placement are the inferior pole of the patella and lateral joint line. There is a soft spot that can be palpated adjacent to the patellar tendon. Vertical incisions are extensile and facilitate portal adjustment if necessary.

- Direct a #11 blade toward the intercondylar notch, with the sharp edge of the blade facing superiorly to avoid any damage to the underlying meniscus or transverse meniscal ligament. Do not penetrate so deep that the articular cartilage or the ACL is injured.
- Pass a 5 mm blunt trocar through the portal to ensure ease of passage. Advance the blunt trocar to all desired areas of visualization to ensure that the arthroscope will be advanced easily into these areas.
- After the anterolateral arthroscopy portal has been established, all remaining portals can be made under arthroscopic control. Use the arthroscope to transilluminate the proposed portal site to document any vascular structures. Use an 18-gauge needle to predetermine the accuracy of the portal placement.
- Then use a #11 blade to establish the arthroscopic portal.

ANTEROMEDIAL PORTAL

- Locate the anteromedial arthroscopy portal 1 cm above the joint line and approximately 5 mm from the medial border of the patellar tendon, to minimize the impingement of the fat pad.
- Use the arthroscope to transilluminate the area to avoid vascular structures and insert an 18-gauge needle at the portal site to ensure proper placement. Direct a #11 blade into the joint, aiming for the intercondylar notch. Place a blunt trocar through the portal to ensure ease of instrument passage into the joint.

POSTEROMEDIAL AND POSTEROLATERAL PORTALS

- Visualize the posterior compartments of the knee using the anteromedial and anterolateral arthroscopy portals, and passing the instruments posteriorly through the intercondylar notch (45°).
- Smaller diameter obturators facilitate passage into the posterior compartments.
- Pass the blunt obturator or sleeve along the intercondylar notch wall by touch. Flexing and extending the knee between 45° and 90° degrees often relaxes the soft tissues and allows the obturator or sleeve to pass into the posterior compartment.
- Establish the posteromedial portal with the knee flexed 90° and the joint distended with fluid. Pass the arthroscopic obturator or sleeve from the anteromedial arthroscopy portal along the medial intercondylar wall into the posteromedial compartment.
- Visualize the posteromedial compartment with a 30° or 70° arthroscope.
- Transilluminate the posteromedial skin area to identify the saphenous vein and other vascular structures.
- Palpate the posteromedial skin to determine the location of the arthroscopy portal.
- Pass an 18-gauge needle to ensure proper anatomic placement of the portal 1 cm posterior to the lateral femoral condyle and 1 cm above the joint line.
- Make an incision in the skin with a #11 blade. Dissect bluntly down to capsule with a hemostat to avoid injury to the saphenous nerve. Pass the blunt obturator into the posteromedial compartment.
- Use the posteromedial portal for visualization of the medial meniscus, PCL, and posterior capsular structures.
- Pass instruments through this portal for loose body removal, meniscectomy, meniscus repair, PCL surger, and synovectomy.
- Establish the posterolateral portal with the knee flexed 90° and the joint distended. Pass the arthroscopic obturator or sleeve along the lateral intercondylar wall from the anterolateral portal.
- Visualize the posterolateral compartment with a 30° or 70° arthroscope and transilluminate the posterolateral skin to identify any vascular structures.
- Palpate the posterolateral skin to identify the location of the portal site, 1 cm posterior to the lateral femoral condyle and 1 cm above the joint line. If the portal is placed too far posteriorly, the peroneal nerve can be injured. Pass an 18-gauge spinal needle into the joint to ensure proper placement.
- Use this portal to remove loose bodies, lateral meniscus from this portal.
- Use this portal for loose body removal, meniscectomy, meniscus repair, and synovectomy.

SUPEROLATERAL AND SUPEROMEDIAL PORTALS

- Place the knee into full extension and distend the joint.
- Pass the arthroscopic obturator or sleeve from the anterolateral portal into the suprapatellar pouch to allow direct visualization. Be careful to avoid injuring the articular cartilage of the troclear groove and patella.
- Place the portals at the superior pole of the patella. If they are placed too distally, the portals will impinge on the patellofemoral joint.
- Transilluminate to identify the vascular structures. Pass an 18-gauge spinal needle to determine proper placement. Insert the spinal needle parallel to the patellofemoral joint axis.
- Use a #11 blade to incise the skin and establish the portal. Pass the blunt obturator into the joint. These portals are routinely used for inflow and outflow.
- Visualize the medial and lateral gutters, suprapatellar pouch, and plicae. Evaluate patellofemoral tracking by flexing the knee from 0° to 90° and observing the patella and its relationship to the troclear groove.
- Assess for plica impingement while actively flexing and extending the knee and observing for plica impingement on the medial femoral condyle.

ACCESSORY PORTALS

In addition to standard arthroscopic portals, accessory portals can be established in almost any anatomic region to facilitate surgery.

- Establish an accessory portal to minimize crowding of instrumentation.
- Use an accessory portal for better angulation for difficult meniscus tears or loose body removal.
- Use the accessory medial and lateral portals to facilitate anterior horn meniscectomy.
- Less commonly used portals are the accessory midpatellar lateral and medial portals, and the accessory posteromedial and posterolateral portals.
- Establish all accessory portals in the standard manner using transillumination and an 18-gauge spinal needle.

DIAGNOSTIC ARTHROSCOPY

The anesthesiologist administers a regional or spinal anesthetic. Examine the knee under anesthesia. Document the range of motion and stability of both knees. Secure the tourniquet to the proximal thigh. Place the injured leg in a leg-holding device distal to the tourniquet. For short thighs, a tourniquet can be placed within the thigh-holding device. There should be a minimum of 6 cm distance between the superior pole of the patella and the lower portion of the thigh-holding device. If the leg-holding device is applied too distally, there is not enough space to establish and use superior portals.

- Lower the foot of the table, allowing the knee to flex to 90°. Place the nonoperative limb in a well-leg support, allowing adequate access to the posteroomedial compartment of the injured knee.
- Prep and drape the operative leg. If using a tourniquet, eschew the leg and elevate the tourniquet. Distend the knee by placing a 2 mm Verres needle into the suprapatellar pouch through the superolateral or superomedial portal, with the knee in full extension. As the needle is inserted, the surgeon usually encounters synovial fluid as the needle enters the joint. Examine the fluid and send it for analysis if needed. Distract the knee with irrigation fluid.
- Flex the knee 90° and establish the anteromedial and anterolateral arthroscopy portals. Insert a blunt 5 mm obturator to ensure ease of passage through the portals into the compartments to be visualized.
- Place the arthroscopic sleeve or obturator through the anterolateral portal, pass posterior to the patella, into the suprapatellar pouch. Use a 4 or 5 mm 30° arthroscope with inflow through the arthroscopic sleeve and outflow through the Verres needle. Outflow through the arthroscopic can allow debris to compromise visualization. Visualize the superior plica. Assess the synovium.
- Direct the arthroscope down the lateral gutter. A normal transverse fold of synovium covers the femoral attachments of the popliteus tendon and the lateral collateral ligament. Distal to this fold, note the popliteal hiatus and lateral meniscus.
- Bring the arthroscope back into the suprapatellar pouch and visualize the medial gutter. Assess the medial plica for impingement.
- Rotate the arthroscope to view superiorly and inspect the articular cartilage surface of the patella. Withdraw the arthroscope slowly, and inspect the articular cartilage surface of the trochlear groove as you bring the knee into 45° of flexion.
- Inspect the intercondylar notch, including the ACL and PCL. Palpate the ACL with a probe and determine its integrity. A prominent inferior plica (ligamentum mucosum) may obscure visualization. Resect the plica with a shaver if it compromises visualization, especially when you are attempting to establish the integrity of the ACL.
- Visualize the medial compartment, placing a valus load on the knee with 10° to 15° of flexion to facilitate the process. Externally rotate the foot 15° to 20°. If the ACL is disrupted, it is important to maintain the external rotation or a subluxation may occur (pivot shift). If it does occur, bring the knee back into the neutral
Arthroscopic synovectomy has evolved into a procedure in which 95% of the diseased synovium can be removed (Fig. 84.26). Technically, it was very difficult to remove the parameniscal synovium.

Open synovectomy gained little popularity because of the significant morbidity associated with the procedure, especially stiffness. With open synovectomy, the posterior compartments of the knee were usually left untreated. Technically, it was very difficult to remove the parameniscal synovium.

Arthroscopic anterior and posterior synovectomy has evolved into a procedure in which 95% of the diseased synovium can be removed (Fig. 84.27). Relative contraindications to arthroscopic synovectomy include joint space narrowing greater than 3 mm, which is best demonstrated on the flexion weight-bearing view. In addition, local skin lesions such as rashes or infection should be resolved before surgery. The patient must be willing to undertake rehabilitation following surgery.

**DIAGNOSIS AND TREATMENT OF SYNOVIAL DISORDERS**

The synovium is the inner layer of the joint capsule and is affected in many knee conditions. Most synovitis is reactive and is noted in association with other intra-articular disorders of the knee, such as a meniscus tear or DJD. The synovium can become proliferative in disorders such as rheumatoid arthritis (51), pigmented villonodular synovitis (53), hemophilia, and synovial chondromatosis (43). In contrast to a reactive synovitis, the synovium in these entities can invade the meniscus, ligamentous structures, and articular cartilage surfaces, causing an acceleration of the degenerative process, which has been best documented in patients with rheumatoid arthritis (70). A careful clinical evaluation, including knee aspiration, can usually eliminate other etiologies for the synovitis noted, limiting the diagnosis to a disorder of the synovium. If the diagnosis remains unclear and symptoms persist, an arthroscopic evaluation of the knee, to include synovial biopsy, is indicated.

Initial conservative management of synovitis is usually recommended. Place patients on a program of strengthening, flexibility, activity modification, NSAIDS, and intra-articular injections. Synovectomy is indicated when the synovial disorder remains symptomatic despite medical management for at least 6 months. Arthroscopic anterior and posterior synovectomy can accomplish a remission or at least a reduction of symptoms (28,51,53).

Open synovectomy gained little popularity because of the significant morbidity associated with the procedure, especially stiffness. With open synovectomy, the posterior compartments of the knee were usually left untreated. Technically, it was very difficult to remove the parameniscal synovium.

Arthroscopic anterior and posterior synovectomy has evolved into a procedure in which 95% of the diseased synovium can be removed (Fig. 84.27). Relative contraindications to arthroscopic synovectomy include joint space narrowing greater than 3 mm, which is best demonstrated on the flexion weight-bearing view. In addition, local skin lesions such as rashes or infection should be resolved before surgery. The patient must be willing to undertake rehabilitation following surgery.

**ARTHROSCOPIC SYNOVECTOMY**

Refer to Figure 84.28.
Using a standard arthroscopy setup, position the leg-holding device to allow easy access to the suprapatellar pouch.

Position the nonoperative leg in a well-leg holder to facilitate access to the posteromedial compartment of the knee.

Perform diagnostic arthroscopy to document all abnormalities before initiating the synovectomy.

Begin the synovectomy in the posterior compartments. Remove the synovium from the intercondylar notch, especially the posterior aspect, to improve visualization significantly and allow for ease in development of the posterior arthroscopic portals.

With the knee flexed 90°, pass a 30° or 70° arthroscope from the anterolateral portal into the posteromedial compartment. Rotation of the arthroscope allows visualization of the majority of the compartment. Inflow is accomplished through the arthroscope (Fig. 84.28A).

Establish the posterior medial portal under direct visualization, with the compartment distended with fluid. Use a spinal needle to ensure proper placement of the posterior portals.

Pass an obturator or sleeve into the posterior compartment through the posterior portal. Insert the 4.5 and 5.5 mm full-radius synovial resectors through the sleeve into the posterior portal and complete the synovectomy.

Under direct visualization, insert an obturator or sleeve through the posteromedial portal. Remove the arthroscope from anterior and place it posteriorly through the sleeve to visualize the intercondylar notch from posteriorly.

Pass the 4.5 mm synovial resector from the anterolateral portal into the posteromedial compartment, and remove the remaining synovium from the posterior intercondylar notch.

With the knee flexed 90°, pass a 30° or 70° arthroscope from the anteromedial portal into the posterolateral compartment (Fig. 84.19B).

Established the posterolateral portal under direct visualization, with the compartment distended with fluid. Use a spinal needle to ensure proper placement of the posteromedial portals. Avoid the peroneal nerve. Pass an obturator or sleeve into the posterior compartment through the posterior portal. Insert the 4.5 and 5.5 mm full-radius synovial resectors through the sleeve into the posterior portal and complete the synovectomy.

Under direct visualization, insert an obturator or sleeve through the posteromedial portal. Remove the arthroscope from anterior and place it posteriorly through the sleeve to visualize the intercondylar notch from posteriorly.

Pass the 4.5 mm synovial resector from the anteromedial portal into the posteromedial compartment, and remove the remaining synovium from the posterior intercondylar notch.

Upon completion of the posterior synovectomy, look for bleeding vessels and cauterize them with an intra-articular cautery. This process can be enhanced by diminishing the inflow rate and allowing a small amount of bleeding to occur.

Place the arthroscope into the suprapatellar pouch through the inferolateral portal with the knee in full extension. Use inflow through the arthroscope or through a separate inflow system.

Insert the 4.5 and 5.5 mm synovial resectors through the superomedial or superolateral portals. In a systematic fashion, remove the entire synovial layer from the suprapatellar pouch (Fig. 84.28C).

Visualize the proximal medial and lateral gutters from the inferior portals with the knee in full extension.

Introduce the synovial resector through the superior portal to allow for triangulation. Reverse the arthroscope and synovial resector and complete the remainder of the synovectomy in each gutter (Fig. 84.28E).

Meticulously debride the chondrosynovial junction, because synovial ingrowth from these areas leads to degeneration of the articular cartilage surfaces.

Position the knee at 90° and visualize the intercondylar area. Use the inferior portals for visualization and insertion of the synovial resector.

Remove diseased synovium invading the ACL and PCL with the 4.5 and 3.5 mm synovial resectors, trying to preserve as much ligament substance as possible (Fig. 84.28E).

Expose the medial and lateral compartments in the routine manner (Fig. 84.28F). Excise the parameniscal synovium with the smaller synovial resectors (Fig. 84.29; see also Color Fig. 84.29).

Curved synovial resectors facilitate excision of the synovium inferior to the anterior horns of the menisci.

Perform a final diagnostic arthroscopy to identify any areas of residual synovitis.

Use the intra-articular cautery for bleeding vessels. Release the tourniquet for a short period of time and then re-elevate it when bleeding occurs. This technique allows most significant bleeding vessels to be identified and cauterized. Use of the electrocautery minimizes postoperative swelling.

Insert a 14-inch hemovac drain for 1 to 4 hours. Keep a compression dressing in place for 2 days and then replace it with a thigh-high TED stocking.

After surgery, begin rehabilitation immediately, emphasizing range of motion and muscle strengthening exercises (see the section entitled Rehabilitation). Patients will need an ambulatory aid for 1 to 2 weeks. They can expect to return to activities in 2 to 3 months. Daily rehabilitation is critical for success. Initiate formal physical therapy as necessary.

DIAGNOSIS AND TREATMENT OF INTRA-ARTICULAR LOOSE BODIES

Chondral and osteochondral loose bodies in the knee are occasionally noted in younger patients. In this age group, OCD and osteochondral fractures associated with ACL tears or patellar dislocations are the usual etiologies. Loose bodies occur more frequently in older patients, and are more often associated with the development of DJD. Osteonecrosis can also contribute to the formation of loose bodies. Synovial chondromatosis and synovial osteochondromatosis can develop in all age groups (8). Cartilaginous or osteocartilaginous loose bodies are formed by synovium and can become free within the knee joint. Thousands of small loose bodies can be formed in this manner.

OSTEOCHONDROSIS DISSECANS

Osteochondritis dissecans (OCD) is most frequently encountered in individuals between the ages of 10 and 20 years (20). Cahill (5) has described a subgroup of young patients with OCD and open growth plates, a condition he called juvenile osteochondritis dissecans (JOCD). JOCD is typically seen in boys younger than 14 years of age and in girls younger than 12 years of age. JOCD has a much better healing potential and hence a better long-term prognosis. Cahill estimated that 50% of patients with JOCD heal with conservative care. In contrast, OCD in the older age group rarely heals without surgery.

The etiology of OCD remains controversial, but it appears to be traumatic, with interruption of the blood supply to consistent anatomic areas on the lateral femoral condyle, medial femoral condyle, and patella (1, 28). In OCD, 80% of lesions are noted in the “classic” location: the posterolateral region of the medial femoral condyle;
15% of lesions are seen on the inferolateral region of the lateral femoral condyle. Less than 5% of OCD is located on the patella or trochlear groove. The overall incidence of OCD has been estimated to be 3-10,000 (37). Men predominate 3:1, with bilateral involvement in approximately 30% of JOCD and 5% of the older age group (46). The goal of treatment in OCD is to allow the lesion to heal either by conservative management or surgical intervention in an attempt to maintain integrity of the articular cartilage joint surface. OCD can progress to a completely detached loose body with a residual crater lesion in the articular cartilage surface. This crater lesion can accelerate the process of DJD.

Historically subjective complaints may be vague and not well localized (1). If the OCD fragment is hinged or detached, catching or locking may be observed. Physical examination findings vary depending on the stage of the disease. There may be joint line tenderness and a knee effusion. If the lesion is located in the classic position on the medial femoral condyle, Wilson's test may be positive (72). Wilson's test is performed by extending the knee from a flexed position, with the foot internally rotated. As the knee nears full extension, the tibial spine impinges on the intercondylar region of the medial femoral condyle. This maneuver can be painful in the presence of an OCD lesion located on the medial femoral condyle. There should be no pain associated with extension of a flexed knee with the foot externally rotated.

Radiographically, OCD appears as a well-circumscribed area of radiolucency surrounding an area of subchondral bone (Fig. 84.30). The standard AP view may not demonstrate the OCD lesion. The notch view or flexion weight-bearing view are best for demonstration of the OCD lesion on the femoral condyles (73). On the lateral radiographs, 90% of the lesions of the medial femoral condyle are located in a region defined by a line drawn through the posterior cortex of the femur and Blumenstadt’s line. Of lesions on the lateral femoral condyle, 75% are located posterior to the line drawn along the posterior cortex of the femur. In the patella, 85% of the OCD lesions are located in the midinferior region.

Fig. 84.30. Notch (A) and lateral (B) view of osteochondritis dissecans of the medial femoral condyle.

Arthrography, tomography, and CT can be used in further evaluation of the OCD lesion, but these methods have largely been replaced by MRI. Bone scans may be of value to stage the OCD lesion and evaluate the healing process. Cahill believed that bone scans were helpful for diagnosis and monitoring the clinical course of JOCD (5). A bone scan may be used to detect an early OCD lesion when radiographs are still normal.

MRI can accurately predict the size of the lesion. The OCD lesion can be staged, because MRI will demonstrate whether or not a breach has occurred in the articular cartilage surface.

Arthroscopy is the final option for diagnosis of OCD. It allows for accurate diagnosis, staging, and treatment. The entire suspected OCD lesion must be carefully probed to identify the extent of the lesion. Grossly, the articular cartilage of the OCD lesion may appear to be almost normal in the early stage of OCD, but careful probing often identifies softening or a depression around the circumference of the OCD lesion.

Guhl developed an arthroscopic classification of OCD that reflects the potential natural history of OCD left untreated (25).

Guhl's arthroscopic classification of OCD correlates accurately with the MRI classification. The MRI findings, in conjunction with the arthroscopic findings, are often necessary to determine the treatment that is indicated for each individual OCD lesion.

**Treatment of Osteochondritis Dissecans**

The goal of treatment of OCD is to restore an intact, congruent articular cartilage surface and prevent the development of degenerative arthritis (66).

- Take a complete history and perform a physical examination. Obtain plain radiographs and MRI to plan treatment of OCD lesions.
- JOCD with an intact articular cartilage surface can be treated without surgery (5). Activity modification with use of crutches until symptoms subside is recommended. Once the individual is symptom free, use of crutches can be discontinued. When radiographic evidence of healing is noted, activities can be
Loose body removal needed. For those patients who have recurrent symptoms, arthroscopic loose body removal is recommended. Conservative management includes a program of strengthening, flexibility, activity modification, and NSAIDs. Use intra-articular injections as needed. Turbulence can quickly cause the loose body to escape into another area of the knee. Intra-articular loose bodies can be formed by substantial pieces of the articular cartilage surface breaking off or osteophytes fracturing. Some intra-articular loose bodies grow and enlarge within the environment of the knee joint.

Noncalcified loose bodies, which are not visible on standard radiographs, can be identified by MRI if they are large enough. The most frequently encountered loose bodies are calcified. A knee effusion is typically present. If the loose body is calcified, it will be seen on standard radiographs. Loose bodies can become entrapped in the knee joint and cause mechanical symptoms of catching or locking. At times, the patient can palpate or observe larger fragments moving around in the knee. A knee effusion is typically present. If the loose body is calcified, it will be seen on standard radiographs. Loose bodies can become entrapped in the knee joint and cause mechanical symptoms of catching or locking. Arthroscopy is indicated for stage II, stage III, or stage IV lesions in all age groups. Arthroscopy is indicated for stage II, stage III, or stage IV lesions in all age groups. Use arthroscopic drilling in stable OCD lesions in skeletally immature patients. Drilling allows a fibrin clot to form and stimulates revascularization. Loose bodies can become entrapped in the knee joint and cause mechanical symptoms of catching or locking. Arthroscopy is indicated for stage II, stage III, or stage IV lesions in all age groups. Arthroscopy is indicated for stage II, stage III, or stage IV lesions in all age groups.
Perform a thorough diagnostic arthroscopy before removing the plica, to identify other possible intra-articular causes for knee symptoms.

- Establish a portal for insertion of a grasping instrument. Loose bodies smaller than 1 cm in diameter can be grasped and removed from the usual and customary arthroscopic portals. Large loose bodies may require enlargement of the arthroscopic portals for removal.
- Remove large loose bodies through the capsule and subcutaneous tissues slowly, while rotating the grasped loose body in a clockwise and counterclockwise fashion. Rotation minimizes the risk of dislodging the loose body in the subcutaneous tissues.
- A large loose body can become dislodged in the soft tissues between the knee joint and the skin incision during removal. If this event should occur, use a 2.75 or 4.0 mm arthroscope to visualize the soft tissues around the arthroscopic portal and localize the loose body. Once the loose body is identified in the soft tissues, insert a grasper through the same portal as the arthroscope and regrasp the loose body. If this technique fails, enlarge the arthroscopic portal and identify and remove the loose body.
- In the posterior compartments of the knee, break the large loose bodies into smaller pieces before removing them.
- For large loose bodies in the anterior compartments of the knee, transport the loose body to the suprapatellar pouch with a grasper. Establish a direct superolateral portal of appropriate size, insert a second grasper, and remove the loose body. There is less subcutaneous tissue present in the lateral parapatellar region, and the risk of losing the loose body in the soft tissues is diminished.
- Determine the site of origin of the loose body. By finding the source of the loose body, it is frequently possible to identify whether or not there are other associated loose bodies remaining in the joint. The fragments removed, like the pieces of a puzzle, should fit the chondral defect.
- Treat the remaining chondral defect (chondroplasty, microfracture, osteochondral transfer, chondrocyte autograft, osteochondral allograft) to diminish the risk of further propagation, loose body formation, and acceleration of the degenerative process.
- Acute osteochondral and chondral fractures are associated with lateral patellar subluxation or dislocation and ACL tears or instability.
- Osteochondral fractures with little attached subchondral bone should be removed as the predictability of healing is limited.
- Reattach osteochondral fractures with K-wires or screws if enough bone is present with the chondral fragment (Fig. 84.35). It appears that screw fixation alone provides the most predictable level of healing. The procedure can be performed arthroscopically but often requires a small arthrotomy.

### DIAGNOSIS AND TREATMENT OF SYNOVIAL PLICAS

In the embryologic development of the knee, mesenchymal tissue fills the space between the distal femoral and proximal tibial epiphyses. During development this tissue resorbs in some areas and becomes more dense in other areas forming the meniscus, ligaments, and articular cartilage surfaces. This resorptive process of mesenchymal tissue during embryologic development also leads to the development of four distinct synovial plicae (Fig. 84.36). The plicae’s anatomic description is based on their relationship to the patella: superior, inferior, medial, and laterally based plicae can be identified. Until the advent of arthroscopy, synovial plicae were rarely diagnosed. As arthroscopy developed, the intra-articular synovial plicae were described and studied.

![Synovial plicae of the knee: medial, superior, lateral, and inferior.](image)

The incidence of synovial plicae varies. It is estimated that approximately 67% of knees have an inferior plica, 55% have a superior plica, 25% have a medial plica, and less than 1% have a true lateral plica. A complete superior plica separating the suprapatellar pouch into two compartments occurs in up to 5% of individuals. The incidence of pathologic plicae causing clinical symptoms remains very controversial (13). Clinically, the medial plica is most commonly implicated in knee disorders. Anatomically, the medial plica extends from the medial border of the suprapatellar pouch and attaches to the inferior fat pad, paralleling the medial border of the patella. The free inner margin of the medial plica can impinge on the medial trochlear groove of the patellofemoral joint. In theory, either inflammation or trauma can lead to fibrosis or thickening of the plica.

Historically, individuals with symptomatic medial plicae will report pain along the medial border of the patella that becomes worse with activities that involve repetitive flexion and extension of the knee. There may be an associated sense of popping, clicking, or snapping. On physical examination, a palpable cord or band is noted 1 cm medial to the medial border of the patella. Palpation of this cord causes pain, and this pain reproduces the symptoms the patient has been experiencing. Medial plica are normally not visualized on plain x-ray studies of the knee. Plicas can be noted on MRI scan, arthrograms, or CT scans. Unfortunately, it is difficult to determine from these studies whether a plica is clinically relevant.

Once the clinical diagnosis has been established, nonoperative management is recommended. Rest, with avoidance of aggravating activities, is most critical. Augment this regimen with a strengthening and flexibility program. Soft-tissue physical therapy modalities and anti-inflammatory medications may be useful. One or two local injections may be helpful in diagnosis and treatment. If all conservative measures fail, arthroscopy is indicated. (21,34,61).

### ARTHROSCOPIC MEDIAL PLICA REMOVAL

Perform a thorough diagnostic arthroscopy before removing the plica, to identify other possible intra-articular causes for knee symptoms.

- Visualize the medial plica from the superolateral arthroscopy portal (Fig. 84.37; see also Color Fig. 84.37). A symptomatic medial plica impinges on the medial trochlear groove between 0° and 60° of knee flexion. There may be an associated articular cartilage injury of the medial trochlear groove from this impingement.
If the plica is not thickened and there is no obvious impingement, it is unlikely that resection of the plica will result in any clinical improvement. Leave normal plicae found incidentally at arthroscopy alone. Resect a clinically significant plica back to the capsular tissues using a combination of basket forceps and a shaver. Use an intra-articular cautery to prevent any postoperative hemarthrosis. Following surgery, use a standard postoperative arthroscopy rehabilitation program.

REHABILITATION

The significance of a rehabilitation program in the treatment of disorders of the knee cannot be overstated. Shelbourne has documented the importance of early rehabilitation for ACL injuries before having surgery (59). His studies have demonstrated that patients with good range of motion and strength preoperatively were able to rehabilitate the knee more predictably following definitive surgery. Shelbourne also pioneered the concept of “accelerated rehabilitation” following surgery (60). Patients who have undergone ACL surgery are immediately allowed to initiate a range-of-motion and muscle-strengthening program and bear weight as tolerated. This accelerated program minimizes the risk of postoperative stiffness. These critical concepts of preoperative and postoperative rehabilitation apply for almost all disorders of the knee.

Rehabilitation following an injury or postoperatively may be initiated immediately in most disorders of the knee. Selected knee problems do require urgent or emergent surgery, such as a locked knee for a meniscus tear or loose body, some fractures about the knee, and certain knee ligament injuries. All other individuals will benefit by a preoperative program of rehabilitation. Most of this rehabilitation can be performed at home or in a gym facility and does not require formal physical therapy. Use formal physical therapy on a selected basis, in addition to the home program of exercise.

The key components of any rehabilitation program involve flexibility, strengthening, cardiovascular conditioning, and the eventual return to activities. Have patients perform passive extension in the supine position (Fig. 84.38) to regain flexibility. Place a roll or pillow under the ankle, with the knee left unsupported. Gravity helps stretch the knee into an extended position. If the patient can tolerate weights on the anterior aspect of the knee, the process can be accelerated. Passive extension can also be facilitated if the patient lies prone with the leg unsupported (Fig. 84.39). Weights can be added to the ankle as tolerated. Flexion can be obtained through an active and active-resistive program. The patient can use a towel or belt underneath the thigh to facilitate knee flexion (Fig. 84.40).

Initiate a strengthening program with SLRs or short arc extensions. Back and hip problems can be aggravated by SLRs; individuals with these disorders should avoid SLRs. Have patients perform short arc extensions in a supine or seated position. Once good muscle control has been obtained, have the patient initiate a program of mini-squats and calf raises. When range of motion and strength permit, begin cardiovascular conditioning with bicycling. Swimming, Nordic Trak, Stairmaster, and Ellipse machines are also useful for cardiovascular fitness in appropriately selected patients. Instruct patients to perform their exercises using light weights or resistance with high repetitions (25 to 50 reps) in order not to aggravate the injured knee.

After surgery, begin a rehabilitation program immediately. With few exceptions, most patients can be mobilized. Formal physical therapy may be required in selected patients. Following surgery, most patients should regain the range of motion by 2 months after surgery. If patients are having difficulty regaining extension, serial casting is frequently instituted, often within 1 or 2 weeks following surgery. Consider gentle knee manipulation under anesthesia for those patients who do not regain knee flexion by 6 to 8 weeks after surgery. Loss of range of motion is one of the most significant complications of knee surgery (29). A comprehensive preoperative and postoperative program of rehabilitation emphasizing flexibility, strength, and cardiovascular conditioning can minimize this risk.
Arthroscopic surgery of the knee, like all surgical procedures, has a well-documented complication rate. Overall, arthroscopic procedures have a lower complication rate in comparison to traditional open knee surgery. In 1988, Small reported on complications occurring in over 10,000 arthroscopic procedures performed by experienced arthroscopic surgeons, including 8,700 procedures involving the knee (63). In his series, the overall complication rate was 1.68%. Knee complications included, in order of frequency, postoperative hemorrhage, infection, deep vein thrombosis, anesthetic complications, instrument failure, reflex sympathetic dystrophy, iatrogenic ligament injury or fracture, and neurologic injury. Of note, Small did not report loss of range of motion as a complication, but other authors have (62).

Iatrogenic articular cartilage injury is the most frequent complication that occurs with knee arthroscopy. Make every attempt to avoid articular scuffing, the risk of which can be minimized by proper portal placement, adequate exposure, and careful technique. A knowledgeable assistant who holds the leg can aid significantly with exposure of the compartment being visualized.

The most common complication reported by Small was postoperative hemorrhage (63). Procedures at risk include lateral retinacular release and synovectomy. This risk can be minimized by using drains and intra-articular cautery in such procedures. Postoperatively, most hemorrhage can be managed by aspiration. Rarely, patients need to have repeat arthroscopy and intra-articular cautery of bleeding vessels.

Injuries to the medial collateral ligament can occur with overzealous stress in an attempt to gain exposure of the medial compartment (12). It is more common in patients older than 50 years of age. Most of these injuries represent second-degree tears that will heal uneventfully.

The most frequent anesthetic complications include nausea and vomiting with general anesthetics and spinal headaches with regional anesthetics. Adult respiratory distress syndrome requiring hospitalization has been reported. Careful preoperative evaluation of patients limits perioperative anesthetic complications.

Fluid extravasation has been reported, especially with pressurized inflow pumps (68). This complication can be minimized by periodically observing the leg to ensure that there is no excessive fluid in the soft tissues surrounding the knee. Compartment syndrome has been described in association with fluid extravasation (69).

Deep vein thrombosis is more frequent in older patients (55). It has been demonstrated that the incidence of deep vein thrombosis is increased by the use of a tourniquet for longer than 50 minutes (53). Pulmonary embolus was noted in 25% of these patients. It is important to recognize that in older patients with postoperative calf pain, tightness, or swelling, deep vein thrombosis is a potential complication. In at-risk patients, it is important to minimize venous stasis. Use elastic hose, sequential compression stockings, or Coumadin prophylaxis in high-risk patients.

Infections have been reported in less than 1% of all knee arthroscopies (62). Staphylococcus epidermidis is a pathogen that can be difficult to diagnose simply by culture. Clinical suspicion of S. epidermidis is warranted in the postoperative patient who has increasing pain and a swollen knee. On aspiration, the WBC is greater than 25,000. The C-reactive protein and sedimentation rate are usually elevated. Early arthroscopic debridement and intravenous antibiotics (frequently vancomycin) eradicates the infection. Institute rehabilitation to prevent permanent stiffness. Routine preoperative antibiotic prophylaxis is not recommended for most patients (70).

When establishing arthroscopic portals, it is not unusual to cause injury to sensory nerves or small vessels located in the subcutaneous tissue. Minimize the risk of such injury by bluntly dissecting through the soft tissues down to the capsular structure with a hemostat when making the portal. When establishing new portals, use transillumination to demonstrate vascular structures. Fortunately, major neurovascular injury is rare. The popliteal artery can be penetrated posteriorly (35). Prompt recognition is critical for successful revascularization of the leg.

Careful preparation and attention to detail can minimize complications of arthroscopic knee surgery. A thorough knowledge of knee anatomy is a prerequisite to performing arthroscopic knee procedures. The skill and experience of the surgeon will influence the complication rate.

CHAPTER 85

MENISCUS TEARS

Joseph C. Milne and Richard A. Marder

The major tenet in current meniscal surgery is meniscal preservation. This has been driven by an enhanced appreciation of the contributions of the menisci to reducing articular contact stresses and to stabilizing the joint in concert with the principal ligaments (1,8,22,32,35,46,52). Of importance has been refinement of the criteria used to select appropriate treatment (repair, partial resection, or nonintervention) for the torn meniscus. Technical advances, including instrumentation for repair and resection, have facilitated both repair and resection. A promising potential development is the use of biological scaffolds and growth factors to enhance repair and stimulate meniscal regeneration (6,11,14,27).

ANATOMY AND FUNCTION

VASCULAR ANATOMY

Based on vascular supply, the meniscus can be divided into vascular and avascular zones (5,15). Only the peripheral meniscal rim (the red zone) is richly vascularized, representing approximately 25% of the entire meniscus. The central meniscus (the white zone) is completely avascular and without healing potential. A middle area (the gray zone) is in the transitional area between the periphery and the central meniscus and has limited potential for healing. Enhancement of healing beyond the red zone (peripheral 3–4 mm of the meniscus) has been attempted with a variety of techniques, including fibrin clot interposition, trephination of the peripheral rim to encourage vascular ingrowth into avascular regions, and various suture configurations; it has also been attempted experimentally by using biological scaffolds, cytokines, and other growth factors (6,11,12,14,26,29,38,42).

HISTOLOGY

The meniscus is 75% water and 25% dry elements. Type I collagen accounts for most of the dry composition, providing tensile strength (21). Other components include hydrophilic proteoglycans and elastin. Proteoglycans regulate water content and, therefore, stiffness of the meniscus. Elastin aids in recovery from meniscal deformation associated with cyclic loading.

Most collagen fibers within the body of the meniscus are arranged circumferentially and are parallel to the tibia (13). Radial tie fibers extend from the periphery, perpendicular to the circumferential bands. This fiber orientation accounts for the increased pullout strength of vertical mattress sutures compared to horizontal mattress sutures (42). The surface layer of the meniscus is composed of randomly oriented fibers, which resist splitting and tearing.

BIOMECHANICS

Of the compressive load in the knee joint, 85% is transmitted through the medial meniscus and 75% through the lateral meniscus (49). Meniscectomy has been shown to significantly decrease contact area and increase peak pressures. Under loading conditions, total meniscectomy can cause a fourfold increase in articular surface stresses, partial meniscectomy increases forces twofold, and repair can restore normal contact stresses (6,46). When compressive force is applied to the knee joint, the anterior and posterior attachments of the meniscus resist extrusion (49). This converts compressive force into hoop stress, which the circumferential orientation of the collagen fibers is ideally suited to withstand. The radial tie fibers and superficial layer resist shear stresses that attempt to separate the circumferential bundles, which would result in a vertical longitudinal tear.

STABILITY

Levy et al. examined the role of the meniscus in limiting anteroposterior (AP) translation of the tibia relative to the femur. Although isolated sectioning of the meniscus had no effect on stability, sectioning it in a knee with a deficient anterior cruciate ligament (ACL) caused a significant increase in AP translation (32). The contributions of the medial meniscus to stabilizing the knee exceed those of the lateral meniscus. Other studies have shown a small but statistically significant increase in varus–valgus laxity after meniscectomy (63). These reports confirm the function of the meniscus as a secondary stabilizer.

MECHANISM OF INJURY

Meniscal tears usually result from a single, acute rotational force applied to the weight-bearing knee that overloads the meniscus. Degenerative tears occur from repetitive submaximal forces applied to a meniscus having already undergone attritional wear from an irregular femoral articular surface; the majority involve the medial meniscus (33). Concomitant meniscal injury often accompanies tears of the ACL as well as multiple knee ligament injuries including dislocation of the knee. Whereas lateral meniscus injuries are most frequent in acute ACL tears, the medial meniscus is most often torn in chronic ACL insufficiency. In combined ACL and medial collateral ligament (MCL) injuries, meniscus tears occur less frequently with complete MCL tears (grade III) than with partial tears (grade II) and, in both instances, predominantly affect the lateral meniscus (49).

Tear patterns are typically described by configuration, acuity, and location. The most common tears are vertical longitudinal (bucket-handle), oblique (flap), radial, horizontal cleavage, and complex (Fig. 85.1). Most tears involve the posterior aspect of the meniscus. Tears are usually complete, traversing the entire surface of the meniscus, but they may be incomplete, affecting only the inferior or superior surface of the meniscus (Fig. 85.2; see also Color Fig. 85.2).
Most meniscal tears are treated by arthroscopic partial meniscectomy. The goal of partial meniscectomy is to remove only the unstable or pathologic portion, leaving as much healthy meniscal tissue as possible while avoiding an abrupt transition to the remaining meniscus. Partial meniscectomy is indicated for radial tears not extending to the periphery, oblique tears, horizontal cleavage tears, degenerative tears, and irreparable vertical longitudinal tears that are more than 5 mm from the absolute periphery.

PERIPHERY.

Most meniscal tears are treated by arthroscopic partial meniscectomy. The goal of partial meniscectomy is to remove only the unstable or pathologic portion, leaving as much healthy meniscal tissue as possible while avoiding an abrupt transition to the remaining meniscus. Partial meniscectomy is indicated for radial tears not extending to the periphery, oblique tears, horizontal cleavage tears, degenerative tears, and irreparable vertical longitudinal tears that are more than 5 mm from the absolute periphery.

CLINICAL ASSESSMENT

The torn meniscus typically causes pain during axial loading and rotation of the knee and may be accompanied by mechanical symptoms of catching, popping, giving-way, swelling, and locking. The patient may describe relief of symptoms with manual reduction of the displaced meniscal fragment. In the arthritic knee, it is useful to distinguish between patients with pain only and those with pain associated with one or more mechanical symptoms. In the absence of mechanical symptoms, it is unlikely that resection of a degenerative tear will give significant pain reduction.

Perform a complete knee examination, including assessment of limb alignment, gait pattern, and hip function, especially in the older patient who might have hip pain referred to the medial knee. Fowler and Lubliner delineated predictive criteria for meniscus tears (25). The most specific findings of a meniscal tear are a positive McMurray’s test and block to extension. Unfortunately, the McMurray’s test is the least sensitive test. Although joint line tenderness is very sensitive for a meniscus tear, it is the least specific test, especially in the presence of an acute ACL injury. Some patients will exhibit an effusion, and many will demonstrate pain with forced knee flexion as well as forced extension (spring or bounce test).

IMAGING

Radiographs are mandatory; perform magnetic resonance imaging (MRI) on a case-by-case basis. For patients over the age of 40, perform AP weight-bearing radiographs in addition to a lateral view of the knee to exclude degenerative joint disease (DJD), loose bodies, osteonecrosis, and tumor. Take additional views such as a Merchant view to evaluate the patellofemoral joint, a notch view to look for loose bodies, and a weight-bearing PA in 45° of flexion to diagnose early DJD on an individual basis.

In the preoperative confirmation of a meniscal tear, MRI is a tremendous asset, with an overall accuracy approximating 90%. If cost were not a consideration, MRI would be routine in every patient as an adjunct to, but not as a substitute for, a thorough physical and adequate radiographic examination. In this day of managed care, however, MRI is performed nonoperatively with resolution of symptoms (33). Usual measures include nonsteroidal anti-inflammatories, a neoprene sleeve, muscle-strengthening exercises for the lower extremity, and sometimes a formal course of physical therapy. For patients with continuing symptoms, arthroscopic intervention is indicated.

While inherently unsettling to most surgeons, partial-thickness tears, incomplete radial tears, and stable vertical longitudinal tears less than 10 mm in length do not need resection. Shelbourne has shown that in patients undergoing ACL reconstruction, these tears have sufficient indication for proceeding directly to arthroscopy (23). In addition, MRI is infrequently helpful in the previously operated meniscus to assess either healing after repair or reinjury in the patient with previous partial meniscectomy.

NONOPERATIVE TREATMENT

Approximately 40% of patients with pain and swelling consistent with a meniscus tear, but with no history of locking, a block to extension, or ACL injury, can be treated nonoperatively with resolution of symptoms (33). Usual measures include nonsteroidal anti-inflammatories, a neoprene sleeve, muscle-strengthening exercises for the lower extremity, and sometimes a formal course of physical therapy. For patients with continuing symptoms, arthroscopic intervention is indicated.

While inherently unsettling to most surgeons, partial-thickness tears, incomplete radial tears, and stable vertical longitudinal tears less than 10 mm in length do not need resection. Shelbourne has shown that in patients undergoing ACL reconstruction, these tears remain asymptomatic and do not progress (24).

SURGICAL TECHNIQUES

PARTIAL MENISECTOMY

Most meniscal tears are treated by arthroscopic partial meniscectomy. The goal of partial meniscectomy is to remove only the unstable or pathologic portion, leaving as much healthy meniscal tissue as possible while avoiding an abrupt transition to the remaining meniscus. Partial meniscectomy is indicated for radial tears not extending to the periphery, oblique tears, horizontal cleavage tears, degenerative tears, and irreparable vertical longitudinal tears that are more than 5 mm from the absolute periphery.

- See Chapter 84 for the general principles of arthroscopy.
- Portal placement is of importance in performing partial meniscectomy. With the arthroscope in the interlateral portal, use a spinal needle to identify proper placement of the inferomedial portal and any accessory portals. The inferomedial portal for medial meniscectomy typically is just inferior to the level of the femoral condyle, use a postero-medial portal. With the arthroscope in the postero-medial compartment, pass through the intercondylar notch.
- If a lateral tear is encountered, make the inferomedial portal with the leg in the figure-four position. This needs to be at a higher level than the inferolateral portal to allow instruments to pass freely above the tibial spines. For posterior tears of the lateral meniscus, instrumentation is usually necessary through the inferolateral portal because of the tighter radius of curvature of the lateral meniscus, which limits access from the inferomedial portal.
- Once appropriate portals are established, resect using a combination of hand instruments and a motorized shaver (Fig. 85.3). Simple flaps and longitudinal tears can often be excised intact, using an arthroscopic knife or scissors to detach the segment. Debride most tears in a piecemeal fashion. A small up-biting punch, straight punch, right and left 90° punches, and a 4.5 mm full-radius resector will suffice for resection of most tears.
Tear pattern. Repair is indicated for vertical longitudinal tears longer than 1 cm and for radial tears that extend into the red zone.

Postoperative Management

Use cryotherapy, compression, and limited weight bearing for 24–72 hours postoperatively to minimize swelling and attendant pain. Implement early isometric quadriceps exercises and range of motion without load when discomfort permits. Within a few days to 1 week after surgery, begin progression to unaided walking, cycling, and short-arc quadriceps exercises. Once the incisions are healed, swimming can be started. Normal activities can usually be resumed within 2–3 weeks but may take as long as 6 weeks. If the tear was complex or degenerative, defer running, squatting, and other stressful activities for a minimum of 3–4 weeks. Physical therapy can be beneficial to achieve an earlier return to activity, but it is not mandatory.

MENISCAL REPAIR

Despite the first meniscal repair in 1885 by Annandale (4), complete or partial meniscectomy remained the treatment of choice of the vast majority of orthopaedists until the early 1980s. Interest in repair has been stimulated by deHaven’s work on open meniscal repair (15,17 and 18) and Henning’s inside-out arthroscopic repair (28,29). Since that time, numerous basic and clinical science reports have validated the concept of meniscal repair (2,20,30,36,37,41,43,44). Accepted techniques include open repair, inside-out arthroscopic repair, outside-in arthroscopic repair, and all-inside repair.

Despite the many available options, the reported success rates of meniscal repair are similar, based on an average of published reports (2,9,13,20,30,34,36,37,41,43,47,51), with an overall healing rate of nearly 85% (Table 85.1). Interstudy comparisons are difficult due to varied techniques, as well as differences in types of tears, patient data, associated injuries, and postoperative assessment criteria. For instance, clinical success rates based on symptoms and function exceed anatomic healing rates (34,45).

Indications for Repair

Suitability for repair requires assessment of location, pattern, and age of the tear; quality of meniscal tissue; patient age; associated injuries; as well as surgical skill.

Location. We repair all tears in the red zone (0–3 mm from the periphery) and most in the gray zone (3–5 mm from the periphery). We repair only nonmacerated, nondeformed fragments in the gray zone. While recent work by Rubman et al. (44) has shown acceptable results from repair of tears in the white zone, this is not yet widely practiced.

Tear pattern. Repair is indicated for vertical longitudinal tears longer than 1 cm and for radial tears that extend into the red zone.
Tissue quality. We do not repair macerated and degenerative menisci. Similarly, we treat with partial meniscectomy those chronic tears that involve a meniscal deformity that precludes a functional repair.

We routinely perform meniscal repair in patients up to the age of 45 years. Over this age, we do repairs in some patients on a case-by-case basis, depending primarily on functional activity level, physiologic age, and willingness to follow a more lengthy and rigorous postoperative management protocol as contrasted to partial meniscectomy. Some older patients may elect partial meniscectomy to allow an earlier return to activity.

Once the reparable meniscus is identified, a surgical technique must be selected. Technical aspects of the two most popular arthroscopic methods are presented.

**Inside-out Technique**

This remains the most popular method. It allows accurate placement of sutures while protecting neurovascular structures by incorporating an accessory incision.

- Use either a rasp or small shaver to debride the tear margins to achieve smooth meniscal surfaces and excoriate the adjacent synovial tissue to produce slight bleeding.
- Make an accessory posteromedial or posterolateral incision to expose the capsule. For a medial tear, transilluminate the posteromedial knee through the notch to identify the saphenous vein, which travels with the nerve. Make a 3 cm longitudinal incision posterior to the MCL, centered just below the joint line (to accommodate the needles that will pass from superior to inferior). Retract the pes tendons posteriorly, along with the saphenous vein and nerve. Dissect the interval between the joint capsule and the medial head of the gastrocnemius, and insert a small vaginal speculum or commercially available specialized retractor into this interval to expose the posterior capsule while protecting the posterior neurovascular structures. The retractor will deflect needles exiting the joint, allowing easy retrieval.
- On the lateral side, make the incision along the posterior aspect of the lateral collateral ligament (Fig. 85.5) with the knee flexed approximately 90°. Develop the interval between the biceps femoris posteriorly and the iliotibial band anteriorly. Separate the lateral head of the gastrocnemius from the joint capsule. Insert the retractor in front of the lateral gastrocnemius to protect the adjacent peroneal nerve.

![Figure 85.5.](image)

Figure 85.5. Exposure of posterolateral capsule. Note that retractor must be placed in front of the lateral head of the gastrocnemius to protect the peroneal nerve.

- As with an all-inside repair (technique below), portal placement must allow the cannula to be placed perpendicular to the tear and horizontal to the joint line. This usually requires placement of sutures into the meniscus from the contralateral portal while viewing from the ipsilateral portal. Placement of the cannula in the contralateral portal also tends to angle the penetrating needle away from the popliteal region (Fig. 85.6). Because of the curvature of the meniscus, it is helpful to utilize cannulas of various angles (Fig. 85.7). A single cannula is preferable because it allows greater flexibility in placing the second arm of the stitch.

![Figure 85.6.](image)

Figure 85.6. A curved cannula inserted through the contralateral portal is used for suturing to avoid popliteal vessels and nerves.

![Figure 85.7.](image)

Figure 85.7. Zone-specific cannulas for meniscus repair.

- For medial tears, position the knee near extension to facilitate passage of the needles into the posterior meniscus and to preserve the posterior capsular fold. For lateral tears, position the knee in flexion to avoid injury to the peroneal nerve, and insert a retractor in front of the lateral head of the gastrocnemius.
- Starting posteriorly, insert the appropriate curved cannula and advance a 10-inch needle with attached suture [2-0 nonabsorbable provides sufficient tensile strength (10)] to engage the torn fragment and reduce it to the margin. With the posterior retractor in place, push the needle through the meniscus margin posteriorly. Visualize the needle’s exit before continuing to push it out of the posterior incision or using a needle driver to grasp and deliver it. Place the second needle vertically (42) with a 3 mm bridge between arms (Fig. 85.8). Place as many sutures as necessary, maintaining a 5 mm interval between sutures. Then tie the sutures directly over the exposed capsule. If concomitant ACL surgery is being performed, delay tying the sutures until after the surgery is completed. Release the tourniquet to allow blood to fill the meniscal repair site and then tie the sutures.
Vertical mattress sutures placed through a cannula.

For tears with an extreme anterior component, an outside-in suturing technique utilizing commercially available, modified spinal needles and suture passers can facilitate repair by allowing more precise needle placement.

**All-inside Technique**

This method does not require additional incisions; it decreases operative time and complications; and its healing rates are similar to those of inside-out repair (2,19). We use a meniscal arrow system (Bionx Implants, Blue Bell, PA). The arrow is made of a biodegradable polyactic acid that resorbs over a 3-year period. The implant has a barbed shaft with a 4 mm T-head, and it comes in 10 mm, 13 mm, and 16 mm lengths (Fig. 85.9). The bars are perpendicular to the T-head to obtain maximum purchase in the circumferential fibers of the meniscal body. Pull-out strength of the arrow has been shown to be equivalent to horizontal mattress sutures (2,12). The instrumentation set contains five different cannulas with varying curvatures, allowing access to all regions of the meniscus (Fig. 85.10).

**Figure 85.8.** Vertical mattress sutures placed through a cannula.

**Figure 85.9.** Bionx meniscal arrows. Note that barbs are perpendicular to the T-head.

**Figure 85.10.** Bionx instrumentation set, including curved cannulas.

**Prepare the tear margins as described above. Occasionally, it may be necessary to rasp the posterior horn of the medial meniscus from a posteromedial portal to avoid injuring the medial femoral condyle. Use a probe to estimate the necessary arrow length. Whenever possible, use 13 or 16 mm long arrows, because of their higher pullout strength (12).**

**Insert the appropriately curved cannula parallel to the joint line and perpendicular to the tear to obtain optimum fixation. Posterior tears are best addressed with the cannula in the ipsilateral portal, while tears in the midportion require that the cannula be inserted through the contralateral portal.**

**Use the cannula to hold the meniscus in a reduced position so that the arrow can enter the meniscus 3–4 mm from the tear. Insert the “spear” into the cannula, pushing it through the meniscus until its handle is seated, preparing a channel for the arrow (Fig. 85.11).**

**Figure 85.11.** Cannula holds the reduction, while a “spear” is used to create a channel for the arrow.

**Remove the spear and insert the appropriate-length arrow into the cannula. Now push the arrow down the cannula and across the tear. Be certain to push the inserter all the way down against the back of the cannula to ensure that the head of the arrow is countersunk into the meniscus. If removal of an arrow is necessary, rotate it 90° with a grasper (T-head perpendicular to tibia) prior to removal. This will reduce meniscal trauma by disengaging the barbs from the circumferential fiber bundles.**

**For posterior tears, place the most posterior arrow first, followed by an arrow in the center of the tear. If the tear is in the midportion of the meniscus, place the first arrow centrally with subsequent arrows in the anterior and posterior extents of the tear. Place arrows every 5 mm (Fig. 85.12).**

**Figure 85.12.** Arrows stabilizing a vertical tear.
Postoperative Management

Historically, most surgeons have prescribed limited motion and no weight bearing for several weeks after surgery, with a delay of 6 months or more to resume sports (16,29). Over the past several years, restrictions on patient activities after meniscal repair have eased considerably. Based on experimental and clinical studies, postoperative rehabilitation has progressed to early, full-weight-bearing, unlimited motion without bracing, and return to sports as soon as normal strength, motion, and flexibility are achieved (9,47).

When meniscal repair is performed in conjunction with ACL surgery, we follow the rehabilitation program for the cruciate ligament (see Chapter 89). When isolated meniscal repair has been performed in an acute tear where satisfactory apposition and fixation have been achieved, we use a modified accelerated protocol with a short, initial period of bracing (Table 85.2). Encourage early use of a stationary bicycle and isokinetic exercises, but avoid squinting and pivoting for 2–3 months. In our experience, return to full activity usually takes 3–4 months. If a patient develops pain or effusion, slow down or regress activity until symptoms subside. If symptoms do not resolve, investigate further (using arthrogram or arthroscopy) to evaluate the knee.

Table 85.2. Postoperative Management for Meniscal Repair

PITFALLS AND COMPLICATIONS

Delayed surgery in the knee with a history of locking, a block to extension, or associated ACL and meniscus tear can be associated with articular degeneration (50). Complications of open or arthroscopic meniscus surgery include failure to heal or retear after meniscal repair, neurovascular injury, hemorrhage, deep vein thrombosis, reflex sympathetic dystrophy, infection, iatrogenic injury to intraarticular structures, especially the femoral condyles, osteonecrosis, and DJD (7,31,40).

The most important factor influencing meniscal healing is knee stability. In knees with concomitant ACL reconstruction, meniscal healing rates are approximately 90% to 100%. This contrasts sharply with success rates as low as 30% in the ACL-deficient knee (53). In isolated meniscal injury, healing rates are less than those observed in the knee undergoing simultaneous ACL reconstruction, but, as noted previously, they average 85%.

Saphenous neuropathy is the most frequent complication associated with meniscal repair (7). Injuries to the saphenous nerve or its infrapatellar branches are transitory in nearly 90%, resolving over several weeks (7). While permanent injury is rare, a neuroma can occur, producing pain and numbness. With lateral meniscal repair, the peroneal nerve is at risk with any inside-out technique. Complications associated with meniscal arrows include pain secondary to prominent arrow tips, as well as breakage of arrows during insertion. A recent randomized study with 68 patients compared arrows to inside-out suture repair. Two infections occurred in the suture group and none in the arrow group; five patients had saphenous nerve pain in the suture group, compared to two in the arrow group (2).

The treatment of articular cartilage injuries remains a difficult challenge. Because joint surfaces have a limited intrinsic capacity for repair after they are damaged, they remain abnormal and may deteriorate over time. The natural history of chondral injuries has not been well defined, and there is a wide range of injuries from small partial-thickness lesions to large full-thickness articular defects. When considering treatment, you must include factors such as lesion location, size, and depth, associated instability, malalignment, age, and activity level (17). Although a broad range of treatment methods has been developed and short-term successes have been reported by many, no procedure has ever been shown to consistently restore a damaged articular surface to normal. Controlled studies comparing several current treatment methods for articular cartilage injuries are underway; however, long-term follow-up data will be needed before conclusions can be drawn.

ARTICULAR CARTILAGE: COMPOSITION AND STRUCTURE

The mechanical and biological properties of articular cartilage are defined by its composition and structure. Normal articular cartilage has a highly organized structure composed of a small chondrocyte population surrounded by a large extracellular matrix (4,5). The matrix elements include collagen (primarily type II), proteoglycan aggrecan, glycoproteins, and water (4,18,20). Up to 80% of the weight of normal articular cartilage is water (4,22). Within this matrix, chondrocytes synthesize developing articular cartilage and play a role in both cartilage maintenance and degradation (5).

It is the biphasic nature of articular cartilage (solid and liquid) that provides its remarkable mechanical qualities. The solid phase consists of collagen and proteoglycans, and the liquid phase contains primarily water and electrolytes (4). When a compressive load is applied to a normal articular surface, the fluid phase takes the majority of the initial stress (5,22). Fluid flows out of the matrix to absorb the force. After a period of continuous loading, fluid has diffused out of the matrix, and the solid phase bears the load. When the load is removed, the fluid flows back into normal cartilage. In abnormal cartilage, the balance of fluid is poorly controlled, leading to abnormal force transmission and abnormal water concentration (19). A cycle of progressive damage is thus initiated (Fig. 86.1).

CARTILAGE INJURY

CLASSIFICATION

A classification system is helpful for understanding the spectrum of articular cartilage injury. In 1961, Outerbridge (28) described a grading system for articular damage that was based on his findings with open operative procedures for patellar chondromalacia. This system was based on the size and gross appearance of surface lesions and did not include factors such as lesion depth or location or associated pathology on other joint surfaces. Although it was developed in the prearthroscopic era and is highly subjective, it remains the most widely used grading system for articular cartilage injury. Noyes and Stabler (23) refined the Outerbridge articular injury classification in 1989, basing their changes on arthroscopic findings. The articular lesion is defined on the basis of depth, diameter, and location. Lesions less than 10 mm are not considered clinically significant (Table 86.1).

Table 86.1. Classification of Articular Injuries
NORMAL TISSUE RESPONSE TO INJURY

When a normal, vascularized tissue is injured, a predictable cycle of repair is initiated (18,20). Necrosis of damaged cells begins immediately and depends on injury severity, blood supply, and oxygen content. Next, an inflammatory phase is mediated by the vascular system, with an influx of undifferentiated cells. A dense fibrin network forms the cellular "glue" to hold the tissue together (29). Finally, tissue repair occurs with neovascularization of the fibrin network into granulation tissue and scar.

ARTICULAR CARTILAGE RESPONSE TO INJURY

Articular damage may result from a single severe impact or repetitive trauma (5). When a partial-thickness injury occurs, a chondral fissure or flap is often produced. The injured chondrocytes undergo necrosis with some matrix disruption, depending on degree of injury. But because the articular surface is avascular, the normal cycle of tissue repair cannot proceed. Without a blood supply, no hematoma is formed, fibrin is not produced, and the inflammatory phase cannot occur (5,18). In addition, without a fibrin network, the repair phase is very limited. The small amount of repair is generated solely by the remaining viable chondrocytes, as no supply of undifferentiated cells is available. These chondrocytes proliferate, but their response is incomplete and short-lived.

Small superficial lesions typically remain stable over time and do not progress to degenerative arthritis (18). Larger lesions with articular flaps and loose articular debris, however, cause joint effusion with mechanical symptoms and have the potential to progress to significant degenerative arthritis. Blunt trauma to articular cartilage is a particularly insidious injury. Initially, the gross appearance of the articular surface may be normal; however, microscopic examination will reveal disorganized collagen, increased water concentration, and decreased proteoglycan concentration (5). This type of blunt articular injury can later progress and degenerate.

OSTEOCHONDROTIS DISSECANS

Osteochondritis dissecans (OCD) represents a special case of articular injury. Although the exact etiology is unknown, both the juvenile and adult forms likely develop from exercise-related repetitive subthreshold trauma that leads to subchondral stress fractures (6). The articular injury results when an osteochondral fragment becomes loose or separates. Ideally, one can initiate conservative or minimally invasive treatment before an OCD lesion separates. In the juvenile form, the open physes provide the potential for spontaneous healing, and the prognosis is good. The adult form, however, has little potential for healing and the prognosis is poor, with frequent early degenerative arthritis.

DIAGNOSIS AND TREATMENT OPTIONS FOR ARTICULAR INJURIES

DIAGNOSIS

Articular injuries are often difficult to identify by physical examination because their clinical presentation may be indistinguishable from or may coexist with a torn meniscus. Joint effusion and mechanical symptoms may be absent, and persistent pain after an injury may be the only complaint. Although a nonspecific finding, point tenderness over an area of articular damage can occasionally be elicited. The mechanism of articular injury is usually a twisting or shearing force, but articular damage may result also from direct trauma. The frequent association of chondral injury with chronic anterior cruciate instability has been well documented (7,13,36).

When a large knee hemarthrosis is aspirated, the presence of fat globules suggests a full-thickness chondral injury or osteochondral fracture. A high index of suspicion must be maintained to recognize a probable articular injury.

Some articular injuries can be detected preoperatively with conventional magnetic resonance imaging (MRI); however, the majority of articular lesions are found at the time of arthroscopic surgery. Specialized MRI using fast-spin echo sequences has been shown to have enhanced accuracy for partial- and full-thickness articular injuries and may allow preoperative diagnosis (29).

PARTIAL-THICKNESS INJURIES

A wide range of articular injuries may be encountered at arthroscopy, and it is important to distinguish symptomatic lesions from those that are incidental findings. Correlate preoperative symptoms and physical findings, and look for associated pathology. Because partial-thickness injuries tend to remain stable over time, treat only those areas that have large articular flaps and impending loose bodies. To avoid making grooves or channels in the remaining cartilage surface, when debriding a lesion, rotate the cutting surface of the arthroscopic debrider blade 90°, and use only the blade edge in a tangential fashion to resect articular flaps (Fig. 86.2).

Figure 86.2. Technique for arthroscopic debridement of loose chondral flaps. A: Do not debride with the mouth of the debrider directed toward the articular surface. B: Keep the mouth of the debrider at right angle (tangential) to the articular surface.

Avoid aggressive debridement, as this does not stimulate healing and may cause degeneration of the underlying cartilage. Despite the improved appearance of the articular surface after chondral shaving, Kim et al. (18) showed that further surface degeneration is common. Do not convert a partial-thickness injury to a full-thickness defect. Although there is enhanced healing potential when the subchondral bone is involved, there is little assurance that the fibrocartilage repair response will be any better than a carefully debrided partial-thickness injury, and it may lead to further deterioration of the damaged joint surface.

Laser chondroplasty may also improve the surface appearance of partial-thickness articular damage, but it has not been shown to stimulate healing. In addition, with a laser, there is the potential for thermal damage to the cartilage deep to the point of laser application that may later lead to development of a full-thickness defect or osteonecrosis. Recently, radiofrequency energy has been suggested as a means of stimulating articular healing (14), but further clinical studies are needed.

FULL-THICKNESS INJURIES

Osteochondritis Dissecans

Although the overall prognoses for juvenile and adult OCD are very different, the treatment principles are similar. When a fragment separates from a weight-bearing surface, replace all potentially viable fragments, as removal of these fragments has a predictably poor outcome (6,33). Only those occasional fragments from non-weight-bearing surfaces may be removed with minimal adverse sequelae. Despite the frequent progression of adult OCD to degenerative arthritis, aggressive treatment with reattachment of the articular fragment may slow the progression or lessen the severity of the arthritis. After a full-thickness defect develops from an OCD lesion, one of the many treatments for focal defects can be used. Lesion size and location will help determine which treatment method is best. With osteochondritis dissecans, there may be an associated large bone defect that may require supplemental bone grafting.

Focal Chondral Defects

Over the last four decades, many treatment techniques have been developed for focal full-thickness chondral defects. These techniques began with open debridement,
spongialization, and osteotomy; evolved into arthroscopic debridement, abrasion arthroplasty, and microfracture; and now include autogenous osteoarticular mosaicplasty, autogenous chondrocyte implantation, and allograft replacement. As is often the case when many treatment options are used, no single method has been shown to be superior on a consistent basis. Because some good results have been reported with each technique, decision making for the treatment of full-thickness defects is challenging.

The various treatments can be categorized into four basic techniques: (a) stimulation of intrinsic healing potential, (b) alteration of loads, (c) transfer of autogenous tissue and cells, and (d) transfer of allograft tissue. Exact guidelines and indications for each technique are controversial. Many factors, including lesion location, size, and depth, patient age, activity level, alignment, and ligamentous instability, must be considered; and deciding which lesions to treat is difficult, as the natural history of chondral injuries is poorly understood (22). Equally important is the experience of the surgeon, as many of these techniques are technically demanding.

**Stimulation of Intrinsic Healing Potential**  Since Pridie described spongialization of degenerative articular surfaces in 1959, many surgeons have developed techniques to stimulate healing of worn or damaged articular surfaces (11). Debridement with drilling, abrasion arthroplasty, and microfracture all share the basic principles of removing loose debris and degenerative cartilage, and penetrating the subchondral bone to produce bleeding. Using hand awls, instead of power drills, to create subchondral holes avoids thermal injury and creates microfractures of the trabecular bone (24-34). This in turn stimulates a tissue healing response (Fig. 86.3), see also Color Fig. 86.3.

**Figure 86.3.** (See Color Fig. 86.3.) Technique for debridement, abrasion arthroplasty, and microfracture. A: Arthroscopic view shows a chondral flap tear on the medial femoral condyle. B: The unstable flap and unstable edges of the cartilage are debrided. Note that this is a full-thickness defect exposing underlying subchondral bone. C: The debridement is completed by smoothing the edges with a curet. D: An awl is used to punch through (microfracture) the subchondral bone to bring cells into the defect. E: Two microfracture holes, with bleeding from one.

With subchondral bone penetration, a pluripotent cell line is released and, in the proper environment, can differentiate into a chondrogenic cell line (20,24). Although the perfect environment for chondrogenesis has not been defined, factors such as protected postoperative weight bearing and continuous passive motion (CPM) have been associated with enhanced healing (34,35). Other factors, such as transforming growth factor-β1, insulin-like growth factor (IGF-1), and bone morphogenetic protein (BMP), appear to play an important role in the cartilage-healing environment and are being studied (4,5).

It is important to understand that subchondral penetration does not produce normal articular cartilage. Unlike hyaline cartilage, which contains primarily type II collagen, the regenerated cartilage from these techniques is fibrocartilage with a high concentration of type I collagen (15). It is not as smooth or durable as normal hyaline cartilage and tends to deteriorate over time (4,17).

An isolated chondral defect in an otherwise normal joint has a much better prognosis than a defect in an arthritic joint with diffuse chondral degeneration. Several studies have shown that drilling and abrasion of arthritic knees do not provide significant benefit over arthroscopic debridement alone and may actually accelerate the degenerative process (1,30). Smaller defects also have a better prognosis than larger ones, and unipolar defects have a better prognosis than bipolar “kissing lesions.” Overall, the short-term outcome from abrasion, drilling, and microfracture is fairly good, with variable degrees of symptomatic improvement for several years. The fibrocartilaginous repair tissue does deteriorate over time.

**Alteration of Loads**  Historically, osteotomy has been used in an attempt to provide symptomatic relief for patients with damaged or degenerative joints. Its underlying principle is to shift a force concentration overload away from a damaged joint surface. Initially, symptomatic improvement can be achieved for patients with isolated unicompartmental disease, but results deteriorate with time. Insall et al. (12) reported good and excellent results from proximal tibial osteotomy in 85% of patients at 5 years but noted only 37% excellent results after 9 years. Some healing of articular lesions has been documented at second-look arthroscopic surgery after proximal tibial osteotomy (8), but preoperative arthroscopic evaluation has not been found to be a positive predictor of outcome (15).

For a focal chondral defect in an otherwise normal knee, consider osteotomy to correct significant associated limb malalignment. The role of osteotomy in a normally aligned limb is limited because the potential benefits are small, the potential complications are significant, and the potential compromise of future prosthetic reconstruction is well known (38).

**Autogenous Tissue Grafting**  Autogenous grafting for articular defects is an attractive option, as it has the potential to transfer normal articular cartilage into a damaged area. There are no risk of disease transmission, no problem with tissue rejection, and a high rate of union. In addition, chondrocyte viability is maintained with fresh autogenous grafts (22). Unfortunately, the supply of expendable autogenous osteoarticular grafts is limited, and donor site morbidity is a major concern.

For smaller defects (up to 2.5 cm²), an arthroscopic mosaicplasty as described by Hangody et al. (19) using small osteoarticular plugs can be performed with minimal donor morbidity (Fig. 86.4). In animal studies, the articular cartilage in the transplanted osteoarticular plugs has been shown to survive, with fibrocartilage filling the area between the plugs. The donor sites were also found to fill with fibrocartilage. Early clinical outcomes are promising, but the long-term outcome with this procedure is not known.

**Figure 86.4.** Technique for osteoarticular mosaicplasty. 1: Preparation of recipient site. 2: Harvest of the grafts. 3,4: Preparation for the plug grafts. 5: Insertion of the plugs. 6: Completed mosaicplasty. (From Mandelbaum BR, Browne JE, Fu F, et al. Articular Cartilage Lesions of the Knee. Am J Sports Med 1998;26:855, with permission.)

For larger defects (>2.5 cm²), there is usually not sufficient expendable articular cartilage to fill the defect by mosaicplasty. For femoral lesions, Outerbridge et al. (27) reported the use of a lateral patellar autograft. Grant incorporation was not a problem, and subsequent biopsy of transplanted articular cartilage demonstrated that the hyaline cartilage survived. However, donor site morbidity remains a major concern. Most of these cases necessitated removal of the lateral third of the patella, and at an average follow-up of 6.5 years, four patients had mild anterior knee pain, two had flexion contractures, and five had nonpainful patellar crepitation. Once again,
short-term results are encouraging, but the long-term outcome is unknown.

Periosteal and Perichondrial Grafting Success with periosteal and perichondrial grafting of articular defects has been reported both in animal models and in humans. The principle behind these procedures is to provide a new source of chondrogenic cells to repair the defect. Several series have been published, and some successful regeneration of hyaline cartilage has been achieved (21,25,26,31), but there are no long-term data or controlled studies. The limited supply of expendable perichondrium limits its use and makes peristemun a more attractive option. Meticulous technique is required in both graft harvest (to maintain cell viability) and graft fixation (to avoid unstable or redundant repair tissue). There is evidence that this technique works best in younger patients (3), and some problems with graft calcification have also been reported (24).

Autologous Chondrocyte Implantation In 1994, Brittberg et al. (3) published their initial clinical series of 23 patients with full-thickness chondral defects treated with autologous chondrocyte implantation (ACI). Their technique, which was developed initially in an animal model, involves a two-stage surgical procedure (9). At arthroscopy, cartilage slices are harvested from the non-weight-bearing trochlear margins or intercondylar notch, placed in sterile medium, and sent to the laboratory. The chondrocyte cells are isolated and cultured over 14–21 days to increase the number of cells 10- to 20-fold. A second open surgical procedure is performed in which a periosteal patch is sutured over the chondral defect and the cultured chondrocytes are injected under the patch. Fibrin glue is used to achieve a watertight seal (Fig. 86.5).

![Figure 86.5. Technique for autologous chondrocyte implantation. (Redrawn from Mandelbaum BR, Browne JE, Fu F, et al. Articular Cartilage Lesions of the Knee. Am J Sports Med 1998;26:856, with permission.)](image)

With this technique, Brittberg et al. (3) reported 87% good and excellent results with femoral condyle lesions and noted repair of cartilage with a hyaline-like appearance at second-look arthroscopy in 73% of these lesions. Defects involving the patellofemoral joint did poorly, with only 28% good and excellent results. This was felt in part to be due to underlying patellar malalignment that was not corrected at the time of ACI.

Histologic studies of the hyaline-like repair tissue demonstrated an abundance of type II collagen. Animal studies have demonstrated that the repair is initiated by the injected chondrocytes, which repopulate the defect, and not by the periosteal patch (9). In addition, it is of particular interest that repeat arthroscopy on the successfully treated femoral condyle lesions demonstrated improvement of the hyaline-like repair tissue over time. Since the initial clinical report, tremendous interest in ACI has been generated, and the technique has been used in 1,896 cases recorded in the Genzyme Tissue Repair Registry (Genzyme, Inc., Cambridge, MA). The early data suggest moderate success with femoral defects, but few surgeons have duplicated the success rate of Peterson and the early Swedish experience (3). This underscores the importance of meticulous surgical technique, careful patient selection, and surgeon experience. Long-term controlled studies are in progress.

Allograft Tissue Grafting Osteoarticular allograft replacement of damaged articular surfaces has been the subject of studies for many years. The advantages of allografts include potential availability of young donor cartilage, graft material from identical anatomic location (orthotopic), and avoidance of donor-site morbidity. Disadvantages, however, include possible disease transmission and immunologic reactions (22). Freezing the allograft tissue decreases the immunogenicity of the subchondral bone but damages the viability of the transplanted chondrocytes (37).

Studies of osteoarticular allografts in humans have not been followed long enough to determine the long-term outcome, but several authors have reported promising early results (32). The best results appear to be in unipolar traumatic lesions treated with young orthotopic allografts (22). Osteoarticular allograft replacement should be reserved for patients with massive osteoarticular defects that cannot be treated with other methods. It can also be considered as a salvage procedure for patients who have large defects for which conventional treatments failed.

**AUTHORS’ PERSPECTIVES**

Although many issues in the treatment of chondral injuries are controversial, it is clear that any underlying ligamentous instability or malalignment must be corrected if the chondral injury treatment is to succeed. Although we recognize that abrasion arthroplasty and microfracture produce fibrocartilage repair tissue and not hyaline cartilage, our bias is to use this technique as the initial treatment for small and medium-sized focal chondral defects. It is an easy, inexpensive, low-morbidity procedure that can be performed at the time of initial arthroscopy. Should this fail, we use a secondary technique with ACI or osteoarticular plug autografts (mosaicplasty). Previous penetration of the subchondral bone does not appear to compromise outcome after ACI, as 7 of 23 patients in Brittberg et al.’s (3) original series had undergone drilling initially.

For larger chondral defects, particularly uncontaminated lesions on weight-bearing femoral condyles in young active athletes, we favor ACI or mosaicplasty as the initial procedure because abrasion arthroplasty with microfracture is less likely to succeed (Fig. 86.6) (17). In addition, for massive articular defects, particularly those associated with significant bone loss, osteoarticular allograft is the salvage option of choice. Until long-term data from controlled studies are available, use the above recommendations as general guidelines. Individualize the treatment of each patient, and perform only those procedures in which you have mastered technical proficiency.

The frequent coexistence of chondral injury with ligament tears and meniscus injuries cannot be overemphasized. All too often, a patient is referred for orthopaedic consultation with an MRI scan showing a meniscus tear. The patient arrives, anticipating that a "work order" for arthroscopic meniscectomy is all that is required. After the simple procedure is completed, the patient assumes that he or she will be "normal" again. The possibility of a chondral injury or defect may never have been considered. If the findings at surgery are primarily chondral damage and the outcome is not "normal," the patient becomes confused and upset. To avoid this, we recommend a brief preoperative discussion of possible chondral damage with all patients undergoing arthroscopic knee surgery. If MRI has been performed, we review the images with the patient, explain the limitations of the study, and discuss the possibility of additional findings at surgery that may require additional treatment.
Historically, the patellofemoral joint received relatively little attention until well into the latter half of the 20th century. Yet today anterior knee pain and dysfunction are among the major reasons patients seek help. Why was this joint overlooked for so long? Perhaps the perspective of history will help to answer this question. During the embryonic stage of orthopaedic surgery, those general surgeons whom we would now call orthopaedists wrote infrequent yet classic articles about the patellofemoral joint. These surgeons were much more concerned, however, with life-threatening and crippling conditions such as compound fractures, osteomyelitis, pyogenic arthritis, tuberculosis, poliomyelitis, and birth defects. World Wars I and II kept the orthopaedic surgeons focused on trauma and infection. Furthermore, the general population in the United States had little time for sports involvement during two world wars and the Great Depression.

The advent of antibiotics in the 1940s and the polio vaccines in the 1950s changed the practice of orthopaedic surgery forever. At the same time, the prosperity of the United States permitted widespread participation in recreational, scholastic, and professional sports. Orthopaedists were ill prepared to treat the increasing numbers of patellofemoral complaints. It remains unknown how many normal menisci were removed for “giving way” and “internal derangement” symptoms that were actually caused by patellofemoral dysfunction. The patellectomy was all too frequently the final answer to a perplexing and unresolved clinical problem. Even during the development of “total” knee arthroplasties, the early designs completely ignored the patellofemoral compartment.

During the mid-1970s, the burgeoning interest in sports medicine, the development of accurate and reproducible axial radiographs, and the explosion of arthroscopy all combined to focus attention on this puzzling joint. Yet why are patellofemoral problems so frequent? I believe the answer is related to the fact that about 20% of an asymptomatic general population demonstrate objective radiographic abnormalities of the patellofemoral joint, presumably on a genetic basis.

Knowing that this joint mediates the forces generated by the largest muscles (quadriceps and hamstrings) through the largest lever arms (femur andibia), one can now understand why these relatively minor variations, which become symptomatic as a result of the added physical demands of sports, are so frequent. This genetic theory also explains why patellofemoral dysplasia has such a strong familial predisposition.

Other factors that have retarded the understanding of this enigmatic and unique joint have been semantic and diagnostic confusion. Years ago a popular diagnosis in the literature was “traumatic dislocation.” But aren’t all dislocations of the patella “traumatic”? Just ask the patient. What that term really implies is that trauma is the sole cause of the dislocation. After the advent of accurate axial knee radiographs in the 1970s, it was quickly recognized that the normal knee rarely suffers a patellar dislocation. Thus, it remains our duty to search for the abnormality or deficiency that causes the pain or instability, and we must remember that there are frequently multiple causes.

“Chondromalacia patellae” has been a misused and popular diagnosis over the years. Aleman (1) originated the term in 1928 to describe the gross appearance at surgery of previously traumatized articular cartilage. For accuracy and precision, this term should be used only within this meaning, never as a solitary diagnosis, and never equated with anterior knee pain. “Anterior knee pain syndrome” is a deception; it is a symptom masquerading as a diagnosis. Our medical colleagues treat a stomachache with a bland diet and antacids without resorting to the use of “stomachache syndrome.” Why then can’t we treat anterior knee pain with rest, proper exercises, and antiinflammatories without calling it a syndrome? If one makes the diagnosis of anterior knee pain syndrome or chondromalacia patellae, there is the tendency to stop there and not continue searching for the primary anatomic cause (or causes, for they are frequently multiple). If a thorough search fails to discover a cause, there is nothing wrong with the diagnosis of “idiopathic chondromalacia” or “idiopathic anterior knee pain.”

Therefore, I would make a plea for a logical and scientific approach to the patellofemoral joint so that the formulation of treatment protocols is based on an accurate understanding of the complex pathophysiology of this fascinating joint.

CLASSIFICATION AND PATHOPHYSIOLOGY

A clinical classification of patellofemoral disorders is presented in Table 87.1. This classification is designed for clinical use and based on etiology. Almost always the clinician can establish a diagnosis, or differential diagnosis, using only a detailed history, a thorough physical examination, and properly selected routine radiographs. Because many different patellofemoral disorders respond very well to the same nonoperative treatment protocols, the clinician can frequently provide definitive relief working only from a differential diagnostic list. Only about 10% of patellofemoral patients will fail to respond to these nonoperative measures. If surgery is the next option, and the diagnosis is still in doubt, then more sophisticated diagnostic studies such as bone scans, computed tomography (CT) scans, or diagnostic arthroscopy may be entertained. Furthermore, by focusing on etiologies rather than symptoms such as anterior knee pain or secondary changes such as chondromalacia (chondrosis), a rational treatment program naturally follows.
The first group of the classification in Table 87.1 lists conditions caused by trauma, whether acute, repetitive, or delayed. These are self-explanatory for the most part and require little comment. Group II (patellofemoral dysplasia) deals with patients who have patellar pain and/or instability produced by the activities of daily living or the normal stress of sports. Patellofemoral dysplasia is discussed in more detail later in this chapter. Group III allows inclusion of that ever-shrinking group of patients with proven chondromalacia patellae for which no cause can be found. Groups IV and V contain the less common patellofemoral disorders, with no attempt to include rare entities such as tumors, infections, or metabolic disorders. Group VI has been added to the original classification (29) to include those patellofemoral disorders of iatrogenic origin.

The same conceptual design of the Hauser procedure (19) that made it so successful in stopping recurrent dislocation of the patella contained the seeds of its own failure. Medial transfer of the patellar tendon down onto the sloping side of the anteromedial facet of the tibia decreased the lever arm through which the extensor mechanism worked, thereby increasing the patellofemoral joint reaction force. Too frequently, this produced secondary patellofemoral arthrosis. The short-term success rate of the Hauser procedure was improved by adding distal transfer as well. This may have been appropriate for those with a significant patella alta. However, the folly of treating all patients who had recurrent dislocations of the patella with one single operation, no matter what factors were causing their dislocations, became apparent in longer-term studies. The distal transfer in many patients produced a severe patella infera, which added to the secondary patellofemoral osteoarthritis. Performing a lateral release on a patient who does not have a tight lateral retinaculum is always a mistake and easily leads to an iatrogenic medial patellar compression syndrome or iatrogenic chronic medial subluxation of the patella. Another cause for these iatrogenic complications is an excessive, or overzealous, release of the retinaculum and the vastus lateralis muscle as well (21,24).

PATELLOFEMORAL DYSPLASIA

The majority of patients with complaints of patellar pain and instability will have objective abnormalities of the extensor mechanism and patellofemoral joint. These abnormalities are present and development. Major examples include a shallow trochlea, an increased quadriceps angle (Q-angle), a vastus medialis obliquus (VMO) deficiency, and a patella alta or infera. These multiple abnormalities or factors often affect the proper function of the patellofemoral joint. Each abnormality is not just present or absent in any given patient but can vary from mild to severe anatomically, thus having a mild to severe effect on patellofemoral pathomechanics and symptoms.

A pattern of preexisting abnormalities, such as a shallow intercondylar sulcus, deficient vastus medialis obliquus, patella alta, chronic patellar subluxation, and so on, suggests an underlying genetic, developmental, or familial abnormality. The expression of these abnormalities can vary from mild to severe, but it is helpful to apply the overall and unifying term “patellofemoral dysplasia.” This term is a better diagnostic category than “maltracking syndrome” because it indicates a cause, developmental dysplasia, rather than a common physical characteristic, abnormal tracking. Patellofemoral dysplasia can be thought of as analogous to developmental dysplasia of the hip. Embryologically, the femoral trochlea develops early in utero (8 weeks), complete with its adult predominance of the lateral condyle (19). At this stage the knee is acutely flexed, and the patella is not even articulating with the trochlea. Therefore, pressure inhibition from a laterally subluxed patella cannot influence the trochlear depth. This is confirmed clinically by the many patients who have a shallow sulcus and no associated lateral patellar subluxation.

Perhaps the best explanation for the existence of patellofemoral dysplasia and why it is so common in the general population can be found in studies of comparative anatomy and phylogeny. Dye (1,13) has demonstrated that the bicondylar, cam-shaped design of the distal femur is of ancient origin, existing in early tetrapods about 360 million years ago. The patella did not appear until about 70 million years ago. The final human adaptations of the knee that allowed erect bipedal gait evolved from quadruped primates and did not occur until 3.5 million years ago. A valgus femorotibial angle allowed the supporting limb to approach the midline for efficient bipedal gait, but this change imparted a lateral thrust on the patella acting through an increased Q angle. The adaptation of a deeper patellofemoral trochlea with a prominent lateral femoral condyle and lateral patellar facet plus the development of the lower oblique fibers of vastus medialis, which is peculiar to humans (4), allowed the extensor mechanism to function without lateral dislocation of the patella. It could be possible that these relatively recent human adaptations of the extensor mechanism are less well “fixed” genetically and therefore show greater variability, thus explaining the frequency of patellofemoral dysplasia.

We should consider this group of patellofemoral disorders as a developmental dysplasia characterized by a continuum of anatomic deficiencies. This will tend to focus our attention on the search for sometimes subtle abnormalities to explain each patient’s symptoms and help individualize our treatment to correct these deficiencies.

Having combined these conditions together under the large category of patellofemoral dysplasia, we must also subdivide this classification. This will allow those patients with symptoms, signs, and severity in common to be assessed as a group. Different treatment protocols can be developed and compared. To do this, we must evaluate each of the factors associated with patellofemoral disorders known to influence patellar instability and pain. The normal lateral vector imparted to the patella by the normal quadriceps angle is resisted by (a) the depth of the femoral trochlea with its larger lateral condyle and (b) the vastus medialis obliquus, whose fibers insert more distally and horizontally on the patella than those of the vastus lateralis. A deficiency of either the intercondylar sulcus or the VMO or both predisposes to patellar subluxation and dislocation. Any increase in the Q angle itself from any cause (e.g., internal femoral torsion, external tibial torsion, genu valgum) increases the lateral vector on the patella. There is also a dynamic increase in the Q angle when the foot is planted and the femur internally rotates during the common maneuver of cutting and pushing off; this predisposes to dislocation. The lateral tethering of a tight lateral retinaculum can also increase the lateral force on the patella, producing the tilt frequently seen radiographically. A high-riding patella (patella alta) will also increase patellar instability because it articulates in the more shallow superior portion of the sulcus for any given degree of knee flexion compared to the normal. That is, the knee must be flexed more to bring a high-riding patella safely within the deeper portion of the trochlea.

CLINICAL EVALUATION

It is elementary—yet bears repeating—that the goal of clinical evaluation is to establish a differential diagnosis, a diagnosis, and a logical treatment plan. Because patellofemoral instabilities and pain almost never arise from a single cause, and in any given patient each of these multiple factors or abnormalities can present within a range from mild to severe, the clinician’s job is to document each and its severity to discover the pathomechanics, the pathophysiology, and the correct diagnosis and to establish a logical treatment plan. It is foolishly to search for one physical sign, such as the apprehension response, or one radiographic finding, such as patellar subluxation, to establish a diagnosis and a treatment protocol. Each element of this evaluation—the history, the physical examination, and the routine radiographs—plays an important and interlocking role. However, the physical examination is paramount in finding the physical abnormalities causing the patient’s symptoms and suggesting corrective treatment, both nonoperative and surgical. Simple checklists can be very helpful in speeding up record keeping and keeping track of data. Both knees should be evaluated—as a control and because patellofemoral disorders are so frequently bilateral.

For the sake of brevity, this discussion focuses on the patellofemoral joint, with the understanding that it is only part of a complete knee evaluation that must also include examination of the ligaments, the menisci, and the femorotibial articulations. Common things do occur commonly, so be mindful that any given patient may have two or more conditions, and they may or may not be symptomatic at any given time or during certain activities.

HISTORY

Anterior Knee Pain

Spontaneous onset of anterior knee pain or persistence after minor trauma indicates a preexisting condition. It is typically aggravated by flexed-knee activities such as going up and down stairs and hills (down often worse than up), squatting, kneeling, jumping, and prolonged sitting (‘theater ache’). Constant and unrelenting pain
suggests reflex sympathetic dystrophy of neuritic origin.

**Giving Way**

Differentiate the sudden collapse, fall, and swelling (combined with a shallow trochlea and/or subluxation on x-ray) of true patellar instability from the sudden pain and inhibition release frequently aggravated by quadriceps weakness (with normal axial-view x-rays). Recurrent patellar dislocation and subluxation almost never occur with normal findings on axial-view radiographs.

**PHYSICAL EXAMINATION**

**Standing Limb Alignment**

**Internal femoral torsion** and **external tibial torsion** cause the patellae to “squint” and produce the “miserable malalignment” of James et al. (23). The final common pathway is an excess laterализing force on the extensor mechanism, resulting in a lateral patellar compression syndrome. Check also for foot alignment, because excess pronation can be a cause for anterior knee pain.

**Sitting Examination**

Assess the tubercle–sulcus angle (Fig. 87.1). Normal is 0°; compare later with the Q angle.

![Figure 87.1. Tubercle–sulcus angle. Normal ~0°.](image)

Watch and feel the patella during its excursion through the trochlea in active extension and flexion. Does it translate, tilt, and rotate laterally at terminal extension? This is a J sign because its track follows the pattern of an inverted J. Look for x-ray confirmation later as patellar subluxation, tilt, or both on the axial view. A good assessment of the patellar position and attitude from 30° to 0° obviates the need for the more costly imaging of CT scans and magnetic resonance imaging (MRIs).

Look for a *deficient vastus medialis obliquus* by asking the patient to extend the knee against a fixed resistance at about 30°. The resultant quadriceps contraction will make the defect more apparent. Normally the VMO should reach and insert into the upper third of the patella.

Check for crepitation under load by palpation during extension and flexion with manual resistance at the ankle. Manual patellar compression at different degrees of knee flexion helps to localize segmental chondral lesions.

Carefully palpate the entire anterior knee to discover patellar or quadriceps tendinitis, lateral or medial patellofemoral joint line synovitis, and any neuromas in the lateral retinaculum or in prior scars.

The patellar glide tests are extremely important. They not only offer clues for the underlying pathomechanics leading to a correct diagnosis but also point to abnormalities to be corrected by exercise, bracing, or surgery. Moving the patella medially and laterally with the knee relaxed and flexed 30° demonstrates retinacular contracture or laxity. (Tip: Palpate the patellar tendon to determine if the patient has relaxed the quadriceps or not. If not, try performing this test with the patient supine and the knee relaxed over a pillow or bolster.) The patella should move about one fingerbreadth in each direction. Excessive lateral glide means medial laxity, even rupture of the medial patellofemoral ligament, and may evoke the “apprehension response” as the patient feels the familiar sensation of dislocation. Restricted medial glide means a tight lateral retinacular tether. (Tip: Performance of an isolated lateral retinacular release in spite of an already lax or normal lateral retinaculum represents unnecessary and possibly dangerous surgery.) Increased medial glide is found in hyperlax individuals (e.g., Ehlers-Danlos) and after a lateral release.

The Fulkerson relocation test (16) for iatrogenic medial subluxation (after either severance of the vastus lateralis tendon or excessive medial tibial tubercle transfer) is a variation of the glide tests. With the knee in extension, push the patella medially as far as possible and hold it there while flexing the knee passively. If the patella starts to impinge on the medial trochlear eminence and then suddenly reduces into the groove, and the patient confirms a reproduction of symptoms, the test is positive.

**Recumbent Examination**

Because most studies have standardized the quadriceps angle assessment with the patient supine, the knee extended, and the patella anterior, measure it that way. If another method is chosen, be consistent. Measure from the anterior superior iliac spine to the patella (make sure the patella is centered at the trochlea) to the tibial tubercle. The complementary angle is the Q angle (Fig. 87.2). The average is about 15° ± 5°. Compare this measurement with the tubercle–sulcus angle performed earlier. The importance of assessing the lateralizing forces exerted on the patella by the position of the tibial tubercle cannot be overemphasized. Again, it provides one more piece of the pathomechanical puzzle for a correct diagnosis and leads to a logical treatment plan and a more accurate prognosis. For example, if a patient suffers recurrent patellar dislocations, and the only abnormalities are a shallow trochlea and a tight lateral retinaculum, the chances are excellent that an isolated lateral retinacular release will be successful. However, the finding of a 25° Q angle ruins that prognosis, and a medial tibial tubercle transfer will be needed in addition.

![Figure 87.2. Quadriceps (Q) angle. Normal ~10°–15°.](image)

The flexion abduction external rotation (FABER) or “Figure 4” test should always be included in every knee examination to rule out referred pain from hip pathology.
Straight-leg raising demonstrates hamstring contracture as well as clues for pain of sciatic origin.

Ober’s test for iliotibial band contracture correlates well with lateral knee pain.

A prone knee flexion examination will reveal quadriceps contracture if present.

With the patient still prone and the knee flexed 90°, the femur can be rotated into maximal internal and external rotation to assess internal and external femoral torsion. Then in the same position with the ankle at neutral, the thigh–foot angle is measured for external tibial torsion. These tests can quickly confirm a “miserable malalignment,” as discussed previously.

**RADIOGRAPHY AND OTHER IMAGING**

Radiographs serve only as adjuncts to a careful history and physical examination of the knee. They are, after all, a physical image extending the physical examination. Radiographs must be used in context with all the rest of the clinical data to reach a differential diagnosis, the final diagnosis, and a reasonable treatment plan.

Rather than a preset battery of radiographic views, order each view based on clinical suspicions. For example, the tunnel view is most helpful when loose bodies or osteochondritis dissecans is suspected. Similarly, when spontaneous meniscal degeneration or osteoarthritis is possible, the anteroposterior (AP) view should be taken during full (100%) weight bearing on one leg using a long (17-in.) film in order to maximize any joint space narrowing and to reveal angular deformity.

*Always order an accurate axial view for all knee disorders.* If the history and physical examination point to a patellofemoral problem, the axial view will provide the most radiographic information. Even if no such problem is suspected, it may be harmful to advise therapy without knowing the status of the patellofemoral joint. In 1988 we demonstrated that approximately 20% of the asymptomatic general population have objective radiographic subluxation of the patella (29). If such a patient is placed on “open chain” quadriceps exercises (an isokinetic machine, short-arc free weights, or isotonic free weights), the abnormally large joint reaction forces applied to the much smaller surface contact area can generate destructive forces very quickly, causing an iatrogenic chondrosis (chondromalacia) that is permanent.

**Anteroposterior View**

Take the AP view as a full, 100% weight-bearing (standing on one leg) exposure on a long (17-in.) film if the patient is more than 35 years of age, has had a meniscectomy, has an angular deformity, or has signs of degenerative joint disease or a degenerative meniscal tear. This maximizes narrowing and reveals angulation. The posteroanterior 45° flexion weight-bearing view described by Rosenberg et al. (33) can be selected in addition. It is more sensitive and specific in assessing articular cartilage loss in the posterior compartments of the knee.

**Lateral View**

The lateral view gives the best assessment of patellar height relative to the joint line: patella alta or infera. The Blackburne-Peel ratio is more accurate and consistent than the Insall-Salvati measurements (3) (Fig. 87.3). A long distal patellar tip, or “nose,” can distort the ratio, and on many films the tibial tubercle is difficult to locate.

![Figure 87.3. Patellar height ratios: (A) Blackburne-Peel ratio 1:1 (±20%); (B) Insall and Salvati ratio 1:1 (±20%).](image)

If the femoral condyles are superimposed as in a true lateral, and the image of the patella is oblique, the patella is tilted (rotated laterally).

**Axial View**

Technique in obtaining the axial view is extremely important (28) (see Fig. 87.4 for various techniques). The clinician must know what technique was used for proper interpretation. Certain techniques cause image distortion (Fig. 87.4A and Fig. 87.5).

![Figure 87.5. Axial radiographs of the same left knee taken at the same time. A: By the Jaroschy (“Hughston”) technique, the patella is congruent, and the trochlea appears normal. B: By the “Merchant” technique, the patella is actually subluxed, and the trochlea is actually quite shallow.](image)
The following criteria are necessary to obtain an accurate axial view:

- Central x-ray beam must be perpendicular to the film plane to avoid image distortion.
- Knees flexed 30° to 45°. Less than 30° is too technically demanding for clinical use, and more than 45° will reduce many subluxed patellae.
- X-ray tube about 2 m (6 ft) from the knee to minimize the distortion of magnification and parallax.
- Expose both knees on one film to allow comparisons. Dysplasias are usually bilateral.
- Strap legs and knees together. This prevents external rotation, which can simulate a low lateral condyle and allows the patient to relax (quadriceps contraction will reduce a subluxed patella).

The patellofemoral congruence angle (Fig. 87.6) provides the least overlap between normal subjects and patients with known recurrent dislocation of the patella compared to other measurements. There is still some overlap, however, so it cannot be used as the only diagnostic criterion.

![Figure 87.6. Radiographic measurements of patellofemoral congruence.](image)

Patellar tilt (17) (Fig. 87.7) is the angle between the transverse plane of the patella and a horizontal line parallel with the x-ray table. The normal value is 5° or less. Tilt can occur without lateral subluxation (translation) and usually is an indication of a tight lateral retinaculum, but physical examination remains the best determinant of lateral retinacular contracture.

![Figure 87.7. Radiographic patellar tilt. Normal ~5° or less.](image)

Radiographic clues in longstanding lateral patellar compression syndrome (Fig. 87.8) comprise the following:

- Condensation (sclerosis) of the subchondral bone of the lateral patellar facet.
- Lateralization of trabeculae (perpendicular to the lateral facet rather than to the transverse plane of the patella).
- Lateral traction spurs.

![Figure 87.8. Radiographic clues of long-standing lateral patellar compression syndrome.](image)

**Summary**

These initial radiographs correlated with the history and physical examination will be sufficient to establish a working diagnosis for the great majority of patients with patellofemoral disorders. Other imaging modalities can be helpful with unusual or problem cases. A limited CT scan (15) can be helpful to evaluate patellar position and lateral tilt when the patient is too obese for physical assessment of a J sign at terminal extension. The three-phase technetium bone scan (scintigraphy) is the only clinical test that shows physiologic bone activity (10). It can be very useful for patients suspected of having reflex sympathetic dystrophy (RSD) and to document progress during treatment in difficult cases. Given the current accuracy of MRI in the community setting, it is best used for a suspected tumor, for preoperative localization of medial patellofemoral ligament tears (see below), or perhaps when no diagnosis can be established.

**Table 87.2** is a diagnostic grid summarizing the various clinical findings needed to make the initial diagnosis or differential diagnosis and to formulate a rational treatment plan.
TREATMENT AND SURGICAL INDICATIONS

All treatment plans, when simplified to their essence, are the same: "fix what's wrong," with the added caveat, "with the least risk." Perhaps that is an oversimplification, but it might encourage the clinician to search for the various abnormalities affecting the extensor mechanism and then to select the safest treatment modality for each abnormality to start treatment. This job is even harder because each abnormality can vary from mild to severe and thus have a mild to severe effect on the extensor mechanism, thereby changing the prognosis for success. In patellofemoral disorders, there is never only one treatment protocol for one diagnosis. Instead, the clinician should try to understand the pathomechanics or pathophysiology leading to that diagnosis in that particular patient, then list each abnormality found in order to select an appropriate treatment modality for each factor.

For example, one frequently encounters patients with anterior knee pain after relatively minor trauma who fail to recover after a reasonable time. Evaluation finds a few mild deformities (mild VMO deficiency, mildly increased Q angle, and mild patellar subluxation on x-ray), leading to the diagnosis of chronic subluxation of the patella (CSP). Because these factors were all present before the injury, it is reasonable to assume that the quadriceps weakness that resulted from enforced rest and inactivity after the injury caused the decompensation. Appropriate quadriceps-strengthening exercises, perhaps along with a lateral buttress patellar brace during recovery, have an excellent chance of success. But should that same patient also have an extremely tight lateral retinaculum that does not respond to patellar taping, mobilization, and exercise techniques (the McConnell protocol) (16) in addition, then a lateral release will give the patient an excellent prognosis.

The treatment protocols must be adjusted not only to each patient's abnormal extensor mechanism factors but also to each patient's age, weight, height, sex, conditioning, activity level, general health, and expectations as well. For these reasons, it is not appropriate to list a treatment protocol or algorithm for each diagnosis but rather to list the various treatment modalities, both nonoperative and surgical, available for each abnormal factor affecting the extensor mechanism. The clinician can then individualize treatment for these multifactorial patellofemoral disorders.

NONOPERATIVE TREATMENT

The nonoperative treatment for patellofemoral disorders will be successful about 90% of the time (8). Surgical indications will vary with the severity of the problem, the degree of disability for the patient, the age and health of the patient, and the specific surgery proposed. In general, the milder the objective findings, the longer one should persist with nonoperative management. In other words, when pain relief is the only measurement of surgical success, the surgeon should take a long time supervising the treatment, monitoring the exercise goals, learning the level of patient commitment to getting well, trying to assess the patient's pain threshold, learning the patient's expectations and desires, educating the patient on the benefits and risks of surgery, and just getting to know the patient and significant family members before embarking on a surgical treatment. Rather than set an arbitrary time limit such as 6 months for exercises before surgery is indicated, it is preferable to use the expected weight level to be reached, for example, 20 pounds. This must be monitored and verified.

Antiinflammatory Treatment

Antiinflammatory treatment has the goal of reducing pain and bringing the knee back into its "envelope of load acceptance" (12). These measures include the classic rest, ice, compression, and elevation (RICE), followed by nonsteroidal antiinflammatory drugs (NSAIDs), and finally judicious use of oral and intraarticular steroids, if necessary.

Exercises

Both hamstring and quadriceps contractures can cause anterior knee pain. Stretching these muscle groups will solve that problem.

Appropriate quadriceps-strengthening exercises are the mainstay of successful treatment and rehabilitation of patellofemoral disorders. I stress appropriate to highlight the unique biomechanical features of the patellofemoral joint. During physiologic loading (climbing for example), the patellar contact surface varies directly with knee flexion and load applied. As the load increases, so does the contact area of the patella, so the unit load on the patellar cartilage (the pounds per square inch) remains relatively stable. Conversely, during nonphysiologic resistive knee extensions, the load (patellofemoral joint reaction force) varies inversely with patellar contact area. Thus, the shrinking contact area of the patella must carry increasing loads; if the contact area is decreased even more by subluxation, the unit load can increase exponentially, and the articular cartilage can be damaged very quickly.

Neve use knee extensions (e.g., isokinetic knee extensions, short-arc knee extensions, or isotonic free weights) against resistance. Start with supine straight-leg raises, assisted if necessary. Add straight-leg raises with weights to about 5 lb. Then switch to seated straight-leg weight lifting using the arms to protect the hip and lower back (Fig. 87.6). To be successful, a weight goal of 20 to 25 lb is average; for the athlete, even more. These exercise protocols have been shown to potentiate VMO strengthening: isometric quadriceps with simultaneous isometric hip adduction exercises, isotonic quadriceps exercises done at 90° knee flexion (6), and foot forward (posterior pedal contact) with open, or VMO strengthening: isometric quadriceps with simultaneous isometric hip adduction exercises, isometric quadriceps exercises done at 90° knee flexion (6), and foot forward (posterior pedal contact) with open, or

Bracing

- A patellar strap can be useful for patellar tendinitis.
- A patellar brace with full ring support can be comforting when the extensor mechanism is already balanced.
- A patellar brace with a lateral buttress pad helps resist lateral vectors.
- Longitudinal arch supports provide medial correction for the pronated foot.

**Taping and Exercise**

The McConnell protocol (19) features patellar taping techniques designed to reduce the abnormal forces on the extensor mechanism to allow the patient to exercise and strengthen the musculature without pain. Once muscles are strengthened, the taping can be eliminated. However, this protocol requires a physical therapist who is dedicated to this complex subject of patellofemoral dysfunction and lower extremity muscular imbalance and is specifically trained in the McConnell technique. Such a therapist can be difficult to find.

**OPERATIVE TREATMENT**

Solely diagnostic arthroscopy for patellofemoral disorders is almost never indicated. All the forces acting on this joint are extraarticular and not visible through the arthroscope. If a pathologic plica is suspected, the arthroscopy is therapeutic. If done for “chondromalacia,” the surgeon had better understand the cause. Assuming it was posttraumatic (e.g., dashboard) and the extensor mechanism is well balanced, then the arthroscopic debridement is therapeutic. If the chondrosis is secondary to extensor mechanism malalignment (dysplasia), then the appropriate realignment surgery should follow the debridement, or the debridement will have been done in vain.

In general, the greater the physical abnormality, such as a severe patellar subluxation on radiographs, and the younger the patient, the sooner surgery should be performed. The results of realignment surgery are better when there is less chondrosis (“chondromalacia”). Conversely, salvage procedures, such as total patellofemoral arthroplasty, can be delayed until the level of disability and future activity expectations are appropriate.

After an initial patellar dislocation, the likelihood of subsequent dislocations will depend primarily on the severity of the underlying dysplasia. Sometimes an osteochondral fracture (loose body) with hemarthrosis is present, prompting arthroscopic surgery for its treatment. When this happens, the surgeon should evaluate the knees further. Axial radiography will show sulcus depth, and an MRI can determine if (and where) the medial patellofemoral ligament is torn. Then, under anesthesia, the lateral retinaculum can be assessed for tightness and the Q angle measured. With this information, at the same operation, the osteochondral fracture can be treated, a tight lateral retinaculum can be released, and a torn medial patellofemoral ligament can be repaired. This has a good chance of reducing the risk of future dislocations.

**Surgical Techniques**

Just as in nonoperative treatment protocols for patellofemoral disorders, there is never just one surgical technique for each diagnosis. Again, the clinician must discover the various abnormal forces producing that diagnosis, try to understand the pathomechanics, and then select the safest technique, or combination of techniques, that has the best prognosis for success. For example, the lateral release is designed only to correct a tight lateral retinaculum. If it is already lax, don’t release it. A medial tibial tubercle transfer is designed only to decrease the Q angle. It bears repeating that the only way to find these abnormalities is by physical examination.

**ARTHROSCOPIC PATELLAR DEBRIDEMENT (“SHAVING”)**

- Be as conservative as possible. Remove only unstable cartilage. Even damaged cartilage will cushion the subchondral bone and reduce friction better than no cartilage.
- Use as many portals as needed to correctly position the instruments. Manipulating the patella can help position it for debridement.
- Try the proximal superomedial portal (see the discussion on arthroscopic lateral release below) for an excellent view.

**ARTHROSCOPIC LATERAL RELEASE**

The indication for arthroscopic lateral release (Fig. 87.10) is a tight lateral retinaculum that is producing the patient’s symptoms, which have not responded to appropriate nonoperative treatment. If it is not tight, don’t release it. If the patient has a large Q angle as well, an isolated lateral release will not be sufficient; the tibial tubercle will usually have to be moved also.

![Image of lateral release](image)

**Figure 87.10. A: Arthroscopic electrocautery lateral release. B: Inset shows the view utilizing the proximal superomedial portal. (Redrawn from Schreiber SN. Proximal Superomedial Portal in Arthroscopy of the Knee. Arthroscopy 1991;7:246.)**

Because we originated the lateral release before the advent of arthroscopic surgery (27), it was an open procedure. As long as the main principles of hemostasis, adequacy of release, and avoidance of overrelease are addressed, the results will be the same. Currently, for cosmesis, we prefer the electrocautery, arthroscopic technique.

- Use the proximal superomedial portal for viewing (34).
- Percutaneously insert a guide needle 1 cm lateral to the lateral corner of the patella.
- Use the anterolateral joint line portal for the electrocautery. Apply but do not inflate the tourniquet. Advance slowly near the lateral superior geniculate artery in order to coagulate it before cutting it. This technique plus the compression dressing has almost eliminated significant postoperative hemarthroses.
- Avoid severing the vastus lateralis tendon by advancing superiority in a straight line, not curving medially, until muscular fibers of the vastus lateralis are reached. Stop at this point, remove all instruments and cannulas, and test for adequacy. If the patella can be tilted up 70° to 90° with the knee in extension, the release is adequate. Frequently, tethering fibers dialedly located near the anterolateral joint line portal need to be cut.

**MEDIAL TIBIAL TUBERCLE TRANSFER**

The indication for medial tibial tubercle transfer (Fig. 87.11) is a large Q angle that is causing the patient’s symptoms, which have not responded to appropriate nonoperative treatment. When combined with an arthroscopic lateral release, this can be done through a short vertical incision at the tibial tubercle for better cosmesis.
Figure 87.11. Medial tibial tubercle transfer. A,B: Tubercle step-cut proximally and drilled distally, front and side views. C: Tubercle transferred medially and fixed.

- Step cut the osteotomy proximally to provide a buttress against the quadriceps force. Thin the cut, or drill the bone distally so it will crack and hinge there as the proximal end is moved medially.
- Correct the Q angle to about 5° to 10° measured intraoperatively with a large sterile metal goniometer. The goal is to normalize and avoid overcorrection. Check the tubercle–sulcus angle (Fig. 87.1) as well as patellar excursion with flexion and extension.
- Three-screw, bicortical, lag fixation provides excellent security. Trim the excess bone from the medial edge of the transferred tibial tubercle and pack it under the medial overhang as a bone graft. Complete the repair by sewing the previously elevated medial tibial periosteum to the medial edge of the patellar tendon.
- Release the tourniquet for hemostasis before closure. The anterior recurrent tibial artery lurks just lateral to the tibial tubercle. Uncontrolled hemorrhage from this artery can cause a disastrous compartment syndrome.

PROXIMAL QUADRICEPS PLASTY

The indication for proximal quadriceps plasty (Fig. 87.12) is a Q angle that is normal or has been corrected to normal and a patella that remains subluxed laterally, causing symptoms, or that recurrently dislocates. This occurs most frequently in the more severe forms of patellofemoral dysplasia, which have abnormally shallow trochleas.

The proximal realignment technique used by Insall et al. (22) offers excellent flexibility to increase the forces acting medially and reduce those acting laterally. It can be used for moderate alignment problems and can be modified laterally by releasing the lower third or half of the vastus lateralis from the lateral intermuscular septum and lateral femur to perform a derotation quadriceps plasty in those children with severe chronic dislocation of the patella.

Selective epidural analgesia for this surgery is shown in Table 87.3. When trying to realign the extensor mechanism when the trochlea is very shallow or flat, it is extremely difficult, if not impossible, to judge the proper correction yet avoid overcorrection. It has been compared to balancing a hockey puck on a cake of ice. If the patient is cooperative, and the anesthesiologist is facile with epidural and regional techniques, selective epidural analgesia will be extremely helpful. Because the motor nerves are spared, the patient can remain awake or under light short-term sedation. With adequate advance warning, the anesthesiologist can awaken the patient after the first several repair sutures are in place. The patient then slowly extends the knee actively from 45° to 0° and back again to test the repair. The surgeon will see immediately if the result is correct, and adjustments can be made until it is.

Table 87.3. Selective Epidural Analgesia

MEDIAL PATELLOFEMORAL LIGAMENT RECONSTRUCTION

Reconstruction of the medial patellofemoral ligament (MPFL) (Fig. 87.13) is indicated in those patients with chronic dislocation of the patella and those with recurrent dislocation of the patella in whom the ligament is either absent or so incompetent as to be irreparable. This ligament has been shown to be the major static medial restraint on the patella (7,9,20). If the trochlea is shallow and does not provide restraint to lateral subluxation, simple imbrication of the medial retinaculum without MPFL repair or reconstruction will frequently fail by gradually stretching out again. Fithian and Meier (13) have described an excellent technique for repair of the MPFL if it can be identified and its femoral origin is found to be intact.
Principles for performing a patellectomy in patellofemoral disorders include the following:

- Chondrosis from a patellofemoral disorder with a shallow and eroded trochlea, the results are generally worse. Furthermore, if pain relief is not achieved, there is no

Patellectomy is a salvage procedure under any conditions; the results are best when it is done for a comminuted patellar fracture with a normal trochlea. If it is done for

**PATELLECTOMY**

By carefully cutting from anterior to posterior all around the tibial tubercle and the adjacent anterior tibial cortex all the way to the posterior cortex using thin saws and thin nontapered osteotomes, a rather large block of underlying cancellous bone can be lifted out carefully with the tibial tubercle (Fig. 87.14A and Fig. 87.14B).

- Cut a flat ledge on the medial side of the tibia (Fig. 87.14C). Flatten and taper the posterior surface of the cancellous bone under the tibial tubercle with a thin saw. Then rotate the tibial tubercle with its underlying bone block up onto that medial ledge with the distal end remaining almost in its original position. As much as 15 to 18 mm anterior elevation can be achieved with this method.

- Perform intraoperative goniometric measurement, temporary fixation, and patellar excursion testing as in the medial tibial tubercle transfer. Again, three-screw bicortical lag fixation provides excellent security. Remember to release the tourniquet before closure.

**PATELLECTOMY**

Patellectomy is a salvage procedure under any conditions; the results are best when it is done for a comminuted patellar fracture with a normal trochlea. If it is done for chondrosis from a patellofemoral disorder with a shallow and eroded trochlea, the results are generally worse. Furthermore, if pain relief is not achieved, there is no good alternative—no fall-back position.

**Principles for performing a patellectomy in patellofemoral disorders include the following:**

- Realign the extensor mechanism during the patellectomy carefully; the shallow trochlea promotes recurrent tendon dislocations. Either the West and Soto-Hall technique (Fig. 87.15) (35) or a modification of Insall's proximal realignment (discussed earlier) with a heavy purse-string suture bunching the soft tissues to create a “pseudopatella” work well.

- If reinforcement of the repair is necessary, a portion of the quadriceps tendon can be turned down.
- If medial tibial tubercle transfer is necessary distally, consider anteromedial transfer to improve the postpatellectomy biomechanics.
- If trochlear chondrosis is present, patellectomy results will be worse; therefore, consider total patellofemoral arthroplasty.

TOTAL PATELLOFEMORAL ARTHROPLASTY

Total patellofemoral arthroplasty (TPFA) is a salvage procedure with indications similar to those for other total joint arthroplasties when isolated patellofemoral arthritis exists. After its introduction in the mid-1970s, TPFA fell into disfavor, largely, I believe, because of improper patient selection. More recent studies (2, 6, 25) have demonstrated 84% to 88% good and excellent long-term results. Because the etiology of most patellofemoral disorders and its secondary isolated patellofemoral arthritis is congenital, the average age of these candidates will be younger than the usual total joint arthroplasty patients. Therefore, it is extremely important for the clinician to impress on patients the need for future activity restrictions just as for total knee arthroplasty patients. If their expectations are higher, they are not ready for this operation.

As in patellectomy for patellofemoral disorders, the extensor mechanism must be aligned correctly at the time of TPFA if it has not been realigned before. The best long-term results have been with techniques that utilize a chrome-cobalt-molybdenum trochlear implant with a deep or anatomically correct groove articulating with a high-density polyethylene patellar replacement that mates with it.

Ideally, the geometry of the trochlear implant should be identical with the geometry of the femoral component from a total knee arthroplasty system by the same manufacturer. This confers a big advantage should a revision to a total knee arthroplasty be required in the future. At that time, only the trochlear implant will need to be replaced by the femoral component. The patellar implant will not need to be exchanged because its geometry will also match the new femoral prosthesis perfectly.

Because these are often multiply operated knees, the use of antibiotic-impregnated cement is recommended.

REHABILITATION

Postoperative rehabilitation for patellofemoral surgery focuses on two major goals: (a) regaining quadriceps strength and (b) restoring knee flexibility while protecting the knee during healing.

After arthroscopy, stiffness is rarely a problem, and no tissues require protection, so follow straight-leg raises quickly by isometric resistive (straight-leg weight-lifting) exercises. The weight goal is the same as the preoperative treatment goal.

Postoperative protection after extensor mechanism realignment requires only an extension knee splint (“knee immobilizer”) for a minimum of 6 weeks. Weight bearing in the extension knee splint does not stress the extensor mechanism, so it can start immediately after surgery and progress as tolerated to full weight bearing.

Gradual flexibility is obtained by having the patient perform passive and active heel slides as soon as pain allows. Teach the patient to sit on a bed (not dangle) and then remove the knee splint. By reaching under the knee with both hands and interlocking the fingers, the patient lifts the knee off the bed, allowing the heel to slide proximally. Because the patient is in control and can stretch the knee into as much flexion as pain allows, postoperative stiffness gradually decreases. A program of 10 repetitions four times a day usually produces 90° flexion in 3 to 4 weeks.

Quadriceps strengthening while protecting the extensor mechanism is more difficult to achieve. Start quadriceps setting immediately after surgery; it is frequently inhibited by pain. If there is no response by 1 week postoperatively, add biofeedback and electrical stimulation techniques. At 3 weeks, start assisted straight-leg raising with full straight-leg raising by 6 weeks. After 6 weeks, begin the patient on isometric resistive (straight-leg weight-lifting) exercises (Fig. 87.15). These are performed daily, two sets of 10 repetitions, with about 1 lb added every day or every other day. At 10 lb, the quadriceps is strong enough to prevent collapse, and the patient can discontinue the splint for walking. However, have the patient continue to lift to a 20- to 25-lb goal, depending on age and size.

PITFALLS AND COMPLICATIONS

REFLEX SYMPATHETIC DYSTROPHY

Patellofemoral surgery is prone to reflex sympathetic dystrophy (RSD), which is much easier to prevent than to treat. Prevention begins by being alert and sensitive to the individual with a low pain threshold and pain out of proportion to objective findings. A passive approach to getting well can be a clue. A prolonged active exercise and strengthening program monitored by the surgeon is invaluable for gaining insight about the patient’s expectations, goals, effort, cooperation, and responses before surgery. Early recognition and treatment is more successful than treating a full-blown case. Keep a high index of suspicion in order to pick up the early warnings and start treatment promptly and aggressively.

INFRAPATELLAR CONTRACTION SYNDROME

Again, prevention is much easier and more successful than treatment. The infrapatellar contraction syndrome begins with postoperative quadriceps shutdown; the patient is unable to activate this muscle. Place all patellofemoral patients on a straight-leg weight-lifting program preoperatively, even if it is not part of the nonoperative treatment. This trains the patient as well as the neuromuscular pathways so that they will be more easily recruited postoperatively. Again, early recognition and aggressive treatment with biofeedback and electrical stimulation are needed.

COMPARTMENT SYNDROMES

Compartment syndromes can be prevented by releasing the tourniquet before closure to assure hemostasis. Also, prevent injury to the anterior recurrent tibial artery when working lateral to the tibial tubercle by staying on the bone; avoid staying into the soft tissues there.

IATROGENIC MEDIAL SUBLUXATION OF THE PATELLA

Do not release the lateral retinaculum if it is already lax. This is especially bad with a hyperlax individual (e.g., Ehlers-Danlos syndrome).

Do not cut the vastus lateralis tendon. This can occur inadvertently by “getting lost” or by trying to achieve greater correction by overreleasing when what is usually needed is medial tibial tubercle transfer.
Avoid transferring the tibial tubercle too far medially. Measure the Q angle intraoperatively. Correct it to about 5° to 10°.

**LOSS OF CORRECTION**

When repairing and realigning the extensor mechanism, use nonabsorbable or permanent sutures. This will allow early motion and exercise without risk of the soft-tissue repair stretching out.

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

35. Willis B, Burkhardt E, Walker J, Johnson M. Preferential VMO Activation Achieved, as a Treatment for Knee Disorders. Personal communication.
POPLITEAL TENDINITIS

Be suspicious of popliteal tendinitis in long-distance runners and walkers who present with atypical posterolateral knee pain (23). Often these individuals are involved in activities such as cross-country running or backpacking where extensive downhill walking or running occurs. Pain will usually present insidiously along the lateral femoral condyle at the insertion of the popliteal tendon. This lateral-sided knee pain can be reproduced with weight bearing and 15° to 30° of knee flexion.

Physical examination will reveal point tenderness just anterior and posterior to the lateral collateral ligament. Palpation of the knee while in a "figure of four" position can help locate the area of maximal tenderness. Close examination will locate the area of tenderness just proximal to the lateral joint line. Often the symptoms can be reproduced by externally rotating the tibia, which places tension on the popliteus tendon.

Other possible etiologies, which can be ruled out by careful history and examination, should include a lateral meniscus tear, biceps femoris tendinitis, and iliotibial band friction syndrome. In those cases where the etiology remains in question, magnetic resonance imaging (MRI) or knee arthroscopy can be helpful in identifying any intraarticular pathology or tendon rupture (15-20,46).

Treatment should start with restricting participation in the inciting activity. Altering training habits such as running on the other side of the road or uphill may help alleviate the symptoms. Oral nonsteroidal antiinflammatory medicines are often helpful (23). In recalcitrant cases, the use of a local steroid injection around the tendon may be required. Other modalities such as ultrasound and deep transverse tissue friction massage may prove beneficial. To maintain aerobic conditioning, a program of cycling or deep-water aerobics should be initiated. After resolution of the symptoms, running can be gradually resumed.

PATELLAR TENDINITIS

Patellar tendinitis is also known as jumper's knee, and for good reason. The extreme demands placed on the patellar tendon by the quadriceps muscle during explosive jumping, and especially eccentric loading, result in microtears and focal degeneration of the tendon at its bony insertion along the inferior pole of the patella. In younger individuals this is known as Sinding-Larsen-Johansson disease and is usually self-limiting. The poor blood supply within the tendon results in a slow rate of healing (6). Therefore, the clinical history of patellar tendinitis is often a long and protracted course, and one that may become a persistent and recurrent problem in the adult population.

Continuing to pursue activities that aggravate the injury will only worsen the degenerative changes within the tendon's origin. Histologic findings include pseudocyst formation at the interface of bone and mineralized fibrocartilage along the inferior pole of the patella (6). The fibrocartilage exhibits thickening with myxomatous and hyalin metaplasia. Areas of microtears within the tendon display mucoid degeneration and fibroblast necrosis (39). These findings are consistent with insertional tendinopathy.

Symptoms usually arrive gradually with no history of a single inciting event. Typically, there is pain along the inferior pole of the patella or within the patella tendon itself. Patients may relate a history of participation in sports, such as basketball or volleyball, that involve jumping and running. Rarely is there a history of trauma. Palpation along the inferior pole will elicit tenderness. In some instances there may be palpable enlargement and thickening of the patellar tendon. In longstanding cases there may be crepitus with range of motion of the knee.

During the examination, take note of any musculotendinous imbalance. Heel cord, hamstring, and quadriceps tightness have been implicated as sources for patellar tendinitis. Also, vastus medialis oblique dysplasia and weakness of ankle dorsiflexors are thought to be possible causes of patellar tendinitis (6).

Radiographs are often unrevealing. Both AP and lateral views may show bony changes along the inferior pole of the patella such as sclerosis and cyst formation. A lateral view may reveal mild patella alta. Patella alta is thought to cause enhanced transmission of the force developed by the quadriceps to the patellar tendon. A bone scan will show increase uptake along the inferior pole. Magnetic resonance imaging is the most revealing study. It will localize the degenerative changes occurring both in the tendon and at the bone–tendon interface (14).

Treatment of patellar tendinitis involves activity modification with a controlled exercise program. It is important to remember that tendons are metabolically active and respond to stress with increased fiber size, number, and tensile strength (7). Initially, flexibility training and avoidance of activities that caused the symptoms are begun. Once the symptoms have subsided, a training program concentrating on eccentric exercises is started.

Treatment modalities such as ice, phonophoresis, and ionophoresis may prove beneficial as second-stage treatments in refractory cases. Ultrasound, deep tissue massage, and manual patellar mobilization may help.

Infrapatellar straps placed across the tendon can improve symptoms by altering the direction of mechanical force across the bone–tendon interface at the inferior pole of the patella. McConnell taping works in a similar manner but seems to have more consistent results than use of an infrapatellar strap (27).

The use of steroid injections for treatment needs to be undertaken with extreme caution. The patellar tendon is one of the highest load-bearing tendons, and there are numerous cases of patellar tendon rupture after steroid injection. If steroid injections are performed, then forced rest is advocated.

In chronic cases that are unresponsive to nonoperative management, an open procedure is warranted. Be cautious about surgical intervention, as the results are unpredictable (6,39). The MRI is useful in identifying the area of degenerative changes within the tendon. This area of focal degeneration needs to be debrided. After removal of the necrotic tissue, the tendon needs to be fixed to the patella through drill holes with use of large, #2 or #5, nonabsorbable suture. Multiple longitudinal incisions, in the direction of the fibers, at the area of degenerative change may stimulate a healing response and revascularity.

Return to activity is based on elimination of pain. After strength and flexibility have been addressed, a gradual return to sports can be started. Plyometrics can be helpful postoperatively. Plyometrics activity should be instituted cautiously and with supervision, however, as it may cause a relapse of symptoms.
QUADRICEPS TENDINITIS

Pain along the superior pole of the patella, at the insertion of the quadriceps tendon, is quadriceps tendinitis. You would expect quadriceps tendinitis to be analogous to patellar tendinitis; however, it is seen much less frequently.

Pain often begins insidiously over the proximal pole of the patella. There may be a history of changes in training habits before the onset of symptoms. Palpation will reveal localized tenderness over the proximal pole. Pain can be reproduced with extension of the knee against resistance or with eccentric loading of the quadriceps.

During the examination, other associated findings such as patellar malalignment or hamstring tightness may be present.

Radiographs usually reveal little (41), but calcifications within the tendon may be identified. The differential diagnosis should include a suprapatellar plica. A bone scan or MRI may be helpful in ruling out other sources of pain. The MRI is very helpful in localizing the affected area if operative intervention is warranted.

Treatment is similar to that for patellar tendinitis. This includes activity modification or active rest. Physical therapy exercises directed toward patellar tendinitis are helpful. Modalities such as ice, massage, ultrasound, iontophoresis, and phonophoresis can be instituted as second-stage treatments. The use of nonsteroidal antiinflammatories may prove beneficial. A corticosteroid injection into the quadriceps tendon is less risky than with patellar tendinitis, but it should be used with extreme caution.

Surgical treatment is rarely needed. When conservative therapy fails, the affected area needs to be localized with MRI. The area of degenerative tissue is excised, and any heterotropic calcifications are removed (42). Reattachment of the quadriceps tendon to the superior pole of the patella is performed with use of drill holes and large #2 or #5 nonabsorbable sutures of suture anchors.

The criteria for return to sports are similar to those for patellar tendinitis. Return to activity is based on the elimination of pain. Once range of motion, strength, and flexibility have been addressed, then a slow return to sports can be pursued.

ILIOTIBIAL BAND FRICTION SYNDROME

Iliotibial band friction syndrome is a common tendinous overuse syndrome of the knee. Activities that involve repetitive knee flexion and extension will incite and aggravate the symptoms located over the lateral side of the knee. This is commonly seen in long-distance runners (29) and cyclists (24), where excessive friction between the iliotibial band and the lateral femoral condyle is the cause of the pain.

Point tenderness is located over the lateral femoral condyle. Inflammation and hypertrophy develop within the synovium below the iliotibial band, which is a lateral extension of the joint capsule (31). There may be a catching or grating noted as the iliotibial band passes over the lateral femoral epicondyle. Maximum discomfort is elicited by flexing the knee to about 30° (32). As this angle of knee flexion is encountered, the iliotibial band is passing posteriorly directly over the prominent lateral femoral condyle. During the physical examination, check for excessive tightness of the iliotibial band. The Ober’s test has been described as a way to determine if any iliotibial band tightness exists. Athletes should be evaluated for other underlying factors that may predispose them to iliotibial band friction syndrome such as genu varum, tibial torsion, or excessive foot pronation.

Other entities that must be included in the differential diagnosis of lateral side knee pain include lateral meniscal pathology, biceps and popliteus tendinitis, and patelofemoral syndrome. The MRI can help confirm the diagnosis of iliotibial band friction syndrome in patients with an appropriate clinical history (30).

Cessation of the inciting activity is the first course of treatment. This, along with time and a stretching program, is often successful in eliminating the symptoms. Alteration of training activities and habits can be helpful. Cyclists may find relief by changing the height of their saddle or their foot position on the pedals. Runners can try altering stride length or changing the direction of running on the track.

Symptomatic treatment should include oral antiinflammatory medications (43). Use of other modalities such as ultrasound, ionophoresis, phonophoresis, and deep tissue friction massage may be beneficial. If the syndrome is recalcitrant to these measures, then complete activity restriction is required. Rarely do athletes not respond to nonoperative treatment.

If conservative measures are ineffective, then surgical intervention is indicated. The surgical technique involves removing inflamed tissue and doing an elliptical excision of the portion of the iliotibial band that contacts the lateral femoral epicondyle when the knee is flexed to 30°. Martens recommends removing a triangular section of the iliotibial band that contacts the lateral epicondyle with the knee in 60° of flexion (29). A gradual return to activities can be started at 3 weeks postoperatively.

PES ANSERINUS BURSITIS

The tendinous aponeurosis of the sartorius, gracilis, and semitendinosus muscles makes up the pes anserinus. The per anserinus bursa is located directly beneath this aponeurosis and lies on top of the superficial medial collateral ligament.

Repetitive flexion and extension of the knee can cause irritation of the bursa or the overlying pes tendons. Point tenderness along the anteromedial surface of the tibia, two fingersbreadths below the joint line, is present on examination. In longstanding cases there may be a palpable boggy fullness to the inflamed bursa. It can be difficult to distinguish bursitis from tendinitis clinically, but distinguishing them is unnecessary, as the two are treated in a similar fashion. It is not uncommon to find medial compartment osteoarthritis associated with pes anserinus bursitis (3). Other entities that must be considered in the differential diagnosis include medial meniscus tear or cyst, juxtaarticular bone cysts (28), and medial collateral ligament injury. The MRI can prove helpful in determining the etiology of pain along the medial side of the tibia (16).

Initial treatment involves active rest and avoidance of irritating activities. At the same time, a stretching and conditioning program is initiated, beginning with isometric exercises and electrical muscle stimulation incorporating resistive exercises as symptoms allow. Ice and nonsteroidal antiinflammatory medication have proven beneficial.

Further treatment modalities can include ultrasound (3), phonophoresis, iontophoresis, and deep tissue transverse friction massage. Corticosteroid injections have also been successful in treating the symptoms (41,42). In refractory cases of chronic pes anserinus bursitis, a bursectomy may be necessary.

SEMMEMBRANOUSUS TENDINITIS
