Semimembranous tendinitis occurs near the tendon’s insertion along the postero-medial corner of the knee. This insertion is made up of a five-footed tendinous expansion that embraces the postero-medial side of the tibia and knee (13, 18). Strenuous, repetitive activities can elicit pain along the postero-medial knee joint.

Palpation of the knee joint often reveals point tenderness inferior to the posteromedial joint line and posterior to the superficial collateral ligament. The examination should include a comprehensive evaluation of the knee to rule out any intraarticular pathology that can mimic or be the source of the resulting tendinitis.

Begin treatment with cessation of any inciting activities. An exercise program with emphasis on hamstring and quadriceps static stretching should be started. As tolerated, an eccentric exercise program can be introduced.

Oral antiinflammatory medications have proven beneficial. Also, modalities such as ultrasound, phonophoresis, iontophoresis, and deep tissue massage can be helpful. A local injection with cortisone and an anesthetic can be beneficial both in differentiating the etiology and in treatment (67).

In chronic cases that fail conservative therapy, look for intraarticular etiology. An MRI can be valuable for evaluating any meniscal or articular cartilage pathology (13, 18, 40). In patients who remain symptomatic with no intraarticular pathology, surgery may be indicated. This involves a postero-medial approach to the tendinous insertion of the semimembranous. Removing overlying inflamed soft tissue can initiate a “healing response.” Care should be taken to avoid violating the tendon itself (47).

PATELLAR TENDON RUPTURE
Unlike patella fractures, ruptures of the patellar tendon are not uncommon and are frequently encountered in athletes. Rupture of the tendon is most often seen in middle-aged individuals who may deny any history of preexisting symptoms. There are case reports of patellar tendon rupture after procedures that violate the integrity of the patellar tendon, such as total knee arthroplasty, or after harvesting a patellar tendon graft for ACL reconstruction (25-35). Often individuals will describe the sensation of a sudden “pop” when force was applied to the extensor mechanism. With complete rupture of the patellar tendon, there is inability to support body weight on the affected side.

The amount of stress leading to rupture can vary greatly. Zernicke et al. describe an incident in which a force of approximately 17.5 times the body weight was produced by a power lifter before rupture of the patellar tendon (60). In other instances, only a trivial amount of force was applied before rupture. In these cases there is often an underlying autoimmune disorder that affects the integrity of the tendon (34,36,38,40).

The typical history of rupture involves application of a force across the extensor mechanism followed by a “pop” sensation (4,12,17,42). There may or may not be a history consistent with chronic inflammatory symptoms. Subsequently, injured individuals are unable to support themselves on the injured limb. They may even report severe proximal displacement of the patella.

On physical examination there will be a diffuse swelling throughout the knee because of the capsular disruption. Tenderness will be located at or below the inferior pole of the patella. The location of the patellae will be asymmetric. Patella alta will be present on the affected side. Patients may still have the ability to extend the knee against gravity if a portion of the extensor retinaculum remains intact. Typically there is a palpable defect in the patellar tendon at or just below the inferior pole of the patella.

Radiographs will demonstrate patella alta, particularly on the lateral view. If there is a question about tendon rupture, flexion of the knee will make any displacement more pronounced on the lateral view.

With patellar tendon rupture, surgical repair is required and should be performed acutely or within a few days for optimal results. There is no place for nonoperative treatment. Delaying the surgical repair will result in contracture of the extensor mechanism, which can seriously complicate the repair (29,49).

**OPERATIVE TECHNIQUES**

- Make a longitudinal incision near the midline. A transverse incision can also be made at the level of the inferior pole of the patella. Because future incisions can be compromised by a transverse incision, most surgeons prefer a longitudinal incision.
- Gently incising the skin down to the extensor mechanism, elevate flaps medially and laterally to allow exposure to the tendon and the torn extensor retinaculum.
- Evacuate the hematomas and identify and mobilize the torn ends of the tendon. By extending the knee, the two ends of the tendon can be reapproximated. If this is a bony avulsion injury, then the avulsion site on the patella should be rasped to expose bleeding bone.
- Then make three drill holes in the patella that begin at the site of the avulsion and exit the proximal anterior surface of the patella. Make these drill holes large enough to pass a #2 or #5 nonabsorbable suture. A wire can be used for the repair but must be removed at a later date; it could fragment. See Chapter 22 for an illustration showing placement of the drill holes.
- Place two large nonabsorbable sutures (#2 or #5) through the patellar tendon in a Bunnell-type weave technique. Pass these sutures through the drill holes and tie them over the proximal anterior surface of the patella. Additional interrupted sutures can be placed to reinforce the repair of the tendon. Multiple interrupted figure-of-eight stitches with a #2 nonabsorbable suture are then used to close the extensor retinaculum medially and laterally. Finally, evaluate the adequacy of repair by putting the knee through a gentle range of motion.

Postoperatively immobilize the knee in extension for 1 to 2 weeks before limited range of motion is allowed. Weight bearing is allowed early on. The amount of motion will depend on the strength of the repair. The extension brace can be discontinued after 6 to 8 weeks. During the rehabilitative course, a patient can actively control knee motion with the hamstrings while lying in the prone position.

**CHRONIC PATELLAR TENDON RUPTURES**

With untreated patellar tendon ruptures, the extensor mechanism can contract so that it is difficult to position the patella distally for repair. The clinical and radiographic exam can help determine if the extensor mechanism can be positioned distally to allow a primary repair. When there is inadequate length, skeletal traction can be placed on the extensor mechanism to regain length as described by Justis (15). Kelikian et al. (16) and others (45). A transverse pin is placed in the patella to apply skeletal traction. This traction can be maintained up to 4 weeks, until the inferior pole of the patella is positioned about 2.5 cm superior to the tibial plateau with the knee in extension. Once the patella has been brought back to its appropriate position, the patellar tendon is primarily repaired.

Unfortunately, there is often a large defect in the tendon that needs to be reconstructed. Justis (15) recommends use of the fascia lata, as do Siwek and Rao (45). Weaving several strips of fascia lata through the two ends of the tendon can bridge the defect. Kelikian suggests use of the semitendinous tendon (16).

**OPERATIVE TECHNIQUES**

- Harvest the semitendinosus tendon in a similar fashion to an anterior cruciate reconstruction (Chapter 89). However, maintain the insertion of the tendon on the tibia.
- Then pass the tendon through a transverse drill hole in the tibia at the level of the tibial tubercle and then through a transverse hole in the distal third of the patella.
- Then suture the free end of the tendon to itself after an appropriate tendon length has been obtained.

Postoperatively immobilize the knee in extension for 6 to 8 weeks. If the fixation is secure or augmented with wire or a large nonabsorbable suture, then motion and weight bearing can be instituted earlier.

Recently, Falconiero and others have described the use of an Achilles tendon–bone allograft to bridge the tendinous defect (6,28). Fixation of the Achilles tendon–bone allograft is augmented with a suprapatellar wire that is removed 8 weeks later. This treatment has allowed for much earlier mobilization and weight bearing. Use of a dacron graft has also been described as a method to reinforce and bridge the tendinous defect associated with a chronic rupture (22).

**QUADRICEPS TENDON RUPTURE**

Rupture of the quadriceps tendon is most often seen in elderly patients and in patients with chronic disease (1,44,45,46). In a healthy population, quadriceps ruptures are often seen in middle-aged individuals. This population is somewhat older than that seen for patellar tendon ruptures. David et al. described bilateral quadriceps tendon repair by putting the knee through a gentle range of motion.

**OPERATIVE TECHNIQUES**

- Pass large, nonabsorbable #2 or #5 sutures through the quadriceps tendon in a Bunnell-type weave. Then pass these sutures through drill holes in the patella and tie them distally over the inferior anterior surface of the patella. Before reapproximation of the tendon, abrade the superior pole of the patella to obtain bleeding bone at the tendon’s insertion site.
- Next, repair the extensor retinaculum with a #2 nonabsorbable suture. The knee is then flexed to evaluate the integrity of the repair. After repair, the knee can usually be flexed 45° to 90°.
It is important to warn patients that rehabilitation and outcome will be limited when repairs are delayed.

ISOLATED ANTERIOR CRUCIATE LIGAMENT INJURY

James D. Ferrari and Bernard R. Bach, Jr.

Anterior cruciate ligament (ACL) injury remains a common orthopaedic problem with an annual incidence of approximately 95,000 cases a year, and some 50,000 of these knees are reconstructed annually (4.74). During the 1990s, an explosion of both basic science and clinical research on the ACL has contributed greatly to our understanding of the ACL-deficient knee and its successful treatment. It is now widely agreed that reconstruction of the ACL is far superior to repair (30) and that extrarticular reconstruction is not necessary for isolated ACL insufficiency (35). Yet despite this plethora of research, controversy still surrounds many issues in ACL reconstruction, such as the appropriate timing of surgery, the method of reconstruction, and the means of fixation of the reconstruction.

The purpose of this chapter is to discuss the state of the art of isolated anterior cruciate ligament reconstruction in the skeletally mature individual. Anatomy and biomechanics of the ACL and ACL injury in the skeletally immature individual are discussed in Chapter 83 and Chapter 97, respectively.

INJURY, INCIDENCE, AND NATURAL HISTORY

The classic history of a person sustaining an isolated ACL injury consists of a noncontact deceleration mechanism, usually occurring with a sudden stopping, cutting, or jumping maneuver. A “pop” is usually felt or heard, and the patient may describe a hyperextension injury. Infrequently, the patient is able to continue activity, and within a few hours the knee swells considerably, secondary to hemarthrosis. With the above history and the presence of a hemarthrosis, the likelihood is more than 70% that the patient has torn the ACL (79). Contact injuries are more likely to result in multiligament injuries, as is seen with O'Donoghue's classic triad in which a direct blow valgus load on the knee results in injury to the ACL, medial collateral ligament (MCL), and medial meniscus. The differential diagnosis for an acute traumatic hemarthrosis includes patellar subluxation or dislocation, osteochondral injury, peripheral meniscus tear, or intraarticular fracture.

The majority of ACL injuries are sustained in sports activities, with basketball, soccer, and skiing predominating in noncontact injuries. Contact injuries are frequently described in football players. The true incidence of ACL injuries is not known, as many patients sustaining injuries are unaware of the severity of the injury and may not seek medical attention initially. A reported 72 ACL injuries per 100,000 skier-years occur in skiing (37). In college football, 2.4 injuries occur per team per season (54). Recent NCAA statistics have also demonstrated an increased incidence of ACL injuries in female athletes compared to their male counterparts in equivalent sports, with women having a three to four times greater likelihood of injuring the ACL in soccer and basketball (4).

Although the natural history of the ACL-injured patient remains controversial, several studies have provided insight into the likely outcome of the ACL-injured patient. Noyes and co-authors specifically evaluated athletically active patients 5 to 10 years after they sustained their injuries (80). Approximately one third had symptoms of pain or giving way with all activities of daily living (ADL), one third had symptoms in sports but not in ADLs, and one third had no symptoms in sports or ADLs. Meniscoclecomy contributed significantly to pain and swelling, and radiographic changes of degeneration correlated with giving-way episodes and the level of athletic participation. Changes became manifest an average 109 months after injury and tended to worsen with increased length of follow-up. Patients who had symptoms with sporting activities and persisted in participation had the poorest prognosis. A subset of these patients underwent rehabilitation and activity modification, and they used a brace in sporting activities (81). One third of these patients were helped with this program, but another third worsened, and a final third remained the same. The patients who were helped still had symptoms with athletic activities, however. Patients who were unwilling to modify their activities had a worse prognosis and tended to require reconstructive surgery.

Barrack et al. (15) evaluated the results of bracing and rehabilitation in an active-duty military population and concluded that young adults involved in athletic and strenuous physical activity can expect unsatisfactory results. Only 11% of the patients were graded as excellent, and only 4 of 72 (5.5%) competed at the same level and performance of sport. Sixty percent either changed sports, discontinued sports, or limited sporting activity, and 88% were symptomatic with pain and giving way of the knee. Similar poor results were seen in a series of 40 patients followed nonoperatively (53). Only 14% were able to return to full athletic activity, and 88% were graded as fair to poor.

In a prospective outcome study, Daniel et al. further evaluated the ACL-injured patient and also evaluated who was most likely to require ACL reconstruction (35). Eighty-one percent of the 292 patients with a hemarthrosis had an ACL tear, and 49% of these patients had a meniscal tear diagnosed by arthroscopy, though not all of these meniscal tears required surgery. The best predictor of which patients required surgery was the number of preinjury hours per year spent in sporting activities that involved jumping, pivoting, hard cutting, and lateral motion (Table 99.1). More than 200 h per year (i.e., 4 h/week) was considered moderate to high risk for requiring surgery. Instrumented knee laxity measurements that demonstrated a manual maximum side-to-side difference greater than 5 mm were also predictive of the need for reconstructive surgery. Patients who required meniscal surgery had a greater incidence of joint arthrosis at final evaluation.

Patients who required meniscal surgery had a greater incidence of joint arthrosis at final evaluation.
anterior subluxated tibia rather than posterior subluxation of a reduced tibia, as can be seen with PCL injuries. Causes of false-negative results include a displaced position, contributing to the reduction. In examining a right knee, palpate the joint line with your left hand to ensure that what is being perceived is reduction of the moved from extension to flexion. This reduction is the result of the iliotibial band moving from an anterior position relative to the center of the knee to a posterior description of this test, with the knee placed in various positions, but all can produce the pivot-shift phenomenon. Our method is to place the hip in slight abduction and compare it to the opposite side. Grade by comparing the amount of increased anterior translation on the injured side to the normal side, with 1 to 5 mm as grade I, 6 to 10 mm as grade II, 11 to 15 mm as grade III, and >15 mm as grade IV. Individual variations may exist; hence, the absence of a firm endpoint is a crucial factor in assessing the range of motion and note any signs of mechanical blocking. This could be secondary to a displaced bucket-handle meniscal tear or a loose osteochondral fragment, but a block to full extension can be caused by hamstring spasm. Furthermore, the distal portion of the ACL may flip forward and produce a block in the anterolateral joint line with the knee in full extension, causing pain, which is usually retropatellar.

PHYSICAL EXAMINATION

- Ideally, examine the knee shortly after the injury, before swelling and pain prevent an accurate diagnosis. Examine the opposite leg to serve as a baseline for comparison. First inspect the injured leg for abrasions, contusions, ecchymoses, and the presence of an effusion. Next, palpate for point tenderness to evaluate associated injuries.
- Examine the patellofemoral joint for the presence of retinacular tearing or a dislocation or subluxation and perform patellar mobility and apprehension testing. Palpate the quadriceps and patellar tendons for defects at their respective insertions and ask the patient to perform a straight-leg raise.
- Examine the patellofemoral joint for the presence of retinacular tearing or a dislocation or subluxation and perform patellar mobility and apprehension testing.
- The lateral femoral condyle may be tender secondary to a bone bruise. Tenderness at the tibiofemoral joint lines may represent an associated meniscal tear, though the evaluation of meniscal pathology in the presence of an ACL tear is not as sensitive. Often do posterior drawer testing, as what may seem to be increased anterior translation from a reduced position may actually be reduction of the tibia from a posteriorly involved in pivoting sports will describe the need to “round out” corners and avoid hard cutting on the affected leg. Effusions may be associated with vigorous activity.
- Occasionally a second traumatic event or a “giving way” episode results in a meniscal tear that causes mechanical symptoms such as locking or catching in the knee.

CLINICAL EVALUATION AND IMAGING

Accurate and early diagnosis of ACL injuries has improved since the 1970s as much as has the treatment for the injury. Historically, many patients did not receive an accurate diagnosis until recurrent instability or mechanical symptoms from a meniscal tear occurred.

HISTORY

Clinical evaluation should begin with a thorough history, and the mechanism of injury is obtained from the patient or any witnesses to the injury. Most ACL injuries are the result of noncontact and rotational forces. Valgus/external rotation, hyperextension, and deceleration mechanisms are commonly described. Varus injuries occur less frequently, are often contact injuries, and usually involve injury to the lateral ligaments. The classic “terrible triad” of ACL, MCL, and meniscal injuries caused by a direct blow to the lateral aspect of the knee is not as common as noncontact injuries and more often involves injury to the lateral meniscus than to the medial meniscus.

A history of hearing or feeling a “pop” or “snap” is highly suspicious for an ACL injury, with this finding accompanying the vast majority of ACL injuries. This is usually accompanied by the inability to continue athletic participation on the day of injury and the onset of a knee joint effusion within a few hours of injury. Any effusion within hours of injury is considered a hemorrhrosis, and 70% to 80% of knee joint hemorrhoses are secondary to ACL tears. Differential diagnosis of a hemorrhrosis with an associated “pop” should include patellar dislocation or subluxation with retinacular tearing, an osteochondral lesion, MCL tear, a posterior cruciate ligament (PCL) tear, a fracture, or peripheral meniscus tear.

Patients who present with chronic ACL tears can generally recall the specific event that caused the injury, but often retrospectively report fewer symptoms after the initial event than are generally recalled by patients who present acutely. Nevertheless, complaints are geared toward a feeling of instability or “giving way.” Patients involved in pivoting sports will describe the need to “round out” corners and avoid hard cutting on the affected leg. Effusions may be associated with vigorous activity. Occasionally a second traumatic event or a “giving way” episode results in a meniscal tear that causes mechanical symptoms such as locking or catching in the knee.

Table 89.1. Sports and Occupation Levels

Clearly, active athletic participation by the ACL-deficient athlete with recurrent episodes of giving way places the knee at high risk for subsequent chondral and meniscal damage. Animal and human studies also support the concept that ACL deficiency predisposes to osteoarthritis, and animal studies demonstrate that ACL reconstruction is protective of articular cartilage. No human studies have yet to demonstrate that ACL reconstruction protects against articular surface degeneration, however. Andersson et al. reported on a randomized trial of three different treatment methods for ACL injury. Group I underwent primary repair with extraarticular augmentation, and group II had primary repair without augmentation, with both groups having all other injured structures concurrently repaired. Group III had an arthroscopic ACL repaired. One third of the patients in group III sustained meniscal tears after reconstruction. Patients in groups I and II had significantly fewer subsequent meniscal tears and had significantly more stable knees. It is well recognized that ACL reconstruction helps protect against further meniscal damage and that loss of the meniscus predisposes the knee to articular degeneration. Success of meniscal repair is greatest when it is done in conjunction with ACL reconstruction. Hence, for the singular reason of protecting the meniscus and its role in protection of articular cartilage, ACL reconstruction may be chondroprotective. Whether ACL reconstruction in and of itself prevents articular degeneration should be seen to be in more controlled, prospective studies with longer-term follow-up.

Aspiration of a tense effusion can be both therapeutic and diagnostic. It will relieve pressure and pain, allowing a more accurate physical examination to be performed, and the hemorrhrosis can be examined for the presence of fat globules, which is indicative of an intraarticular fracture. It should be noted that with acute ACL tears, other pathologies commonly coexist, with an approximate 60% incidence of meniscal tears, 10% to 20% incidence of osteochondral fractures, and 20% incidence of associated ligamentous injuries.

Assessment of a tense effusion can be both therapeutic and diagnostic. It will relieve pressure and pain, allowing a more accurate physical examination to be performed, and the hemorrhrosis can be examined for the presence of fat globules, which is indicative of an intraarticular fracture. It should be noted that with acute ACL tears, other pathologies commonly coexist, with an approximate 60% incidence of meniscal tears, 10% to 20% incidence of osteochondral fractures, and 20% incidence of associated ligamentous injuries. Accurate and early diagnosis of ACL injuries has improved since the 1970s as much as has the treatment for the injury. Historically, many patients did not receive an accurate diagnosis until recurrent instability or mechanical symptoms from a meniscal tear occurred.

PHYSICAL EXAMINATION

- Ideally, examine the knee shortly after the injury, before swelling and pain prevent an accurate diagnosis. Examine the opposite leg to serve as a baseline for comparison. Aspiration of a tense effusion can be both therapeutic and diagnostic. It will relieve pressure and pain, allowing a more accurate physical examination to be performed, and the hemorrhrosis can be examined for the presence of fat globules, which is indicative of an intraarticular fracture. It should be noted that with acute ACL tears, other pathologies commonly coexist, with an approximate 60% incidence of meniscal tears, 10% to 20% incidence of osteochondral fractures, and 20% incidence of associated ligamentous injuries.

Assess the range of motion and note any signs of mechanical blocking. This could be secondary to a displaced bucket-handle meniscal tear or a loose osteochondral fragment, but a block to full extension can be caused by hamstring spasm. Furthermore, the distal portion of the ACL may flip forward and produce a block in the anterolateral joint line with the knee in full extension, causing pain, which is usually retropatellar.

Stress the collateral ligaments in both full extension and 30° of knee flexion. Laxity is graded from I to III in 5-mm increments of joint opening. Grade III injuries connote complete disruption of the ligament. Rule out injury to the posterolateral structures by the “dial test,” in which external rotation of the tibia at 30° and 90° of knee flexion is compared to that on the opposite side. More than 10° of increased external rotation at 30° is indicative of a posterolateral corner injury and, if also present at 90°, indicates an injury to the posterior cruciate ligament as well.

The Lachman test is the most sensitive and reliable test for diagnosing ACL insufficiency. Flex the knee to 20° to 30°, stabilize the thigh with one hand (left hand for examining a right knee), and translate the tibia forward with the other hand. Note the amount of anterior translation and the presence or absence of a firm endpoint and compare it to the opposite side. Grade by comparing the amount of increased anterior translation on the injured side to the normal side, with 1 to 5 mm as grade I, 6 to 10 mm as grade II, 11 to 15 mm as grade III, and >15 mm as grade IV. Individual variations may exist; hence, the absence of a firm endpoint is a crucial factor in determining the presence of an ACL tear.

The anterior drawer test is much less sensitive in diagnosing ACL tears. It is performed with the knee flexed 90° and the foot stabilized. Perform it with the tibia in neutral rotation as well as in both internal and external rotation, as increased anterior translation in external rotation may signify injury to the posterolateral structures. Also do posterior drawer testing, as what may seem to be increased anterior translation from a reduced position may actually be reduction of the tibia from a posteriorly subluxated position. The quadriceps active test is a useful adjunct to the posterior drawer.
further injury and is a candidate for surgery. Patients at risk for recurrent injury may still have symptoms with activities of daily living, however. Essentially any patient with recurrent episodes of giving way is at high risk for ACL injury.

As outlined above, the true natural history of the ACL-deficient knee is not accurately known because of the differences in study design, the nonrandomized nature of many studies regarding treatment, the lack of truly long-term follow-up, and the inclusion of methods of treatment that have been shown to be inferior to current methods for surgical reconstruction and rehabilitation. Nevertheless, the studies outlined above clearly demonstrate that nonoperative treatment for the ACL-deficient patient who is involved in athletic activities that require cutting and jumping is uniformly unsuccessful and places the knee at risk for chondral injury and degeneration.

INSTRUMENTED LAXITY TESTING

Instrumented knee laxity testing has been extremely useful in the office diagnosis of the ACL-injured knee. Testing is especially helpful in the acute setting when patient guarding precludes an accurate physical examination. Instrumented laxity testing is generally minimally painful, and the support that rests under the patient's thigh facilitates hamstring relaxation. An objective and quantitative method of documenting ACL laxity also helps gain the patient's trust in the physician's diagnostic acumen, and it is imperative that laxity testing be performed for follow-up studies of ACL reconstruction.

Several studies have demonstrated the diagnostic accuracy of laxity testing (9,34). It is extremely unusual for normal knees to have an anterior maximum manual translation of more than 10 mm. Other criteria that are useful in diagnosing ACL injury are a maximum manual side-to-side difference exceeding 3 mm and a compliance index (the difference between the readings at 15 and 20 lb) of more than 2 mm. The maximum manual test is the strongest predictor of differentiating between normal and ACL-injured knees. Essentially, if the side-to-side difference between the injured and normal knees is 3 mm or greater at 15 lb, 20 lb, or maximum manual testing with the KT-1000 arthrometer (Medmetric, San Diego, CA), the likelihood of ACL injury is greater than 95%. Furthermore, if anterior translation of the injured knee is greater than 11 mm at any level tested, the likelihood of ACL injury is 95%.

IMAGING

All patients being evaluated for an acute knee injury or under consideration for reconstructive surgery should undergo routine knee radiographs. Our current protocol is to take weight-bearing AP, lateral, and 45° PA views as well as a Merchant view of the patellofemoral joint. This allows us to evaluate the medial and lateral joint spaces for degeneration or osteochondral injuries, and the patellofemoral joint can also be examined for subluxation and for tilt as well as degeneration or osteochondral injury. Though it is unlikely that plain film radiographs will have tremendous yield, occasionally bony avulsions of tibial eminences are noted; other findings, such as the lateral notch sign and the lateral capsular sign, or Segond fracture, may be pathognomonic of ACL injury (Fig. 89.1) (121).

Imaging modalities such as knee arthrogram, CT scan, and bone scanning have little place in the evaluation of the ACL-injured patient. A thorough history, physical examination, and plain film evaluation, with the addition of instrumented laxity testing, is generally all that is needed for proper diagnosis. The addition of magnetic resonance imaging (MRI) (Fig. 89.2), though quite sensitive and specific for detection of ACL disruption and meniscal pathology as well as bone bruises, frequently does not change the treatment plan and adds cost to the care of the patient (41,45).

Adalberth et al. prospectively evaluated 40 patients with acute hemarthroses of the knee with physical exam, plain radiography, scintigraphy, MR imaging, and arthroscopy. Eighty-five percent had ACL tears, and 83% of these had meniscal tears diagnosed by arthroscopy. The MRI was an excellent tool to detect meniscal tears that required surgery, but it was not sensitive or accurate in detecting partial-thickness meniscal lesions and stable full-thickness lesions (1). Eighty percent of ACL tears had bone bruises detected by both scintigraphy and MRI, usually in the lateral femoral condyle. The authors concluded that scintigraphy and MR imaging added little information to the physical examination, did not guide treatment, and was not as good as an arthroscopic evaluation. Other authors have also demonstrated that many of these meniscal tears associated with ACL injury are not symptomatic on exam and can be left alone at the time of surgery (156). Knowledge of their presence before surgery will not change the operative plan. Currently, we do not use routine MR imaging, and our primary utility of MRI is when a patient with an acute ACL tear still exhibits a painful knee flexion contracture 2 weeks postinjury. In this instance we use it to rule out a displaced bucket-handle meniscal tear. Should this be the case, we prefer to operate earlier than usual in order to reduce the meniscal tear, repair it if possible, and reconstruct the ACL.

INDICATIONS AND TREATMENT

As outlined above, the true natural history of the ACL-deficient knee is not accurately known because of the differences in study design, the nonrandomized nature of many studies regarding treatment, the lack of truly long-term follow-up, and the inclusion of methods of treatment that have been shown to be inferior to current methods for surgical reconstruction and rehabilitation. Nevertheless, the studies outlined above clearly demonstrate that nonoperative treatment for the ACL-deficient patient who is involved in athletic activities that require cutting and jumping is uniformly unsuccessful and places the knee at risk for chondral injury and degeneration.

The decision to treat the ACL-injured patient operatively is based on many factors (Fig. 89.3). Activity level is perhaps the most important; the patient who is involved in many hours of level I and II sports, as defined by Daniel et al., is most at risk for recurrent instability and potential chondral injury (55). Patients employed in physical labor that places the knee at risk for giving way should be considered for reconstruction as well. Sedentary patients who do not participate in activities that place them at risk for recurrent injury may still have symptoms with activities of daily living, however. Essentially any patient with recurrent episodes of giving way is at high risk for further injury and is a candidate for surgery.

Figure 89.1. A: Anteroposterior radiograph of a skeletally mature right knee with chronic ACL insufficiency. A healed Segond fracture is noted by the bony spur on the lateral tibial plateau's lateral cortex, proximal to the fibula. B: Anteroposterior radiograph of a skeletally immature individual with a painful traumatic effusion. The x-ray reveals a lateral capsular avulsion, indicative of an injury to the ACL.

Figure 89.2. Magnetic resonance image of an ACL-injured knee. A: Coronal T<sub>1</sub>-weighted image depicting the intercondylar notch. The torn ACL displays higher signal intensity than the PCL. B: Intermediate and C: T<sub>2</sub>-weighted sagittal images demonstrate the increased signal intensity of interstitial damage to the ACL. Also, note the increased signal intensity in the posterolateral tibial plateau indicative of a bone bruise.
As discussed above, patients with clear-cut signs and symptoms of meniscal injury should be considered for ACL reconstruction. Meniscal repair at the time of reconstruction is more successful than the patient in isolation or in the face of a chronically unstable knee. The status of the meniscus is perhaps the most important factor in preserving the articular cartilage over time.

Combined ACL and MCL injuries represent a more severe knee injury, but nonoperative treatment of the MCL with later reconstruction of the ACL results in fewer motion problems and more predictable healing of the MCL and stability of the reconstructed ACL than combined repair and reconstruction (104). On the other hand, associated lateral ligamentous injury should be addressed within a few weeks of injury with primary repair with or without augmentation, as results of acute repair of lateral ligamentous structures are superior to results of reconstruction of chronic laxity of the lateral ligaments (13,58). Acute repair should be done along with ACL reconstruction.

Currently, no arbitrary cutoff for age exists with regards to ACL reconstruction. Though it seems intuitive that the older patient likely spends less time in high-risk activities, in today’s society more and more people are actively involved in athletic pursuits and wish to continue participation throughout their life. As ACL reconstruction has evolved into a less invasive and more successful procedure, age has become less of a determining factor in advocating operative treatment, and equivalent results can be expected in the older patient (14,92). In our practice, patients over 35 years of age comprise 8% of the ACL reconstructions, and those over 40 comprise 3%.

Once thought to be a contraindication to ACL reconstruction, preexisting chondral degeneration does not preclude successful ACL reconstruction (84,105). Shelbourne et al. in fact demonstrated that ACL-deficient patients with preexisting osteoarthritis had not only improvement in stability but also decreased pain, and the level of activity was able to be increased postoperatively as well (105). Noyes et al. were also able to demonstrate that patients with articular cartilage damage who underwent ACL reconstruction had improvements in pain, giving way, and function, and 79% were able to increase their athletic participation without aggravating their preexisting cartilage degeneration (84).

In general, guidelines we use in recommending ACL reconstruction to our patients include (a) participation in level I and II sports more than 4 h weekly, (b) KT-1000 maximum manual difference over 5 mm, and (c) more than two episodes of instability per year. Patients with definite displaced bucket-handle meniscal tears or knees with combined ACL and lateral ligament injury are also encouraged to have reconstruction. Perhaps the only contraindications to ACL reconstruction are active infection in the knee joint and loss of motion in the knee that is secondary to adhesions and/or arthrosis. A relative contraindication would be a patient with highly unrealistic expectations or a patient who is unwilling to participate in the postoperative rehabilitation.

**NONOPERATIVE TREATMENT**

When nonoperative treatment is chosen, it does not mean that no treatment is given. After an acute injury, control of pain and swelling via the established principles of rest, ice, compression, and elevation (RICE) is undertaken. Efforts are made early to reestablish full range of motion, especially full extension; although a knee immobilizer and crutches are generally used initially, a normal gait with full weight bearing is encouraged after 7 to 10 days. The acute inflammatory phase generally resolves within 1 to 3 weeks, and full range of motion is regained. Should full motion not be reestablished in this time frame, an MRI is recommended to evaluate the knee for a mechanical block, such as a displaced bucket-handle meniscal tear.

Once full range of motion is regained, a more aggressive rehabilitation is begun that emphasizes muscle strengthening and endurance. Avoid open-chain exercises such as leg extensions, which allow the quadriceps to anteriorly translate the tibia. Emphasize closed-chain exercises, which cause cocontraction of the quadriceps and hamstrings and thus minimize anterior tibial translation and patellofemoral contact stresses. These include minisquats, stairmaster, seated leg press, and cycling. Open-chain hamstring exercises can be performed without risk. One goal of these exercises is to equalize the quadriceps/hamstring strength ratio from its normal 3:2 ratio to a 1:1 ratio.

When strength of the injured extremity is 70% of that on the normal side, begin proprioceptive exercises such as those done on a balance board. Proprioception is an awareness that may require cutting, pivoting, and twisting motion can be undertaken when the knee has 90% of the strength of the normal side. Though basic science studies have not been able to demonstrate that functional braces provide significant mechanical stability to prevent giving-way episodes, some patients feel that these braces improve confidence and enhance knee proprioception (62-67).

The final aspect of rehabilitation of the ACL-deficient knee is for the patient to determine which activities create instability, pain, and swelling, and then to modify the life style to avoid such activities. This will help avoid further injury and potential risk of degenerative joint disease.

In the chronic setting, patients often have marked quadriceps atrophy, which is a time-related phenomenon secondary to “quadriceps avoidance” and “hamstring overuse” (17). In these patients as well, begin a rehabilitation program that emphasizes muscle strengthening and endurance, proprioceptive control, and avoidance of activities that provoke instability.

**TIMING OF SURGERY**

One issue regarding ACL reconstruction that remains controversial is the timing of surgery. Many studies have shown that reconstruction done before 3 weeks carries a significantly higher incidence of postoperative arthrofibrosis and loss of motion (31,75,103). Studies that evaluated acute repairs and reconstructions had higher rates of postoperative knee stiffness that resulted in the need for reoperation (50). It must be realized, however, that many of these patients did not undergo an accelerated rehabilitation program emphasizing early restoration of full hyperextension, and in many cases the patients were immobilized for a period of time. Subsequently, some authors have demonstrated that acute reconstruction can be done without any increased risk of postoperative stiffness (50). Hunter et al. evaluated patients who were operated on within 48 h, between 3 and 7 days postinjury, between 1 and 3 weeks postinjury, and more than 3 weeks postinjury. Despite equivalent results for KT-1000 testing and passive flexion and extension at 1-year follow-up among all four groups, patients who were operated on more than 3 weeks postinjury achieved their full range of motion sooner than the other three groups. Furthermore, no patients operated on more than 3 weeks postinjury required repeat operation for motion problems or revision surgery, whereas 11 patients in the other three groups did require additional procedures.

The theoretical benefit to acute reconstruction is to prevent any additional trauma to the knee that could occur with a giving-way episode and to possibly decrease rehabilitation time. Despite the persistence of this controversy, no study has been able to demonstrate any benefit to acute reconstruction before the patient regains full range of motion, and the risk of motion problems and possible need for repeat operation to treat motion limitations remain higher. Furthermore, regaining motion preoperatively may allow postoperative rehabilitation time to be lessened by an easier restoration of motion.

Our current protocol is to operate when the patient has regained near full range of motion, has minimal effusion, and has regained quadriceps control. No time limit is placed on the patient. Some patients will regain motion within a few weeks, and others may take longer. It is extremely unusual, however, to operate before 2 weeks postinjury. Patients are generally enrolled in preoperative therapy to help with the restoration of motion and quadriceps function and to help prepare for the postrehabilitation rehabilitation process. The patient is seen on a weekly basis to gauge progress and to ensure that a displaced bucket-handle meniscal tear is not present. It should be noted that often the distal stump of the ACL may flip anteriorly, and this may become impinged when the knee is passively extended, causing pain. This is not a concern and should not be interpreted as a displaced bucket-handle meniscal tear, which usually causes a more significant flexion contracture along with a loss of full flexion. This "prehab" process is invaluable in allowing us to get to know our patients and mentally preparing the patient for both surgery and

**Figure 89.3.** Treatment algorithm for the ACL-deficient patient. This algorithm is meant only as a guide. No absolutes are intended. The decision to reconstruct the ACL should be made only after a discussion between the patient and the treating orthopaedic surgeon regarding ACL reconstruction has taken place.
GRAFT SELECTION

Once the decision is made to operatively reconstruct the ACL-deficient knee, the next decision to be made is how to reconstruct it. This is a complex issue, as there are not only autogenous and allograft tissues from which to choose, but also a multitude of ways to secure the graft to bone fixed in an anatomic position. In ACL reconstruction, the principal tissues used include both autograft and allograft bone–patellar tendon–bone grafts (BTB), autogenous semitendinosus and gracilis tendons (STG), and autograft quadriceps tendon (QT). All of these grafts have advantages and disadvantages that must be weighed by both the surgeon and the patient in deciding on which graft source to use (Table 89.2).

BIOMECHANICAL FACTORS

Several biomechanical concepts must be understood when comparing grafts. The ultimate strength is the load at which a particular graft material fails. The material properties of a graft refer to the substance of the graft, whereas the structural properties refer to the entire graft complex. Material properties are determined by the orientation and collagen makeup of the tissue and are reflected by the stress–strain curve, whereas the structural properties are affected by the stiffness, thickness, and three dimensions of the entire graft and are illustrated by the load–deformation curve. Stiffness of tissues is determined by the slope of the stress–strain or load–deformation curve. Stiffer grafts will take up load before less stiff grafts will, and less stiff grafts may stretch out, causing greater forces on the graft per amount of energy absorbed by the graft relative to a stiffer graft. It should be noted that most studies of strength and stiffness of graft materials and their fixation evaluate the structural properties by a single load to failure, which is probably not the primary mode of clinical graft failure. Cyclic loading more closely resembles the milieu in which grafts are subjected to stress and is in all likelihood the mode in which grafts most commonly fail clinically, especially in the first few months.

An appropriate graft will have similar strength and stiffness characteristics as the native ACL. The ultimate strength of the ACL is roughly 1,750 N, though this value is age-dependent (82,120). The eventual strength of the graft material will be decreased by roughly half when it is fully incorporated; hence, the graft material should initially be twice 1,750 N, or 3,500 N. Despite the high strengths of numerous graft materials, the limiting factor for biomechanical failure is the fixation of the graft until it has been incorporated into its femoral and tibial tunnels, as failures often occur within the first 3 to 6 months postoperatively. Bone-to-bone healing, as occurs with BTB grafts, is a process that takes approximately 6 weeks, whereas tendon-to-bone healing takes 8 to 12 weeks (84). During this time period the patient is undergoing a rehabilitation program that places the graft under stresses approaching 450 N (72). It is therefore critical that the fixation be adequate at this time frame so that the fixation is the limiting factor for failure of the graft fixation construct. Once graft incorporation has occurred, it is the strength of the graft that limits failure. Hence, the fixation should be able to withstand the stresses applied to the graft–fixation construct during the early rehabilitation program before graft incorporation.

BONE–PATELLAR TENDON–BONE AUTOGRAFT

The most common and best-studied graft source for ACL reconstruction is the BTB autograft, harvested from the central third of the patella tendon. Numerous studies advocate its excellent short- and medium-term results (10,11 and 12,107). It is an easily accessible graft source; through the incision by which one harvests the graft, the inferolateral and inferomedial portals may be made as well as the entrance to the tibial tunnel. It is a strong graft, with an ultimate strength of 2,977 N (80), and its two bone blocks can be rigidly fixed with interference screws, leading to early graft incorporation. Because of the graft’s strength and the rigidity of the fixation, aggressive rehabilitation can be undertaken with little risk of damage to the graft–fixation construct.

The use of interference screws for graft fixation is popular and well studied. Their appropriate use provides a construct that approaches the strength of the native ACL and nearly equals its stiffness (114). It is recommended that 9-mm screws be used on the tibial side, and 7-mm screws can be used on the femoral side in an endoscopic technique, but 9-mm screws should be used for a double incision technique (23,67). Screw length should equal the length of the bone plug. Pitfalls are many and include screw divergence or convergence, bone plug fracture, traction suture laceration, laceration of the graft’s tendon, and graft advancement (7). These problems can be avoided with meticulous attention to detail and the use of appropriately sized cannulated screws. Alternatively, buttons on each end of the graft secured by sutures placed through the bone plugs can be used, but this results in a weaker, less stiff graft–fixation construct (263).

As with any graft source, however, drawbacks exist. Direct complications such as patella fracture or tendon rupture are exceedingly rare but do occur (13,22,28,47). Some studies indicate that its harvest may contribute to anterior knee pain, quadriceps weakness, and extensor mechanism dysfunction (85,87). Careful review reveals that many patients in these studies were acutely fixed, had failed repairs as revealed by positive pivot shifts, and were immobilized for up to 6 weeks, hence not undergoing an accelerated rehabilitation program. Later studies have not had nearly the rate of patellofemoral complications (11,12,107), and this is felt to be a result of accelerated rehabilitation programs and avoidance of acute rehabilitation. Some reports evaluating the morbidity of harvesting the graft by comparing autograft BTB and patients with allograft BTB patients show no difference in anterior knee pain (98). Methods of decreasing graft site morbidity include bone grafting of the patellar and tibial defects and loose closure of the tendon rent with the knee in flexion. Some kneeling pain, which may in fact be a result of the incision and not the graft harvest, is quite common in the first year post surgery but diminishes with time.

HAMSTRING TENDONS

Hamstring tendons, specifically the semitendinosus and gracilis tendons (STG), have been used for ACL reconstruction with clinical success equal to that of BTB autograft (2,71,88,89). The tendons can be harvested through a smaller incision than that used for harvesting BTB, which may help to minimize perioperative pain. Propionts of the use of STG point to its avoidance of causing donor site morbidity to the extensor mechanism. Nevertheless, this issue remains unresolved. Aglietti et al. noted a 16% incidence of anterior knee pain in BTB patients versus a 3% incidence in STG patients, whereas Mander et al. noted no difference (2,71). The tendons can be doubled, tripled, or even quadrupled, depending on the length of the tendon harvested, and a multibudded graft construct that is round rather than rectangular can be produced. This theoretically creates a larger surface area for graft incorporation as well as a geometric configuration that more closely resembles the native ACL. The strength of the tendons appears to be adequate, as extrapolating data from Noyes et al. reveals that doubling both semitendinosus and gracilis tendons could produce a graft construct with twice the strength of the native ACL (69).

The use of hamstring tendons has been criticized by some, as harvesting them removes a critical antagonist to anterior translation of the tibia. Hamstring strength recovery appears to be adequate at 2 years of follow-up, but weakness is noted for up to 9 months postsurgery (69,122). Local donor site pain is self-limiting and does resolve within 3 months, and the tendons themselves appear to regenerate (32).

Fixation of the STG tendons continues to evolve. Initial biomechanical studies comparing STG to BTB demonstrated that both graft constructs had strengths comparable to the intact ACL but that BTB was significantly stiffer than STG and more closely approximated the stiffness of the native ACL (114). This is likely because of variations in the construct, which is fixed at the stress of the femoral and tibial tunnels rather than within the tunnels as the BTB with interference screws is (61). Later studies using younger specimens revealed that the differences in stiffness between quadrupled semitendinosus and BTB graft fixation constructs were not significant but that semitendinosus grafts fixed with endobuttons and polyester tape proximally and 45 braided polyester suture around a post screw distally were stronger than BTB fixed with interference screws (89). Another method of STG fixation that appears to have biomechanical features that would support accelerated rehabilitation stresses includes placing the loop of tendons around a post placed through the femoral condyles into the femoral socket (29). Because of concerns with intratunnel graft motion and long distances between fixation points in constructs depending on sutures and buttons, some authors have advocated fixing STG grafts with
bioabsorbable interference screws, and strengths approaching those needed to withstand the stresses of rehabilitation were achieved in older cadaveric bone (25).

One critical feature of STG grafts is the time it takes for graft incorporation. Unlike bone-to-bone healing, tendon-to-bone healing takes longer, with graft incorporation taking at least 8 to 12 weeks (64). Hence, the graft-fixation construct will be under stress for a longer period of time than the BTB graft-fixation construct.

QUADRICPS TENDON

The quadriceps tendon may be harvested with or without a bone block from the proximal pole of the patella, providing a graft that has a tendinous length of 7 cm and a thickness that is twice that of the patellar tendon (43,51). It can generally be harvested with an incision 4 to 5 cm in length, and notochlasy can often be performed concurrently with graft harvest. Minimal pain and morbidity to the extensor mechanism has been reported (44).

Biomechanical studies have found the graft to be of sufficient strength to undergo reconstruction and accelerated rehabilitation (51). As for graft fixation, the bony end may be fixed with an interference screw, and the tendinous end may be fixed with sutures tied over a post or with a bioabsorbable interference screw. Graft incorporation combines both bone-to-bone and tendon-to-bone healing. To date, no published reports of clinical results in peer-reviewed English journals exist, nor do any studies evaluating graft site morbidity.

BONE–PATELLAR TENDON–BONE ALLOGRAFT

Obvious benefits exist in using allograft tissues for reconstructive surgery. The most common allograft tissue used in ACL reconstruction is BTB allograft. No donor site morbidity exists, and smaller incisions are used in performing the reconstruction, which enhances cosmesis and allows for shorter operative time. Allograft tissues are readily obtainable, and appropriately sized grafts may be fashioned without compromising remaining structures. Though final outcome regarding graft site morbidity at 2 years is similar in studies comparing allografts versus autografts, the early postoperative morbidity is less (50,112,115). The allograft tissue of choice for ACL reconstruction is BTB because of the ability of rigid fixation with interference screws and bone-to-bone healing.

Several disadvantages to using allograft BTB exist, however, including the increased cost of the surgery because of the allograft. The most significant downside by far to using allografts is the possibility of disease transmission. Viral diseases such as human immunodeficiency virus and hepatitis are not eradicated by freezing tissue, and it is impossible to kill viruses with radiating energy. Proper donor screening is the most effective means of decreasing the risk of viral transmission, and the use of polymerase chain reaction techniques to screen for the presence of viruses decreases the risk even further in roughly 1 in 2 million. Since proper donor screening has been in place, no case of disease transmission has been reported (5).

A second major concern with allografts is the longer remodeling time. Though allografts readily heal in patterns similar to the healing and ligamentization of autografts, they do so at a slower rate (64). Mechanical properties of allografts are affected by the sterilization and processing methods as well. g-Irradiation weakens the graft (40,83) and, because it is not efficacious in eliminating viral disease, is probably not recommended. Ethylene oxide sterilization is effective in sterilization but produces synerial reaction after implantation and is not recommended (62). Sterility is assured through strict aseptic procurement and repeated bacterial and fungal culturing. Immunogenicity of grafts is a third concern, but appropriate processing can eliminate this problem. Deep freezing to −70°C decreases the antigenicity of the grafts without affecting the mechanical properties. This is a preferable method to freeze drying, as these grafts require long periods of time to rehydrate. Cryopreservation is also an excellent means of processing but is more costly and is best reserved for cartilage grafts.

CHOOSING THE GRAFT

Several factors affect graft choice, and all must be tempered by the surgeon’s familiarity with the technique and success with using a particular reconstructive method. Considerations are given in Table 89.2. The graft with the best track record is BTB autograft. Young, highly athletic individuals who will undergo an accelerated rehabilitation program and wish to return to competitive athletics in 4 to 6 months are excellent candidates for BTB autograft. Patients who desire less early postoperative graft site morbidity and do not wish to return to competitive athletics in such a short period of time may also consider hamstring reconstruction. Laborers who often kneel in their occupation and patients with preinjury abnormal patellofemoral biomechanics may also consider grafts other than autogenous BTB. The exact role for the use of quadriceps tendon is still evolving, though it may also have less early postoperative donor site morbidity. Allograft BTB is an excellent choice for older patients who desire no donor site morbidity and are not returning to competitive athletics in an accelerated time frame. Results in patients with chronic ACL deficiency, however, may not be as good as those with acute injury (60,83).

SURGICAL TECHNIQUES

Though many graft choices and fixation techniques are available in ACL reconstruction, one common feature is the anatomic, impingement-free placement of the graft. If the integrity of the joint can be maintained without undue stress on the graft, and the patient can undergo an accelerated rehabilitation program and eventually return to athletic endeavors with full function. In this section we discuss methods for reconstructing the ACL with autogenous BTB using both endoscopic and two-incision techniques, allograft BTB reconstruction, endoscopic STG reconstruction using cross-pin femoral fixation, and endoscopic QLT reconstruction. We go into detail on notch preparation and tunnel placement in the endoscopic BTB section and restrict our descriptions of the other techniques to aspects specific to that reconstructive method.

ENDOSCOPIC BONE–PATELLAR TENDON–BONE AUTOGRAFT TECHNIQUE

Positioning and Arthroscopic Setup

The majority of our patients undergo general endotracheal anaesthesia using propofol (Diprivan, Stuart Pharmaceuticals, Wilmington, DE); narcotic anaesthetics are avoided to reduce postoperative nausea.

- Place the patient in the supine position. Before placing the leg in a leg holder, perform a thorough examination under anesthesia including Lachman, anterior and posterior drawer, varus/valgus, and pivot-shift testing. Evaluate external rotation at 30° and 90° of flexion to assess for postero-lateral instability and compare findings to the contralateral knee.
- If pivot-shift testing clearly demonstrates ACL insufficiency, harvest the BTB graft before diagnostic arthroscopy so that the inferolateral and inferomedial portals can be placed through the operative wound and the graft can be prepared by an assistant during the diagnostic arthroscopy.
- Though it is rarely used, place a tourniquet on the upper thigh before placing the leg in a leg holder. Secure the contralateral leg in a padded foot holder with the hip and knee slightly flexed, paying careful attention to padding the common peroneal nerve. The foot of the table must be fully flexed, and flexing the waist slightly minimizes lumbar extension. In the endoscopic technique, one must be able to flex the knee 100° to 110° of flexion to facilitate femoral screw placement in a parallel fashion. In the two-incision technique, it is not as crucial.
- Give 1 g of a first-generation cephalosporin such as cefazolin intravenously or 600 mg of clindamycin or 1 g of vancomycin if the patient is allergic to penicillin. After the leg is prep and draped, infiltrate all portal sites and the anterior wound with 0.5% Marcaine (bupivacaine) with epinephrine in the subcutaneous tissue.

Diagnostic Arthroscopy

- For diagnostic arthroscopy, establish a superomedial or superolateral portal for outflow. The use of an arthroscopic pump has nearly eliminated the need for inflating the tourniquet for intraarticular hemostasis. Use an inferolateral portal for arthroscopic placement and an inferomedial portal as a working portal. Attach the inflow to the arthroscopic cannula.
- Thorough diagnostic arthroscopy consists of evaluation of the suprapatellar pouch, patellofemoral joint, medial and lateral gutters, medial and lateral femoral compartiments, and the intercondylar notch.
- Pay particular attention to the menisci, which must be carefully evaluated for the presence of tears. Make all attempts to repair full-thickness longitudinal and bucket-handle tears, generally using an inside-out technique. Partial thickness tears and small tears less than 1 cm that are stable to probing we leave alone. Carefully note and grade all articular cartilage injuries.
- Visualize the intercondylar notch for evidence of the torn ACL: a long tibial ACL stump scarred to the PCL or roof (“vertical strut” sign) or failure of the ACL to posteriorize properly on anterior drawer, varus/valgus, and pivot-shift testing. Evaluate external rotation at 30° and 90° of flexion to assess for posterolateral instability and compare findings to the contralateral knee.

Graft Harvest
Make the incision (Fig. 89.4) from the tip of the patella to 2 cm below the tibial tubercle, slightly medial to the midline, so the tibial tunnel can be placed through the incision. A smaller, more cosmetic incision can be used if adequate skin mobility is present. Carry the incision down sharply to the peritenon and then incise it with a #15 scalpel blade.

![Figure 89.4. View of a right knee. Make the incision slightly medial to the midline, from the distal tip of the patella to 2 cm below the tibial tubercle, approximately 8 cm in length. Placement of superomedial, inferomedial, and inferolateral portals is depicted as well. Should the graft harvesting occur before arthroscopy, place the inferomedial and inferolateral portals through the graft harvest incision.](image)

- Extend the peritenon incision proximally and distally with Metzenbaum scissors and retract the edges medially and laterally to fully expose the patellar tendon.
- Measure the width of the tendon and document it in the operative dictation. Mark the midline both proximally and distally with a sterile marking pen and plan on a 10-mm-wide tendon with 10 mm by 25 mm bone plugs.
- Use a #10 scalpel blade to incise the tendon on one side of the graft. Extending the knee facilitates incising the patellar and tibial bone block edges, and flexing the knee places the tendon on tension, which helps guide the scalpel down the longitudinal axis of the tendon fibers. Placing a retractor distally helps prevent inadvertent extension of the distal aspect of the operative incision when outlining the tibial bone block with the scalpel. Incise the other side of the graft with the scalpel, being careful to remain parallel with the opposite side of the graft's fibers.
- Outline the distal cross-cut on the tibia and the proximal cross-cut on the patella. Use an oscillating saw with a #238 saw blade to create the tibial and femoral bone plugs. With the saw in your dominant hand, stabilize the saw with the nondominant thumb and place the nondominant index finger in the axilla between the inner and outer aspects of the graft to prevent inadvertent graft damage (Fig. 89.5).

![Figure 89.5. View of a right knee, harvesting the medial aspect of the tibial bone plug. Place the left index finger between the graft's tendon and the remaining medial third of the patellar tendon, and use left thumb to stabilize the oscillating saw.](image)

- When making the other side of the bone plug, use an identical technique with hands switched. Score the tibial cortex and make an equilateral triangle on profile with the saw in order to maximize the remaining bone in the tibia region beneath the medial and lateral thirds of the remaining patellar tendon (Fig. 89.6).

![Figure 89.6. This illustration depicts the geometric configuration of the trapezoidal patellar and triangular tibial bone plugs. (Redrawn from Hardin GT, Bach BR Jr, Bush-Joseph CA, Farr J. Endoscopic Single-Incision Anterior Cruciate Ligament Reconstruction Using Patellar Tendon Autograft. Surgical Technique. Am J Knee Surg 1992;5:144.)](image)

- Make the distal cross-cut with the saw blade held 45° oblique to the cortex, with the corner of the blade used to cut the bone on each side of the tibial plug. Before lifting out the tibial bone plug, create the patellar bone plug with the saw. Make a trapezoidal graft on profile to avoid penetrating the articular cartilage; the depth of the cut should not exceed 6 to 7 mm.

**Graft Preparation**

- First measure the length of the graft's bone blocks, tendinous portion, and total length. Ideally one has harvested 10 mm × 25 mm bone plugs. If one bone plug is longer, use it on the femoral side to decrease length construct mismatch between the tibial tunnel and the graft.
- Use a small rongeur to contour the bone plugs. Save the excess bone removed for subsequent patellar defect bone grafting. A small spur of bone is often present proximal to the tendon insertion into the tibial bone plug and should be removed so that the bone edge is flush with the tendinous insertion. If one bone block is 11 mm wide, use it for the tibial tunnel side.
- Use a 0.062-in. Kirschner (K-) wire to make two drill holes in the tibial bone plug, placed parallel to the cortical surface through the cancellous portion of the graft. Place a #5 Ticron suture in each hole (Fig. 89.7).

![Figure 89.7. Photograph of the harvested tendon. Place two #5 Ticron sutures in the tibial bone plug and mark the distal cortical surface of the tibial plug with the](image)
We have not had any incidences of suture cutout through the cancellous bone using this technique in more than 700 cases of ACL reconstruction. The suture holes are placed perpendicular to the cortex because of the risk of lacerating the sutures, as we place our interference screws on the cortical surface of the bone plugs. Alternatively, a 22-gauge wire can be placed rather than suture to preclude the potential for suture laceration. Because we use a “push-up” rather than “pull-through” technique in placing our graft intraarticularly, we do not need to place sutures in the femoral bone plug. If a “pull-through” technique using a passing pin is used, sutures may be placed in the femoral plug in an identical manner.

After the graft is prepared, wrap it in a moist lap pad and place it in a kidney basin in the middle of the main instrument table. It is not immersed in water, as this will cause the graft to become edematous.

**Notch Preparation and Notchplasty**

- Intercondylar notch preparation is performed while the graft is being prepared at the back table. While evaluating the notch configuration, note the presence of tibial eminence and notch wall osteophytes. Although significant notch width variability may be encountered, 20 to 22 mm is required to avoid graft impingement.
- Removal of the ligamentum mucosum from the notch apex facilitates visualization, and it is occasionally necessary to debride some fat pad.
- Remove the remaining ACL tissue with the combination of arthroscopic scissors, arthroscopic osteotome, and motorized 5.5 mm full-radius resector and remove all soft tissue from the lateral wall of the notch. Synovium overlying the PCL laterally may be removed to help visualize the posterior notch. This can often create bleeding that requires electrocauterization, however.
- The notchplasty is performed for two purposes. First, it promotes visualization of the “over-the-top” position and accurate placement of the femoral tunnel.
- Second, it helps prevent impingement of the graft with the knee in full extension.
- Initiate the notchplasty with a ¼-in. osteotome placed through the inferomedial portal. This allows for a more expeditious notchplasty, and the osteocartilaginous fragments can be removed with a burr. The cartilaginous portion removed, and the remaining bone used to graft the patellar and tibial defects. Complete the notchplasty with a motorized 5.5 mm round burr, moving from anterior to posterior and from apex to inferior, with care taken to avoid misinterpreting a vertical ridge two thirds posteriorly as the true posterior outlet (Fig. 89.8).

**Figure 89.8.** Arthroscopic view of a right knee. The 5.5 mm round burr is just posterior to a vertical ridge that is two-thirds posterior to the entrance to the notch. Take this down to fully visualize the “over-the-top” position.

- When the ridge is identified, place the burr posterior to the ridge and move it from a posterior to anterior direction to smooth the ridge. Use a curet to remove soft tissue from the posterior outlet, and then hook a probe over the posterior edge to confirm proper “over-the-top” positioning (Fig. 89.9). Remove minimal bone from the femoral ACL insertion to avoid lateralizing the isometric point. Proper perpendicular camera orientation is crucial in avoiding excessive removal of lateral femoral condyle bone in the midportion of the notch and insufficient bone from the inferior portion of the notch.

**Figure 89.9.** Arthroscopic view of a right knee. All soft tissue has been cleared out to ensure visualization of the posterior edge of the notch. A probe is placed over the posterior edge of the femur in the “over-the-top” position.

**Tibial Tunnel Placement**

- After completion of the notchplasty, prepare the tibial tunnel. Make a medially based rectangular periosteal flap just medial to the tibial tubercle graft harvest site. The tibial tunnel entrance is generally 1.5 cm medial to the tubercle, 1 cm proximal to the pes anserine tendons, and in line with the middle of the tibial graft site.
- Take care to avoid injuring the superficial medial collateral ligament, the pes anserine tendons, or the medial aspect of the patellar tendon as well. A more posteromedial starting point is desirable in the endoscopic technique to allow straighter access to the correct femoral tunnel position. The tibial tunnel's position will dictate to a certain extent the position of the femoral tunnel, as the femoral tunnel guide is placed through the tibial tunnel, unlike the two-incision technique (Fig. 89.10).

**Figure 89.10.** Illustration of proper placement of the tibial tunnel. A: In general we tend to use steeper angles, such as 55° (as determined by the “n + 7” rule). A well-placed tunnel will allow for proper endoscopic placement of the femoral tunnel. A tunnel that is too steep (inset B) will preferentially place the femoral tunnel too far anteriorly, whereas a tunnel that is flat (inset C) will tend to place the femoral tunnel too posterior, risking posterior cortical violation. Minor variances may be treated with appropriate flexion of the knee before placement of the “over-the-top” guide and femoral guide pin. (Redrawn from Hardin GT, Bach BR Jr, Bush-Joseph CA, Farr J. Endoscopic Single- Incision Anterior Cruciate Ligament Reconstruction Using Patellar Tendon Autograft. Surgical Technique. Am J Knee Surg 1992;5:144.)

- Several commercially available tibial tunnel guide systems are available for use in drilling the tibial tunnel. Attempt to optimize the match of the graft and tunnel length. The “n + 7” rule is helpful (but not absolute), whereby 7° is added to the length of the tendinous portion of the graft, producing the setting for the guide (Fig. 89.11). For instance, if the tendon measures 48 mm in length, 7° is added to make 55, and the guide is set at 55°.

- We use several parameters to determine guide pin placement. By using the tibia ACL insertion footprint, ideally the guide pin should pierce the tibial cortex in the
middle of the footprint. This also should be keyed off the posterior edge of the anterior horn of the lateral meniscus by following the contour of the posterior edge to the midpoint of the notch. This is just lateral to the medial tibial spine. Last, the guide pin should enter the joint 7 mm anterior to the PCL (65,76). It should be kept in mind that because of soft tissue overlying the tibial plateau, where one sees the pin enter the joint is not necessarily where it exits the plateau surface. For this reason, erring more posteriorly prevents unwanted anterior tunnel placement. This, along with prevention of intercondylar notch "cyclops lesions," is the purpose of debriding the ACL stump. In the coronal plane the tunnel should be midline in the notch. Erring slightly medially helps prevent impingement from the lateral femoral condyle.

Each commercially available tibial tunnel guide system has inherent peculiarities. Place the tibial guide aimer through the inferomedial portal and use the anatomic guides discussed above to appropriately place the stylet of the guide (Fig. 89.11). The guide pin of the Acufex Protrac aimer (Smith & Nephew Endoscopy, Mansfield, MA) contacts the elbow of the aimer above the surface of the plateau, so we place the point of the aimer more posteriorly to prevent anterior tunnel placement. The arm of the aimer should be parallel to the articular surface. In cases of patella alta, when the anteroinferior portals are high relative to the articular surface, parallel placement of the point arm may be impeded by the soft tissues. It may be necessary to make an accessory inferomedial portal to ensure parallel placement.

Figure 89.11. Arthroscopic view of a right knee. Position the stylet tip of the arm of the aiming guide so that the guide pin enters the joint in the center of the ACL’s tibial footprint, 7 mm anterior to the PCL. Use the posterior edge of the anterior horn of the lateral meniscus as a guide to judge anterior–posterior positioning.

Figure 89.12. Arthroscopic view of a right knee. The guide pin has entered the joint and engaged the elbow of the aiming guide’s arm. At the level of the tibial plateau it is in the center of the tibial footprint of the ACL, 7 mm anterior to the PCL.

■ Retract the distal soft tissues and slide the cannulated guide arm of the aimer up to the tibial cortex, 1.5 cm medial to the tibial bone plug site, 1 cm above the pes anserine tendons (65). Drill a guide pin through the guide arm and into the joint (Fig. 89.12).

After the pin penetrates the joint, remove the guide, check the pin placement, and extend the leg to ensure impingement-free extension (55,56). Slight alterations in pin placement may be done by free-hand drilling of another guide pin held lightly with Kocher clamps against the first pin, with appropriate adjustments made in the AP and medial–lateral planes.

■ Depending on graft size, ream with a 10- or 11-mm cannulated headed reamer placed over the guide pin. Before entering the joint, turn off the arthroscopic pump.

■ Collect all bone reamings with a cannulated bone chip harvester (Linvatec, Largo, FL) and use them for grafting the patellar and tibial bone plug defects (33,39) (Fig. 89.13). After the reamer and guide pin are removed, inspect the tip of the guide pin. Wash cancellous reamings out the tunnel and collect them onto an Owens gauze, which makes removal of the graft easier than from a standard laparotomy sponge. Plug the tunnel and turn the pump back on.

Figure 89.13. Photograph of cannulated bone collector and reamer after reaming of the tibial tunnel. An abundance of bone can be collected and used to graft the patellar and tibial graft defects. (From Ferrari JD, Bach BR. Technical Note: Bone Graft Procurement for Patellar Defect Grafting in Anterior Cruciate Ligament Reconstruction. Arthroscopy 1998;14:543.)

■ Remove loose bone and cartilage around the tunnel entrance with the shaver, and smooth posterior ridges of the tunnel with a motorized chamfer reamer and an arthroscopic hand rasp (Fig. 89.14).

Figure 89.14. Illustration of a right knee. After the tibial tunnel has been created, a posterior cortical lip is often present. This is smoothed down with the aid of a chamfer reamer and curved rasp (inset). Left alone and not smoothed, this edge could abnormally anteriorize the graft, cause chafing and possible rupture at the posterior aspect of the graft, and create difficulty in passing the graft into the femoral tunnel.

Femoral Socket Placement

The goal of femoral socket placement is to prepare a tunnel that originates at the 1 o’clock position in the left knee and 11 o’clock position in the right knee and has a 1-
to 2-mm posterior cortical shell (Fig. 89.15). This provides for an anatomic and near-isometric position of the graft. Avoidance of posterior cortical “blow out” is minimized by meticulously clearing the soft tissue surrounding the “over-the-top” position and confirming the position with a probe. Use a retrograde femoral offset guide placed through the tibial tunnel that positions the guide pin 7 mm anterior to the posterior cortex. This leaves a 2-mm bone shell when a 10-mm reamer is used to make the tunnel (Fig. 89.16A). Alternatively, one could create an accessory inferomedial portal, place the femoral aimer through the portal, hyperflex the knee, and drill the femoral socket (Fig. 89.16B).

**Figure 89.15.** Sagittal cross section of a femur showing a 7-mm “over-the-top” guide placed over the posterior edge of the notch and a guide pin placed through the guide and into the femur. Overreaming with a 10-mm reamer will leave a 2-mm posterior wall in the femoral socket. (From Hardin GT, Bach BR Jr, Bush-Joseph CA, Farr J. Endoscopic Single-Incision Anterior Cruciate Ligament Reconstruction Using Patellar Tendon Autograft. Surgical Technique. *Am J Knee Surg* 1992;5:144.)

**Figure 89.16.** A: Illustration of a right knee with the “over-the-top” guide placed through the tibial tunnel. B: Alternatively, place the guide through a low inferomedial portal and, with hyperflexion of the knee, position the guide and drill the pin. This method creates a femoral socket that is not dependent on the position of the tibial tunnel.

- With the pump turned off and the knee “dry,” place the offset guide through the tibial tunnel and in its “over-the-top” position. If necessary, place a probe in the inferomedial portal to retract the PCL.
- As mentioned above, we use a “push-in” rather than a “pull-through” technique, which doesn’t require a passing pin. Drill the guide pin through the guide and to a depth of 2.5 to 3.5 cm, essentially the length that one plans on reaming, into the femur.
- Remove the guide and probe the pin for correct placement. Ream with a 10-mm reamer 1 cm into the femur, creating an “endoscopic footprint.” Back it out and probe for posterior cortical integrity and proper tunnel orientation. When this is confirmed, ream to a depth 5 to 7 mm greater than the length of the femoral bone plug (Fig. 89.17). This is done so that the femoral plug can be recessed to minimize graft–tunnel mismatch if needed. Furthermore, because the tunnel is drilled at an angle, the anterior aspect of the tunnel is not colinear with the posterior aspect. If one leaves the femoral plug flush with the anterior aspect of the tunnel, the graft will be anteriorized, which increases graft strain in flexion. Furthermore, if the bone plug protrudes below the posterior wall, it may be at risk for fracture. Hence, the graft must be recessed a few millimeters with respect to the anterior aspect of its tunnel regardless of graft–tunnel mismatch.

**Figure 89.17.** Illustration of a right knee. Place the 10-mm reamer over the guide wire and drill to desired depth. (Redrawn from Hardin GT, Bach BR Jr, Bush-Joseph CA, Farr J. Endoscopic Single-Incision Anterior Cruciate Ligament Reconstruction Using Patellar Tendon Autograft. Surgical Technique. *Am J Knee Surg* 1992;5:144.)

- After the reamer is removed, flush loose bone from the knee with the aid of the pump and collect these reamings with the Owens gauze. Again, check tunnel integrity definitively by placing the arthroscope retrograde through the tibial tunnel into the femoral tunnel (Fig. 89.18).

**Figure 89.18.** Arthroscopic view of the right knee. The femoral socket's integrity is checked by placing the arthroscope up through the tibial tunnel.

- Perform a “phase II” notchplasty (Fig. 89.19). During the process of femoral tunnel reaming, if the reamer engages the lateral wall, use this observation to assist in fine-tuning the amount of lateral wall expansion. The femoral tunnel entrance should appear circular. If there is an oval appearance laterally, abrade the opening to produce a circular configuration. “Ellipticize” (i.e., eccentrically abrade) the anterolateral quadrant to aid in screw placement and chamfer the anterior ridge with a shaver to facilitate guide-pin placement.
**Graft Placement and Fixation**

- After removing the graft from its gauze, place a two-pronged pusher at the base of the femoral bone plug (Fig. 89.20) and position a curved hemostat through the inferomedial portal with its tips pointed up. Then “push up” the graft through the tibial tunnel and grasp it with the hemostat at the junction of the proximal and middle third of the bone plug (Fig. 89.21A). Remove the pusher and guide the graft up into the femoral socket (Fig. 89.21B). Orient the cortical surface of the femoral plug posteriorly and in the coronal plane.

**Figure 89.20.** Illustration of a right knee. Use a two-pronged pusher to guide the graft up the tibial tunnel. Remove the pusher from the tunnel before the tibial bone plug enters its tunnel, however, or the pusher will be difficult to remove. (Redrawn from Hardin GT, Bach BR Jr, Bush-Joseph CA, Farr J. Endoscopic Single-Incision Anterior Cruciate Ligament Reconstruction Using Patellar Tendon Autograft. Surgical Technique. Am J Knee Surg 1992;5:144.)

- Before fully seating the femoral plug into its socket, place the Nitinol hyperflex guide pin (Linvatec, Largo, FL) into the femoral socket at the 11 o’clock position of the graft. If difficulty is encountered in placing it in the tunnel, use the hemostat to create a small opening to guide it into the tunnel. Once the pin is initially positioned within the tunnel, flex the knee 100° to 120° and fully seat the guide pin within the tunnel (Fig. 89.21C). The pin should not be forced and should slide easily. It potentially could be placed through the bone plug or posterior cortex. If the guide pin appears too divergent from the graft, as often can be seen if patella alta is present, the accessory inferomedial portal is helpful in placing the guide pin more parallel with the graft and reducing screw divergence. As the knee is flexed, adjust the camera to visualize the “gap space interval” anteriorly between the femoral socket and the bone plug. Then use a satellite pusher to fully seat the bone plug in its socket (Fig. 89.21D).

**Figure 89.21.** Arthroscopic views of the right knee. A: Grasp the femoral bone plug with a curved hemostat placed through the inferomedial portal with tip pointed up. B: Then guide the graft up into the femoral socket. C: Once the plug is seated roughly 85% into its socket, place a Nitentol Hyperflex guide pin at the 11 o’clock position of the graft. Hyperflex the knee and gently push the pin to the back of the socket. D: Place the satellite pusher to the inferior edge of the femoral bone plug and tap the plug to seat it fully in its socket.

- Check the tibial plug to make sure it is not protruding excessively from its tunnel. If there is marked graft–tunnel mismatch at this time, remove the graft and deepen the femoral socket.

- Use a 7 × 25 mm titanium fully threaded cannulated interference screw on the femoral side, as biomechanical studies indicate no significant difference between 7-mm and 9-mm interference screws for femoral fixation (67). We prefer interference screw fixation with nonheaded Kurosaka screws (Linvatec, Largo, FL), and we generally use a screw that matches the length of our graft. Apply maximum tension to the sutures as the screws are placed to avoid graft advancement. Place the femoral screw against the cancellous surface, thus reducing the potential for soft tissue injury or laceration; the tibial screw is placed against the cortical surface. Use cannulated screws to help prevent divergence.

- Place the screw over the guide wire and push it into the joint (Fig. 89.22). To maximize the potential for parallel placement of the femoral interference screw, hyperflex the knee 100° to 110°. This additional knee flexion will “compensate” for the difference created between the tibial tunnel angle and the angle created by the flexible Nitinol pin placed through the inferomedial portal. As the screw is being placed, apply light tension to the tibial plug’s sutures, which helps prevent the graft from being lacerated by the screw. Pay careful attention to the tendinous portion of the graft just inferior to the femoral plug. If this tissue begins to rotate, the screw may be wrapping up or beginning to lacerate the tendon. When the screw is halfway positioned, remove the guide pin, or it may be difficult to remove the wire when the screw is fully seated. The screw is fully seated when its base is flush with or slightly above the base of the femoral plug; if it is not, fraying and graft disruption can occur with motion. Commercially available graft protection sleeves are available to reduce the potential for soft tissue laceration. If we decide to recess the femoral bone plug more than 5 mm, we will routinely use a protection sleeve.

**Figure 89.22.** Illustrations of a right knee. A: Lateral view depicting the interference screw being placed over the guide wire. The tibial plug has been externally rotated 180° so that the cortical surface is facing anteriorly. B: Anteroposterior view of the screw being placed. An accessory inferomedial portal facilitates parallel screw placement. (Redrawn from Hardin GT, Bach BR Jr, Bush-Joseph CA, Farr J. Endoscopic Single-Incision Anterior Cruciate Ligament Reconstruction Using Patellar Tendon Autograft. Surgical Technique. Am J Knee Surg 1992;5:144.)
Check the graft for “gross isometry.” Hold the sutures in the tibial plug tightly and place an index finger at the extraosseous entrance of the tibial tunnel. Flex the knee from 100° to complete extension or hyperextension. As the knee moves from 30° to complete extension, 1 to 2 mm of motion is generally noted. Cycle the knee several times with tension placed on the graft. Last, view the graft arthroscopically to ensure that it is impingement-free in extension and does not abrade along the lateral wall with knee motion.

An alternative means of graft passage is the use of a passing pin, which has an open slot at its base for placing suture. When using this technique, place two #5 Ticron sutures through both bone plugs. Place the pin through the “over-the-top” guide and drill through the femur. Tap the pin with a mallet through the anterolateral thigh and out the skin. Overdrill with the 10-mm reamer and pass the sutures through the bottom slot of the pin. Pull the pin out of the anterolateral thigh and securely grasp the sutures protruding out the pin hole. With a hand on each group of sutures, bring the graft into the knee joint. A probe in the interomedial portal can facilitate placement of the femoral bone plug into its socket. After placing the femoral interference screw, remove the two #5 Ticron sutures from the anterolateral thigh.

We prefer the “push-in” technique over the “pull-through” method because it avoids placing a pin through the thigh and possible complications such as a break in sterility, pin breakage, and creation of a stress riser in the femur (73,87). The “phase I” notchplasty and visualization of the femoral socket are also easier because the passing pin is not present, and no sutures need be placed through the femoral bone plug. Before tibial fixation, we externally rotate (i.e., toward the lateral side) the graft (100). This allows an anatomic rotation of the graft, can reduce graft–tunnel mismatch by shortening the graft construct, and allows the tibial screw to be placed against the cortical surface of the tibial plug, anterior to the graft. We do this for four reasons. First, with the screw placed anteriorly, when the knee flexes, there is no abrasion of the screw against the graft. If the screw is placed posteriorly and the screw tip extends beyond the tendo-osseous interval, knee flexion may result in abrasion of the graft. Second, the screw is more likely to diverge if placed posteriorly along the cancellous portion of the graft. Third, a screw placed posteriorly will anteriorize the graft, adversely affect isometry, and possibly create impingement of the graft. Last, fixation is greater when placed along the cortical surface.

One must ensure that the tibial plug is moving freely within the tibial tunnel before distal fixation is done. Occasionally the distal tip of the plug can get caught inside the tunnel on the inferior edge. If the plug is fixed in this position, graft tension will be lax. For fixation on the tibial side, position the knee in full extension and firmly tense the tibial plug sutures. Place a Nitenol hyperflex pin anterior to the tibial plug and secure the graft with a 9 × 20 mm screw. Recess the head of the screw just below the cortical surface of the tibia so that it is less likely to become symptomatic but is not difficult to remove should the situation arise. If the tibial plug has been recessed in its tunnel as a result of mismatch, choose a longer screw (Fig. 89.23).

![Figure 89.23](image_url)

**Figure 89.23.** Anteroposterior (A) and lateral (B) views of a right knee after ACL reconstruction with an endoscopic technique. The lateral view demonstrates proper posterior placement of the femoral tunnel with parallel screw placement. The tibial tunnel enters the joint in the midpoint of the tibial plateau, and the tibial screw is parallel to its bone plug. The AP view confirms parallel screw placement and placement of the femoral socket at the 11 o’clock position.

Methods of Addressing Graft Construct Mismatch

As with most surgical problems, prevention is the best cure. By following the “n + 7” rule, most but not all graft construct mismatches can be avoided (73,87). Currently, our largest mismatches occur in using BTB allografts, when the allografts are derived from a cadaver of significantly larger size than the patient. Several methods are available to address mismatch problems. As mentioned above, small mismatches may be reduced by recessing the femoral bone plug deeper within its socket. If one is going to recess the femoral bone block, parallel placement of the interference screw is essential, as the potential for graft injury increases. Commercially available graft protectors can be used to further protect the soft tissue component of the graft. An accessory interomedial portal should also be considered for screw placement.

To reduce graft–tunnel mismatch, externally rotate the graft 180° or, if more shortening is needed, one additional revolution (180° + 360°). If 15 mm of tibial bone is within the tibial tunnel, our choice is to use an interference screw. Alternatives to interference screw fixation include tying the sutures over a bicortical screw and washer or recessing the tibial tunnel’s bed so that the tibial plug can be placed within it and be fixed with either two 7/8-in. barbed staples or a bicortical 3.5-mm screw placed in a lag fashion. Last, should the entire bone plug be protruding, we remove the tibial bone block, place two #5 Ticron screws in the tendon, perpendicular to one another in a Krackow fashion (see Fig. 89.44), for traction, and then place the free tibial bone block into the tunnel. We secure this entire construct with a 9 × 20 mm interference screw placed over a guide wire. This construct has been found to be significantly stronger and stiffer than fixation with the bone block sutures tied over a post (78).

![Figure 89.44](image_url)

**Figure 89.44.** The modified Krackow suture placed on the tendinous portion of the QT graft, begun 1.5 to 2 cm from the end of the tendon. See text for details. A second suture is placed in an identical fashion on the opposite side of the tendon.

Closure

Loosely reapproximate the patellar tendon defect with three or four interrupted #1 Vicryl sutures while the knee is flexed, avoiding excessive shortening of the tendon. The osteoperiosteal flap overlying the tibial drill hole is also closed with #1 Vicryl. We graft the patellar bone defect with the collected bone reamings, and any remaining bone is used to graft the tibial donor site. We close the peritendon with a running 2-0 Vicryl suture, the subcutaneous layer with interrupted 2-0 Vicryl, and the skin with a running 3-0 Prolene. We inject 0.5% bupivacaine (Marcaine) with epinephrine into the periosteal region, deep surgical wound region, portals, skin, and intraarticularly. We do not use hemovac drains. Steri-Strip the wounds, then apply dry sterile gauze, Kerlex roll, an ice cryotherapy pad, and ace wrap. The cryotherapy pad must not contact the skin, or a superficial frostbite can occur. Last, place the leg in a hinged knee brace, which can be locked in extension.

ENDOSCOPIC BONE–PATELLAR TENDON–BONE ALLOGRAFT TECHNIQUE

The technique of using BTB allograft differs little from that of BTB autograft. Other than arthroscopic portals, the only incision is a 1.5- to 2.0-cm incision made in line with the interomedial portal, 1 cm above the pes anserine tendons and 1.5 cm medial to the tibial tubercle. A medially based periosteal flap is raised as previously
described for placement of the tibial tunnel. We prepare the graft in a fashion identical to that of autogenous BTB, with the only exception being using a 1- to 2-mm-wider tendinous portion.

Choice of allograft size and its preparation is critical. We use frozen, nonirradiated allograft prepared at a tissue bank certified by the American Association of Tissue Banks. The length of the patellar tendon should be known, as allografts with tendon lengths over 50 mm are too long for almost all women and smaller men, and this will create a graft–tunnel mismatch with an endoscopic technique. The tibial bone plug will thus protrude out of its tunnel, requiring alternative means of fixing the tibial side of the graft.

Because of the skin overlying the standard inferomedial portal, an accessory inferomedial portal is almost always required for placement of the femoral interference screw. This diminishes divergence between the femoral bone plug and the screw's guide pin.

**TWO-INCISION BONE–PATELLAR TENDON–BONE AUTOGRAFT TECHNIQUE**

The primary difference between endoscopic and two-incision ACL reconstruction using BTB autograft is the creation of the femoral tunnel. The orientation of the two-incision femoral tunnel differs from that of the endoscopic femoral tunnel, although the actual intraarticular placement should be identical. This is an important concept to recognize, particularly in revision situations. Graft harvest and tibial tunnel preparation are identical, but it is not critical that the tibial tunnel be placed as steep and in a distal anteromedial to proximal posterolateral direction, as the creation of the femoral tunnel is not dependent on the tibial tunnel's orientation. Graft preparation differs, as it includes placing sutures through both bone plugs for control of the graft during passage into the knee.

Benefits to the two-incision technique versus the endoscopic technique are that graft construct mismatches rarely occur, and complications of creation of the femoral socket such as posterior wall "blow out" are avoided. Disadvantages obviously include the extra lateral skin incision and morbidity of dissecting down to the "over-the-top" position. Femoral graft fixation necessitates a 9-mm screw for strength comparable to that of a 7-mm screw placed endoscopically, and because the femoral bone plug is not flush with the posterior wall of the femoral socket, stresses are placed on the tendinous portion of the graft.

Despite these theoretical disadvantages, no studies have demonstrated superior outcome of one technique over another (49,70,101). It is a technique that all ACL surgeons should have in their armamentarium, as it is especially useful in the revision of endoscopic reconstructions and in the unfortunate circumstance of posterior wall "blow out" (24,89). One of us (B. R. B.) performed two-incision ACL reconstructions from 1987 to 1991 before converting to an endoscopic technique.

**Femoral Tunnel Placement**

Historically, our normal sequence of events was to (a) place our tibial guide pin, (b) perform the lateral approach for femoral tunnel placement and place the femoral guide pin, (c) drill the femoral tunnel, and (d) drill the tibial tunnel. We preferred to prepare the femoral tunnel before the tibial tunnel in order to better maintain knee joint distention, allowing improved visualization of the femoral socket's integrity. If we were performing a two-incision technique today, however, we would most probably create our tibial tunnel initially and use the femoral endoscopic aimer to create a pilot hole on the femur. This would allow us to more easily and accurately create the femoral tunnel.

- To begin femoral tunnel placement, make a lateral skin incision over the midportion of the iliotibial band (ITB), from the lateral femoral epicondyle extending 4 cm proximally (Fig. 89.24).

![Figure 89.24](https://example.com/figure89_24)

*Figure 89.24. Photograph of a right knee depicting the lateral incision for placement of the femoral tunnel. The iliotibial band is exposed. (From Bach BR Jr. Arthroscopy-Assisted Patellar Tendon Substitution for Anterior Cruciate Ligament Insufficiency. Am J Knee Surg 1989;2:3.)*

- Split the ITB in line with its fibers 2 cm anterior to its posterior edge. Elevate the vastus lateralis from posterior to anterior off the lateral intermuscular septum and femur and place a Chandler or Z retractor over the anterior femur to retract the extensor mechanism. Take care to avoid injury to the lateral collateral ligament origin at the flare of the metaphysis. The entry point should always be proximal to the origin of the ligament (Fig. 89.25).

![Figure 89.25](https://example.com/figure89_25)

*Figure 89.25. Bone model of a right knee. Place the bullet tip of the femoral drill guide at the flare of the metaphysis. This point is always proximal to the lateral collateral ligament.*

- The superior lateral geniculate vessels require electrocauterization, as they may be a source of postoperative bleeding or hematoma. Bluntly dissect with a finger and use a 0.75-in. Cobb elevator subperiosteally to facilitate palpation of the posterior intercondylar notch (Fig. 89.26).

![Figure 89.26](https://example.com/figure89_26)

*Figure 89.26. Photo of a right knee. Use a Cobb elevator to reflect the vastus lateralis from posterior to anterior to expose the lateral condyle. (From Bach BR Jr. Arthroscopy-Assisted Patellar Tendon Substitution for Anterior Cruciate Ligament Insufficiency. Am J Knee Surg 1989;2:3.)*

- Place a J-parser through the inferomedial portal or midpatellar rent to the “over-the-top” position and out the posterior capsule (Fig. 89.27A). A pistoning motion will dilate the capsule slightly, allowing for easier entrance intraarticularly.
Attach the side-specific rear-entry guide to the J-passer and bring the guide into the joint via the “over-the-top” position. Once this is in place intraarticularly, push the bullet tip of the guide flush against the lateral femoral condyle (Fig. 89.27B). Reconfirm the position of the stylet arthroscopically with a probe. The goal is to achieve a tunnel with an intact posterior cortex 1 to 2 mm thick placed at the 11:00 to 11:15 position for a right knee or the 12:45 to 1:00 position for a left knee. Drill the guide pin from outside in, proximal to the lateral epicondyle and slightly posterior to the midline of the femoral metaphysis. Entry point of the femoral tunnel should be at or just proximal to the flare of the metaphysis. If it is placed any further distally, the angle into the intercondylar notch is too acute, placing bending stresses on the tendon as it enters the notch. If the entry is too proximal and the femoral cortex is violated, a stress riser could predispose to femoral fracture (Fig. 89.28).

Graft Passage and Fixation

Prepare the tibial tunnel as described above for the endoscopic technique (Fig. 89.31). Flex the knee 60° for graft passage. Place a Yankauer suction tube retrograde through the tibial tunnel and into the femoral tunnel, and then place two 22-gauge wire loops retrograde through the suction tube and clamp them before removing the tube. Alternatively, commercially available silastic tube graft passers may be used.
Loop the sutures from the tibial bone block separately through the wire loops and withdraw the wires out the tibial tunnel. Clamp the sutures outside the tibial tunnel and pull the graft into the femoral tunnel (Fig. 89.32).

Under arthroscopic visualization, bring the tibial plug into the tibial tunnel, using a probe or hemostat to manipulate the plug into place. Potential obstructions include the PCL, lateral femoral wall, and intercondylar eminence.

When the tibial plug is in place and the femoral plug is within its tunnel, place tension on both sets of sutures to assess for graft laxity. If laxity is present, either plug may be incarcerated within its tunnel, preventing the graft from being fully tensioned. Then assess the graft for impingement along the lateral femoral wall and anterior notch. If impingement is present, appropriate lateral or anterior notchplasty is required to prevent fraying of the graft.

Secure the femoral side first. We prefer interference screw fixation with cannulated interference screws (Linvatec, Largo, FL). A screw that matches the length of our graft is generally used. One must apply maximum tension to the sutures as the screws are placed to avoid graft advancement. Direct the femoral plug's cortex laterally, and place a 9-mm screw against the cortex. If the graft is recessed within the tunnel, use a longer screw so that it can be more readily identified and removed in the future if need be.

Rotate the tibial plug 90° externally to place the plug's cortex anterior, and place a 9-mm screw anterior while the knee is in full extension without a posterior Lachman, placing maximum tension on the tibial plug's sutures (Fig. 89.33). Fixation in extension avoids overconstraining the knee. One should avoid burying the interference screw intrasosseously, as screw removal may be quite difficult in revision cases or if subsequent high tibial osteotomy is required (Fig. 89.34).

Close the lateral wound with interrupted #1 Vicryl suture in the ITB, 2-0 Vicryl suture in the subcutaneous tissue, and a running 3-0 Prolene suture in the subcuticular skin. Cover the incision with Steri-Strips and a dry gauze dressing.

ENDOSCOPIC HAMSTRING TENDON TECHNIQUE

The semitendinosus and gracilis tendons have been used effectively in ACL reconstruction for many years. Numerous methods can be used to reconstruct the ACL, and the tendons can be folded to produce double-, triple-, or quadruple-stranded graft constructs. Various means of fixation are available, such as suture–post fixation, screws with spiked washers, barbed staple, soft tissue interference screws (both titanium and bioabsorbable), endoscopically placed buttons, and cross-pin fixation. Combinations of these techniques are generally used. Despite the numerous biomechanical studies that have evaluated these techniques, few studies clinically evaluating these newer methods exist in the literature. Our current method of hamstring reconstruction utilizes both semitendinosus and gracilis tendons looped over a femoral cross-pin (TransFix, Arthrex, Inc., Naples, FL). This results in four strands of tendon that can be fixed to the tibia with a combination of sutures tied over a post and a bioabsorbable interference screw. If sufficient tendon length is present, directly fix the tendons to the tibia with a screw and spiked washer, and a bioabsorbable...
Graft Harvest

- In most patients the pes anserine tendons are palpable over the proximal medial tibial crest. Center a longitudinal 3- to 4-cm incision three fingerbreadths below the medial joint line and two fingerbreadths medial to the tibial tubercle. After incising the skin and gently spreading through the subcutaneous tissues, bluntly dissect the subcutaneous tissue off the sartorial fascia as far back as the popliteal space. Identify the gracilis and semitendinosus tendons as they lie beneath the sartorial fascia. At their lateral tibial insertions, the two tendons coalesce. Three to four centimeters medial to the insertion, the tendons are distinct (Fig. 89.35).

Graft Preparation

- At a back table, remove all muscle tissue from both tendons and trim any fascial slips. Place identical baseball stitches on the proximal ends of the tendons. Because 20 cm is usually more than enough tendon length, the thin proximal ends of the tendons may be trimmed accordingly. Place different clamp types on each tendon’s sutures to identify later when the tibial side is fixed. Use an umbilical tape to form a loop around the gracilis tendon from the underlying MCL and tibia. Do the same with the semitendinosus. Passing a Penrose drain around the tendons often helps with mobilization and retraction.

- Sharply detach the periosteal insertion of the gracilis from the tibia, taking care to gain the additional 2 cm the insertion provides. Grasp the end of the tendon with an Allis clamp. With a #2 Ethibond suture, run a baseball stitch from distal to proximal for 5 cm up one side of the tendon and then proximal to distal down the other side of the tendon. Clamp the two suture ends with a straight clamp. Perform the identical steps for the semitendinosus tendon, but clamp the sutures with a curved clamp.

- Harvest the gracilis tendon first because it is easier. With the leg in a figure-4 position, place traction on the gracilis sutures and palpate around the tendon for fascial slips to other structures. These need to be removed before tendon stripping. After this is done, place a closed-ended tendon stripper (Arthrex, Inc., Naples, FL) around the gracilis and gently advance the stripper up the leg parallel to the path of the gracilis. The leg should be in the figure-4 position to reduce the risk of injury to the saphenous nerve, which crosses the gracilis at the posteromedial joint line. With gentle tension on the sutures, advance the stripper up the leg; when it is fully advanced, slowly increase the tension on the sutures until the graft releases. Note that the gracilis has muscle on both sides of the proximal tendon, whereas the semitendinosus has muscle on one side only.

- The semitendinosus has up to four fascial bands arising from its main tendon, and a consistent slip exists 7 mm proximal to the tendon’s tibial insertion, inserting into the medial gastrocnemius fascia. By gently tugging on the sutures, one can observe the skin overlying the popliteal fossa dimpling, indicating that tendinous slips are still present. The tendon should move freely out of the wound when tugged on and rebound when tension is released. All slips must be released before stripping. Place a finger around the tendon and palpate deeply for any remaining slips. Pass the tendon stripper over the tendon and proceed proximally and parallel to the tendon’s course. The semimembranosus fascia envelops the semitendinosus 12 to 15 cm proximal to its insertion. Take care to advance the stripper into the sling rather than outside of it, or premature cutting of the tendon will occur (33) (Fig. 89.36). With the leg in the figure-4 position, gently advance the stripper with light tension on the sutures to maintain a parallel course. One should be able to harvest more than 20 cm of tendon, and the stripper should be advanced as far as possible. When this has been done, stabilize the stripper and place traction on the sutures, releasing the tendon.

- Release the saphenous nerve, which crosses the gracilis at the posteromedial joint line. With gentle tension on the sutures, advance the stripper up the leg; when it is fully advanced, slowly increase the tension on the sutures until the graft releases. Note that the gracilis has muscle on both sides of the proximal tendon, whereas the semitendinosus has muscle on one side only.

- Careful attention is essential when passing the tendon stripper over the semitendinosus tendon. The head of the stripper must pass beneath a fascial sling of the semimembranosus muscle or premature cutting of the semitendinosus will occur.

Figure 89.35. A: The semitendinosus and gracilis tendons lie deep to the sartorial fascia. The tendons coalesce at their insertions distally and are more distinct as one palpates posteromedially. The gracilis is proximal to the semitendinosus, and the saphenous nerve crosses the gracilis at the posteromedial joint line. A consistent semitendinosus fascial band arises 7 to 9 cm proximal to the tendon's tibial insertion and inserts into the medial gastrocnemius fascia. B: Cross-sectional illustration revealing the relationships of the pes anserine tendons to the medial collateral ligament (MCL). ST, semitendinosus; SART, sartorius; G, gracilis.

Graft Passage and Femoral Fixation

- Fit the size-specific tunnel hook onto the drill guide C-ring at the 90° position and place the hook through the tibial tunnel into the femoral socket (Fig. 89.37).
Figure 89.37. With the drill guide C-ring set at 90° and the tunnel hook placed flush up the femoral socket, drill a 2.0-mm drill pin through the femoral condyles.

Move the guide-pin sleeve down to mark the skin over the lateral femoral condyle and make an 8-mm incision in the skin and iliotibial band.

While maintaining a constant knee flexion angle, place the guide-pin sleeve against the lateral femoral condyle, and drill a 2.0-mm guide pin through the femoral condyles and out the medial skin.

Remove the C-ring but keep the tunnel hook up the femoral socket. Overdrill the pin with the 5-mm drill until the depth stop reaches the lateral femoral cortex, remove the drill, and place the TransFix dilator over the pin; tamp it down to the cortex and remove it (Fig. 89.38).

Figure 89.38. After drilling the outer femoral cortex with the 5.0 mm drill, dilate the channel for the TransFix implant with the dilator.

Place the wire loop of the Nitenol graft-passing wire into the slot on the lateral end of the guide pin and pull the graft-passing wire through the condyles from lateral to medial (Fig. 89.39). Equal lengths of wire should be protruding out both condyles, and both ends should be clamped with needle holders. The passing wire is now beneath the tunnel hook, which can be withdrawn out the tibial tunnel.

Figure 89.39. Place the looped end of the Nitenol passing wire (A) into the lateral notched end of the drill pin and pull the passing wire through the femoral condyles. Withdraw the Nitenol passing wire into the femoral and tibial tunnels (B) with the tunnel hook to form a loop exiting the tibial tunnel (Inset C).

Disengage the tunnel hook from the Nitenol graft-passing wire, leaving a wire loop. Be careful not to form a twist in the wire, or difficulty can be encountered in passing the graft.

Pass the tendons through the wire loop so that equal tendon lengths are present distally (Fig. 89.40). By pulling equal tension on both sides of the graft-passing pin with the needle holders, pass the graft through the tibial tunnel into the femoral socket. To ensure that the graft is fully seated in the femoral socket and that no bends in the wire are present, which could prevent wire removal after the TransFix implant is placed, slide the passing wire medially and laterally.

Figure 89.40. Evenly loop the STG tendons around the loop of the passing wire and slide the tendons into their tunnels by pulling evenly on the medial and lateral ends of the passing wire.

Place the implant over the wire until the lateral threaded head contacts the femoral cortex. Do not apply tension to the graft sutures. Tamp the implant's head flush to the cortex with the impactor (Fig. 89.41).

Figure 89.41. Insert the TransFix implant into its channel over the guide wire and tamp the implant into place until the depth stop on the impactor contacts the lateral femoral cortex.

Confirm proper location of the implant by firmly pulling on the graft's sutures, then remove the Nitenol passing wire. Check for “gross isometry” and cycle the knee.
several times to remove creep from the graft construct.

**Tibial Fixation**

- If adequate tendon length protrudes out of the tibial tunnel, we prefer to fix the tibial side with a screw and spiked washer (Linvatec, Inc., Largo, FL). Prepare a bone bed beneath the fixation point by roughening the tibial cortex. Drill bicortically and measure and tap. Add the width of the tendons and 2 mm for the washer to the measured depth.

- We find placing the screw bicortically and then backing it out is helpful to ensure both proper length and accurate screw passage. With the knee in full extension, grasp the gracilis sutures and semitendinosus sutures separately and place one end of each tendon around each side of the screw. With firm tension on all sutures, secure the screw bicortically.

- Should insufficient tendon length preclude using a screw and spiked washer, we choose to tie the graft's sutures over a bicortical post. Tension each tendon separately rather than as one large group. Because a one-handed knot-tying technique is used, make sure to change suture posts while tying to avoid creating a long slip knot. Secure the screw with a smooth washer bicortically. Another alternative is to secure the tendons with two barbed staples in a belt-buckle fashion (Fig. 89.42).

**Graft Harvest**

Several anatomic features of the quadriceps tendon and its insertion on the patella are worth noting. Unlike the distal pole of the patella, the proximal pole has a curve in the sagittal plane, and a central ridge is readily palpable. The cortical bone is thicker proximally as well. From a point approximately 3 cm proximal to the patellar insertion, the quadriceps tendon's rectus femoris and vastus intermedius portions are inseparable, but farther proximally they can be parted. The tendon is also not perfectly centered with respect to the patella. Because the vastus medialis musculature curves laterally, it is best to harvest the graft slightly to the lateral aspect of the center of the patella, or deficient tendon may be left medially.

- Make the incision beginning 4 to 5 cm proximal to the tip of the patella and end at the proximal pole. Raise deep flaps to expose the proximal half of the patella and the quadriceps tendon and note the medial and lateral edges of the tendon.

- Plan for a bone plug that is 10 mm wide by 20 to 25 mm in length. This length is usually half the total length of the patella. With a #10 blade, outline the bone block and then make the medial cut in the quadriceps tendon. The desired depth is 7 mm, which is conveniently also the width of the #10 blade.

- Because of the central ridge in the patella, one must be cognizant of underestimating tendon depth where the tendon inserts. An assistant can spread a curved hemostat between the edges of the graft and remaining tendon for improved visualization of graft depth, as one also does not want to penetrate into the suprapatellar pouch. Should this occur, repair the pouch with 2-0 absorbable suture, or fluid distention will be lost in the knee. Seven to 9 centimeters of graft length can be harvested. Make a parallel cut in the lateral side of the tendon of the same length as the medial side for a tendon width of 9 to 10 mm (Fig. 89.43).

**ENDOSCOPIC QUADRICEPS TENDON TECHNIQUE**

Though to date no peer-reviewed results of the use of the quadriceps tendon for ACL reconstruction appear in the English literature, the technique is gaining acceptance as an alternative graft source (43,113). Its primary benefit is its thickness and subsequent strength (43,51).

**Graft Preparation**

- With a #238 oscillating saw blade, harvest the bone plug, which should be trapezoidal in profile. Initially score the cortical bone by holding the saw perpendicular to the patella, then angle in slightly to form the trapezoid. The cross-cut can be made holding the saw at a 45° angle to the patella both medially and laterally, and both sides can be completed by placing the saw blade into both sides, proximal to distal, parallel to the cut edge.

- Place a ¼-in. osteotome at the proximal aspect of the bone block, deep to the tendon. Gently tap the osteotome from proximal to distal to make the floor of the bone plug. Use ¼-in. and ¼-in. curved osteotomes to lift the bone block out gently. The bone block can then be grasped with a laparotomy sponge, and traction placed distally to bring the proximal aspect of the bone block beneath the fixation point by roughening the tibial cortex. Drill bicortically and measure and tap. Add the width of the tendons and 2 mm for the washer to the measured depth.

- Place distal and anterior traction on the bone block to separate the graft from the posterior 1 to 2 mm of vastus intermedius tendon that remains behind. Place the curved hemostat from lateral to medial between the graft and the underlying vastus intermedius to facilitate separation of the graft. Use a scalpel or curved Mayo scissors to divide tendon fibers. Once adequate length is obtained, place firm traction on the bone block and cut the proximal end of the graft with curved Mayo scissors.

- Bring the needle end through the tendon from posterior to anterior, proximal (toward the bone block) to the suture overlying the tendon. Using a free Mayo needle, perform the identical step with the free end of the suture on the other side of the graft. Next, bring the needle through the tendon from posterior to anterior, distal to the first locking stitch, and lock this stitch as well. Do the same with the free end of suture. Clamp the suture ends together with a hemostat. Flip
the graft over and perform the same steps with another suture, which results in two #5 Ethibond sutures with two parallel rows of double Krackow locking sutures, 180° to one another. One must avoid piercing the first stitch with the second, and the sutures must be tensioned without any slack.

**Tunnel Preparation and Graft Fixation**

- **One benefit to the quadriceps tendon is that notchplasty can be performed while graft harvest takes place. Perform a notchplasty as outlined above and make a second incision over the proximal tibia for the tibial tunnel, as is done for the BTB allograft technique. Both tunnels may be 10 mm in diameter.**
- **Using either a “push-up” or “pull-through” technique, seat the bone plug in the femoral socket and fix the graft with a titanium interference screw 7 mm in diameter and with a length matching that of the bone plug.**
- **After cycling the graft several times, fix the tibial side with the sutures tied over a 4.5-mm bicortical screw post with a washer, with the knee in full extension. Tie the two ends of one suture to those of the other suture, ensuring equal tension on the graft. If desired, the graft construct can be theoretically strengthened and stiffened by placing a bioabsorbable interference screw up the tibial tunnel (61). We prefer a screw made of polylactic acid, 9 mm in diameter and with a 20 to 25 mm length. The tip of the screw can be placed just below the articular surface.**
- **Alternatively, place the tendon portion of the graft in the femoral socket and secure it with a bioabsorbable interference screw. Secure the bony portion of the graft in the tibial tunnel with a 9 × 20 mm interference screw in a fashion identical to that described for a bone–patellar tendon–bone graft (see above).**

**Closure**

- **Place bone graft collected during tunnel preparation in the patellar defect. The remaining tendon edges are not reapproximated. Palpation of this defect postoperatively reveals that it “fits in” within 6 weeks. Minimal tenderness is present at the donor site.**
- **Close the portals and tibial incision as described above and reapproximate the proximal wound with interrupted 2-0 Vicryl in the subcutaneous layer and a running subcuticular 3-0 Prolene. Cover with Steri-Strips.**

**REHABILITATION**

The stages of postoperative rehabilitation for ACL reconstruction coincide with the phases of graft healing and ligamentization. With a properly placed anatomic graft that employs modern fixation techniques, the graft–fixation construct is able to withstand the stresses placed on it by the tailored accelerated rehabilitation program. The program is not altered if meniscal repair has been performed, but a period of 3 to 4 weeks of protected weightbearing is instituted if microfracture arthroplasty or osteochondral autograft transfer has been done concurrently. We break down our ACL rehabilitation program into phases, each of which has its own set of goals, activities, and time course (Table 89.3) (113). Undoubtedly the most important goal to reach is obtaining full knee hyperextension, as this may diminish patellofemoral symptoms in the long term (102, 108, 109). Obtaining full flexion, normal patellar mobility, and a normal gait are other goals that are best achieved within the first few weeks. We utilize closed kinetic chain knee extension exercises and prone open kinetic chain knee flexion exercises. When the patient regains strength, endurance, agility, and confidence in the reconstructed knee, return to sport can occur. This is generally somewhere between 4 and 6 months.

**PITFALLS AND COMPLICATIONS**

Generalized complications such as infection, neurovascular injury, and thromboembolic disease are extremely rare. The rate of deep infection is reported at 0.3% (119). Suspected infections should be treated aggressively with repeated arthroscopic debridement and irrigation with intravenous antibiotics for 4 to 6 weeks. If infection cannot be brought under control, the graft must be removed. Patients can expect loss of motion, but the exact amount will vary and usually involves loss of flexion.

Motion problems can be avoided by ensuring that the patient has regained full range of motion before the reconstruction. Should motion difficulties arise postoperatively, they must be recognized early and treated aggressively, as described above. One other area where motion problems may arise is if the graft has not been placed anatomically. Proper placement of the graft's tunnels is crucial to obtaining a successful result and cannot be overemphasized. A tibial tunnel placed too far anteriorly will restrict extension as it becomes impinged on by the intercondylar notch. Either the extension loss persists, causing anterior knee symptoms, or the graft attenuates and fails (56). A femoral tunnel placed too far anteriorly will also be tight in extension and lead to failure.

Many specific pitfalls and complications are inherent in an exacting technical procedure such as ACL reconstruction, and most can be avoided by strict attention to detail and adequate visualization during the arthroscopic portion of the procedure. Specific pitfalls, their causes, and methods of correcting the problems are listed in Table 89.4.

---

**Table 89.3. Outpatient ACL Surgical Rehabilitation Activities and Goals**

As our patients undergo surgery on an outpatient basis, and third-party payers often do not reimburse for their use, we forgo the use of continuous passive motion (CPM) machines. Electrical stimulation is not used either. We do place patients in a postoperative rehabilitation brace. Patients wear this for 6 weeks and lock it in extension at night to minimize flexion contracture from intercondylar notch scar formation. It is taken off for range-of-motion exercises, and its use during ambulation is discouraged. We do not utilize surgical programs that employ modern fixation techniques, the graft–fixation construct is able to withstand the stresses placed on it by the tailored accelerated rehabilitation program. The program is not altered if meniscal repair has been performed, but a period of 3 to 4 weeks of protected weightbearing is instituted if microfracture arthroplasty or osteochondral autograft transfer has been done concurrently. We break down our ACL rehabilitation program into phases, each of which has its own set of goals, activities, and time course (Table 89.3) (113). Undoubtedly the most important goal to reach is obtaining full knee hyperextension, as this may diminish patellofemoral symptoms in the long term (102, 108, 109). Obtaining full flexion, normal patellar mobility, and a normal gait are other goals that are best achieved within the first few weeks. We utilize closed kinetic chain knee extension exercises and prone open kinetic chain knee flexion exercises. When the patient regains strength, endurance, agility, and confidence in the reconstructed knee, return to sport can occur. This is generally somewhere between 4 and 6 months.

**Table 89.4. Complications and Pitfalls of ACL Reconstruction and Their Solutions**
AUTHORS’ PERSPECTIVE

One of us (B. R. B.) recently reported minimum 2-year follow-up results using the endoscopic BTB technique (12). One hundred three patients were evaluated. Seventy-four percent had negative Lachman exams, 24% had grade 1 exams with firm endpoints, and two patients had grade 2 exams. Ninety percent had negative anterior drawer exams, with the remainder having grade 1 exams. Ninety-one percent had negative pivot-shift testing, and 9% had grade 1 pivot “slides.” The overall mean manual maximum side-to-side difference on KT-1000 testing was 1.1 mm. Eighty-six patients (83%) had side-to-side differences less than 3 mm. 14 (14%) had differences between 3 and 5 mm, and only three (3%) patients had differences greater than 5 mm. The mean Lysholm score was 89. Preinjury and postoperative Tegner activity levels were not significantly different. Ninety-five percent indicated that they would undergo the same procedure if the contralateral knee were injured similarly. Ninety-three percent were completely or mostly satisfied with the procedure, 7% were somewhat satisfied, and only one patient was dissatisfied with the procedure. Five patients (5%) required reoperation for debriement of fibroproliferative “cyclops” lesions. A 14% incidence of patellofemoral complaints was present, with nearly all having minimal or mild complaints.

A recent 5- to 9-year follow-up study of patients operated on at our institution with the two-incision BTB technique has revealed excellent long-term results (11). Eighty-three percent of the 97 patients had a negative pivot-shift exam, with the remaining 17% having a grade 1 + “slip.” Seventy percent had less than 3 mm side-to-side difference on KT-1000 manual maximum side-to-side testing, and functional testing averaged less than 2% asymmetry for vertical jump, single-legged hop, and timed 6-m hop. Tegner activity levels were similar to preinjury levels, the mean Lysholm score was 87, and the Noyes sports functional score was 89. A low incidence of patellar pain (13%) on stair climbing was noted, and no patients exhibited any long-term patellar tendinitis symptoms. Ninety-seven percent of patients were satisfied with the results of the surgical procedure and would have the operation performed if they tore their contralateral ACL. Most importantly, when compared to an earlier 2- to 4-year follow-up study in the same cohort of patients, the results did not deteriorate with time (19).

A recent study that have compared endoscopic to two-incision arthroscopically assisted ACL reconstruction have not demonstrated any significant differences between the two techniques (49,70,101). The endoscopic technique is technically more difficult but does result in less early perioperative morbidity. The two-incision technique, however, is one with which surgeons who perform ACL surgery should be familiar, as it is often employed in revision situations and is invaluable when posterior cortical “blow-out” occurs during endoscopic reaming of the femoral socket.

Results of ACL reconstruction using BTB allograft and comparing these results to those of BTB autograft are summarized in Table 89.5. Differences between the two groups with regard to graft donor site morbidity become less apparent with longer follow-up, and significant differences with regard to subjective and objective stability are rarely found.

Evaluation of the results of STG reconstruction reveals similar results in comparison to the BTB technique. Howell et al. evaluated their results using double-looped STG grafts and found that 10% had positive pivot shifts and that 69% had KT-1000 manual maximum differences of less than 3 mm (67).

Few studies have directly compared the results of patellar tendon and hamstring techniques (Table 89.6). Marder et al. prospectively compared BTB and double-looped STG and found no significant differences with regard to KT-1000 testing, laxity examination, subjective complaints, quadriceps strength, or patellofemoral symptoms (21). The STG patients did have significantly weaker hamstring strength, however.

A recent study compared endoscopic BTB to double-looped STG (2). No significant differences were noted in arthrometric measurements, pivot-shift testing, or patellofemoral crepitation. Significantly more patients returned to sport in the BTB group. More patients in the BTB group also had minor (<3”) extension loss. The authors concluded that routine use of BTB as a graft source was justified but that STG is preferable in older patients, patients with preexisting patellofemoral disease, and previous BTB harvest.

O’Neill prospectively evaluated endoscopic and two-incision BTB and quadruple-stranded STG and also found no differences in arthrometric measurements or IKDC evaluation (58). Quadriceps and hamstring strength testing results were similar as well. No advantages were noted for any of the three reconstructive techniques. Pivot-shift results were not reported.

SUMMARY

Tremendous progression in basic science research and improvements in clinical follow-up studies have led to advances in the treatment of the ACL-deficient patient. Anterior cruciate ligament reconstruction is effective in restoring anterior stability of the knee and subsequently protecting the menisci. Studies with longer follow-up are needed to determine if ACL reconstruction will halt progression to osteoarthritis in the ACL-deficient patient. Numerous effective methods are now available for reconstruction. Though each method possesses inherent strengths and weaknesses, all follow the principles of anatomic placement of the graft with a fixation construct that can withstand the stresses of accelerated rehabilitation. This rehabilitation program is essential in restoring full range of motion and physiologic hyperextension and in diminishing postoperative patellofemoral complaints.

CHAPTER REFERENCES

ISOLATED POSTERIOR CRUCIATE LIGAMENT INJURY AND POSTEROLATERAL LAXITY

Leslie J. Bisson and William G. Clancy, Jr.

The posterior cruciate ligament (PCL) is the stronger of the two cruciate ligaments and is the primary restraint to posterior tibial translation at 90° of knee flexion. The recent emphasis on reconstructive surgery in cases of anterior cruciate ligament (ACL) injury has stimulated an increased interest in the PCL, and investigators have begun to study the anatomy, biomechanics, and function of the PCL in greater detail. Additionally, there have been attempts to better document the natural history of the PCL-deficient knee as well as to define the optimum time and method of reconstruction in cases in which surgery is deemed necessary. Despite the large numbers of articles published recently on these topics, the management of injury to the PCL continues to be controversial. Support for both surgical and nonsurgical management can be found in the orthopaedic literature.

The posterolateral corner (PLC) is a complex that includes the lateral collateral ligament (LCL), popliteus tendon, fabellofibular ligament, arcuate ligament, popliteofibular ligament, and the short lateral ligament. The LCL resists straight varus rotation of the tibia, and the remaining structures restrain external tibial rotation. Isolated injury of the posterolateral corner is uncommon. When PLC injury occurs with injury to the PCL, both injuries must be appropriately diagnosed and treated to obtain a satisfactory outcome.

This chapter provides a summary of what is known about the epidemiology, mechanism of injury, clinical evaluation, imaging, treatment, and results of treatment of injuries to the PCL and PLC. A section at the end of the chapter outlines the preferences of the senior author (W.G.C.), who has treated more than 400 patients with PCL insufficiency.

EPIEMIOLOGY

Injuries to the PCL are much less frequent than those to the ACL (11,39,41). Indeed, it is thought that the PCL is injured about one-tenth to one-twentieth as often as the ACL (11,39,41). The incidence of both isolated and combined PCL injuries in series of surgically treated knee injuries ranges from 3.49% (11) to 20% (12). The symptoms and clinical signs of isolated PCL injury, however, may be subtle both to patient and to physician, and the injury may often be missed (17,28,77). When diagnosed, the isolated PCL injury is often treated nonsurgically.

These factors suggest that the true incidence of PCL injury is higher than that quoted in the literature. It is interesting to note that approximately 2% to 5% of the players participating in the National Football League’s predraft physical examinations have evidence of isolated PCL laxity, and most of these players are unaware of having had a significant ligamentous injury (4). In a study that analyzed 501 knee ligament injuries with pathologic motion as measured by a KT-1000 arthrometer, 63% were found to be ACL injuries, and 7% were PCL injuries (19). Seventy-five percent of the ACL injuries were isolated, compared with 49% of the PCL injuries. It is not uncommon for PCL injuries to have associated injury to the ACL, medial collateral ligament (MCL), and the posterolateral corner (PLC) (33,34,47).

MECHANISM OF INJURY

When discussing the mechanism of injury to the PCL, it is helpful for the examiner to differentiate between low-energy (i.e., athletic) and high-energy (i.e., motor vehicle accident) etiologies because of the higher incidence of combined ligamentous injuries and associated injuries in the latter (62). Injury to the PCL has been described as occurring in one of four ways (Fig. 90.1, Fig. 90.2, and Fig. 90.3): (a) a posterior force applied to the tibia with the knee in flexion (which often results in a midsubstance injury) (22), (b) a fall onto the flexed knee with the foot in plantarflexion (11,25), (c) hyperflexion (28), and (d) hyperextension (45). Two other less common means of injury have recently been described, including a noncontact, external rotation/posterior translation injury (67) as well as an external rotation/valgus injury (68).

Figure 90.1. Mechanism of injury to the PCL: a posterior force applied to the proximal tibia with the knee in 90° of flexion. (From DeLee JC, Bergfeld JA, Drez Jr, Eds. Orthopaedic Sports Medicine. Principles and Practice. Philadelphia: WB Saunders, 1994,
Injury to the PLC often results from a blow to the anteromedial proximal tibia, most commonly with the knee in extension (3,25,35,80). The result is a varus and rotational moment about the knee. Hyperextension alone or combined with external rotation and knee extension have also been implicated in noncontact injuries to the PLC (10,13,80).

CLINICAL EVALUATION

ISOLATED PCL INJURY

Many authors agree that diagnosis of injury to the PCL can often be confusing, particularly when it occurs acutely and is isolated. The presence of quadriceps muscle spasm may mask some of the findings on physical exam, and isolated injury to the PCL may be dismissed by the athlete as insignificant (4). A tense effusion such as occurs with an acute ACL injury is usually absent. For this reason, the history and physical exam are of paramount importance, not only to diagnose the injury itself but also to determine the site of the injury and therefore to help determine the appropriate treatment plan.

History

Knowledge of the mechanism of injury in cases of suspected PCL injury can help determine the likelihood of injury to the ligament as well as suggest the potential site of involvement along the length of the PCL. Injury to the midsubstance of the PCL often occurs following a direct blow to the anterior proximal tibia with the knee flexed (27,28). Midsubstance injuries may also occur after a fall onto the flexed knee with the foot in plantarflexion, which concentrates the bulk of the force on the tibial tubercle (25).

A blow to the anteromedial aspect of the proximal tibia with the knee in extension is a common mechanism in sports-related injuries and also results in midsubstance injury to the PCL as well as injury to the posterolateral corner structures. A pure hyperflexion injury without a force being applied directly to the proximal tibia often results in avulsion of the origin of the ligament from the medial femoral condyle, offering a chance for primary repair (25) (although the senior author has never seen a successful result of primary repair).

In cases of chronic PCL injury, a common complaint is discomfort in the knee while weight bearing in a semiflexed position, such as ascending or descending stairs or squatting down (18). Aching in the knee when walking long distances is also a common complaint (18). Approximately 50% of patients with symptomatic PCL insufficiency complain of instability or a sense of instability in the knee that is problematic when they are walking on uneven ground (18). Approximately half of the patients reported on by Cross and Powell (17) complained of retropatellar pain in the knee that was not present initially but developed at some point after the injury. Swelling and stiffness may vary and depend on the degree of associated chondral damage.

Physical Examination

Acute injury to the PCL may often be missed for several reasons. Often the athlete is unaware of having sustained a significant injury, because many patients have a full range of motion with very little hemarthrosis (4,11,16,18). Often it is only the posterior drawer test that causes any pain. The presence of a contusion over the proximal anterior tibia may be very helpful in suggesting injury to the PCL.

The importance of noting the relationship of the proximal tibia to the femur when the knee is flexed to 90° cannot be overemphasized. When the PCL is intact, flexion of the knee to 90° results in the anterior proximal tibia being positioned approximately 1 cm anterior to the distal femoral condyles (Fig. 90.4), referred to as a normal anterior stepoff. Loss of this normal anterior stepoff signifies injury to the PCL (11). The importance of detecting this posterior subluxation has been emphasized by Clancy et al. (11), who state that it is best viewed from the side with the knee flexed to 90°. This posterior subluxation of the proximal tibia with the knee flexed to 90° is also known as the posterior sag sign (of Godfrey).
Combined injuries to the PCL and posterolateral corner structures are often caused by a blow to the anteromedial tibia with the knee in extension. This mechanism of injury results in the line of action of the patellar tendon being directed anteriorly, and this quadriceps contraction evokes a notable anterior translation of the proximal tibia. Daniel et al. (20) found the quadriceps active drawer test to be positive in the knees of 41 of 42 patients with documented disruption of the PCL. Anterior translation did not occur in the contralateral normal knee of these patients, nor did it occur in 25 knees with known disruption of the ACL. These authors found this test to be useful in both acute and chronic cases.

The posterior drawer test performed at 70° to 90° of flexion has been regarded as the most reliable sign of PCL disruption (33,65) (Fig. 90.5). This test is graded with respect to the opposite knee. Loss of the normal anterior tibial stepoff compared with the opposite side, but with the proximal tibial eminence remaining anterior to the distal femoral condyles, is considered to be a 1 + posterior drawer. When the proximal tibial eminence can be translated posteriorly to the point where it is flush with the distal femoral condyles, the posterior drawer is graded 2 + . It is thought to signify complete disruption of the PCL. Translation of the proximal tibial eminence posterior to the distal femoral condyles is considered to be grade 3 + and is thought to signify complete PCL disruption and usually posterolateral ligamentous injury as well. This test, however, has been reported to be positive in as few as 10% to as many as 76% of patients with acute PCL disruptions (33,44,53,60).

The accuracy of the posterior drawer test in the chronic setting has been documented by Rubinstein et al. (65). These examiners found that the posterior drawer test, including palpation of the tibial stepoff, was the most sensitive and specific clinical test for PCL insufficiency. Clinical examination for chronic PCL injury was 96% accurate, 90% sensitive, and 99% specific. The interobserver agreement for the grade of the injury was 81%.

Because the presence of muscle spasm has been shown to limit the effectiveness of the posterior drawer test in the acute setting, Daniel et al. (20) introduced the quadriceps active drawer test to detect PCL injury (Fig. 90.6). This test is based on the biomechanical relationship between the line of action of the patellar tendon and the resultant quadriceps muscle force. In an intact knee, the line of action of the patellar tendon tends to pull the proximal tibia anterior at low knee-flexion angles. At high knee-flexion angles, the PCL causes the femur to roll back on the proximal tibia, and the line of action of the patellar tendon therefore tends to pull the proximal tibia posterior.

The angle of knee flexion at which the line of action of the patellar tendon is directly perpendicular to the surface of the tibial plateau is called the quadriceps-neutral angle and occurs at 60° to 90° of flexion in the intact knee. In a knee with the PCL injured or absent, rollback of the femur on the tibia does not occur with increasing knee flexion. Therefore, the line of action of the patellar tendon is always directed anteriorly.

The quadriceps-active drawer is performed with the subject relaxed in the supine position with the knee flexed 70° to 90°. The examiner stabilizes the patient’s foot on the table and then asks the patient to slide the foot distally on the table. In the normal knee, the patellar tendon line of action will be directed posteriorly. In the patient with deficiency of the PCL, however, the posterior sag of the proximal tibia results in the line of action of the patellar tendon being directed anteriorly, and this quadriceps contraction evokes a notable anterior translation of the proximal tibia. Daniel et al. (20) found the quadriceps active drawer test to be positive in the knees of 41 of 42 patients with documented disruption of the PCL. Anterior translation did not occur in the contralateral normal knee of these patients, nor did it occur in 25 knees with known disruption of the ACL. These authors found this test to be useful in both acute and chronic cases.

**COMBINED PCL AND COLLATERAL LIGAMENT INJURY**

**History**

Combined injuries to the PCL and posterolateral corner structures are often caused by a blow to the anteromedial tibia with the knee in extension. This mechanism of injury results in the line of action of the patellar tendon being directed anteriorly, and this quadriceps contraction evokes a notable anterior translation of the proximal tibia. Daniel et al. (20) found the quadriceps active drawer test to be positive in the knees of 41 of 42 patients with documented disruption of the PCL. Anterior translation did not occur in the contralateral normal knee of these patients, nor did it occur in 25 knees with known disruption of the ACL. These authors found this test to be useful in both acute and chronic cases.
We have found stress lateral radiographs to be helpful in documenting the presence of injury to the PCL. Radiographs taken at 70° to 90° of flexion with first an anterior STRESS RADIOGRAPHS the reconstruction by the varus alignment would be expected to result in failure of the reconstruction. posterolateral laxity and varus alignment has a ligamentous reconstruction without correction of the mechanical axis by osteotomy, the abnormal stresses imposed on It is essential to take preoperative weight-bearing radiographs using a plumb line to determine the mechanical alignment of the limb (54). If the patient with posterolateral laxity and varus alignment has a ligamentous reconstruction without correction of the mechanical axis by osteotomy, the abnormal stresses imposed on the reconstruction by the varus alignment would be expected to result in failure of the reconstruction. STRESS RADIOGRAPHS We have found stress lateral radiographs to be helpful in documenting the presence of injury to the PCL. Radiographs taken at 70° to 90° of flexion with first an anterior

Gollehon et al. (30) have shown that a 15° increase in tibial external rotation at 30° of knee flexion is indicative of significant injury to the posterolateral structures. Increased external rotation of the tibia at 90° of flexion indicates injury to both the PCL and posterolateral ligament complex. The reverse pivot-shift test, introduced by Jakob et al. (38), is another test that is used to assess the posterolateral ligaments. In the reverse pivot-shift test, the knee is reduced in full extension. As the examiner applies a valgus and external rotation force while flexing the knee, the lateral tibial plateau can be felt to subluxate posteriorly. This maneuver creates a shifting sensation similar to that felt during the classic pivot shift in patients with ACL laxity. All of these tests are more profoundly positive in the presence of associated PCL insufficiency.

Detect injury to the MCL in combination with PCL injury by looking for increased valgus laxity at both full extension and 30° of flexion. The above-mentioned tests for PCL injury are also positive. There will also be a greater posterior translation of the medial tibial plateau during the posterior drawer test at 90° of knee flexion. It should be noted that PCL/MCL injury is less common than PCL/PLC injury. Finally, patients with injury to the PCL as well as both the medial and lateral sides of the knee combined PCL and collateral ligament injury there an incidence of peroneal nerve injury that approaches 30% (23).

Figure 90.7. The external rotation recurvatum test. (From Hughston JC, Norwood LA. The Posterolateral Drawer Test and External Rotational Recurvatum Test for Posterolateral Rotary Instability of the Knee, Clin Orthop 1980;147:82, with permission.)

Jakob et al. (38), is another test that is used to assess the posterolateral ligaments. In the reverse pivot-shift test, the knee is reduced in full extension. As the examiner applies a valgus and external rotation force while flexing the knee, the lateral tibial plateau can be felt to subluxate posteriorly. This maneuver creates a shifting sensation similar to that felt during the classic pivot shift in patients with ACL laxity. All of these tests are more profoundly positive in the presence of associated PCL insufficiency.

Figure 90.8. Lateral radiograph of the knee demonstrating avulsion of the insertion of the PCL from the tibia. (From Cooper DE, Warren RF, Warner JJP. The Posterior Cruciate Ligament and Posterolateral Structures of the Knee: Anatomy, Function and Patterns of Injury. Instr Course Lect 1991;40:249, with permission.)

Exhibit symmetric posterior displacement of both tibial plateaus during the posterior drawer test. It should be noted, however, that these tests have a relatively low sensitivity, being positive in only 25% and 33% of patients, respectively (83).
and then a posterior stress are helpful for diagnosis of PCL insufficiency as well as for comparison with postoperative stress radiographs in order to allow an objective evaluation of results among investigators. Correction of the total AP translation to that present in the normal opposite knee is one objective way of suggesting that the restoration of normal biomechanics of the knee has been achieved.

Hewett et al. (32) recently studied the utility of stress radiographs in the documentation of complete PCL injury as well as in the differentiation between complete and partial tears of the PCL. These investigators found that 8 mm or more of increased posterior translation occurring with the application of an 89-N posterior load at 70° of flexion was indicative of a complete rupture of the PCL. They also found that stress radiographs were superior to both KT-1000 arthrometry and clinical exam in assessing the status of the PCL.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) has greatly increased the accuracy with which acute ligamentous injuries of the knee may be detected and correctly diagnosed and has allowed the detection of other associated injuries to the menisci, cartilage, and subchondral bone (79). Not only can MRI confirm suspected injury to the PCL, it can also determine the site of injury to the ligament (Fig. 90.9). One of us (W.G.C.) has also noted that MRI may show a lesion in continuity of the PCL. This injury is characterized by increased signal in the midsubstance of the ligament without evidence of complete disruption and is characterized by laxity of the PCL on clinical exam. This injury may heal with a decrease in the initial laxity.

BONE SCAN

A bone scan may be helpful in evaluating the progress of a patient with pain and isolated PCL insufficiency. Isolated chronic PCL insufficiency rarely leads to instability, and the disability from this injury is more often a result of pain secondary to articular cartilage changes. For this reason, it has been suggested that serial bone scanning may allow early diagnosis of changes of the articular cartilage in the patient who is being treated nonsurgically. Early recognition of increased joint contact pressures secondary to the abnormal knee biomechanics present in the knee with PCL insufficiency may allow a reconstruction to arrest these changes before irreversible progression takes place. This argument, however, assumes that reconstruction of the PCL restores the knee biomechanics to normal and prevents further deterioration of the articular cartilage. To date, no scientific study has confirmed this hypothesis.

TREATMENT

The treatment of the knee with a PCL injury is controversial, and recommendations have been made for both surgical and nonsurgical management. A large part of the controversy arises from the fact that there are very few studies that document the long-term results of any form of treatment. Many studies do not differentiate between results obtained with isolated PCL injury versus combined injury patterns, or between results obtained in cases of chronic versus acute PCL insufficiency. The relative infrequency of PCL injury combined with the limited indications for operative treatment also make it difficult for one surgeon to gain a large experience in the treatment of the PCL-insufficient knee.

NONSURGICAL MANAGEMENT OF PCL INJURIES

Several authorities have recommended nonsurgical management for isolated PCL injuries (14,18,28,44,57,64,74). Short-term follow-up studies of patients treated without surgery indicated that these individuals generally did well (28,57,64), but more recent long-term follow-up reports have documented worse clinical results as well as radiographic deterioration (21,42). When the PCL is torn, the patella and patellar tendon take on a more prominent role in the prevention of posterior tibial translation (6,17). Also, the increased posterior tibial sag that occurs in the PCL-deficient knee shortens the moment arm of the quadriceps, decreasing its mechanical advantage (71). Therefore, nonoperative management of PCL injuries should emphasize quadriceps strengthening as a key component of the rehabilitation program (57). Restoration of satisfactory quadriceps strength, however, does not necessarily ensure a good long-term clinical result (52).

The goal of physical therapy is to strengthen the muscles that act to prevent posterior tibial translation, particularly the quadriceps, while minimizing gravity-induced posterior tibial sag (60). Avoid open-kinetic-chain hamstring exercises (performed with the foot free, compared with closed-kinetic-chain exercises, which are performed with the foot fixed), which cause posterior tibial translation in the PCL-deficient knee (49). Closed-kinetic-chain exercises such as the squat cause less shear force at the tibiofemoral joint (49) and are the preferred method for strengthening the quadriceps.

Properly performed open-kinetic-chain exercises such as the leg extension may be used if certain precautions are followed. Green et al. (31) found that open-kinetic-chain extension exercises in the range from 70° to 0° of flexion minimized posterior tibial translation. Placement of the resistance pad distally on the leg during the exercise routine lessens articular contact pressures in the medial compartment and diminishes the posterior stresses on the secondary restraints (14,46).

The rehabilitation program employed for the patient with PCL injury involves three phases: (a) a maximum protection phase, which is used during the first 2 weeks following injury; (b) a moderate protection phase, used from week 4 to week 6 after injury; and (c) a minimal protection phase, used 6 to 8 weeks after injury.

Initiate the maximum protection phase following acute PCL injury and progress over the first 2 to 3 weeks. Encourage weight bearing as tolerated using two crutches. Use a brace permitting range of motion from 0° to 60°. When the individual is comfortable, begin straight-leg raises, knee extension from 60° to 0°, quadriceps isometrics at 60°, 45°, and 20°, and minimus and leg presses from 0° to 45°. Over the next 2 to 3 weeks, progress to full weight bearing, begin cycling for range of motion, and increase leg-press range of motion up to 60° of flexion.

The moderate protection phase takes place from weeks 3 to 6 after the injury. Increase range of motion to normal as tolerated and discontinue bracing. Increase resistance exercises and begin activities such as the use of rowing and stairclimber machines. Running may be initiated in the pool during this phase. Introduce light resistance hamstring curls and step-ups.

The minimal protection phase begins at week 6 to 8. Continue all strengthening exercises and begin a running program, if appropriate. Patients may gradually return to sporting activities. Criteria to be met before returning to sports include absence of pain, tenderness, and swelling as well as isokinetic testing documenting at least 85% strength, comparing the injured to the normal side.

SURGICAL MANAGEMENT

Manage patients diagnosed initially with either acute or chronic isolated injury to the PCL with the above rehabilitation program. Patients with injury to another major knee ligament in addition to the PCL, as well as those with isolated PCL injuries who continue to have pain or instability despite use of the above rehab program for at least 3 months, require evaluation for surgical reconstruction.

Avulsion Fractures of the Tibial Insertion of the PCL
Most authors have recommended operative repair of a displaced bony avulsion of the tibial insertion of the PCL (Fig. 90.10 and Fig. 90.11) (14,52,75,76 and 77). Treat undisplaced fractures with immobilization of the knee in extension, using the intact collateral ligaments to help prevent posterior sag (85,56).

Figure 90.10. Avulsion of the PCL from the tibia fixed with a screw. (From Bowen MK, Warren RF, Cooper DE. Posterior Cruciate Ligament and Related Injuries. In: Insall JN, Windsor RE, Scott WN, et al., eds. Surgery of the Knee. New York: Churchill Livingstone, 1993:536, with permission.)

Figure 90.11. Tibial avulsion of the PCL reattached with sutures placed through the bony fragment and secured over a button. (From Bowen MK, Warren RF, Cooper DE. Posterior Cruciate Ligament and Related Injuries. In: Insall JN, Windsor RE, Scott WN, et al., eds. Surgery of the Knee. New York: Churchill Livingstone, 1993:536, with permission.)

Surgical fixation of tibial avulsion fractures of the PCL has given almost uniformly excellent results, whereas nonsurgical treatment has a significant incidence of residual instability (46,77).

Torisu (75) treated 21 patients with avulsion fractures of the tibial insertion of the PCL using cast immobilization in small or nondisplaced fractures and staple fixation in large or displaced fragments. All patients had excellent or good result at an average of 4 years of follow-up. He reported satisfactory results in fractures less than 7 weeks old, whereas repairs delayed beyond 11 weeks resulted in less satisfactory outcomes.

Isolated PCL Injury

Most authors have recommended a nonsurgical approach to the treatment of isolated PCL injuries (Table 90.1).

Several conclusions can be made from these studies:

- The subjective results of nonsurgical treatment of the isolated PCL injury are not excellent (42). There is a 20% to 25% failure rate, and the majority of patients continue to complain of knee pain and activity limitations (42).
- There may be some correlation between quadriceps strength and outcome.
- There does not appear to be a strong association between subjective results and ligamentous stability.
- A substantial number of patients with isolated PCL injury will go on to develop degenerative changes of the knee, particularly in the medial compartment, with time.

To recommend reconstructive surgery for the isolated injury to the PCL, one must be convinced that the results of reconstruction are superior to those of nonoperative management. Unfortunately, there are no prospective randomized studies of operative versus nonoperative treatment. Very few reports divide the patients into isolated PCL versus combined PCL injuries. Bianchi (5) and Loos et al. (47) noted mixed results in surgically treated isolated PCL insufficiency, with the majority rated good or fair. Objective stability was often not restored, but patients rarely complained of functional instability. Richter et al. (61) reported an 8-year follow-up of 53 patients with isolated and combined PCL instabilities treated surgically with only 13% graded as nearly normal.

In contrast, Clancy et al. (11) reported excellent results in 15 patients treated operatively for acute PCL insufficiency, using ligament repair supplemented with a central third patellar tendon autograft passed through bony tunnels. Although this study offers good early results, it remains to be seen whether there is a decrease in the long-term incidence of degenerative arthritis.

Acute PCL Combined with Other Ligaments

Disruption of the PCL as well as other major ligaments is usually a result of higher-energy injury but may also occur in sports. These injuries result in gross instability of the knee; therefore, most authors advocate operative treatment. For this reason, there are no large long-term studies of the results of nonoperative treatment; thus, it is impossible to determine whether surgical management improves on the natural history of these combined injuries. A wide variety of surgical approaches and tissues for
Kennedy and Grainger (44) believe that repair of an injured PCL is superior to reconstruction. For reconstruction, they recommended passing hamstring tendons through drill holes in the tibia and medial femoral condyle, a procedure originally proposed by Hey-Groves. McCormick et al. (51) described reconstruction of a PCL and LCL injury using the tendon of the popliteus passed through drill holes in the medial femoral condyle. Soughmayd and Rubin (69) reported similar use of the semimembranosus tendon, preserving its distal attachment.

The results of several larger series are summarized in Table 90.2. Despite the fact that the materials used for repair or reconstruction were inferior to those used today, the results were a satisfactory functional outcome in the majority of patients. The stability of the knee after these procedures, however, is far from normal. Newer anatomic methods of PCL reconstruction using more than one graft and multiple femoral tunnels appear promising both biomechanically and clinically, but results using these methods are still preliminary.

**Table 90.2. Surgical Treatment of PCL and Combined Ligament Injuries**

**Chronic PCL Insufficiency**

Chronic PCL insufficiency usually results in symptoms from degenerative changes in the medial and patellofemoral compartments or from instability with subsequent stretching of the secondary restraints, particularly the posterolateral corner. There are few reports of successful nonsurgical management of chronic lesions. Hughston and Degenhardt (34), however, demonstrated that nearly half of their patients obtained functional stability with an aggressive rehabilitation program. These patients may have had lesser degrees of instability, however (22).

A number of procedures have been proposed to treat chronic instability. Tellberg (73), using lateral meniscus as a graft, had mixed results in seven patients. He advocated use of the meniscus because its length and size are appropriate, it is not dependent on revascularization, and it is a nearby intraarticular structure.

**Table 90.3 summarizes the results of surgical treatment of chronic PCL insufficiency. Most of these studies used the medial head of the gastrocnemius muscle or meniscus as a substitute for the PCL; more recently, the central third of the patellar tendon and hamstring autografts, as well as patellar tendon and Achilles tendon allografts, have been used. Autografts provide strong, readily available tissue without the risk of disease transmission, whereas allografts have the advantage of no donor site morbidity. These reconstructions emphasize placement of bony tunnels at the sites of origin and insertion of the PCL, followed by insertion of strong graft tissue to substitute for the ligament. Paulos (58) has described an arthroscopically assisted technique using an Achilles tendon allograft.

**Table 90.3. Surgical Treatment of Chronic PCL Injuries**

Clancy et al. (11) summarized their experience in 33 patients with chronic PCL insufficiency in whom reconstruction was done using the central third of the patellar tendon as autograft. Twenty-three of 33 patients had evidence of degenerative changes on preoperative radiographs. Of 13 patients available for evaluation at a minimum of 2 years, four patients had associated ACL repairs, one had repair of the posterolateral corner, and one had repair of the MCL. All but two patients had good or excellent results.

Although the above studies included patients with associated laxity of the posterolateral structures, none specifically mentioned the preoperative alignment of the limb. Several authors have recently stressed the significance of varus alignment of the limb and, more important, of a varus thrust during gait (14, 26, 37). Soft-tissue procedures performed on the posterolateral corner in a limb that has a varus thrust during gait will tend to stretch out and fail over time. Despite the lack of studies demonstrating a long-term benefit, many authors (26, 37) feel that the most reliable procedure in such a setting is a high tibial osteotomy.

It can be concluded from the above series that the majority of properly selected individuals who undergo PCL reconstruction for either isolated or combined injuries will obtain a satisfactory subjective result. It appears that the majority of individuals treated surgically for isolated PCL insufficiency will return to their preinjury activity level and have subjective, but not objective, stability. The results of surgery in combined PCL and other major knee ligament injuries are less predictable but offer satisfactory subjective results in the majority of patients. None of these operations, however, reliably restores objective stability, re-creates normal biomechanics, and prevents or delays the onset of degenerative disease. Although newer methods of reconstruction using multiple grafts to recreate both anatomic bundles of the PCL appear promising both biomechanically and clinically, long-term outcomes are currently unavailable.

**AUTHOR'S PERSPECTIVE**

The senior author (W.G.C.) has surgically treated more than 400 patients for symptomatic isolated or combined PCL insufficiency. The following outlines his indications and preferred techniques.

**ACUTE PCL INJURY**

We treat the majority of acute injury isolated PCL injuries without surgery. For displaced fractures of the origin or insertion of the PCL, we do an open reduction and internal fixation, followed by early motion. Incomplete injuries with a 1 + drawer test are a tear in continuity with interstitial lengthening, which can be seen on MRI. These injuries often tighten as healing progresses, and the posterior drawer test often diminishes to trace. Nonsurgical treatment is appropriate.

Laxity of 2+ on posterior drawer testing is consistent with a complete disruption of the PCL. In the absence of other major ligamentous injuries, we treat this injury without surgery. We advise surgery only if the patient exhibits continued instability or medial joint pain secondary to increased contact pressures in the medial compartment. In the patient with medial joint line pain and normal radiographs, we have found a technetium bone scan to be useful in defining the source of the pain.
Laxity of 3+ on posterior drawer testing indicates injury to the PCL and secondary restraints, most commonly the posterolateral corner structures. The treatment of these injuries is discussed in the section below.

**COMBINED PCL AND PLC INJURY**

Try to repair PCL combined with PLC injury within 3 weeks of injury; early treatment permits primary repair rather than reconstruction. Split the knee until the acute pain subsides and encourage active and active-assisted range of motion. Allowing 5 to 7 days to elapse from the time of injury until the time of surgery permits the joint capsule to seal and avoid extravasation of arthroscopic fluid into the leg from the injured posterolateral structures during the arthroscopic part of the procedure. We repair the PCL first, using the procedure outlined below, and then repair the PLC structures through a standard lateral approach. If a satisfactory primary repair is not possible, we do a biceps femoris tenodesis when the biceps femoris tendon is intact. We perform posterolateral corner reconstruction with an Achilles tendon allograft when the popliteus and biceps tendon complex are irreparable. These techniques are described below.

**COMBINED PCL AND ACL INJURY**

As discussed earlier, these injuries are often unrecognized knee dislocations, requiring thorough neurovascular evaluation. Once the knee is reduced, split it until the acute pain of the injury subsides, in a few days. Begin active range of motion within the limits of pain; once full extension and approximately 120° of flexion are achieved, perform elective reconstruction of the ACL and PCL. Reconstruct the ACL using an endoscopic technique with a patellar tendon graft. Reconstruct the PCL using the technique described below. Also see [Chapter 31].

**COMBINED PCL AND MCL INJURY**

Combined injury to the ACL and MCL is somewhat unusual. Grade I or II MCL injuries combined with PCL disruption can usually be treated without surgery, and the emphasis is on early range of motion and quadriceps strengthening. Grade III MCL injuries, characterized by laxity to valgus stress applied at full extension, have injury to the posterior oblique portion of the MCL as well as the anterior longitudinal portion. We treat these injuries with splinting and early range-of-motion exercises followed by early repair of the MCL and posterior oblique ligament as well as reconstruction of the PCL. It is important to ensure isometric repair of the MCL and posterior oblique ligament to avoid creating a flexion contracture. Reconstruct the PCL as described below.

**CHRONIC PCL INSUFFICIENCY**

The patient with chronic insufficiency of the PCL may or may not have concomitant injury to the posterolateral structures. In isolated PCL injuries, we prescribe a rehab program to strengthen the quadriceps. Failure of this program to result in improvement of symptoms after 3 months results in our offering the patient the option of a PCL reconstruction. Combinedly, the symptomatic patient also has some laxity of secondary restraints, particularly the posterolateral structures. In this setting we offer the patient a PCL reconstruction as well as reconstruction of the posterolateral structures using a tenodesis of a portion of the biceps tendon (7). When this procedure has been performed previously and failed, or when injury to the biceps tendon has occurred, we use an Achilles tendon allograft. Both of these techniques are described below.

**SURGICAL TECHNIQUES**

**FIXATION OF PCL AVULSION INJURIES**

- Two approaches for fixation of the displaced avulsion of the tibial insertion of the PCL have been advocated. Trickey (73) recommends the direct posterior approach, which gives the best view of the avulsion and allows easier internal fixation of the fragment with a screw. Perform the surgery in conjunction with an arthroscopic evaluation of the knee joint to allow treatment of any coexisting pathology.
- The second approach is that of a combined anterior medial arthrotomy and, when needed, a posterior medial arthrotomy performed through a medial parapatellar skin incision, as recommended by Hughston and associates (31,34). Tensioning of the knee ligament preparations in which bony avulsions occurred suggests that plastic deformation may occur within the ligament, resulting in a permanent increase in length. If this is the case, any bony avulsion should be countersunk at the time of fixation so that proper functional length and isometricity will result.
- Deliver the ACL and the attached bony avulsion through the intercondylar notch anteriorly. If there is a ligament of Humphrey or Wrisberg, and it is blocking delivery of the avulsion, transect it.
- Drill 10-mm-long Steinmann pins from the anterior tibia and direct them posteriorly into the bed of the avulsion site, using the postero-lateral capsular opening to protect the deeper structures. Pass right-angle curets through the intercondylar notch to deepen the bed and allow countersinking of the avulsed fragment.
- Drill holes in the bone fragment and pass #2 or #5 nonabsorbable sutures through them. Then put the sutures in suture passers that have been placed through the holes previously drilled in the tibia. Pull these sutures through the tibial drill holes and tie them anteriorly while applying an anterior drawer with the knee flexed to 90°.
- Then place the knee in a splint in full extension, using the taut posterior capsule to prevent tibial rollback from gravity, which will occur if the knee is held in flexion. Use the splint for 6 to 8 weeks, but remove it daily to perform range-of-motion exercises as outlined in the postoperative rehabilitation protocol.

**TWO-BAND AND TWO-FEMORAL-TUNNEL RECONSTRUCTION OF THE PCL**

We believe that there is excellent biomechanical evidence to support the theory that the PCL acts primarily as two separate functional bundles, with the anterolateral or anterocentral portion of the ligament acting predominantly in flexion and the posteromedial or posterior oblique portion of the ligament acting predominantly in extension (15). Because of the size of the sites of origin and insertion of the PCL, reconstruction of the ligament using a single graft requires that only one of these two bundles be reconstructed.

The majority of researchers to date have preferred to reconstruct the anterolateral or anterocentral portion of the ligament and have recommended tensioning the graft at 90° of flexion (7,70). This method reduces the posterior drawer as measured at the time of surgery, but laxity seems to develop with time. We feel that the laxity occurs as this portion of the PCL tightens with flexion and loosens with extension. Because the majority of functional activities are performed at less than 70° of flexion, the graft is subjected to posterior stresses at flexion angles that are significantly less than those at which it was tensioned. The result is cyclic fatigue and lengthening of the graft.

The posterior and posterior oblique portions of the PCL contain some fibers that exhibit isometric behavior under certain conditions, but placement of a 10- to 11-mm graft at the sites of origin and insertion of these fibers results in a large portion of the graft being outside the anatomic boundaries of the PCL.

We prefer to reconstruct both bundles of the PCL and pass two separate grafts through two separate femoral tunnels. These grafts are then passed through a single tibial tunnel, with the anterolateral or anterocentral graft being tensioned at 90° of flexion and the posteromedial/posterior oblique graft being tensioned at 30° of flexion, as described below.

The technique of PCL reconstruction involves 11 steps. Attention to detail and satisfactory performance of each of these steps in the proper order is necessary to ensure a satisfactory result.

- **Step 1:** Perform and document a complete examination of the knee under anesthesia.
- **Step 2:** Perform an arthroscopic inspection of the knee joint. Following the examination under anesthesia, prepare and drape the knee and insert a 30° arthroscope via a medial peripatellar portal. We do not use a tourniquet for any of our repairs. Make this portal with a vertical stab wound along the medial border of the patellar tendon at the level of the inferior pole of the patella, with the knee in approximately 30° of flexion. Inspect the knee in a systematic fashion, with particular attention to the medial and patellofemoral compartments. Substantial involvement of these compartments with degenerative changes is a relative contraindication to PCL reconstruction. Inspect the intercondylar notch, and identify the site of injury to the PCL. Chronic cases of PCL injury often show only laxity of the ligament, which may be most evident as diminished tension of the ligament at its insertion site into the tibia. There may also appear to be abnormal laxity of the anterior cruciate ligament, which is usually due to the abnormal posterior position of the tibia and which is eliminated with placement of the proximal tibia into its normal position with respect to the distal femur.
- **Step 3:** Harvest the graft from the central third of the patellar tendon. Harvest of the graft at this point in the procedure allows subsequent creation of a central portal through the fat pad at the site of the defect in the patellar tendon, and this portal will be used both to debride the remnant of the PCL from the femur as well as to position the tibial guide for the tibial tunnel. Extend the incision along the medial border of the patellar tendon both proximally and distally and define the medial and lateral borders of the patellar tendon. We prefer to harvest a 10-mm-wide graft from the central third of the patellar tendon and take 10-mm-wide, 20-mm-long grafts from both the patella and the tibial tubercle. Prepare the graft to allow easy passage through 10-mm tunnels and place three #6 Ethibond
sutures through each end of the graft.

- Step 4: Debride the PCL remnant from the femur. Reinsert the arthroscope into the knee through the medial peripatellar portal and introduce the motorized shaver through the defect left by harvest of the patellar tendon. Debride the origin of the PCL from the medial femoral condyle. Preserve a portion of these fibers during the debridement; they are a valuable landmark for later tunnel placement. Preserve the curved ridge on the medial femoral condyle; it is also a helpful landmark because no PCL fibers occur posterior to this point.

- Step 5: Debride the tibial insertion site of the PCL through a postero medial portal created at the level of the junction of the proximal medial tibia with the posterior portion of the medial femoral condyle. Advance the arthroscope into the intracondylar notch and insert the motorized shaver through the postero medial portal. Debride with the shaver always facing toward the tibia to avoid inadvertent damage to the posterior capsule or neurovascular structures. Identify the tibial fovea. Define it using a curved shaver placed through the central fat pad portal, followed by use of an angled curette. Fully visualize the insertion site of the PCL to ensure proper placement of the tibial guide pin and to avoid popliteal artery or tibial nerve damage during subsequent drilling.

- Step 6: Create the tibial tunnel (Fig. 90.12). Once the site of insertion of the PCL has been fully identified, drill a guide pin from the anterior tibia, approximately 12 to 15 mm distal to the site of graft harvest from the tibial tubercle into the center of the insertion of the PCL. This entry point is quite important because it creates a rather vertical tunnel that eases graft passage into the tibia and also facilitates tensioning of the graft. It also avoids creating an oblique hole at the exit site of the tunnel in the tibia. Drilling a hole that enters medial or lateral to the tibial tubercle creates an oblique exit hole in the tibia fovea and may result in excessive medial or lateral placement of the graft. Run a 10-mm reamer over the guide wire, followed by a 12-mm reamer. Keep the arthroscope in the postero medial portal during reaming to ensure that neither the guide pin nor the reamers penetrate the knee joint. Once the tibial tunnel has been reamed, debride the foveal site of any remaining tissue. Next pass a #5 ethibond suture through the tibial drill hole and out the central fat pad portal. This suture will be used during passage of the graft into the tibia tunnel.

![Figure 90.12](ideal site for the tibial tunnel, which enters the tibia distal to the site of graft harvest from the tibial tubercle and exits the proximal tibia in the center of the insertion site of the PCL.)

- Step 7: Creation of the femoral tunnels (Fig. 90.13 and Fig. 90.14). Drill the femoral tunnels using the remaining fibers of the PCL on the medial femoral condyle as a guide. We drill a 10-mm anterior/proximal tunnel and an 8-mm posterior/distal tunnel, keeping the tunnels separated by a 3- to 4-mm bony bridge. Use a 00 curette to make marks in the medial femoral condyle at the desired tunnel sites. Insert the anterior/proximal tunnel guide pin in the intracondylar notch at the 10:30 position in a left knee (the 1:30 position in a right knee), approximately 6 mm posterior to the articular surface of the medial femoral condyle. Place the posterior/distal tunnel approximately 5 mm posterior and 5 mm distal to the anterior/proximal tunnel, taking care to keep the tunnel sites within the anatomic site of origin of the PCL. Both tunnels must be entirely anterior to the ridge in the medial femoral condyle (see Step 4, above). Make an incision over the vastus medialis muscle at the level of the adductor tubercle and elevate the fibers of the vastus medialis anteriorly. Use a vector guide to place a pin from the region of the adductor tubercle into the desired position of the anterior/proximal tunnel and drill with a 10-mm reamer over this guide. Drive a second guide pin from a separate site in the medial femoral condyle into the desired site of the posterior/distal tunnel and drill with an 8-mm reamer over this guide pin. Make sure that an adequate bony bridge separates these two tunnels. Pass two separate #5 ethibond sutures (which will be used later for graft passage) through these tunnels and out the central fat pad portal.

![Figure 90.13](ideal sites for the positions of the femoral tunnels, as viewed from the side of a left knee with the lateral femoral condyle removed.)

- Step 8: Harvest the hamstring or quadriceps tendon graft that you will use to reconstruct the posteromedial/posterior oblique portion of the PCL. Depending on your preference, use either the quadriceps tendon or the semitendinosus tendon. If you use the quadriceps tendon, make a separate vertical incision centered over the superior pole of the patella. Identify the quadriceps insertion into the patella and harvest an 8-mm wide, 20-mm-long bone plug from the patella. Take an 8-mm-wide strip of quadriceps tendon that runs the length of the tendon. If the quadriceps tendon is excessively thick, harvest only the superficial lamina of the tendon. Place a #5 nonabsorbable braided suture through the tendon, which will be used to fix the tendon to the tibia.

- The semitendinosus tendon may be used instead of the quadriceps tendon. Harvest it in standard fashion, using the distal end of the original incision. Double the tendon over itself to form a double-stranded graft and fix it in the femur using either a standard button or an Endobutton (if an endoscopic technique is chosen).

- Step 9: Pass the grafts into the femur (Fig. 90.15). Pass the grafts into the femoral tunnels using the previously placed sutures through the central fat pad portal and the femoral tunnels. Place the quadriceps or semitendinosus graft first and then fix it at the medial femoral condyle using either a simple button (open technique) or an Endobutton (endoscopic technique). Following femoral fixation of this graft, pass the patellar tendon graft into the femur and fix it in a similar fashion.
Step 10: Pass the grafts into the tibia (Fig. 90.16 and Fig. 90.17). Once both grafts have been fixed at the medial femoral condyle, pass them through the central fat pad portal and into the tibia. Use the previously placed suture through the tibial tunnel. A graft passer (Depuy), which encloses the grafts and provides a smooth surface to slide through the tibial tunnel, facilitates the process. We have found that application of an anterior drawer at the time of graft passage into the tibia helps the graft to turn the corner at the proximal part of the tibial tunnel.

Step 11: Fix the grafts. The final step in the procedure is fixation of the grafts to the tibia. Fix the patellar tendon graft first. Tension it at 90° of flexion with an anterior drawer test. Tie the sutures from the patellar bone plug over a screw and washer and tighten them at the end of the procedure. Tighten the quadriceps or hamstring graft at 30° of flexion and tie these sutures over the same screw as those from the patellar tendon graft. Then irrigate the wounds and close in routine fashion. Begin a standardized rehab protocol on the first postoperative day. The patient is usually discharged from the hospital on the second postoperative day.

BICEPS FEMORIS TENODESIS

Perform the procedure with a proximal thigh tourniquet and the patient in the supine position. Prep the leg and drape it free. Arthroscope the knee, and treat any injury to meniscal or ligamentous structures before doing the posterolateral surgery.

Flex the knee to 90° and make a lateral curvilinear incision centered proximally over the lateral femoral epicondyle and progressing distally to the interval between Gerdy's tubercle and the fibular head (Fig. 90.18). Develop a posterior subcutaneous flap. Identify the common peroneal nerve posterior to the biceps tendon and protect it throughout the procedure.

Split the iliotibial band parallel to its fibers from its midsubstance at the level of the lateral femoral epicondyle to its distal insertion (Fig. 90.19). Dissect the distal attachment of the iliotibial band free from the intermuscular septum to permit later passage of the biceps tendon. Strip any muscle fibers attached to the biceps femoris tendon distally so as not to interfere with the tenodesis (Fig. 90.20). Leave the lateral collateral ligament and its origin from the inferior half of the lateral epicondyle undisturbed. Use a ⅛-in. osteotome to create a trough centered in the upper half of the lateral epicondyle, measuring 1 cm in width and 3 cm in length. Insert a 3.2-mm guide wire for a 7.0-mm cannulated cancellous screw into the trough, starting at the point anterior to the most proximal edge of origin of the lateral collateral ligament (Fig. 90.21). Drill the wire medially and slightly cephalad to avoid any tunnels used in cruciate ligament reconstruction.
POSTEROLATERAL CORNER RECONSTRUCTION

- Pass the biceps tendon beneath the inferior portion of the iliotibial tract and over the guide wire. Place a retractor around the transferred tendon to protect it from being cut by the threads of the screw (Fig. 90.22). Tighten the cancellous screw and a spiked ligament washer while tensioning the graft with the knee flexed to 30° and the tibia internally rotated (Fig. 90.23). The tip of the screw should engage the opposite cortex. Close the wound in routine fashion over a drain and place the leg in an extension splint. Allow weight bearing to tolerance and begin range-of-motion exercises at 6 weeks. Remove the screw and washer at 6 months.

- Use the same incision as for biceps tenodesis. Divide the midportion of the iliotibial tract longitudinally in similar fashion. Retract the biceps tendon and lateral head of the gastrocnemius from the posterior tibia and fibula.

- Drive a Kirschner (K-) wire through the tibia from anterior to posterior, entering just below Gerdy’s tubercle and exiting just medial to the midsection of the fibular head at the posterolateral corner of the tibia. This maneuver will place the tunnel at the musculotendinous junction of the popliteus (Fig. 90.24). Drive a K-wire into the lateral epicondyle at the anterior superior aspect of the popliteal fossa. Use a suture through the tibial tunnel and then tie it to the K-wire to determine isometry as the knee is taken through a range of motion. The K-wire is ideally located when excursion of the suture is 3 mm or less through a full range of motion (Fig. 90.25). Once proper tunnel location is determined, drive a 10-mm reamer to a depth of 25 mm in the lateral epicondyle.
Fashion an Achilles tendon allograft with the calcaneus bone plug measuring 10 × 25 mm. Weave #5 nonabsorbable suture through the proximal end of the tendon to assist in graft passage. Fix the bone plug in the lateral epicondyle with a 7 × 25-mm interference screw. Pass the tendon medial to the iliotibial band and through the tibial tunnel from posterior to anterior. Put the knee through a range of motion to pretension the graft. Fix the graft to the proximal tibia with the knee flexed 30° and internally rotated. Provide fixation with two staples (Fig. 90.26) or with the #5 suture tied over a screw and washer if the graft is too short.

FIBULAR COLLATERAL LIGAMENT RECONSTRUCTION

- If significant varus laxity exists after reconstruction of the posterolateral corner, reconstruct the fibular collateral ligament using patellar tendon allograft or autograft.
- Fashion a 10-mm graft with a 20- to 25-mm bone plug. Make a bony trough of similar dimensions in the lateral epicondyle. The inferior aspect of the trough should not extend beyond the inferior aspect of the lateral epicondyle (Fig. 90.27). Alternatively, a 10-mm tunnel can be created at the lateral epicondyle. Secure the bone block with a screw and washer for trough fixation or a 7-mm interference screw for tunnel fixation.

Make a transverse tunnel from anterior to posterior at the base of the fibular head (Fig. 90.27) with a ¼-in. drill bit. Protect the peroneal nerve during this procedure. Split the 10-mm graft longitudinally into two 5-mm strips and pass #0 suture through the tendon ends to allow graft passage. Pass the free tendon ends in opposite directions through the fibular tunnel and suture the ends to one another over the fibular head while applying a valgus force to the knee. Then close the longitudinal rent in the graft, which allows further tensioning (Fig. 90.26).
POSTOPERATIVE REHABILITATION

We divide the postoperative rehabilitation following PCL reconstruction into five phases: (a) immediate postoperative phase (first 2 weeks after surgery), (b) maximum protection phase (weeks 2 to 6), (c) controlled ambulation phase (weeks 6 to 12), (d) light activity phase (weeks 12 to 16), and (e) return-to-activity phase (weeks 16 to 24).

In the immediate postoperative phase, encourage the patient to bear 50% of weight as tolerated using two crutches and to perform ankle and hip exercises and knee extensions from 60° to 0°.

During the maximum protection phase, proceed with full weight bearing, multiangle quad isometrics at 60°, 40°, and 20°, leg press and squats from 0° to 60°, and well-leg bicycling. By week 4, range of motion should be to 90°, and bicycling can be encouraged for range of motion and endurance. Begin pool exercises at week 5.

The controlled-ambulation phase aims to increase quad strength by initiating swimming, closed-kinetic-chain rehabilitation, and a stretching program. By week 12, begin lateral step-ups, cycling for endurance (30 minutes), hamstrings curls from 0° to 60° with low weight, and a walking program.

The light-activity phase continues with the above exercises and allows a light running program. By 5 to 6 months after the surgery, the patient should be performing plyometric exercises as well as agility and balance drills and may return to sport when KT-2000, isokinetic testing, and functional testing are satisfactory.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

The rupture of multiple knee ligaments in conjunction with extensive capsular, meniscal, chondral, and extraarticular tendon injury comprises a potentially devastating condition. The spectrum of injury can range from multiplanar laxity to frank dislocation of the knee. Of foremost concern is the potential for neurovascular injury. Popliteal artery injury requires emergent multidisciplinary evaluation and treatment. Once perfusion of the limb has been assured, the orthopaedic surgeon faces a major task to stabilize the joint, restore a functional range of motion, and minimize, if not prevent, future degenerative changes of the joint.

VASCULAR AND NEUROLOGIC CONSIDERATIONS

The popliteal artery, tethered proximally by the adductor hiatus and distally by the fibrous arch of the soleus, traverses the popliteal fossa adjacent to the posterior capsule of the knee (Fig. 91.1). These attachments create a bow string effect, rendering the artery susceptible to injury whenever the knee dislocates or even whenever multiple ligaments are torn (4,10,21,22,25,34). Approximately one third of knee dislocations have associated arterial injury, with anterior and posterior dislocations having the highest incidence, approaching 40% (7). Posterior knee dislocation, in which the tibia is driven posteriorly into the popliteal fossa, can directly contuse or lacerate the artery, whereas anterior dislocation, a result of excessive knee hyperextension, can result in complete arterial rupture or injury confined to the intimal lining, producing immediate or delayed thrombosis (10,21,22,25). Occlusion or rupture of the popliteal artery jeopardizes perfusion of the lower extremity in the vast majority of patients because of the inadequate collateral circulation about the knee (23).

![Figure 91.1. Anterior and posterior views of the popliteal artery with its collateral circulation.](image)

The posterior tibial and common peroneal nerves spanning the popliteal fossa are less rigidly fixed than the artery. This may account for a slightly lower incidence (approximately 25% overall) of nerve trauma in reported series (9,10,17,18,30,31,32 and 33). Injury is most likely to involve the peroneal nerve, although injury of the posterior tibial nerve can occur (38). Kennedy found that as little as 15° of hyperextension caused stretching of the peroneal nerve because of the cam-like effect of the lateral femoral condyle against the closely positioned nerve (16). Complete disruption or severe stretching with the nerve remaining macroscopically intact can occur. Good and Johnson (6) have reported the natural history of nerve injuries based on published series to be as follows: 60% no improvement, 32% complete recovery, and 8% incomplete recovery (6,10,17,18,30,31,32 and 33).

DEFINITIONS

KNEE DISLOCATION

A knee dislocation usually results in injury to both cruciate ligaments and one collateral ligament. Occasionally, knee dislocation can occur with one of the cruciates remaining intact (1,10,17,29,36). Typically, a dislocation causes extensive capsular injury as well as injury to the menisci, articular cartilage, extensor mechanism, and other structures including the iliotibial band as well as popliteus, biceps, and pes anserine tendons. After dislocation, the tibiofemoral joint may spontaneously reduce and be normally aligned or may remain subluxated or dislocated.

COMBINED LIGAMENT INJURY
Combinations of one cruciate and one collateral ligament injuries occur, many of which also have extensive capsular injury. These patterns include:

- ACL + MCL
- ACL + MCL + medial capsule
- ACL + posterolateral complex (LCL, popliteus, arcuate complex)
- PCL + posterolateral complex
- PCL + MCL + medial capsule

**ETIOLOGY**

Most knee dislocations are caused by high-energy trauma such as motor-vehicle accidents, pedestrians being hit by cars, or contact sports (24, 28, 30, 32); however, high-energy forces are not a prerequisite for knee dislocation, as lower-energy trauma from a fall or stationary hyperextension can cause dislocation (10).

**CLASSIFICATION**

The dislocated knee has traditionally been classified according to the position of the tibia relative to the femur. Kennedy (10) identified five types of dislocation: anterior, posterior, medial, lateral, and rotatory (Fig. 91.2). Anterior and posterior dislocation account for the majority of cases.

**ANTERIOR DISLOCATION**

Anterior dislocation (Fig. 91.3) is produced by knee hyperextension with anterior displacement of the tibia relative to the femur. Kennedy observed tearing of the posterior capsule and PCL at an average of 30° of hyperextension. Continued hyperextension to 50° caused popliteal artery injury. Girgis observed that PCL injury occurred only following ACL rupture, which is consistent with clinical experience (5).

**POSTERIOR DISLOCATION**

Posterior dislocation (Fig. 91.4) results from a posteriorly directed force applied to the anterior tibia of the flexed knee (dashboard injury). Experimentally, posterior dislocation has been produced by the application of 75 to 100 in.-lb of torque to the tibia with the knee in 20° of flexion (10). Kennedy found this injury difficult to reproduce in cadaveric experiments because of the tethering effect of the extensor mechanism that blocked displacement. He noted that patellar tendon rupture was associated with experimentally produced posterior knee dislocation. Clinically, a direct blow to the anterior tibia with the knee flexed nearly 90° is the mechanism responsible for most posterior dislocations.

**MEDIAL, LATERAL, AND ROTATORY DISLOCATIONS**

Medial and lateral knee dislocations result from either direct valgus or varus forces applied to the proximal tibia. Kennedy noted that experimental reproduction was commonly associated with tibial plateau and supracondylar femur fractures. Clinically, medial and lateral dislocations have been observed in heavy laborers or victims of motor-vehicle accidents, mining accidents, and crush injuries (10).

Knee dislocations can have a mixed plane or rotatory component. This occurs when one element of the supporting structures remains intact, allowing the tibia to angulate and rotate relative to the femur. Of the rotatory types of injuries, posterolateral dislocation is important to recognize because it is often irreducible by closed
methods (8,23) (Fig. 91.5A, Fig. 91.5B). Reduction of this dislocation can be blocked by a buttonhole tear in the medial capsule, trapping the medial femoral condyle (Fig. 91.5C, Fig. 91.5D). This can result in a medial cutaneous skin furrow (35). This sign is an indication for immediate open reduction; delay may result in skin necrosis or further neurovascular compromise.

Figure 91.5. A: Anteroposterior radiograph of a posterolateral dislocation with marginal patellar fracture. B: Lateral radiograph of a posterolateral dislocation. C: Appearance of knee before reduction. D: Medial femoral condyle buttonholed through medial capsule, blocking closed reduction.

SPONTANEOUSLY REDUCED DISLOCATION

A knee can dislocate and then spontaneously reduce. The diagnosis may not be suspected because there is normal alignment and lack of excessive swelling. Diagnosis requires clinical demonstration of cruciate and collateral ligamentous injuries. A knee dislocation that has spontaneously reduced may demonstrate one or more of the following (35):

- Greater than 30° recurvatum (indicates PCL and posterior capsule disruption).
- Greater than 1 cm of anteroposterior (AP) excursion (indicates ACL and PCL tears), with soft endpoints.
- Lateral capsular sign (indicates ACL and lateral complex disruption).
- Large hematrhrosis or hematoma.

CLASSIFICATION BY LIGAMENT INVOLVEMENT

Although Kennedy’s scheme is helpful for understanding the mechanism of injury and applying reversing forces to effect closed reduction, a more useful classification identifies the structures that are torn and will need repair or reconstruction. Modified from Schenck to include associated capsular injury, the following are patterns of dislocation most often encountered (26):

1. ACL + PCL torn; MCL + LCL + capsule intact.
2. ACL + PCL + MCL + medial capsule torn; LCL + posterolateral intact.
3. ACL + PCL + LCL + posterolateral complex torn; MCL intact.
4. ACL + PCL + MCL + medial capsule + LCL + posterolateral complex torn.

Conceptually, this can be simplified to:

1. AP laxity; intact medial and lateral hinges.
2. AP laxity + medial laxity; intact lateral hinge.
3. AP laxity + lateral laxity; intact medial hinge.
4. AP laxity + lateral + medial laxity (global laxity).

CLINICAL ASSESSMENT

An algorithm for management of the dislocated knee is shown in Fig. 91.6.

Figure 91.6. Algorithm for management of the dislocated knee. ROM, range of motion.

KNEE DISLOCATED WITH INTACT CIRCULATION

Evaluation of the grossly malaligned knee requires immediate vascular and neurologic assessment of the limb, followed by gentle closed reduction. Because fractures of the distal femur and proximal tibia as well as knee dislocation can cause gross deformity, gentle reduction is similarly beneficial in improving circulation in these conditions. Gentle longitudinal traction is usually sufficient to effect reduction or at a minimum improve alignment. Lifting the femur anteriorly in addition to longitudinal traction is helpful to avoid further trauma to the popliteal structures in the instance of an anterior dislocation. At this point, reassess the pedal pulses and repeat the neurologic exam. If pulses are present and bilaterally symmetric, split the knee in 5° of flexion, avoiding hyperextension, and obtain radiographs. Once this is completed, methodically and gently assess the knee for ligamentous laxity (Fig. 91.7, Fig. 91.8 and Fig. 91.9). Apply AP stress at 30° of flexion. Check varus–valgus laxity at 0° and 30° of flexion. If significant ligamentous injury has occurred, there will be abnormal tibial excursion and soft endpoints. If the collateral ligaments are intact but stretched (grade II sprain), return of intrinsic varus–valgus stability will be noted after reduction of the dislocation. Have the patient attempt to actively extend the knee even with some assistance while you palpate anteriorly for any defect in the extensor mechanism. An arteriogram (Fig. 91.10) in the radiology suite is necessary to exclude complete thrombosis, a small laceration, or an intimal injury. Obtain immediate consultation from a vascular surgeon if any abnormality is noted (see below). Admit the patient for observation of peripheral circulation and potential compartment syndrome and formulate the plan for surgical repair.
Figure 91.7. Gentle valgus stress testing in extension reveals medial complex injury.

Figure 91.8. Gentle varus stress testing in extension indicates lateral complex injury.

Figure 91.9. Recurvatum of involved extremity, as compared to the contralateral extremity, indicates posterior laxity.

Figure 91.10. Postreduction arteriogram reveals popliteal artery disruption.

KNEE DISLOCATED WITH ABNORMAL CIRCULATION

Immediate consultation with a vascular surgeon is needed for any of the following: abnormal distal pulses before or after attempted reduction, fullness in the popliteal area, open injury, or irreducible dislocation. Arteriography is usually performed in the operating room in expectation of popliteal exploration. This saves valuable time, as opposed to obtaining the arteriogram in the radiology suite. The return of distal pulses following reduction does not negate the urgency of further vascular evaluation. Return of distal pulses following closed reduction has been reported in the presence of complete popliteal artery disruption (9, 16, 22, 25).

Revascularization is most successful when performed in the first 6 to 8 h after injury (2). It has been shown that after this time interval, irreversible muscle damage and gangrene occur, even if blood flow is reestablished (19). When revascularization is performed within 6 h, there is an 87% limb survival rate (7). Conversely, treatment of a popliteal vascular injury after 8 h has been reported to have an amputation rate as high as 85% (7).

Although these time limits have been well established, a successful and timely repair does not guarantee limb survival. Other factors such as age, the presence of an open wound, associated crush injuries, fractures, and extent of damage to the collateral circulation may affect the results. Delayed revascularization may be successful on occasion. Because ischemic tolerance is variable, delayed revascularization (from 36 h up to 4 days after injury) has led to limb survival (3, 12). Therefore, the need for amputation should be evaluated on an individual basis and not performed prematurely if there is any potential for revascularization.

The usual vascular repair consists of a reversed interpositional saphenous vein graft, harvested from the contralateral limb. On completion of revascularization, a full four-compartment fasciotomy must be performed (4), followed by maintenance of the reduction of the knee. This requires cooperation between the orthopaedic and vascular surgeons to ensure protection of the vascular repair while facilitating treatment of the knee instability.

KNEE DISLOCATION, SPONTANEOUSLY REDUCED

Consider the patient with multiplanar knee laxity to have sustained a knee dislocation. These injuries have a similar incidence of neurovascular complications as do knees that present with gross deformity. Therefore, perform an examination as described above for the dislocated knee with intact circulation. We routinely obtain arteriograms for these patients, although satisfactory assessment using Doppler pressure measurements (ankle/arm pressure ratios) has been reported (34).

COMBINED KNEE LIGAMENT INJURY

The diagnosis of injuries to the cruciate ligament(s) and the collateral ligament(s) is usually obvious. It is crucial to establish whether there is accompanying injury to
either the posterolateral complex (PLS) or the medial complex [medial capsule and posterior oblique ligament (POL)]. Although ACL + MCL is a common injury pattern and does well with initial nonoperative treatment for the MCL followed by ACL reconstruction alone, untreated injury to the other medial structures (capsule and POL) can compromise an ACL reconstruction. Extensive injury to the medial capsular-ligament complex is indicated by:

- Greater than 5 mm valgus opening in full knee extension.
- Increased external tibial rotation at 30° of knee flexion.
- An increased anterior drawer test at 90° of flexion while in external rotation.

Similarly, extensive injury to the posterolateral corner (PLS) is characterized by:

- Increased (>10°) side to side external tibial rotation at 30° of flexion.
- Varus opening 5 mm in full extension.
- Anterior tibial translation in full extension greater than when in flexion (when ACL torn).

Because of the extensive soft tissue injury with these injuries, use a well-padded Robert-Jones (R-J) dressing incorporating medial and lateral splints with the knee in 5° of flexion. This is superior to a knee immobilizer. Subtle peroneal nerve injury (in situ injury) may accompany posterolateral disruptions. Although motor function can be difficult to grade accurately in the acute setting, decreased sensation in the first dorsal web space may be a clue to such injury. Monitor the patient in hospital for at least 24 h for possible vascular injury and remain alert to the potential for compartment syndrome. Early primary repair of a capsular injury typically has an outcome superior to reconstruction performed for chronic instability. Ideally, undertake surgical repair by 14 days, although surgery can still be successful as late as 3 weeks postinjury.

**IMAGING STUDIES**

After reduction, obtain planar radiographs. At a minimum, an AP and a lateral in extension are necessary to determine if tibiofemoral alignment has been restored and can be maintained in a splint. Posterior subluxation can be difficult to detect, and, especially if nonoperative treatment is considered, a comparison view with the normal knee can be helpful. Oblique and tunnel views may demonstrate subtle avulsions and fractures. Stress radiographs are not routinely performed in acute cases but can be used to document instability in chronic cases.

Magnetic resonance imaging (MRI) is helpful to evaluate the articular cartilage and menisci as well as subtle posterolateral complex injury because the popliteus tendon and other lateral structures can be well visualized. Often MRI will show the type of cruciate injury (avulsion vs. midsubstance) that is helpful in preoperative planning of the type of repair or reconstruction (Fig. 91.11).

**Figure 91.11.** Magnetic resonance image demonstrating midsubstance PCL rupture (A) and ACL tibial avulsion (B).

**TREATMENT**

The goals of treatment are to:

- Ensure perfusion of the lower limb.
- Stabilize the knee joint while restoring functional range of motion (ROM).
- Minimize the development of posttraumatic joint degeneration.

Treatment of the dislocated knee can be divided into methods that rely on prolonged immobilization to achieve stability and those that allow early mobilization by primarily repairing or reconstructing torn structures. Immobilization choices include casting, casting supplemented with transarticular Steinmann pins transfixing the tibia to the femur, and external fixation bridging the knee joint. Another method is “olecranization” of the patella, which transfixes the patella to the tibia, preventing posterior tibial subluxation while allowing limited motion of the knee. All of these methods rely on indirect healing of ligaments, capsule, and muscles supplemented by scar formation during a period of immobilization. Methods that promote mobilization of the knee and limb involve surgical repair with limited or comprehensive reconstruction.

**IMMobilization METHODS**

**Casting or Bracing**

After reduction and arteriogram, position the knee in 5° of flexion using a well-padded R-J dressing incorporating splints, extending from the proximal thigh to include the foot. Elevate the extremity, monitor the patient for 24 to 48 h in hospital, and then apply a groin-to-toes long leg cast in 5° of flexion or properly fit a long leg functional brace. Obtain radiographs to ensure that alignment is normal. Continue immobilization for 4 weeks and then begin range-of-motion exercises. This method is suitable for patients who are inactive or uncooperative either because of other injuries or personality or who decline surgical treatment.

**Casting and Supplemental Steinmann Pin**

If the reduction cannot be maintained by splints alone, reduce the knee under regional or general anesthesia and insert a single large-diameter Steinmann pin into the upper tibia starting medial to the tibial tuberosity and under fluoroscopic control advance it into the intercondylar notch to engage the lateral part of the distal femur in the metaphyseal region. The knee must be reduced before the pin is seated in the femur; perform a lateral radiograph if the fluoroscopic image is not clear. Use supplemental casting as described above. Disadvantages of this technique include the need for removal of the pin and the possibility of pin breakage with motion.

**“Olecranization” of the Patella**

This technique involves insertion of two parallel Steinmann pins from the superior pole of the patella to exit the inferior pole and engage the anterio most portion of the intercondylar eminence on the tibia. This prevents posterior subluxation; however, with excessive motion of the knee, the pins can break or erode through the articular surface of the patella. Therefore, we rarely use this method of stabilization.

**External Fixation**

This is an effective method to maintain alignment of an unstable knee that does not rely on hardware traversing the interior of the joint. Its major indication is to treat the open dislocation where repeated wound procedures are necessary. The major disadvantage is that motion is sacrificed, and because of the passage of pins into the anterior or lateral femur, quadriceps adhesions are likely to develop. We prefer to remove the fixator at 3 to 4 weeks if wound healing is satisfactory, and, provided the knee is stable, start motion in a hinged brace. If the knee is unstable, then once motion is regained, perform arthroscopic assisted ACL and PCL reconstruction as described in Chapter 89 and Chapter 90.
SURGICAL REPAIR AND RECONSTRUCTION

Indications

Absolute indications for surgical treatment include open and irreducible dislocations. Relative indications include a redislocating or subluxating knee despite splinting and a knee dislocation or multiple ligament injuries in an active patient. Surgery is contraindicated in uncooperative patients and in patients likely to be unable to successfully rehabilitate the knee after surgery (e.g., patients with concomitant head trauma or severe polytrauma). Treat this group by immobilizing the knee initially, followed by reconstructive surgery if needed at the time their other injuries have resolved.

Key Considerations

Developing a preoperative plan requires specific questions to be answered:

- When to perform surgery?
- What type of skin incision(s) to use?
- How to treat cruciate and collateral ligament, and capsular tears?
- What to do with the nerve injury?
- What is the role of arthroscopy?

Timing of Surgery

Surgery can be performed immediately, early in the postinjury phase (up to 21 days), or months later. The advantages of performing surgery within a 21-day period is that structures can be discretely identified and repaired; once stability is achieved, motion of the knee at least on a limited basis can be initiated; and articular injuries can be precisely identified, which can be helpful in prognosticating outcome as well as guiding rehabilitation. Unless otherwise indicated (see below), there is no advantage in surgery performed immediately versus 7 to 21 days postinjury. This short delay allows ample preoperative monitoring of limb perfusion, promotes resolution of soft-tissue swelling, and allows the surgeon to put together a well-thought-out operative plan. Usually after a 48-h period of observation, the patient can be discharged home with the knee splinted. Forewarn the patient about the signs of delayed thrombosis and the possible need for urgent readmission, and schedule elective repair of the knee ligaments about 14 days after injury.

Exceptions to this regimen are open dislocations, irreducible dislocations, and dislocations redislocating or subluxating after splinting. Immediate surgery is performed in instances of dislocations associated with open injuries and irreducible dislocations. For open dislocations, irrigate and debride the wounds and joint as for an open fracture and then apply an external fixator to maintain reduction. For irreducible dislocations, perform open reduction, close the wound, and splint the knee. We prefer to wait 10 to 14 days before performing definitive surgical repair. If vascular repair is necessary, ligament surgery can be delayed up to 3 weeks if needed. This is because the extreme medial incision used by vascular surgeons does not allow adequate exposure of the joint without the mobilization of a large subcutaneous flap. In the face of compromised circulation, this can impair wound healing. Perform surgery within 5 to 7 days for dislocations that subluxate despite proper splinting.

Skin Incision

If the posterolateral complex is torn and/or the peroneal nerve is injured, use a midlateral incision for exposing these structures together with a medial parapatellar skin incision for any medial knee and cruciate injuries, maintaining at least a 7 cm bridge of skin between the two incisions (Fig. 91.12 and Fig. 91.13). If the lateral structures are intact, then a longitudinal midline anterior incision can be used to expose the posteromedial corner, medial side, as well as the intercondylar region and remainder of the interior of the joint.

Cruciate Surgery

Repair avulsion-type injuries, especially where the PCL is avulsed from the femur, by advancing the ligament stump into its bony attachment. Treat midsubstance PCL tears by primary reconstruction with a patellar tendon bone (PTB) graft and midsubstance ACL tears with doubled semitendinosus and gracilis grafts. An alternate method advocated by Shelbourne et al., is to reconstruct only the PCL, leaving the ACL to be reconstructed on a delayed basis in the hope of minimizing postoperative stiffness (28). In our experience it is difficult to tension the PCL adequately while maintaining normal tibiofemoral alignment in the absence of the ACL. We utilize Clancy’s method of simultaneously tensioning both ACL and PCL at 20° of knee flexion to achieve neutral positioning of the knee (see Chapter 90).

Collateral Ligaments and Capsule

Repair avulsions with suture anchors and reapproximate midsubstance tears with nonabsorbable suture. Repair of the capsule is crucial for protecting the cruciate repairs. The capsule is often avulsed from one side of the joint. Drill holes placed in the AP plane are satisfactory for posterior capsule avulsions. Fix the capsular and collateral ligament repairs with the knee in 30° of flexion; secure the posterior capsule with the knee at no greater than 15° of flexion to avoid limitation of knee extension.
KNEE WITH ACL + PCL + MCL + MEDIAL CAPSULE TORN; POSTEROLATERAL COMPLEX INTACT

Perform repairs and reconstructions using open technique utilizing arthroscopic guides and instruments as described below. Most knee dislocations involve significant capsular and collateral tears that require open surgery. In these cases, we prefer to use arthroscopy for diagnosis only and cruciate reconstruction can be performed in selected cases when the ACL and PCL ligaments are torn and the capsule and the collaterals are for the most part intact, the knee usually requires less than 5 min, provided that gravity inflow is used, and therefore poses little risk of fluid extravasation into the calf. Although arthroscopic hemorrhage. Satisfactory results have been reported when surgery was delayed for 3 months (37).

**Arthroscopy**

Once capsular tears have partially healed (10–21 days), arthroscopy can be used to identify associated articular and meniscal injuries. Arthroscopic inspection of the knee usually requires less than 5 min, provided that gravity inflow is used, and therefore poses little risk of fluid extravasation into the calf. Although arthroscopic cruciate reconstruction can be performed in selected cases when the ACL and PCL ligaments are torn and the capsule and the collaterals are for the most part intact, most knee dislocations involve significant capsular and collateral tears that require open surgery. In these cases, we prefer to use arthroscopy for diagnosis only and perform repairs and reconstructions using open technique utilizing arthroscopic guides and instruments as described below.

**Surgical Techniques**

**Knee with ACL + PCL + MCL + Medial Capsule Torn; Posterolateral Complex Intact**

- Repeat the ligamentous examination of the knee to confirm the preoperative assessment. Administer a prophylactic antibiotic (cefazolin). Prep and drape both lower extremities free to determine correct AP positioning using lateral radiographs and observation of the normal knee's tibial plateau to femoral condyle relationship. Tourniquet use should be cleared by the vascular surgeon in cases with arterial injury and repair. Inflate the tourniquet no higher than 275 mm Hg.
- With the knee slightly flexed, start the incision 5 cm above the patella, extending it over the medial border of the patella, parallel to the medial aspect of the patellar tendon, and ending at the border of the pes anserinus, about 6 cm below the medial joint line. Open the patellar retinaculum incorporating any tears, beginning at the superior border of the pes anserine tendons near the tibial tubercle. Identify the MCL and its site of rupture (usually from the medial femoral epicondyle or midsubstance) and continue to open the retinaculum along the sartorius toward the anterior corner of the knee to the vastus medialis muscle.
- At this point, swing the retinacular incision proximally toward the adductor tubercle in the interval between the medial gastrocnemius and the posterior oblique ligament. Open the joint anteriorly alongside the medial border of the patellar tendon. Retract the fat pad inferiorly, the MCL and medial capsule medially, and the patellar ligament and patella laterally to inspect the notch. It may be necessary to extend the capsular incision proximally to the midpoint of the patella.
- Remove any chondral debris and inspect the medial meniscus. To visualize the lateral meniscus, flex the hip to 90° and position the knee in the figure-of-four relationship. Tourniquet use should be cleared by the vascular surgeon in cases with arterial injury and repair. Inflating the tourniquet no higher than 275 mm Hg.
- For femoral avulsions of the ACL, use a drill guide to insert, from outside in, parallel 3 mm Kirschner wires at the femoral insertion of the ACL (at the junction of the roof and wall of the notch, 2 to 3 mm anterior to the over-the-top position). Using a suture hook, deliver the sutures previously placed in the torn ligament to the lateral femur.
- If the ACL is avulsed from the tibia or femur, place at least two sutures (#2 nonabsorbable) through the avulsed end of the ligament. For a tibial avulsion, pass the sutures through parallel drill holes placed in the curetted central bed of the tibial ACL attachment, using a tibial aiming device (Fig. 91.16). If the ACL is avulsed from the femur, maximally flex the knee and similarly place sutures in the torn end.
- If the nerve is grossly intact, do nothing other than decompress any external fascial bands, as there is approximately a 40% chance of spontaneous partial or complete recovery (6,10,17,30,31,32 and 33). Postoperatively, incorporate an ankle–foot orthosis (AFO) into the hinged knee brace (Fig. 91.14). If the nerve is disrupted (Fig. 91.15), tag the ends for later grafting. Unlike transection injuries, the extent of damage cannot be accurately assessed immediately because of proximal and distal hemorrhage. Satisfactory results have been reported when surgery was delayed for 3 months (37).

**Peroneal Nerve**

If the nerve is grossly intact, do nothing other than decompress any external fascial bands, as there is approximately a 40% chance of spontaneous partial or complete recovery (6,10,17,30,31,32 and 33). Postoperatively, incorporate an ankle–foot orthosis (AFO) into the hinged knee brace (Fig. 91.14). If the nerve is disrupted (Fig. 91.15), tag the ends for later grafting. Unlike transection injuries, the extent of damage cannot be accurately assessed immediately because of proximal and distal hemorrhage. Satisfactory results have been reported when surgery was delayed for 3 months (37).

**Arthroscopy**

Once capsular tears have partially healed (10–21 days), arthroscopy can be used to identify associated articular and meniscal injuries. Arthroscopic inspection of the knee usually requires less than 5 min, provided that gravity inflow is used, and therefore poses little risk of fluid extravasation into the calf. Although arthroscopic cruciate reconstruction can be performed in selected cases when the ACL and PCL ligaments are torn and the capsule and the collaterals are for the most part intact, most knee dislocations involve significant capsular and collateral tears that require open surgery. In these cases, we prefer to use arthroscopy for diagnosis only and perform repairs and reconstructions using open technique utilizing arthroscopic guides and instruments as described below.

**Figure 91.14.** Hinged knee brace incorporating AFO to maintain ankle in neutral position in patient with knee dislocation and complete peroneal nerve palsy.

**Figure 91.15.** Stretch-and-tear injury to the common peroneal nerve results in “mop ends” that are difficult to reapproximate.

**Arthroscopy**

Once capsular tears have partially healed (10–21 days), arthroscopy can be used to identify associated articular and meniscal injuries. Arthroscopic inspection of the knee usually requires less than 5 min, provided that gravity inflow is used, and therefore poses little risk of fluid extravasation into the calf. Although arthroscopic cruciate reconstruction can be performed in selected cases when the ACL and PCL ligaments are torn and the capsule and the collaterals are for the most part intact, most knee dislocations involve significant capsular and collateral tears that require open surgery. In these cases, we prefer to use arthroscopy for diagnosis only and perform repairs and reconstructions using open technique utilizing arthroscopic guides and instruments as described below.

**Surgical Techniques**

**Knee with ACL + PCL + MCL + Medial Capsule Torn; Posterolateral Complex Intact**

- Repeat the ligamentous examination of the knee to confirm the preoperative assessment. Administer a prophylactic antibiotic (cefazolin). Prep and drape both lower extremities free to determine correct AP positioning using lateral radiographs and observation of the normal knee’s tibial plateau to femoral condyle relationship. Tourniquet use should be cleared by the vascular surgeon in cases with arterial injury and repair. Inflating the tourniquet no higher than 275 mm Hg.
- With the knee slightly flexed, start the incision 5 cm above the patella, extending it over the medial border of the patella, parallel to the medial aspect of the patellar tendon, and ending at the border of the pes anserinus, about 6 cm below the medial joint line. Open the patellar retinaculum incorporating any tears, beginning at the superior border of the pes anserine tendons near the tibial tubercle. Identify the MCL and its site of rupture (usually from the medial femoral epicondyle or midsubstance) and continue to open the retinaculum along the sartorius toward the anterior corner of the knee to the vastus medialis muscle.
- At this point, swing the retinacular incision proximally toward the adductor tubercle in the interval between the medial gastrocnemius and the posterior oblique ligament. Open the joint anteriorly alongside the medial border of the patellar tendon. Retract the fat pad inferiorly, the MCL and medial capsule medially, and the patellar ligament and patella laterally to inspect the notch. It may be necessary to extend the capsular incision proximally to the midpoint of the patella.
- Remove any chondral debris and inspect the medial meniscus. To visualize the lateral meniscus, flex the hip to 90° and position the knee in the figure-of-four relationship. Tourniquet use should be cleared by the vascular surgeon in cases with arterial injury and repair. Inflating the tourniquet no higher than 275 mm Hg.
- For femoral avulsions of the ACL, use a drill guide to insert, from outside in, parallel 3 mm Kirschner wires at the femoral insertion of the ACL (at the junction of the roof and wall of the notch, 2 to 3 mm anterior to the over-the-top position). Using a suture hook, deliver the sutures previously placed in the torn ligament to the lateral femur.
- If the ACL is avulsed from the tibia or femur, place at least two sutures (#2 nonabsorbable) through the avulsed end of the ligament. For a tibial avulsion, pass the sutures through parallel drill holes placed in the curetted central bed of the tibial ACL attachment, using a tibial aiming device (Fig. 91.16). If the ACL is avulsed from the femur, maximally flex the knee and similarly place sutures in the torn end.
- If the ACL is avulsed from the tibia or femur, place at least two sutures (#2 nonabsorbable) through the avulsed end of the ligament. For a tibial avulsion, pass the sutures through parallel drill holes placed in the curetted central bed of the tibial ACL attachment, using a tibial aiming device (Fig. 91.16). If the ACL is avulsed from the femur, maximally flex the knee and similarly place sutures in the torn end.

**Figure 91.16.** Avulsion of ACL from tibia held with #2 nonabsorbable suture. Notice anteromedial capsular stripping, exposing proximal tibia.
If tibial avulsion of the PCL has occurred, enter the joint through the usual tear or make an incision in the posteromedial capsule. Incise the inferior aspect of the posteromedial capsule along the upper tibia and identify the PCL bed. Place a tibial aiming device for the PCL through the notch into the tibial attachment site, staying on the lateral edge, and drill a 3 mm Kirschner wire to this point from the anteromedial tibia, starting immediately below the tibial tubercle. Make sure that there is sufficient spread between tibial tunnels for the PCL and an ACL graft to avoid convergence or fracture. Protect the contents of the popliteal fossa with a retractor or fingertip through the posteromedial incision. Overream the guide wire with a 6 mm cannulated drill and deliver the sutures placed in the torn end of the PCL through this tunnel with a suture-passer.

- Reconstruct a midsubstance rupture of the PCL with an autogenous patellar tendon bone graft as described in Chapter 90.
- Provisionally tension and fix the cruciate repairs/reconstructions simultaneously using an assistant. Position the knee in 20° of flexion to restore the normal tibiofemoral relationship. Lateral radiography of the injured and uninjured knees may be needed.
- Sutures around posts or tied over buttons allow repeated tensioning and graft retightening as needed to restore normal AP tibiofemoral position.
- After the cruciate ligaments have been provisionally addressed, repair the medial structures. Avulsion of the posteromedial capsule is usually from the tibia. Repair with sutures (#2 nonabsorbable) placed from anterior to posterior along the upper medial tibial plateau. If needed, reflect the retinacular layer from posterior to anterior to expose the MCL at the level of the medial femoral epicondyle and the joint. Gentle distal retraction of the pes tendons permits inspection of the MCL tibial attachment.
- Inspect the medial capsule and ascertain the status of the medial meniscus from inside the joint, using both the anteromedial and posteromedial capsular incisions. Repair the meniscus to the medial capsule (coronary ligaments) with vertical mattress sutures (#1 nonabsorbable).
- Fix MCL avulsions from the tibia or femur with a 6.5 mm cancellous screw and a soft-tissue spiked washer. Repair midsubstance injuries with whipstitch sutures (#2 nonabsorbable). Repair the posteromedial capsule incision or injury in vest-over-pants fashion using horizontal mattress sutures (#2 nonabsorbable) in 15° of flexion.
- Release the tourniquet before final closure. Close the iliotibial band, medial retinacular layer, and anteromedial capsular incision with absorbable sutures. Place drains in the subcutaneous layer. Reapproximate the subcutaneous layer with minimal sutures, and close the skin.

KNEE WITH ACL + PCL + FCL + POSTEROLATERAL COMPLEX TORN; MEDIAL STRUCTURES INTACT

- Use positioning, draping, and tourniquet as described above.
- Make two incisions—midlateral and anteromedial—separated by more than 7 cm. Make the lateral incision first, starting 7 cm proximal to the lateral femoral epicondyle in line with the posterior edge of the iliac-tibial band (ITB). With the knee flexed to 90°, curve the incision distally to pass over the anterior portion of the fibular head.
- With blunt dissection, elevate the posterior subcutaneous flap in the proximal part of the incision. Identify the peroneal nerve as it exits under the biceps; distally, the ITB and biceps insertion are frequently avulsed or torn (Fig. 91.18). Follow the peroneal nerve distally. If it is stretched, divide the fascial roof at its entrance into the anterolateral leg near the fibula. If it is torn, tag the ends for delayed reconstruction.

![Figure 91.17](image)

**Figure 91.17.** A: Avulsion of PCL from femur with long stump of ligament remaining intact. B: Avulsed PCL after repair through bony tunnel with sutures tied over 14 mm button.

- Identify tears in the lateral capsule. This often is avulsed as a single sheet from one side of the joint. If not avulsed, open the capsule behind the PCL, which is avulsed or torn in its midsubstance. Repair the meniscus using vertical mattress sutures (#1 nonabsorbable).
- Find and repair the popliteus. It may be necessary to make an anterolateral capsular incision if the popliteus is torn from its femoral attachment. When opening the thin layer of capsule overlying the popliteus, avoid injury to it. Repair the popliteus and capsule with suture anchors (#2 nonabsorbable).
- Approach the medial knee as previously described using a curved skin incision centered over the medial femoral epicondyle and extending along the midmedial leg, maintaining at least 7 cm between the two incisions.

KNEE WITH ACL + PCL + MCL + MEDIAL CAPSULE + FCL + POSTEROLATERAL TORN (GLOBAL LAXITY)

- Perform surgery as described above using two incisions.
- In this injury expect to find the extensor mechanism torn. Inspect the patellar tendon using gentle subcutaneous dissection from the anteromedial incision. Repair midsubstance rupture of the patellar tendon with interrupted whipstitches (#2 nonabsorbable) reinforced by two or more interlocking, horizontal weaving (Krackow) sutures (#2 nonabsorbable) placed through drill holes in the patella or tibial tubercle, depending on where the tear is located (Fig. 91.19, B). Repair avulsion injuries with similar interlocking sutures passed through drill holes in the respective bony attachment. Tighten all repairs to allow knee flexion to 60°. Do not use cerclage slures.

![Figure 91.19](image)

KNEE WITH ACL + PCL TORN; MEDIAL AND LATERAL HINGES INTACT

- This injury is not operated early. After motion has been regained (>120°), perform open or arthroscopic assisted reconstruction of both ligaments.
- These procedures are described in detail in Chapter 89 and Chapter 90. A few technical aspects deserve emphasis, however.
- For the ACL, use autogenous PTB, allograft PTB, or Achilles.
- For the ACL, use autogenous hamstring, allograft PTB, or an achilles tendon graft. We prefer autogenous PTB for the PCL and doubled hamstrings for the ACL.
- Position the tibial tunnels carefully to avoid convergence. Place the PCL tibial tunnel inferior to the tibial tuberosity in the midline and the ACL tibial tunnel medial, midway between the posteromedial tibial brim and the tibial tuberosity.
- Pass the PCL graft first. Tension the grafts simultaneously with the knee at 20° of flexion. By using suture fixation around a post or over a 14-mm button, readjustment of graft tension is easy to accomplish. Simultaneous tensioning of the grafts aids in defining the neutral position of the tibia in relation to the femur.

POSTOPERATIVE CARE

- At the completion of surgery, position the knee in near extension, avoiding hyperextension and using splints incorporated into a bulky R-J dressing from foot to groin. Elevate the extremity for 48 h, monitoring the neurovascular condition of the limb and remaining alert to the potential for compartment syndrome.
- Remove the drains by 48 h and replace the bulky dressing with a well-fitting, adjustable-hinged knee brace that is locked at 0° but allows motion from 0° to 45° during exercises. Do not allow the knee to hyperextend.
- At 2 to 3 days, start continuous passive motion (CPM) for 2-h sessions four times daily. Flexion in this range does not significantly increase strain in the PCL. If flexion to 90° or less is desired, the CPM machine can be used in the hospital and preferably for an additional week at home.
- At 10 to 14 days, increase passive flexion to 60°. Use passive heel slides for flexion, but active extension can be performed from 60° to 0°.
- At 3 weeks start intermittent passive flexion to 90°, but restrict active flexion to 60°.
- Keep the brace locked in extension at all other times for the first 6 weeks, during which partial weight bearing is allowed. During this 6 weeks, use electrical stimulation, isometric quadriceps exercises, and straight-leg raises.
- At 6 weeks unlock the brace for unlimited motion if the patient can control the knee with the quadriceps. At 6 weeks the brace is not necessary for sleeping or sitting in a safe environment.
- Continue bracing for another 2 to 3 weeks or longer, depending on patient preference. Thereafter, perform exercises in accordance with the protocol(s) for cruciate ligament injuries (Chapter 88 and Chapter 90).

MODIFICATIONS OF POSTOPERATIVE CARE

Extensor Mechanism Injury

Do not allow straight-leg raises or any active extension of the knee until 6 weeks. Delay resistive quadriceps exercises until 3 months.

Posterolateral Complex Repair

Use non-weight-bearing activities for the first 6 to 8 weeks to minimize distraction of the lateral compartment with weight bearing. Use passive knee flexion only for the first 6 weeks, and no resistive hamstring exercises should be performed until 3 months after surgery.

RESULTS

There are no long-term prospective studies to evaluate the results of the different methods of treating ligamentous injuries in the dislocated knee. The long-term incidence of degenerative arthritis remains unknown. Historically, a stable knee with 85° of flexion was considered a good result, and 105° was regarded as an excellent result. More recent studies have demonstrated improved results with early surgical repair/reconstruction and immediate motion (4,20,26,27,31).

Based on our experience with 35 knee dislocations or near dislocations, we have observed acceptable short- and midterm results (2 to 10 years) following early surgical repair/reconstruction of all torn ligaments combined with early motion of the knee in cooperative, active patients. With this regimen, 80% of operated patients can be expected to have 1+ or less total AP laxity and only trace to 1+ mediolateral knee laxity with an arc of motion of 120°. This has allowed return to activity in nearly 75% of patients, although only 50% are able to resume preinjury activity levels without symptoms.

PITFALLS AND COMPLICATIONS

Arterial occlusion has the potential to lead to amputation acutely and the development of chronic claudication if perfusion is incompletely restored. Nerve injury frequently results in sensory and motor abnormalities of the leg and foot. As previously noted, the majority of patients (60%) do not experience any improvement over time. Weakness or absent peroneal nerve function leaves the patient with a foot drop that usually requires an AFO, although tendon transfers or hindfoot arthrodesis may be used in certain cases.

Stiffness (arthrofibrosis), chronic knee instability, and degenerative joint disease are the major problems the orthopaedic surgeon must be prepared to deal with after initial injury and treatment. Although early motion minimizes the risk of stiffness, the intense fibroblastic response to injury may not be held in check. As many as 30% to 50% of patients may require treatment intervention to regain motion (20,27,31). If loss of extension is 10° or more at 4 weeks, and/or flexion is less than 90° and not improving at 6 weeks, then arthroscopic release of adhesions and gentle manipulation should be tried. Delay in treatment of limited motion in the postoperative period makes later treatment more difficult and often requires extensive soft-tissue releases.

Treat chronic instability with reconstruction of the cruciate ligaments and repair and reftting of the capsule and collateral ligaments. When repair is not possible, perform Clancy’s biceps tenodesis for posterolateral instability (14) and reconstruct the MCL with a free hamstring or PTB graft in cases of chronic medial laxity (13). Progression of degenerative changes may require osteotomy or even joint replacement at a later time.

SUMMARY

Knee dislocation is a complex injury that often requires a multidisciplinary approach. After satisfactory stabilization of the patient and treatment of any associated vascular injury, obtaining a stable knee with functional motion is the next goal. This requires accurate clinical assessment and good imaging to formulate an operative plan. It is important that the patient understand that a normal knee is not expected following such a severe injury. With technically well-performed surgical repair and/or reconstruction, early motion can be initiated, which is crucial in reducing postoperative stiffness. In our experience this provides the best short-term results.

Nonetheless, the patient remains at risk for developing degenerative changes over time.

1 ACL, anterior cruciate ligament; MCL, medial collateral ligament; LCL, lateral collateral ligament; PCL, posterior cruciate ligament.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: * , classic article; #, review article; 1, basic research article; and +, clinical results/outcome study.

The rate of complications associated with knee surgery has decreased dramatically with the development and evolution of operative arthroscopy. Although all surgical procedures have some inherent risk, these less invasive techniques, when combined with meticulous surgical techniques, have a low incidence of problems. When complications do occur, early recognition and prompt intervention are essential.

INCIDENCE AND CAUSES

The overall incidence of complications with knee arthroscopy is low, with published rates ranging from 0.6% to 8.2%. It is not surprising to note that both the frequency and severity of complications are lower with experienced arthroscopic surgeons.

In 1988, Small (25) reported a 19-month prospective Arthroscopy Association of North America study, which included 8,791 arthroscopic knee procedures performed by 21 surgeons with an average of 11 years of experience in operative arthroscopy. Based on rigid criteria, the overall rate of complication for knee arthroscopy was 1.85%. Hemarthrosis was the most common complication, followed by infection, thromboembolic disease, and anesthetic problems.

Among arthroscopic procedures in this study, lateral retinacular release had the highest rate of complications. Allograft and synthetic anterior cruciate ligament (ACL) reconstruction, synovectomy, and abrasion arthroplasty also had an increased incidence of problems. Meniscus repair (both inside-out and outside-in) had a lower rate of complication than meniscectomy.

CONDITIONS AND MANAGEMENT

HEMARTHROSIS

Postoperative hemarthrosis is the most common complication of knee arthroscopy, comprising 60% of all complications. It occurs in approximately 1% of all cases and is seen most often after lateral retinacular release (6,25). Other procedures that frequently result in hemarthrosis include arthroscopic synovectomy, meniscectomy, and ACL reconstruction. Use of a tourniquet can be associated with postoperative hemarthrosis because unrecognized intraoperative bleeding may occur (6,23). A coagulopathy (ASA-induced, liver dysfunction, or hemophilia) may first present as abnormal intraoperative or postoperative bleeding.

Treatment for hemarthrosis consists of brief immobilization, elevation, compressive dressing, and isometric quadriceps exercises. Oral nonsteroidal antiinflammatories may also be of benefit. Resume range-of-motion exercises once swelling is decreased. A tense effusion may require aspiration, but repeated aspiration may lead to septic arthritis and is not recommended. Rarely, a large hematoma may require repeat arthroscopic surgery. Consider checking a coagulation screen and a bleeding time in patients with unexplained bleeding.

INFECTION

Infection following arthroscopic knee surgery is uncommon and occurs with an overall incidence of 0.24% (25). Risk of infection is increased with perioperative use of intraarticular steroids, with any break in sterile operative technique, in immunocompromised patients, and in patients with skin lesions in the operative field. Postpone elective arthroscopic procedures in any patient who has wounds, scrapes, or skin rashes that involve the operative field. Avoid intraoperative injection of corticosteroids because this has been associated with an increased rate of infection (1,11). In those patients who have had recent intraarticular corticosteroid injections, it is preferable to postpone elective procedures for 3 to 4 weeks to minimize the risk of infection.

The effectiveness of routine prophylactic antibiotics for knee arthroscopy remains unproven, but it should be considered for high-risk patients and with more extensive procedures (21). I recommend antibiotics for procedures that involve implants, internal fixation, osteotomy, or osteoplasty.

Delay in diagnosis is common with postoperative knee infections, and a high index of suspicion is necessary to ensure early recognition (6,25). Immediate and aggressive treatment is required in any suspected septic knee to avoid severe articular damage. Make the diagnosis of infection by knee joint aspiration, sending the fluid for immediate Gram stain, cell count, and differential. Order routine aerobic and anaerobic cultures as well. Once an infection is confirmed, urgent surgical debridement, arthroscopically or open, and postoperative intravenous antibiotics are required. The type and duration of antibiotic therapy are dependent on the causative organisms and severity of infection. In some cases repeat surgical debridements may be necessary. With infection after ACL reconstruction, graft retention may be possible, but arthroscopic debridement alone may be inadequate because extraarticular spread of infection is frequent (5).

DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM

All surgical procedures of the lower extremity have some risk of thromboembolic complications. Knee arthroscopy, however, is associated with a lower risk than more extensive procedures such as total knee arthroplasty. Small (25) reported the overall incidence of deep venous thrombosis (DVT) with arthroscopic knee surgery to be 0.15%, and the incidence of pulmonary embolism (PE) was 0.05%. Of the 12 DVTs that occurred in Small’s series, eight involved cases in which the tourniquet was used for an average of 50 min or more. Demers et al. (6) also reported a significantly higher incidence of DVT after knee arthroscopy with prolonged tourniquet times, suggesting a relationship between tourniquet use and thrombosis.

Although rare, fatal pulmonary embolism has been reported in young healthy patients after routine elective outpatient knee arthroscopy (20). A high index of suspicion is necessary to ensure early identification and treatment of thrombosis to reduce the risk of embolization. Noninvasive studies (or venography) are mandatory in any patient with suspected postoperative thrombosis. Initiate anticoagulation immediately for all patients with positive tests. The presence of a negative test in a patient with the clinical picture of DVT does not exclude the possibility of an evolving DVT, and careful follow-up with repeat studies is required. A ruptured popliteal cyst may mimic
thrombosis, but this diagnosis can also be established with noninvasive studies such as ultrasound or MRI.

Risk factors for postoperative thromboembolism include prolonged tourniquet use, hypercoagulable states (malignancy, oral contraceptives), morbid obesity, congestive heart failure, and history of prior thrombosis or pulmonary embolism (6,21).

Prevention of postoperative thromboembolic complications is best accomplished with early mobilization, range-of-motion exercises, and weightbearing as soon as possible. Aspirin may be of benefit for routine postoperative prophylaxis. Consider coumadin or low-molecular-weight heparin in patients at increased risk.

ANESTHETIC COMPLICATIONS

Anesthetic complications may occur with procedures using general, regional, or local anesthesia. Intubation may result in laryngeal, dental, or temporomandibular joint (TMJ) injury. Jaws may be injured by use of retractor blades or neuromuscular blockade may result in hypoventilation or malformations. If intraoperative cardiac arrhythmia, infarction, or arrest may occur, although rarely. Spinal or epidural anesthesia can lead to spinal headache, transient spinal block, or epidural hematoma. Local anesthetics in high doses may produce systemic effects. A careful preoperative assessment by both surgeon and anesthesiologist can identify those patients at increased risk and minimize the likelihood of anesthetic-related complications.

INSTRUMENT FAILURE AND BREAKAGE

Most intraoperative instrument failure and breakage is preventable and results from improper instrument use or maintenance. With proper surgical technique and instrument care, the incidence of instrument breakage is minimal (6.25). Arthoscopic instruments, unlike osteotomes and elevators, are fragile and delicate and require special care and handling.

Never use an arthroscopic instrument that is dull, worn, or bent. If a broken metallic instrument fragment (or guide pin) does become an intraarticular loose body, a prepackaged sterile magnetic probe (for example, the “Golden Retriever,” Instrument Makar, Okemos, MI) is an indispensable tool. Intraoperative x-ray or fluoroscopy may occasionally be required to localize elusive fragments. Most broken instrument and pin fragments can be removed arthroscopically; although an accessory portal may be helpful, an arthotomy is seldom necessary.

REFLEX SYMPATHETIC DYSTROPHY

Reflex sympathetic dystrophy (RSD) of the knee is most common in patients who have sustained diffuse crush injuries or direct injuries to motor and sensory nerves. Patients who develop RSD often have some predisposing diathesis that is triggered by an injury. It may present initially as pain out of proportion to injury or physical findings.

Although many tests, including three-phase bone scan, can support the diagnosis of RSD, the diagnosis is made primarily on clinical grounds. The findings of delayed recovery with severe diffuse pain, skin sensitivity, and erythema should suggest early RSD (12,15,18). Treatment consists of sympathetic blockade, gentle restoration of joint motion to prevent fibrosis, and, if possible, elimination of the underlying painful stimulus.

Careful surgical technique and careful patient selection are the best means to avoid RSD. Inaccurate arthroscopic portal or meniscus repair incision placement can injure the infrapatellar branch of the saphenous nerve and incite RSD (15,18). Avoid prolonged immobilization, prolonged protected weightbearing, and diagnostic arthroscopy in patients with severe diffuse knee pain.

ARTHROFIBROSIS, PATELLA INFERA, AND LOSS OF MOTION

Arthrofibrosis of the knee can develop after trauma or elective surgery. It is seen most commonly with anterior cruciate injuries, particularly when ligament reconstruction is performed early following injury (3,22). The initial phase of arthrofibrosis begins with adhesions, which, if allowed to progress, lead to patellar entrapment, joint fibrosis, capsular contracture, and extracapsular scarring. Once patella infera has developed, permanent loss of motion is likely.

Treatment of arthrofibrosis is based on stage and severity (13). Early recognition and treatment are the best means to restore movement and function. In the prodomal stage (2 to 8 weeks), direct therapy at patellar mobilization and restoration of motion. Correct underlying causes of stiffness, such as graft impingement. Arthroscopic lysis of adhesions followed by gentle manipulation under anesthesia can relieve early patellar entrapment. A valuable technique involves using a blunt arthroscopic obturator in the superomedial portal to disrupt patellar adhesions. To maintain improvements in motion, postoperative epidural pain control combined with continuous passive motion (CPM) for 3 to 5 days is beneficial.

Once the active stage (8 to 20 weeks) of arthrofibrosis has developed, all patellar mobility has been lost, capsular contracture is established, and joint fibrosis has begun. At this stage, open surgical release is often required. When patella infera with severe limitation of motion is present, it is indicative of the burned-out stage. At this point, salvage procedures such as iliobibular osteotomy or patellar tendon lengthening may be necessary to improve knee flexion; however, do not expect restoration of normal motion (13).

Risk factors for developing arthrofibrosis include poor rehabilitation before surgery, early extensive ligament reconstruction, prolonged postoperative immobilization, older patients, associated fractures, and nonisometric graft placement (3,13,17,22). To prevent arthrofibrosis, postpone reconstructive procedures until knee motion has been restored following injury. At the time of reconstruction, it must be confirmed intraoperatively that full knee motion is possible, and postoperative immobilization should be avoided. Ligament reconstruction is performed early following injury (3,13,17,22). Arthroscopic instruments, unlike osteotomes and elevators, are fragile and delicate and require special care and handling.

LIGAMENT INJURIES

Iatrogenic ligament injuries occur most often when stress is applied to the knee during arthroscopy. The medial collateral ligament is most commonly injured, particularly when a rigid ligating device is used (5). In contrast, intraoperative cruciate ligament injuries are usually the result of instrumentation errors. Ligament damage may occur during notching and tunnel preparation for cruciate reconstruction. Aggressive motorized debridement combined with poor arthroscopic visualization may lead to significant ligament injury. Many misadventures, including patellar ligament resection, have been reported (2).

Intraoperative ligament injury can best be avoided by careful surgical technique. Visualization is better accomplished by accurate portal placement than by forceful ligament manipulation. Careful instrument placement under direct arthroscopic visualization will prevent inadvertent damage to ligaments and articular surfaces.

FRACTURES

Fractures of both the femur and tibia have been reported during knee arthroscopy (21,25). They are most often the result of excessive forceful manipulation of the leg but may also occur in pathologic bone. Before surgery, review a current set of knee radiographs (AP and lateral) in all patients scheduled for arthroscopic surgery to prevent instrument breakage or other bone pathology (6).

Technical errors during ACL reconstruction may lead to perioperative fracture. Eccentric or aggressive patellar tendon harvest from the anterior patellar cortex may lead to fracture. Do not violate the proximal third of the patella and minimize the use of mallets and osteotomes. I recommend autogenous grafting of the bone defect with tunnel reamings. With endoscopic femoral tunnel preparation, multiple guide-pin perforations of the femoral cortex produce a stress riser and may lead to postoperative fracture (27).

Manipulation of the stiff postoperative knee requires caution because overly aggressive manipulation may yield disastrous results. Patellar fractures, long-bone fractures, extensor mechanism ruptures, and avulsions have all been reported to occur (5,21,24,25). Significant force during manipulation is seldom required or beneficial.

SYNOVITIS AND SYNOVIAL FISTULA

Persistent synovitis following knee arthroscopy may occur from chemical irritation induced by glutaraldehyde (Cidex) residue, from mechanical irritation caused by retained debris or degenerative arthritis, from crystalline arthritis (e.g., gout, pseudogout), and with septic arthritis (7). Once infection has been excluded, treat chronic
Knee arthroscopy is a valuable but technically demanding procedure. Complex arthroscopic reconstructive procedures require a higher level of proficiency than routine procedures and may lead to complications when attempted by an inexperienced arthroscopist. Regard newly developed procedures and instrumentation with caution until the necessary motor skills have been acquired and surgical indications have been established.

Motor skills laboratories provide an excellent opportunity for improving technical skills and learning new procedures. The Orthopaedic Learning Center at the American Academy of Orthopaedic Surgeons in Rosemont, Illinois, offers a broad range of hands-on arthroscopic surgical courses utilizing cadaver specimens. This type of training should be considered by most surgeons as a prerequisite for performing new and complex arthroscopic procedures.

Many arthroscopic complications result from careless preoperative evaluation, poor surgical technique, and inadequate postoperative rehabilitation. Base all surgical indications on thorough clinical evaluation because surgery without a preoperative diagnosis is seldom fruitful. Although operative speed is not always an indication of technical ability, abort procedures that cannot be completed in a reasonable amount of time to avoid problems from excessive tourniquet time, fluid extravasation, or compartment syndrome. Although the actual deficit from a sensory nerve injury is usually minor, it may lead to neurona formation or trigger reflex sympathetic dystrophy.

The infrapatellar branch of the saphenous nerve is most commonly injured (18). It may be damaged by inaccurate portal placement or with a posteroomedial incision for meniscal repair. To minimize the risk of nerve injury with medial meniscus repair, use a posterior retractor, pass sutures with the knee extended using the anterolateral portal for suture placement, and tie suture under direct vision (26).

Motor nerve injuries are fortunately rare. Peroneal nerve injury may occur with lateral meniscus repair, but it has also been reported with both diagnostic arthroscopy and partial lateral meniscectomy (14,19). Perform operative procedures in the lateral compartment with the knee flexed in the figure-4 position, as the nerve is most easily injured by arthroscopic instruments with the knee extended (14). When repairing the lateral meniscal instruments to the risk of nerve injury by using a posterior retractor placed through a posterolateral incision, combined with suture passage from the anteromedial portal with the knee flexed (26).

Popliteal artery injury is rare and can be avoided with attention to the anatomy and proper surgical technique. Instrumentation of the posterior horn of the lateral meniscus must always be under direct arthroscopic visualization because of the close proximity of the popliteal artery. Prepare the tibial tunnel for PCL reconstruction only under direct arthroscopic observation to avoid guide-pin migration or overreaming. If a popliteal artery injury is suspected, an intraoperative vascular surgery consultation is mandatory.

AUTHOR’S PERSPECTIVE

Knee arthroscopy is a valuable but technically demanding procedure. Complex arthroscopic reconstructive procedures require a higher level of proficiency than routine procedures and may lead to complications when attempted by an inexperienced arthroscopist. Regard newly developed procedures and instrumentation with caution until the necessary motor skills have been acquired and surgical indications have been established.

Motor skills laboratories provide an excellent opportunity for improving technical skills and learning new procedures. CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; 1, basic research article; and +, clinical results/outcome study.

Ankle arthroscopy is an evolving technique that became widely available to the orthopedist only during the past 15 to 20 years. With major advances in technique and equipment over the decade of the 1990s, ankle arthroscopy has proved to be an indispensable tool for the surgeon to both diagnose and treat pathology of the ankle (55). Arthroscopy was first performed in Japan in 1918 by Takagi, who used a cystoscope to examine the intra-articular anatomy of a cadaveric knee (71). Kreuscher (45), in 1925, was the first American to report the use of an arthroscope in the knee. These early cystoscopes were cumbersome for articular use, with diameters of nearly 8 mm. Arthroscopy was considered not to be applicable to the ankle given the large diameter of these early instruments. However, a 3.5 mm arthroscope was invented in 1931. Soon after, in 1939, Takagi (71) published a standard arthroscopic examination of the ankle. Arthroscopy remained dormant, however, until the advent of fiberoptics, which afforded improved visualization potential. Watanabe (75) described the first ankle portal anatomy and portal placement in 1972 following 28 ankle arthroscopies. Chen (14,15) conducted the first large study with 67 clinical and 17 cadaveric ankle arthroscopies, including detailed descriptions of surgical anatomy. Owing in part to the innovation of such surgeons as Drez, Guhl, Andrews, Parisien, Ferkel, and others, and owing in part to the rapid advances in fiberoptics and general arthroscopic technology, ankle arthroscopy and its applications have advanced exponentially during the past 15 years. Small-joint arthroscopy and instrumentation have made the clinical application of ankle arthroscopy safer, more reproducible, and more widely accepted as a standard of care for certain disorders of the ankle. The advantages of direct visualization of intra-articular anatomy and treatment of pathology via percutaneous incisions about the ankle are numerous and potentially include decreased pain and morbidity, faster rehabilitation, and an earlier return to activities of daily living and athletics.

**CLINICAL EVALUATION AND IMAGING**

**HISTORY**

Each patient has a unique history, which often leads to a narrowed differential diagnosis. Common descriptions include pain, catching, grinding, giving way, and swelling. It is essential to determine whether the problem is acute or chronic, because this feature directly affects evaluation and treatment. If possible, attempt to define the etiology; unfortunately, this can be vague for chronic injuries. Find out what exacerbates or improves the symptoms. The type of shoewear that was worn at the time of injury or during the onset of a more insidious problem is important. Prior history, including prior ankle injuries, as well as a general medical history, can lead to a particular diagnosis. A family history may raise suspicion for certain congenital anomalies.

Pain is the most common complaint. Localize it to very specific areas, and note its association with particular maneuvers. In the lateral ankle, for example, differentiate between the pain at the syndesmosis, anterior talofibular ligament, or sinus tarsi. Locking is often confused with catching; however, these are two very separate entities. Locking generally indicates a mechanical block to motion secondary to a loose body, scarring, osteophyte, or some other abnormal intra-articular component. Catching generally indicates a tendon or cartilage abnormality affecting supple joint motion. Most important, give the patient the opportunity to tell you thoroughly in his or her own words what the chief problem is and to what extent this is incapacitating him or her.

**PHYSICAL EXAMINATION**

Begin with observation of the patient’s gait without shoes. Note any limp or asymmetry, and attempt to establish at what point in the gait cycle these abnormalities occur. Examine the general alignment of the lower extremities. Inspect the patient’s shoes and the wear of the sole. Check carefully foot and ankle alignment while weight-bearing and look for pes cavus or pes planus.

Next, seat the patient and inspect the ankle for swelling, contusion, or erythema. Palpate to elicit focal pain or tenderness. In chronic ankle sprains, look for tenderness at the syndesmosis, lateral ligaments, lateral gutter, or sinus tarsi. Posterior ankle pain is sometimes difficult to reproduce on examination; however, palpation can often differentiate between postero medial osteochondral lesions of the talar and injuries to the Stieda process or the os trigonum. Assess both passive and active range of motion with comparison to the opposite side. Normal motion is approximately 20° of dorsiflexion and 50° of plantarflexion. The normal range of subtalar motion noted by Isman and Inman (43) in cadaver specimens varied from 20° to 60° of total motion. Clinically, subtalor motion is very difficult to isolate and determine (50). If limits in dorsiflexion are noted, remember to flex the knee to determine the source of the limitation. Examine the heel and heel cord. Achilles tendon problems are common and may be noted on palpation by nodular thickening, with patients with chronic tendinosis. Assess muscle function.

Ligament testing is discussed in Chapter 95. Place the foot in plantarflexion, and invert the hindfoot while palpating the joint line to determine joint displacement and test the anterior talofibular ligament. Place the foot in dorsiflexion, and then invert the foot again while palpating the joint line for displacement to test the calcaneofibular ligament. Always compare with the contralateral side to determine if the laxity is pathologic or not.

Perform the anterior drawer test by holding the ankle in neutral and, with the tibia secured, pull the heel forward and internally rotate it while palpating the joint line.
Anterior displacement greater than 4 mm indicates a tear of the anterior talofibular ligament and may even indicate a double ligament tear, which includes the calcaneofibular ligament (27).

Injuries to the tibiofibular syndesmosis may be difficult to detect unless you have a high index of suspicion and specifically examine this structure. Perform the “squeeze test” by gripping the leg just above the midportion of the calf and squeezing on the fibular shaft. If distal pain is noted, then suspect an injury to the interosseous ligament and syndesmosis. Perform the “external rotation test” by applying an external rotation force to the ankle with the patient seated, with knees and ankles at approximately right angles. A syndesmosis injury results in pain over the anterior inferior tibiofibular ligaments or the inferior portion of the interosseous ligament.

**IMAGING**

Routine radiographs of the ankle include anteroposterior (AP), lateral, and mortise (20° internal oblique) views. On the AP view, the fibula should overlap the tibia approximately 6 mm. On the mortise view, look for widening of the medial clear space of more than 3 mm.

Stress x-ray studies may be done manually or by using a mechanical device, or jig. Comparison x-ray studies are essential because there is a large variation in normal ligamentous laxity. We use the Telos device to generate a reproducible amount of stress. Sausser et al. (67) as well as Chrisman and Snook (47) using the Telos device, found that a talar tilt of 10° or more when compared with the opposite normal side was associated with a lateral ligament instability in 99 percent of cases. Normal values of talar tilt range from 5° to 23° (65).

Flick and Gould (33) believed that an increase of 4 mm in the anterior drawer test showed instability in the anterior talofibular ligament, whereas Laurin et al. (49) consider an increase of more than 9 mm to be abnormal. In general, an anterior drawer of 5 mm is normal; 5 to 10 mm may be within normal, whereas over 10 mm is definitely abnormal.

Tomograms are occasionally helpful for evaluating nonunions, or the presence of arthrosis. However, with improved computerized tomography, plain tomograms are used far less. Arthrograms can be useful occasionally, but these images have been supplanted by magnetic resonance imaging (MRI) to evaluate ligament disruption. Ultrasound has limited applications to the ankle; however, it is an evolving technology that is useful for delineating cystic versus solid masses, and for locating foreign bodies and tendon tears (73).

Bone scans using technetium-99 have a high sensitivity and relatively low cost, which make them a useful screening tool for enchepathies, stress fractures, occult trauma, delayed unions, and any other pathology causing increased bone turnover. Gallium-67 and indium-111 may be useful in the detection of infection (30).

Computed tomography (CT) is excellent for delineating cortical outlines and changes in bony densities, and to detect osteochondral lesions, loose bodies, coalitions, and fractures of the hindfoot. Both feet can be imaged simultaneously to help determine asymmetry, however anatomy is better defined when only one extremity is imaged at a time.

MRI is the preferred study to image soft tissues around the ankle and to evaluate bone and soft tissue tumors, ischemic necrosis, infection, and ligament and tendon injuries. Controversy exists over the best imaging technique for osteochondral lesions of the talus. CT is better for cortical anatomy; however, MRI provides an accurate assessment of the cartilage (30).

**INDICATIONS AND CONTRAINDICATIONS TO ANKLE ARTHROSCOPY**

**INDICATIONS**

Diagnostic indications for ankle arthroscopy include unexplained pain, swelling, stiffness, instability, hemorrhage, locking, and popping. Therapeutic indications for ankle arthroscopy include articular injury, soft-tissue injury, bony impingement, arthrofibrosis, fracture, synovitis, loose bodies, osteophytes, osteochondral defects, arthrodesis, ankle instability, and ankle fractures.

**CONTRAINDICATIONS**

Relative contraindications for ankle arthroscopy include moderate to severe degenerative joint disease with restricted range of motion, significantly reduced joint space, severe edema, and tenuous vascular status. The absolute contraindications for ankle arthroscopy include localized soft-tissue infection and severe degenerative joint disease.

**SURGICAL TECHNIQUE**

The technique of ankle arthroscopy was originally adapted from knee arthroscopy, and shares similar equipment. However, the ankle joint is much smaller and tighter than the knee joint, which necessitates smaller instruments and a method of distracting the joint to maximize the working area. We prefer a 2.7 mm video arthroscope using both the 30° and 70° oblique lenses. With this setup, a lightweight chip camera is screwed directly onto the arthroscope. This method shortens the overall length than the knee joint, which necessitates smaller instruments and a method of distracting the joint to maximize the working area. We prefer a 2.7 mm video arthroscope using both the 30° and 70° oblique lenses. With this setup, a lightweight chip camera is screwed directly onto the arthroscope. This method shortens the overall length of the arthroscope and instruments to each portal while minimizing the risks of reentry. Standard instruments can be used; however, small-joint instruments are preferred. These instruments include 2.9 mm and 3.5 mm shavers and burrs, 3.5 mm and 4.5 mm ring and cup curets, 1.5 mm probes, 2.9 mm and 3.5 mm graspers and baskets, small osteotomes, rongeurs, and banana blades (Fig. 93.1 and Table 93.1).

**Figure 93.1.** Ankle arthroscopy instruments are both shorter and smaller than large joint instruments. Various biters, graspers, curets, probes, suction punches, and small joint drill guides (as shown here) have been developed for the ankle and are essential to the ankle arthroscopist. See Table 93.1 for a complete listing of instruments needed for the majority of arthroscopic ankle procedures.
It is very important to have a high inflow and outflow system in ankle arthroscopy without the added risks of a pump. This can be obtained with a gravity flow system using a third portal in the posterolateral position. A pump system can be used with caution, if necessary, to help with hemostasis and distention for visualization. Fluid extravasation can occur rapidly in the ankle, causing rapidly increased compartment pressure, particularly in the anterolateral compartment of the leg.

An ankle distraction device is very important in ankle arthroscopy to maximize the working area and ability to visualize the entire joint. Methods may be either invasive or noninvasive. Invasive distractors use pins in the tibia and hindfoot for mechanical distraction. These pins have fallen out of favor owing to the development of improved noninvasive distraction devices. At present, sterile disposable straps attach to a distraction system hooked to the operating table and provide excellent access to the ankle (Fig. 93.2).

**Figure 93.2.** The operative setup for ankle arthroscopy using soft-tissue distraction.

- Place the patient in the supine position with the hip flexed 45° to 50°, using a nonsterile thigh support and a tourniquet, which is used at the surgeon's discretion. Place a post against the greater trochanter to prevent external rotation of the hip (Fig. 93.3). With this setup, both anterior and posterior portals can easily be accessed without further manipulation of the patient's extremity.

**Figure 93.3.** The patient is secured in a thigh holder that is well padded with additional foam pads anterior as well as posterior. A side bolster is used just proximal to the thigh support to minimize external rotation.

- Outline the dorsalis pedis artery, saphenous vein, and anterior tibial and peroneus tertius tendons on the surface of the ankle with a marking pen.
- Attempt to mark the superficial peroneal nerve and its branches as it crosses the joint while holding the foot and toes in plantar flexion and inversion (Fig. 93.4). The superficial peroneal nerve is the structure most at risk during ankle arthroscopy. It divides into the intermediate and medial dorsocutaneous branches approximately 6.5 cm proximal to the tip of the fibula. The intermediate dorsocutaneous branch passes the joint line just anterior to the common extensors of the fourth and fifth digits. The medial dorsocutaneous nerve crosses superficial to the common extensor tendons, parallel to the extensor hallucis longus tendons.

**Figure 93.4.** By inverting and plantarflexing the foot, the superficial peroneal nerve can be palpated and the location noted. (Copyright 1996 by Lippincott-Raven Publishers. From Ferkel RD. *Arthroscopic Surgery: The Foot and Ankle.* Philadelphia: Lippincott-Raven Publishers:107, with permission. Illustration by Susan Brust.)

- Mark out the joint line and exsanguinate the extremity. Use a noninvasive ankle distractor, which is placed sterilely after prep and draping (Fig. 93.2).
- Do not overdistract the ankle, and remember to release the distraction partially after 1 hour to minimize the risk of nerve injury.
- See Figure 93.5A and Figure 93.5B for the standard portal placement.

**Figure 93.5.** Portals for ankle arthroscopy. A: Anterior anatomy and portals. The anterolateral and anteromedial are routinely used. B: Posterior anatomy and portals. saphenous nerve is 7.4 mm medial to the anteromedial portal (20).

- Use a #11 scalpel to make a vertical stab wound while palpating the anterior tibial tendon. Dissect with a mosquito clamp through the subcutaneous tissues and capsule.
- Insert a blunt trochar with the arthroscopic cannula into the ankle joint, and insert the arthroscope into the cannula.
- Distend the ankle with normal saline in a 50 ml syringe attached by intravenous (IV) tubing to the arthroscopic cannula.
- Establish the anterolateral portal next under direct vision, using an 18-gauge spinal needle. Branches of the superficial nerve that are most at risk average 6.2 mm away from this portal (20). The incision is usually lateral to the tendon of the peroneus tertius, but placement can vary depending on the pathology to be addressed. Transillumination can help avoid injury to the underlying structures.
- Establish the posterolateral portal in the soft spot just lateral to the Achilles tendon, approximately 0.5-inch above the tip of the fibula. This portal is made under direct vision using an 18-gauge spinal needle placed through the posterolateral portal under the transverse ligament.
- Make a stab incision and insert a blunt trochar at approximately 45° toward the medial malleolus, entering inferior and slightly medial to the transverse tibiofibular ligament. The lesser saphenous vein and sural nerve are at risk when establishing this portal. The sural nerve is posterior to the lesser saphenous vein and generally 6 to 9 mm anterolateral to this portal (20).
- Attach the inflow to the posterolateral portal initially and outflow through the arthroscopic cannula and IV tubing.
- The anterocentral, posteromedial, and trans-Achilles portals are not used due to the increased morbidity associated with them (20).
- Transmalleolar and transtalar portals can be used for arthroscopic drilling or for screw insertion.
- Perform a 21-point examination.

The intra-articular anatomy of the ankle can be confusing and disorienting. The 21-point examination was developed by Richard D. Ferkel (22) to establish a reproducible and thorough intra-articular examination of the ankle. It consists of an 8-point anterior examination, a 6-point central examination, and a 7-point posterior examination (Table 93.2). View initially via the anteromedial portal. Use switching sticks to view the ankle from all three portals to provide a complete examination. This method also provides the arthroscopist with a reproducible means of documenting pathology found at time of arthroscopy (Fig. 93.6, Fig. 93.7, and Fig. 93.8; see color Fig. 93.6B, color Fig. 93.7B, and color Fig. 93.8B).

POSTOPERATIVE CARE

The ankle is quite different from other joints in which we commonly use the arthroscope in regard to wound sealing and healing. Whereas not suturing portals at the knee can be advantageous, this is not the case at the ankle. Careful attention to wound closure is important. Close the portals with a 4-0 nylon, and then apply a compression dressing and short-leg posterior splint. Immobilization and elevation are important for the first 5 to 7 days postoperatively. If a compression stocking is used, it can be removed at 48 hours, dressings removed and bandages applied, followed by the stocking and splint. At 5 to 7 days, remove the splint and begin early motion with progressive weight bearing as tolerated, depending on the pathology treated.

PITFALLS AND COMPLICATIONS

There are many potential complications of ankle arthroscopy (Table 93.3). In a series of 612 cases, Ferkel et al. (25) found an overall complication rate of 9%, with injury to superficial sensory nerves the most frequent problem. The superficial peroneal nerve was involved in 15 cases, the sural nerve in six cases, and the greater saphenous nerve in five cases, and the deep peroneal nerve in one case. These complications were noted early in the development of the technique and are thought to be much lower using the technique described in the previous section. In this early study, Ferkel also reported complications with the invasive distractor, such as transient pain along the pin tracks, two stress fractures of the tibia, and one in the fibula secondary to the pin placement. Superficial wound infection was noted in six patients and deep wound infection in two patients. Compartment syndrome has not been reported.

In general, complications can be minimized with careful preoperative planning and patient selection, noninvasive distraction, meticulous surgical technique, the use of switching sticks to change portals, careful use of shavers by always pointing away from the capsule, and appropriate postoperative care. We use perioperative antibiotics routinely.

CONDITIONS AND RESULTS

SOFT-TISSUE LESIONS

Soft-tissue lesions account for 30% to 50% of problems around the ankle. Most soft-tissue problems are related to the synovium; however, the capsule and ligamentous tissues can also be a source of pathology. Some of the common synovial etiologies include rheumatologic, infectious, degenerative, posttraumatic and neuropathic disorders (9, 26-27, 35, 63). Capsular and ligamentous disorders tend to cause soft-tissue impingement located anterolateral, posterolateral, and in the region of the syndesmosis.

SYNOVITIS

Synovitis can be generalized to the entire ankle or localized to a specific anatomic area. Patients with nonspecific generalized synovitis of the ankle may present with swelling, aching, and soreness throughout. Trauma to the ankle is the most common cause; however, there may be no clear etiology. After a thorough workup and a sufficient course of conservative therapy, consider ankle arthroscopy. A high-flow volume system using a posterolateral portal for inflow is crucial in maximizing arthroscopic visualization. Depending on the findings, debride all synovitis, scar, or fibrosis. Treatment is essentially the same for both generalized and localized synovitis. Postoperatively, place the ankle in a short-leg splint for 1 week, followed by an elastic compression stocking and range-of-motion exercises with weight bearing as tolerated. Avoid active physical therapy for 2 to 3 weeks to allow soft-tissue healing and resolution of postoperative inflammation.

ANTERIOR SOFT-TISSUE IMPINGEMENT

Chronic ankle pain following an inversion injury is quite common. The discomfort is usually located anterolaterally. This lateral gutter is bordered by the talus medially, the fibula laterally, the tibia and syndesmosis superiorly, and the anterior inferior tibiofibular ligament inferiorly. In 1950, Wolin et al. (77) first described a “meniscoid” band of thickened tissue between the fibula and talus as a source of anterolateral pinching and potential pain. This mass was thought to originate from a torn joint capsule. Wailer (74) in 1982 described an anterolateral corner compression syndrome, which was similar to Wolin’s description but was proposed to be the result of recurrent inversion injuries. In addition to soft-tissue impingement, other causes of chronic sprain pain include osteochondral lesions of the talus, loose bodies, occult fractures, peroneal tendon subluxation or tears, tarsal coalition, subtalar pathology, and degenerative joint disease (18).

Ferkel et al. (26) have performed arthroscopies in more than 290 patients with persistent anterolateral symptoms following inversion injury of the ankle. Their evaluation of 75 of these patients treated with arthroscopic debridement following failed conservative therapy demonstrated good to excellent results in 63 (84%) patients, with an average follow-up of 34 months. Others have noted similar results (18, 47, 52, 62). The surgical findings generally include synovitis and fibrosis in the anterolateral gutter, with an occasional thickened band of tissue similar to the meniscoid lesion, as described by Wolin et al. (77) (Fig. 93.9).

Figure 93.9. Viewed from the anteromedial portal, anterolateral soft-tissue impingement with fibrosis and synovitis can be seen. (From Ferkel RD, Scranton PE Jr: Arthroscopy of the Foot and Ankle. J Bone Joint Surg Am 1993;75:1233. Copyright 1993 by The Journal of Bone and Joint Surgery, Inc., reprinted with permission.)

- Perform a careful ankle exam.
- Use 70° arthroscope from the anteromedial portal to look over the dome of the talus into the lateral gutter or view from the anterolateral portal and shave from
Osteochondral lesions of the talus (OLT) have been described as a transchondral fracture, an osteochondral fracture, osteochondritis dissecans, a talar dome fracture, and a flake fracture (3). Controversy regarding uniform terminology is due mostly to the lack of a widely accepted mechanism of injury. Berndt and Harty's (5) original description in 1959 proposed the term “transchondral fracture” of the talus secondary to trauma (1,12). Other authors (11) have concluded that because not all cases have a clearly defined traumatic insult, the etiology must be due to bone pathology such as idiopathic osteonecrosis. We prefer the term “osteochondral lesions of the talus” to describe these lesions.

The true incidence of these lesions is unknown, but the incidence of diagnosis of OLT in a group of patients with chronic ankle pain has been reported as high as 81% (23). The incidence of bilateral lesions is approximately 10% (2,6). Medial lesions are more common and tend to be located more posterior than lateral lesions, which are more anterior (2,13,34). Medial lesions are deeper, cup shaped, and usually undisplaced, whereas lateral lesions are thin, wafer shaped, and often displaced. A history of chronic lateral ankle pain is common, and depending on the extent of the lesion, symptoms of swelling, stiffness, and giving way are common.

The diagnosis can be confirmed with plain radiographs; however, Zinman et al. (78) reported CT scans to be superior to plain films for diagnosis and follow-up. Berndt and Harty (5) described a classification based on plain radiographs in which four stages were proposed based on the compression and displacement of the fragment. Ferkel and Saglione (31) proposed a classification based on CT appearance (Table 93.4), which corresponds to the Berndt and Harty system but also considers the integrity of the articular surface and the presence of subchondral cysts (Fig. 93.12). Anderson et al. (2) have also developed an MRI classification. Based on our recent study (32), we recommend that MRI be performed in cases of chronic pain with unclear etiology, whereas CT can be performed when an OLT is seen on plain x-ray studies. Ferkel and Cheng (23) have also reported an arthroscopic staging system to help predict clinical outcome (Table 93.4; Fig. 93.13; see color Fig. 93.13).

### SYNDESMOTIC IMPINGEMENT

Following injury to the syndesmosis, synovitis and exuberant scarring can be a source of impingement. Clinical diagnosis is difficult unless there is a high incidence of suspicion. At arthroscopy, the synovium is inflamed in this area and encompassing the anterior inferior tibiofibular (AITF) ligament, often extending into the distal tibiofibular joint. A fascicle of the AITF has been noted by Bassett et al. (4) to be an additional factor in impingement, particularly if it is associated with laxity of the anterior tibiofibular ligament.

- Carefully examine the ankle.
- Remove posterior synovitis and pathologic posterolateral synovial nodules.
- Debride tears of the posterior ligaments.
- Be careful not to injure flexor hallucis longus and neurovascular structures.

### POSTERIOR SOFT-TISSUE IMPINGEMENT

Posterior soft-tissue impingement can occur either independently or in conjunction with anterior soft-tissue impingement. Clinical evaluation and imaging are often not successful in identifying this entity. The diagnosis is usually made at the time of arthroscopy. The patients usually have a history of recurrent inversion injuries of the ankle. Symptoms may be more vague than in the patient with anterolateral impingement. Arthroscopic viewing from both anterior and posterior portals and distraction are essential in making the diagnosis (22).

Surgical findings in posterolateral impingement include hypertrophy or tearing of the posterior inferior tibiofibular ligament, transverse tibiofibular ligament, or the tibial slip (the tibial slip runs between the posterior inferior tibiofibular ligament and the transverse tibiofibular ligament) (23) or a pathologic “labrum” on the posterior lip of the tibia, causing impingement.

- Carefully examine the ankle.
- Remove posterior synovitis and pathologic posterolateral synovial nodules.
- Debride tears of the posterior ligaments.
- Be careful not to injure flexor hallucis longus and neurovascular structures.

### EVALUATION ALGORITHM

Figure 93.11 outlines a treatment plan to assist in decision making for patients with chronic ankle pain.

Figure 93.12. CT scan classification of osteochondral lesions of the talus: Stage I is a cystic lesion within the dome of the talus, intact roof. Stage IIA is a cystic lesion with communication to the talar dome surface. Stage IIB is an open articular surface lesion with overlying nondisplaced fragment. Stage III is an undisplaced lesion with lucency. Stage IV is a displaced fragment. (Ferkel RD, Sgaglione NA. Arthroscopic Treatment of Osteochondral Lesions of the Talus: Long Term Results. Orthop Trans 1993;17:1011. Copyrighted 1996 by Lippincott-Raven Publishers. Illustration from Ferkel RD: Arthroscopic Surgery: The Foot and Ankle. Philadelphia: Lippincott-Raven Publishers, 1996. Illustration by Susan Brust.)

Figure 93.13. (See color Fig. 93.13). Arthroscopic picture of a Stage D osteochondral lesion of the talus.

Treatment of OLT has generally been based on whether there is a displaced fragment that needs debridement (5,6,13,64). Conservative treatment consists of 6 to 12 weeks of casting, with progression to weight bearing as tolerated. For those who fail conservative treatment, open arthroscopy with malleolar osteotomy, distal tibia grooving, and percutaneous drilling under fluoroscopy have all been described for surgical treatment (1,31,36,72). These surgical approaches all can have significant morbidity, including soft-tissue trauma, malunion or nonunion of the malleolus, joint stiffness, and prolonged rehabilitation.

Ankle arthroscopy provides improved access and visualization for treatment of osteochondral lesions of the talus and is associated with reduced morbidity, results superior to open treatment, and faster rehabilitation (24,38).

OLT Treatment Principles

Acute

- Conservative treatment for most stage I to III lesions
- Immediate surgery for all stage IV lesions
- Surgery for stages I to III that fail conservative treatment

Chronic

- Conservative treatment for stages I and II in adults, and stages I to III in children 18 or under
- Surgery for adults with stages III and IV, and children with stage IV
- If conservative treatment fails, surgery is performed regardless of the stage.

The most appropriate surgical treatment for full-thickness loss of articular cartilage is controversial. Penetration of the subchondral bone is required to create bleeding, fibrin clot formation, and eventual fibrocartilage formation (44,54,56). Different techniques have been developed to penetrate the subchondral bone, including drilling, abrasion, and microfracture (7,44). A recent comparison of the long-term effects of abrasion to drilling in rabbits demonstrated better results with drilling (34). Recently, microfracture has been advocated to avoid placing holes through the malleolus and to prevent heat necrosis; it also allows increased holes to be placed in the lesion with less morbidity (69). We recommend arthroscopic debridement and microfracture for small defects, and arthroscopic debridement and drilling with microfracture for larger defects. Bone grafting of defects larger than 1.5 cm in depth may also be considered. All patients are generally kept non-weight bearing for 4 to 8 weeks, but early range of motion should start at 1 week.

Operative Technique

- Arthroscopically inspect, identify, and stage all lesions of articular surfaces.
- Excise any loose bodies or osteochondral fragments.
- Palpate and measure the talar articular surface to determine the size and extent of the lesion.
- Use a banana knife and ring curet to remove the primary osteochondral lesion if it is loose and avascular.
- Use 2.9 mm and 3.5 mm shavers, if desired, to debride the talar bed to smooth the edges.
- Insert a 90° microfracture awl for small lesions (Fig. 93.14A).
**Figure 93.14.** (See color Fig. 93.14A, color Fig. 93.14B and color Fig. 93.14C). Arthroscopic treatment of osteochondral lesions of the talus. A: The left ankle is shown. Viewing from the posterolateral portal, a microfracture awl from the anteromedial portal penetrates the subchondral bone of a posteromedial lesion. B: Microfracture of the subchondral surface using an awl. C: Using a drill guide for transmalleolar drilling of the subchondral bone. D: The result of the above two treatments is a bleeding bone surface providing vascular access for cartilage formation.

- For larger lesions, use a 90° microfracture awl along the peripheral edge of the lesion and use a MicroVector (Smith and Nephew, Endoscopy, Andover, MA) to drill multiple holes in the center of the lesion (Fig. 93.14B and Fig. 93.14C; see color Fig. 93.14A, color Fig. 93.14B and color Fig. 93.14D).
- Drilling also can be performed transtalarly, through the sinus tarsi; this is usually done with an 0.062-inch K-wire.
- Use a bone graft for large deep cystic lesions (Fig. 93.15A, Fig. 93.15B, Fig. 93.15C and Fig. 93.15D; see color Fig. 93.15A, color Fig. 93.15B, color Fig. 93.15C and color Fig. 93.15D).

**Figure 93.15.** Management of large osteochondral lesions of the talus. A: Preoperative MRI, T2-weighted image, demonstrates a large posterior osteochondral lesion. B: Arthroscopic view from a posterior portal shows the inside of the osteochondral lesion and depth. C: Arthroscopic bone grafting is performed via an osteochondral transplant cylinder. D: Arthroscopic view from a posterior portal of the bone graft filling the cyst near completion.

**Results**

Our results using this arthroscopic approach in 136 consecutive patients with OLT and in a subgroup of 64 patients, who fulfilled the study criteria, yielded 72% good to excellent results (American Orthopaedic Foot and Ankle Society Ankle/Hindfoot score of 84). At an average follow-up of 71 months, there was no correlation between imaging studies and clinical outcome; however, there was statistically significant correlation between arthroscopic staging and long-term results (31).

**OTHER METHODS**

A variety of newer methods have been developed to treat articular cartilage defects. Chondrocyte transplantation has been studied extensively in Sweden and is currently undergoing clinical trials in the United States (10,55). Transplantation of autogenous osteochondral grafts taken from a donor site on the supracondylar ridge of the femur has also been tried in the ankle. Debate exists as to whether one large graft should be used or multiple small grafts (mosaicplasty) to fill the osteochondral lesion bed. A preliminary report (39) indicates excellent results in 11 patients with mosaicplasty. All techniques mentioned earlier so far require an arthrotomy, and future research is needed to determine their effectiveness.

**LOOSE BODIES**

Loose bodies may either be chondral or osteochondral, and they usually are secondary to trauma. There are certain nontraumatic disorders, such as synovial chondromatosis, in which loose bodies may form as well (Fig. 93.16). Those fragments that contain bone may be detected on radiographs, but a cartilaginous fragment is not usually seen on plain radiographs. An arthrogram would likely show these intra-articular loose bodies, but MRI is the study of choice for cartilage lesions. Occasionally, a magnetic resonance arthrogram using gadolinium may be necessary to detect the more discrete lesions as well as show a possible cartilage area of origin. The surgeon needs to know preoperatively if the loose body is intra-articular, intracapsular, or extra-articular.

**Figure 93.16.** Lateral radiograph of an ankle showing multiple loose bodies in the anterior and posterior recess of the ankle joint.

A 21-point arthroscopic examination must be thorough to avoid missing any fragments. Closely examine the articular cartilage following removal of fragments to address any residual articular defect.

- Look both anteriorly and posteriorly for loose bodies.
- Squeeze the posterior capsule to try to extrude loose bodies hidden in the posterior joint.

Postoperatively, place the ankle in a bulky compressive dressing with a short-leg splint for 5 to 7 days. Then change to a compressive stocking and begin early motion. Results depend on the underlying etiology of the loose bodies but are much less predictable in patients with degenerative changes (51).

**OSTEOPHYES**

Osteophytes most commonly occur at the distal anterior lip of the tibia and the adjacent talus. Normally, the angle between the distal end of the tibia and the talus is
greater than 60°. With osteophytic formation on the distal part of the tibia or talus neck, this angle can diminish to less than 60°, resulting in impingement.

Anterior impingement secondary to osteophyte formation is quite common following ankle injuries in athletes, with a reported incidence of 45% in football players and 59.3% in dancers (60). This spurring may cause decreased motion or pain, or both, at the ankle with dorsiflexion. Other areas in the ankle, such as the medial malleolus and the posterior tip of the tibia at the articular surface, may also have similar osteophyte formation. A classification system has been developed by Scranton and McDermott (68) to describe patterns of osteophyte formation around the ankle. A positive bone scan suggests that spurring may be the source of pain. CT scans can be helpful to determine the size and location of the osteophytes. Obtain weight-bearing and non-weight-bearing lateral radiographs in plantarflexion to identify the extent of the osteophyte and any loose bodies (Figs. 93.17A and 93.17B).

Figure 93.17. A: Lateral radiographs of the tibiotalar joint showing preoperative osteophytes anteriorly. B: A postoperative radiograph following arthroscopic removal of the osteophyte.

- Remove all soft tissue around the osteophytes. Peel the soft tissue off anterior and inferior spurs with a Freer elevator and shaver.
- Identify the extent of the osteophyte before resection.
- Remove the osteophytes with a burr or osteotome, and rongeurs, as needed.
- Use intraoperative radiographs or fluoroscopy to verify complete excision.

Postoperatively, apply a bulky compressive dressing with a short-leg splint for 5 to 7 days, followed by early range-of-motion exercises and progressive weight bearing as tolerated. Commence physical therapy at 2 to 3 weeks postoperatively, and include stretching, strengthening, and proprioceptive training.

HINTS AND TRICKS

If osteophytes are very large, look from the posterolateral portal to find the joint space and remove the medial corner of the osteophyte first, then switch back to the anterior portals for visualization and treatment of the remainder of the osteophyte.

DEGENERATIVE ARTHRITIS

For surgery to be of any measurable benefit in an ankle with either posttraumatic or primary degenerative arthritis, a clearly defined reason for arthroscopy is required (16). Ankles with advanced degenerative disease do not benefit from ankle arthroscopy (19). Ankle arthrodesis may be indicated for the advanced degenerative ankle. Open arthrodesis requires an extensive surgical approach and has significant potential complications. With new advances in ankle distraction and ankle arthroscopic equipment, arthroscopic arthrodesis is an attractive alternative (56, 61).

Indications and Contraindications for Arthroscopic Ankle Arthrodesis

Indications for arthroscopic ankle arthrodesis include intolerable ankle pain in the ankle with advanced degenerative arthritis that does not respond to conservative treatment. Contraindications include varus or valgus malalignment of more than 15 degrees, malrotation of the ankle, significant bone loss, active infection, previous failed fusion, reflex sympathetic dystrophy, neuropathic destructive process and AP translation of the tibiotalar joint requiring correction.

Operative Technique for Arthrodesis

- Position the patient supine on a radiolucent operating table. Position the leg such that the image intensifier can easily be positioned. The optimal position for arthrodesis of the ankle is neutral dorsiflexion. Avoid equinus, especially more than 10°, unless the patient has residual paralysis of the knee from poliomyelitis.
- Perform standard diagnostic arthroscopy with ankle distraction.
- Remove the entire articular surface of the tibial plafond, talar dome, and medial and lateral talomalleolar surfaces systematically using a motorized shaver, abrader, ring and cup curets, and pituitary rongeurs (Fig. 93.18; see color Fig. 93.18).

Figure 93.18. (See color Fig. 93.18). When performing arthroscopic fusion take care to remove all articular cartilage with a combination of instruments. A curved curet is shown here.

- Make multiple small dimples in the subchondral bone of the tibia and talus with a burr to facilitate early bony union (Fig. 93.19; see color Fig. 93.19).

Figure 93.19. (See color Fig. 93.19). A small joint drill guide can be used to drill the guide wires transmalleolar and thus arthroscopically assist in placement of the screws for fusion.
Take care at all times to maintain the anatomic bony contour of the talar dome and tibial plafond.

- Remove all anterior and posterior osteophytes before insertion of screws.
- Insert the MicroVector arthroscopically to facilitate guide pin insertion.
- Then fix the ankle by placing a guide pin for a cannulated screw from the proximal part of the medial malleolus to just above the joint line. Drill a second pin laterally through the lateral malleolus into the posterior aspect of the joint line. Insert both medial and lateral guide pins from the posterior aspect of the malleoli, and angle them 45° inferiorly and 45° anteriorly (Fig. 93.20).

**Figure 93.20.** Both pins are inserted from the posterior aspect of the malleoli and angled approximately 45 degrees anterior and inferior. Copyrighted 1996 by Lippincott-Raven Publishers, *Arthroscopic Surgery: The Foot and Ankle.* Richard D. Ferkel, *Figure 11-13,* pp. 26-27. Illustration by Susan Brust.

- Release distraction and put the ankle into a neutral position. Under fluoroscopy, also check the position of the guide pins.
- Advance the guide pins under fluoroscopic control, being careful not to penetrate the subtalar joint.
- Measure the length of the pins and insert 6.5 or 7.3 mm self-drilling, self-tapping screws under fluoroscopic control (Fig. 93.21).

**Figure 93.21.** Transmalleolar screw insertion with a 6.5 mm, self-drilling, self-tapping screw is performed such that all threads of the screw are within the talus; therefore, compression across the surfaces, and not distraction, will assist in fusion. (Copyrighted 1996 by Lippincott-Raven Publishers. Ferkel RD. *Arthroscopic Surgery: The Foot and Ankle.* Philadelphia: Lippincott-Raven Publishers, 1996:26, with permission. Illustration by Susan Brust.)

- Take radiographs to verify screw position and length, as well as ankle alignment.

Postoperatively, apply a well-padded short-leg cast that is split in the recovery room. At 1 week, remove the stitches and apply a new cast. Begin weight bearing at 2.5 to 3 weeks. Discontinue the cast or removable cast-boot device when bony union is seen on radiographs.

**Results**

Early clinical results with arthroscopic ankle arthrodesis are good to excellent in 85% to 92% of patients (37, 55). When compared with open arthrodesis, arthroscopic fusion seems to have lower overall morbidity, quicker time to union, and shorter recovery and rehabilitation (57).

**ACUTE ANKLE FRACTURES**

Arthroscopy of acute ankle fractures allows the surgeon to assess directly the articular surfaces, remove fracture debris, assess for ligament damage, and in some instances, assist fracture reduction and percutaneous screw insertion (28, 29). Arthroscopically assisted reduction and internal fixation can be accomplished in fractures with minimal to mild displacement that are easily reducible by manipulation, with minimal to mild ankle swelling and no neurovascular injury. Arthroscopy is also useful in treating syndesmosis disruptions, deltoid ligament tears, and posterior malleolar fractures, and in assisting in removal of debris in reduction of talar fractures. Triplane fractures have also been reportedly reduced with arthroscopic assistance with success (53, 76).

- Place the patient supine on a radiolucent operating table.
- Use a standard arthroscopic setup.
- Apply gentle soft-tissue distraction.
- Remove all fracture debris, loose bodies, and hematoma.
- If the fracture cannot be reduced arthroscopically, then perform open reduction internal fixation.
- If arthroscopic fracture reduction is possible, reduce the fracture with large fracture clamps and maintain the reduction with guide pins from the AO cannulated screw set. After visual and fluoroscopic verification of reduction, measure the screw lengths and insert the appropriate size screws (Fig. 93.22A, Fig. 93.22B and Fig. 93.22C).

**Figure 93.22.** Arthroscopically assisted treatment of a medial malleolar fracture. **A:** Preoperative x-ray study shows a displaced fracture with rotation. **B:** Intraoperative fluoroscopy shows initial fracture reduction and pin placement. These guide pins can be used to complete the reduction and then cross the fracture for screw placement. **C:** Screw placement and fracture healing 8 weeks postoperative.

Postoperatively, apply a cast that is split in the recovery room. Keep the patient non-weight-bearing, and remove sutures at the first postoperative visit. Subsequent immobilization is determined by the nature of the fracture and its fixation (see Chapter 25).

**Results**

Loren and Ferkel (48) reviewed 47 consecutive patients with acute fractures of the ankle treated with arthroscopy of the tibiotalar joint, followed by open reduction and internal fixation. Damage to the articular surfaces was noted in 29 of 47 (62%) ankles. Fracture debris and hemarthrosis were noted in all ankles. Several other
institutions have reported on the utility of arthroscopy for fractures (21,42,53,66). Further studies are needed to determine the long-term benefit of ankle arthroscopy in patients with acute ankle fractures.

ANKLE INSTABILITY

Ankle instability is discussed in detail in Chapter 95. Arthroscopy can be a useful tool in the evaluation of chronic lateral ankle instability. Dynamic information that is not available with stress radiographs can be obtained at the time of arthroscopy (45,49). In a recent study, 92% of patients with ankle instability had intra-articular pathology (27). Failure to recognize these lesions may jeopardize the patient's clinical outcome following stabilization procedures (60). Before ligament reconstruction, we advocate arthroscopic ankle examination (70). Arthroscopic ligament stabilization is an evolving technique, and its use has been reported by Hawkins (40) for patients with mild instability with promising short-term results.

AUTHORS' PERSPECTIVE

The future of ankle arthroscopy is exciting. With the development of new equipment and techniques over the past decade, we have seen the applications of ankle arthroscopy grow remarkably. Perhaps more important, the procedure has become more user friendly. Therefore, more patients can be treated with the lower morbidity and speedier recovery that is associated with arthroscopic surgery of the ankle compared with the standard open arthrotoomy procedures for treatment of the same pathology. We can anticipate the evolution of this field to continue to parallel the rapid technological advances seen in computers, optics, and audio and video equipment. These advances, along with improved surgical technique, experience, and long-term outcome studies, will pave the way for the next generation of ankle specialists.

TENDON LACERATIONS

Lacerations to tendons about the foot and ankle can be caused by stepping on or dropping a sharp object such as glass onto the foot, which usually results in a clean sharp isolated tendon laceration. More violent crushing-type lacerations occur with motor vehicle accidents, power saw and lawnmower injuries, or dropping objects on the dorsum of the foot, all of which cause more extensive associated injuries. Floyd et al. showed that all tendon lacerations, with the possible exception of the flexor digitorum tendons, benefit from primary repair. They found in a number of cases that surgical exploration revealed additional significant injuries that were not appreciated in the clinical examination.

PATHOPHYSIOLOGY

The tendon lacerations discussed here involve the following tendons: flexor hallucis longus (FHL), flexor digitorum longus (FDL), extensor digitorum longus (EDL), extensor hallucis longus (EHL), anterior tibial (AT), and posterior tibial (PT) tendons.

The FHL muscle originates from the deep posterior compartment of the leg. The FHL tendon passes beneath the sustenaculum tali and continues distally, crossing deep to the FDL tendon at the flexor knot of Henry. At this point the tendon produces a tendinous slip that inserts into the FDL tendon. The FHL tendon is covered by two synovial sheaths. The first provides coverage from the ankle joint to a point just distal to the flexor knot of Henry; the second provides coverage from the first metatarsal base to the tendon insertion.

The EDL, EHL, and AT tendons originate from the anterior compartment in the leg. Each muscle produces a tendon that is enclosed in a synovial sheath and is retained in position by a thickened section of crural fascia known as the extensor retinaculum. There are individual sheaths for the anterior tibial tendon and extensor hallucis longus tendon and a common sheath for the extensor digitorum longus tendons.

The anatomic features of the posterior tibial tendon are described in the posterior tibial tendon dysfunction section of Chapter 118.

The subcutaneous positions of the tendons about the foot and ankle predispose them to injury by direct trauma. Laceration of the plantar or dorsal aspect of the foot may produce disruption of tendinous, vascular, or neurologic structures.

PRINCIPLES OF TREATMENT

Injuries associated with foot lacerations are commonly missed. Establish the full extent of the injury by careful physical examination, appropriate radiographic imaging, and, when necessary, surgical exploration. When primary repair is indicated, techniques used are similar to those for flexor tendon injuries in the hand.

ASSESSMENT

Document the mechanism of injury. Determine the exact anatomic area of injury. Check the vascular and neurologic status and follow this by an analysis of tendon function. Remember that the FHL tendon provides a tendinous slip to the FDL tendon. If the FHL tendon is disrupted proximal to this slip, active flexion at the hallux may produce disruption of tendinous, vascular, or neurologic structures.

CLASSIFICATION

Tendon lacerations can be classified on the basis of mechanism of injury, degree of injury (complete versus incomplete), location of injury (insertional versus noninsertional, relation to synovial sheath, relation to retaining structures), and by the presence of associated neurovascular or tendinous injury. With regard to laceration of the FHL tendon, the integrity of the flexor hallucis brevis is an important consideration.

PREOPERATIVE MANAGEMENT

In the emergency department, provide routine wound care and give appropriate tetanus prophylaxis. Generally speaking, isolated tendon laceration about the foot may be treated by nonsurgical or surgical means. Repair primarily complete laceration of the Achilles, PT, AT, peroneal, EHL, and FHL tendons when local conditions are favorable. Functional (partial) lacerations as well as laceration of the brevis tendons are typically not repaired. Do a meticulous debridement and evaluation of associated structures and repair if needed.

OPERATIVE TECHNIQUES
**Surgical Exploration and Repair of FHL Tendon Laceration**

- Use general or regional anesthesia and a proximal thigh tourniquet. Enlarge the plantar wound with proximal and distal extensions as required. If possible, avoid the weight-bearing surface of the foot.
- Inspect the FHL tendon, the FHB muscle and tendon, and surrounding neurovascular structures. If the FHL tendon laceration is distal to the tendinous connection with the FDL tendon, retraction of the FHL tendon is limited. Identify both ends of the tendon and meticulously debride the wound; then perform a primary tendon repair. Use a single-core 2-0 nonabsorbable suture. Repair the peripheral edges of the tendon with a smaller polydioxanone (PDS, Ethicon, Inc., Wayne, NJ) or nylon suture. After completion of the repair, verify excision of the tendon.
- If primary repair cannot be accomplished, tenodese the adjacent FDL tendon to the proximal and distal ends of the FHL tendon. In the unusual event of a nonrepairable FHL tendon laceration accompanied by disruption of both heads of the FHB muscle, anastomose the proximal FHB muscle and the distal end of the FHL tendon.
- Because of the risk of formation of a painful neuroma, we do not repair digital nerve lacerations primarily but rather transplant them to a protected position, such as into a muscle belly. Repair the surgical extensions to the foot wound and immobilize the foot in slight plantarflexion.
- Postoperatively, do routine wound care to assure a viable wound with eventual successful closure. Over the course of 2 to 3 weeks, bring the foot gradually up to a neutral position. Begin passive range of motion at the hallux interphalangeal and the metatarsophalangeal joints. At 6 weeks postoperatively, start weight bearing in a removable cast boot. At 8 weeks postoperatively, begin a strengthening program followed by gradual resumption of activities without the cast boot.

**Surgical Exploration and Repair of the EDL, EHL, and AT Tendons**

- Use general or regional anesthesia and a proximal thigh tourniquet. Extend the dorsal wound as necessary in proximal and distal directions. If possible, keep the incision in line with, but not over, the injured tendon to minimize adhesions with overlying skin.
- Identify the proximal and distal ends of the lacerated tendons and systematically inspect surrounding structures. After meticulous debridement and irrigation of the wound, perform a primary tendon repair. Use a core suture of nonreactive, nonabsorbable material within the tendon substance to provide primary apposition, supplemented with a whipstitch of the tendon ends with a smaller running nylon or PDS suture (Ethicon, Inc., Wayne, NJ). If end-to-end or side-to-side repair cannot be performed, use a proximal or distal Z-lengthening to provide additional length.
- Close the surgical wound extensions primarily and immobilize the foot in a neutral to slightly dorsiflexed position. The addition of toe dorsiflexion may also be required.
- Postoperatively, provide routine wound care as discussed for FHL tendon lacerations. At 6 weeks postoperatively, begin range-of-motion exercises and weight bearing in a removable cast boot. At 8 weeks postoperatively, begin a strengthening program. Finally, discontinue the cast boot once local warmth and swelling have resolved. Maintain range of motion. Motion is often limited as a result of formation of local adhesions.

**COMPLICATIONS**

Placing sutures in a traumatic wound increases the risk of infection. Therefore, perform primary tendon repair only if local wound conditions are favorable. Digital nerve injury may be complicated by neuroma formation or the onset of reflex sympathetic dystrophy. Minimize the risk of posttraumatic neuroma formation by transplanting the proximal end of the lacerated digital nerve into a local muscle belly. If a painful neuroma occurs, treatment with desensitization modalities is indicated. Occasionally, referral to a pain management specialist is required.

**CONCLUSIONS**

When local conditions permit, we prefer primary tendon repair, especially in the pediatric and athletic population. Because of their propensity to form neuromas, we do not repair digital nerve lacerations but transplant the proximal nerve to a well-protected location.

**FLEXOR HALLUCIS LONGUS TENDON**

Injury to the FHL tendon at the ankle has been recognized mostly in runners and dancers (2, 3, 6, 8, 10, 12, 15, 19). The FHL tendon enters the foot through a fibro-osseous tunnel along the posteromedial ankle. This is defined superiorly by the posterolateral process of the talus, and it extends inferiorly to the sustentaculum tali on the medial side of the hindfoot. The tendon undergoes a change in direction within this tunnel from vertical proximally to horizontal distally (11). As a result, it can become irritated and develop intrasubstance tears that cause it to swell and become tethered.

**CLINICAL PRESENTATION**

Pain is present in the posterior ankle deep to the Achilles tendon. Deep palpation in this area may cause tenderness. The pain may be aggravated by passive motion of the great toe. With significant swelling, the tendon may become entrapped and cause triggering, leading to clawing of the great toe (2, 6, 8, 10, 12, 15, 19). Entrapment can be verified by comparing great toe dorsiflexion with the ankle in the plantarflexed position and when dorsiflexed. With entrapment, dorsiflexion of the toe is limited with the ankle also dorsiflexed but possible when the ankle is plantarflexed (6).

**RADIOGRAPHS**

Routine radiographs will be unremarkable. The presence of a large posterior process or os trigonum may cloud the diagnosis. Magnetic resonance imaging (MRI) is a useful test for evaluating questionable cases (11, 19) where fluid can be identified about the tendon in the fibro-osseous tunnel and intrasubstance tears in the tendon may also be present.

**NONOPERATIVE TREATMENT**

Nonoperative treatment consists of activity limitation and nonsteroidal antiinflammatory medications for 10 to 14 days. Immobilization in a short-leg walking cast with extended toe plate to prevent great toe motion may be helpful as well.

**OPERATIVE TREATMENT**

Treat athletes who do not obtain relief with conservative methods or those who have persistent triggering of the great toe with release of the fibro-osseous tunnel of the FHL. This minimally invasive approach is favored because it allows access to the entire fibro-osseous canal. Full return of function can be expected with this procedure (2, 6, 10, 12, 14, 19).

**Surgical Release of the FHL Sheath**

- Use a general or regional anesthetic and a thigh tourniquet. Place a bump under the opposite thigh to aid in exposure of the medial side of the posterior ankle.
- Make a curving longitudinal incision in line with the flexor tendons posterior to the medial malleolus. Begin 5 cm above the malleolus and extend distally to the level of the navicular bone.
- Divide the flexor retinaculum in line with the incision and identify the FDL by passively moving the toes. Enter the interval behind the FDL tendon and in front of the posterior tibial artery.
- Identify the FHL tendon and protect the neurovascular bundle, which is posterior. Retract the FDL tendon anteriorly. Passive motion of the great toe will aid in identifying the FHL tendon.
- Split the sheath from proximal to distal to the level of the sustentaculum tali. Identify the neurovascular bundle over the course of this dissection to avoid injuring it. Inspect the tendon for any tears and repair them as indicated.
- Close the wound by repairing the flexor retinaculum with 4/0 absorbable sutures. Close the subcutaneous layer and skin and apply a posterior splint.

Postoperatively, use crutches for 1 week and then remove skin sutures. Then start weight bearing as tolerated. Start strengthening therapy but avoid training activities for 6 weeks.

**ANTERIOR TIBIALIS TENDON**
ANATOMY

The anterior tibialis (AT) muscle originates from the proximal tibia and interosseous membrane. It becomes tendinous at the level of the distal tibial metaphysis. The anterior tibialis tendon passes over the front of the ankle and runs with a straight course under the superior extensor retinaculum to attach to the dorsum of the medial cuneiform and base of the first metatarsal. It is the primary dorsi-flexor of the ankle and also helps invert the foot (3). Despite its subcutaneous course, the tendon is rarely injured, probably because it does not change direction against a bony fulcrum and because of its excellent blood supply (6,20).

CLINICAL PRESENTATION

Tendinitis can occur from overuse, particularly from hiking downhill, and has been described from direct pressure against the tendon by ski boots (20). Rupture of the anterior tibialis tendon is an unusual injury that occurs in two distinct populations. The most common presentation is in the elderly, who usually have an atraumatic rupture and typically note the insidious onset of a foot drop (6,13). The second presentation is an acute traumatic rupture in older athletes, but it can also occur in young athletes (6,13,18).

Patients with tendinitis have tenderness over the course of the tendon and pain on resisted dorsiflexion of the ankle. A rupture can be diagnosed by a visual or palpable defect in the tendon, foot drop, and weakness of ankle dorsiflexion (Fig. 94.1).

Figure 94.1. Rupture of anterior tibialis tendon. The ruptured anterior tibialis tendon has retracted, leaving a soft-tissue prominence on the dorsum of the foot.

RADIOGRAPHS

Plain radiographs are unremarkable. The rupture can be easily identified with an MRI scan (11,13). This is essentially a clinical diagnosis, however, and an MRI is usually not necessary.

TREATMENT

Treat tendinitis with activity limitation and nonsteroidal medications. If pain is caused by direct pressure against the tendon, remove the irritant.

Chronic rupture in the older patient may be satisfactorily treated with a brace or may even be left untreated (1). The acute rupture is probably best treated with surgical reconstruction. In cases in which it is recognized early, a direct repair of the tendon is possible (6,13,18,20). If it has been unrecognized for several months, reconstruction with either an EHL tendon transfer or interposition of an EDL tendon graft may be used, allowing return to recreational activities (13).

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Sprains of the lateral ankle ligaments are among the most common musculoskeletal injuries (32). Most injuries are mild and heal uneventfully, but as many as 20% of patients develop chronic lateral instability (1,22,43-45). Injuries of the distal tibiofibular ligaments (syndesmosis sprains) are often associated with a protracted course of recovery and, in the case of extensive injury, can cause diastasis of the ankle mortise leading to subsequent arthritis (15).

PATHOMECHANICS

Of the three lateral ankle ligaments reinforcing the tibiotalar capsule, the anterior talofibular (ATaF) and calcaneofibular (CF) ligaments are the most clinically significant (8), functioning in reciprocal fashion to resist inversion loads applied to the ankle (33). The ATaF progressively tightens as the ankle is moved from dorsiflexion through plantarflexion, with the CF developing maximal tautness in dorsiflexion (13,48).

Injury to the lateral ligaments typically occurs when excessive inversion force is applied to the plantarflexed ankle during loading or unloading of the foot. Sequentially, the ATaF is torn, followed by the CF and, ultimately, the posterior talofibular ligament (PTaF) (1,6,17,47). The spectrum of injury ranges from a mild sprain of one ligament to frank rupture of both. Rarely, the PTaF is the ultimate ligament to fail, an event that can cause frank dislocation of the ankle. Although isolated injury of the ATaF is common, isolated rupture of the CF is clinically unlikely (7,47).

The ankle mortise is stabilized by the anterior and posterior tibiofibular ligaments (ATF and PTF), the inferior transverse ligament, and the interosseous ligament. The ATF develops increasing strain with external rotation of the talus, and both tibiofibular ligaments undergo elongation with ankle dorsiflexion (13,14). The spectrum of injury to the syndesmosis can include latent or frank diastasis of the ankle mortise.

CLINICAL ASSESSMENT OF ACUTE LATERAL SPRAINS

A comprehensive clinical assessment is required to properly evaluate the acutely sprained ankle (41) and is paramount to avoid missing adjacent injuries such as Achilles tendon rupture, peroneal tendon dislocation, or severe midfoot injury (Table 95.1). The mechanism may provide a clue to the type of injury: an inversion mechanism suggests a lateral ligament sprain, whereas a dorsiflexion or external rotation injury points to the possibility of a syndesmosis injury. A "pop" or tearing sensation combined with pain that precludes weight bearing as well as rapid swelling usually indicates a more severe injury.

Table 95.1. Differential Diagnosis of Lateral Ankle Injuries

<td>Swelling over the sinus tarsi, difficulty in weight bearing</td>
</tr>
</tbody>
</table>

Swelling and delayed ecchymosis are common. For the first few hours swelling remains localized and can aid in diagnosis. Swelling confined to the inframalleolar area that occurs with a lateral ligament sprain can be differentiated from the supramalleolar swelling seen in a syndesmosis injury as well as the more distal swelling seen over the sinus tarsi and midfoot that accompanies a subtalar or midfoot sprain. Localized tenderness is suggestive of but not specific to individual ligament injury. Palpate the malleoli, the entire fibula, joint margins, and tendons about the ankle, confirming structural integrity and eliciting any tenderness and crepitus. Tenderness proximal to the ankle joint is characteristic of a syndesmosis injury. Active and passive motion of the ankle is painful and decreased in both types of sprains. Measurement of motion does not aid in diagnosis or determination of severity. In addition to ascertaining the integrity of the Achilles by squeezing the calf muscles and looking for plantar flexion (33), assess the function of the peroneal tendons by active dorsiflexion and evasion. An important part of the exam is assessment of pedal pulses and the motor and sensory function of the ankle and foot. Peroneal compartment syndrome as well as traction injuries of the posterior tibial and peroneal nerves have been described in severe sprains (44,50).

SPECIALIZED TESTS: ANTERIOR DRAWER AND TALAR TILT TESTS

Tests to evaluate stability of the lateral ankle ligaments include the anterior drawer test (ADT), which measures displacement of the talus in relation to the tibia (1,16). The primary restraint to the ADT is the anterior talofibular ligament. Injury of the calcaneofibular ligament does not affect the ADT (32). The preferred testing position is 10° of ankle plantarflexion, which allows maximum anterior talar translation (27). This test usually can be performed in the presence of swelling without inducing significant discomfort, as can Lachman's test for rupture of the anterior cruciate ligament of the knee. Stabilizing the distal leg with one hand, apply an anterior force to...
the heel using the fingers while the thumb rests along the anterior aspect of the ankle over the talus. An increase of 3 to 5 mm side-to-side difference (STSD) on the ADT indicates rupture of the anterior talofibular ligament (1,25).

The talar tilt test (TTT) assesses both the anterior talofibular (primary restraint) and calcaneofibular (secondary restraint) ligaments. Performed in 10° of plantarflexion, the test also measures inversion of both the tibiotalar and subtalar joints. Palpating with the thumb along the tibiotalar joint allows an estimation of talartilt to be made. A STSD of at least 5° on the TTT indicates rupture of both the anterior talofibular and calcaneofibular ligaments (9,10,15). Unlike the ADT, the TTT is often difficult to perform in the acute injury because of pain and swelling. In addition, in the chronic injury, it may prove difficult to differentiate subtalar motion. If abnormal laxity is suspected, the talar tilt test should be assessed using stress radiographs.

**RADIOGRAPHY**

Take anteroposterior (AP), mortise, and lateral radiographs of the ankle after suspected injury of the lateral ankle ligaments. These radiographs may reveal associated osteochondral injuries, avulsion fractures of the collateral ligaments from the distal fibula, unsuspected widening of the mortise, as well as unsuspected fractures of the malleoli. Occasionally, additional radiographic views are necessary. If swelling and tenderness appear distal to the lateral malleolus along the lateral foot, include a medial oblique and an AP view of the foot to exclude fractures of the anterior process of the calcaneus or base of the fifth metatarsal.

Take stress radiographs on a case-by-case basis. If the anterior drawer and talar tilt tests are negative on physical examination, then stress radiographs are unnecessary. If clinical laxity is apparent, the specific degree of abnormal translation can be documented by obtaining both anterior drawer and talar tilt stress radiographs (Fig. 95.1 and Fig. 95.2). If desired, 15 ml of 1% lidocaine can be injected into the ankle for pain relief. The amount of anterior talar translation is measured as the distance from a constant point on the posterior aspect of the talus to the posterior lip of the tibia. Talar tilt is measured as the degree of angulation of the superior aspect of the talus as referenced against the neutral position of tibial plafond.

**ANKLE ARTHROGRAPHY AND MRI**

Previously, ankle arthrography as well as peroneal tonography were utilized to diagnose lateral ankle ligament tears. Because so few acute lateral ligament injuries require early surgery, these studies are now rarely performed. Magnetic resonance imaging (MRI), although capable of demonstrating the anatomy of the injury, is best used for diagnosing suspected osteochondral lesions of the talus and peroneal tendon tears.

**DIAGNOSIS AND CLASSIFICATION**

Individual ligament injuries are usually graded as mild, moderate, or severe depending on the degree of injury. Grading is more difficult in the ankle than in other structures because injuries can involve combinations of capsular rupture as well as partial or complete tearing of one or more ligaments. Black (3) introduced the concept of single-and double-ligament injuries, and Singer and Jones (50) popularized the concept of stable and unstable injuries. Table 95.2 is a compilation of various classification criteria to provide a useful system for characterizing these injuries (29,45,50). Stable injuries consist of a partial or complete tear of the anterior talofibular ligament alone or with at most a partial tear of the calcaneofibular ligament. Unstable injuries involve complete tears of both ligaments. In a stable injury the ADT alone may be slightly positive (3–5 mm STSD); in an unstable injury, however, the ADT will be markedly positive (>5 mm STSD), and the TTT will show more than 5° to 10° of STSD.

**Table 95.2. Classification of Lateral Ankle Sprains**

For the purposes of injury management, it is useful to differentiate stable from unstable sprains as well as to identify those patients with one of the following factors: (a) bony avulsion or osteochondral fragment or (b) acute injury superimposed on chronic, recurrent lateral instability.

**TREATMENT OF ACUTE INJURIES**
The goals of treatment are to achieve a stable, painless ankle with normal motion and to minimize the time lost from activity. Although operative repair of significant ligament injuries has been the standard previously, control studies have shown no difference between the results of surgery and of nonoperative methods (26,22,34,43).

NONOPERATIVE TREATMENT

Stable Lateral Sprain

Nonoperative treatment is indicated for stable lateral sprains. Initially use splinting and crutches until weight bearing is nonpainful and there is no limp. Prescribe range-of-motion (ROM) exercises and such modalities as ice, whirlpool, and electrical stimulation, as pain allows. Start dorsiflexion and peroneal strengthening exercises. Most patients can return to activity within 2 to 4 weeks.

Unstable Lateral Sprain

If supervised therapy is not available or the patient is unlikely to cooperate with the treatment schedule, then initial splinting and elevation followed by immobilization by a short-leg weight-bearing cast or a controlled ankle motion (CAM) walker is used to treat all unstable injuries for a period of 3 to 4 weeks. If access to therapy exists, prescribe an early functional rehabilitation program similar to that advocated by Garrick (24). Initial treatment utilizes intermittent cryotherapy and mechanical compression, splinting with a removable compression splint incorporating a felt horseshoe pad around the lateral malleolus or a U-shaped splint, and avoiding weight bearing until ambulation is nonpainful and there is no limp. Begin a program of ankle range of motion, peroneal and dorsiflexion muscle strengthening, followed by functional exercises (tilt board, jump rope, hopping). Depending on severity of injury, return to activity can take 4 to 10 weeks. Use of taping, an orthosis, and even high-top shoes may help decrease the likelihood of future sprains (28,39,46).

ACUTE SURGICAL REPAIR

For bony avulsion injuries, use the approach to the distal fibula described in Chapter 3. Usually only one 4.0-mm cancellous screw can be inserted (Fig. 95.3). Protect the ankle in a splint for 1 week and have the patient use a CAM walker until clinical and radiographic evidence of union are seen (usually 6–8 weeks).

Figure 95.3. ORIF of avulsion injury of the lateral malleolus.

Especially in the high-performance athlete, when a severe sprain occurs superimposed on a pattern of chronic recurrent instability, acute surgery may be necessary. For repair of these injuries, use the approach described for delayed repair (modified Brostrom) (6,7).

POSTINJURY SEQUELAE

A number of patients continue to experience residual symptoms after a “routine” inversion sprain (Table 95.3). Common postinjury complications include ankle pain secondary to osteochondral lesions, ossicles, or the development of soft-tissue impingement syndrome at the anterolateral corner of the tibiotalar articulation (2,21,42). The most frequent problem, however, is recurrent instability.

Table 95.3. Causes of Continuing Symptoms after Lateral Ankle Sprains

CHRONIC LATERAL ANKLE INSTABILITY

CLINICAL ASSESSMENT

Following one or more inversion injuries, the patient may note continuing pain, swelling, giving way, or functional instability associated with pivoting and twisting on the affected ankle and foot. Physical examination demonstrates peroneal weakness and calf atrophy, tenderness to palpation over the lateral ligaments with chronic soft-tissue swelling, and, most significantly, abnormal laxity during the anterior drawer and the talar tilt tests. Routine radiographs may demonstrate ossicles about the tip of the lateral malleolus. The key to establishing the diagnosis is demonstration of abnormal laxity using stress radiographs, as previously described.

If radiography does not confirm laxity, consider another diagnosis. Peroneal subluxation can be diagnosed by observing retromalleolar tenderness and crepitus, with the ability to displace the tendons on examination or spontaneous subluxation of the tendons from the peroneal groove on active dorsiflexion and eversion of the foot and ankle. Suspect subtalar instability, which can mimic or coexist with lateral ankle instability, if total subtalar inversion exceeds that of the normal side. Subtalar instability, however, may go undetected unless stress radiographs are obtained or stress tomography of the subtalar joint is performed (38). In the absence of mechanical instability, loose bodies or ossicles of the tip of the lateral malleolus can produce symptoms of instability. Functional instability, as popularized by Freeman et al. (22), occurs from loss of proprioception after lateral ligament injury and is ameliorated by the same nonoperative exercise program utilized for mechanical instability.

TREATMENT

Nonoperative Treatment

The majority of patients with symptomatic mechanical instability of the ankle respond to a program of peroneal strengthening, proprioceptive training, and use of an
ankle orthosis or brace or taping. A tilt board is especially helpful to recondition the ankle and lower leg and facilitates the transition back to sports.

Operative Treatment

There are two main types of surgical procedures: delayed repair of the torn ligaments (7,13) and reconstruction (11,12,19,53). Success rates are approximately 85% for each procedure (11,12,19,26,29,53). In most instances, delayed primary repair of the anterior talofibular and calcaneofibular ligaments is possible and, as such, is the procedure of choice. Potential disadvantages of reconstructive procedures include limitation of ankle and subtalar motion by the nonanatomic location of the tendon graft and local morbidity from graft harvest (8,12). Indications for reconstruction as opposed to delayed primary repair include severe lateral ankle instability of long duration, evidence of subtalar hypermobility, or failure of a previous repair or reconstruction.

Delayed Primary Repair (Modified Brostrom)

- Arthroscopy as described in Chapter 93 is useful as the initial procedure because a number of patients may have chondral lesions of the medial talar dome.
- Before performing arthroscopy, mark the lateral branches of the superficial peroneal nerve as they cross the ankle to the foot. Plantarflexion of the ankle facilitates this procedure.
- Place a bump underneath the ipsilateral hip of the supine patient to allow internal rotation of the foot and ankle, exposing the lateral malleolus. Prepare the skin and drape the extremity free.
- Under tourniquet control, incise the skin (Fig. 95.4) using an oblique incision, starting along the anterior border of the lateral malleolus 2 to 3 cm proximal to the tip, passing inferiorly to end proximal to the visible and palpable peroneal tendons. Alternatively, with the ankle in maximum equinus, make the skin incision immediately posterior to the prominence of the lateral malleolus starting 3 cm proximal to the tip and following the peroneal tendons distally (Fig. 95.5). This incision completely avoids the lateral branches of the superficial peroneal nerve and the sural nerve, provides better access to the calcaneofibular ligament, and can be extended to perform an anatomic reconstruction with split peroneus brevis tendon, if necessary.

**Figure 95.4.** Oblique skin incision for modified Brostrom repair. Note proximity of branches of superficial peroneal and sural nerves to ends of incision. (From Mann RA, Coughlin MC. Video Textbook of Foot and Ankle Surgery. St. Louis: Medical Video Productions, 1991.)

**Figure 95.5.** With ankle plantarflexed, a longitudinal incision centered over the posterior aspect of the lateral malleolus allows access to lateral ankle ligaments. Proximal and distal extension (dotted lines) of the incision enables reconstruction using peroneus brevis tendon graft.

- Protect the lateral branches of the superficial peroneal nerve along the anterior extent of the incision and the sural nerve inferiorly and posteriorly as the subcutaneous tissue is incised. Palpate the talus and the tip of the fibula while passively moving the ankle to avoid inadvertently opening the subtalar joint.
- Starting anteriorly, incise the capsule and the normally attenuated anterior talofibular and calcaneofibular ligaments 5 mm from their insertion on the fibula (Fig. 95.6). Do not transect the ligaments more than midway from their fibular attachment points to avoid overtightening. For better exposure of the calcaneofibular ligament, open the sheath and posteriorly retract the peroneal tendons.

**Figure 95.6.** Capsular incision for ATaF and CF ligament repair.

- Inspect the joint if it has not already been examined arthroscopically, debride chondral lesions, and remove loose bodies, as necessary.
- Preserving the proximal attachments of the anterior talofibular and calcaneofibular ligaments, perform gentle subperiosteal dissection of their fibular attachments in order to roughen the fibular surface for improved healing.
- Place two 1-0 nonabsorbable sutures in each distal ligament using a horizontal mattress-weaving configuration and advance the distal ligaments under the tips of their respective proximal attachments (Fig. 95.7). Tie the sutures on the anterior aspect while the ankle and foot are maintained in neutral flexion and slight eversion. Next, imbricate the proximal end of each ligament over its distal end in a vest-over-pants manner.

**Figure 95.7.** A: Isolate and transect the ATaF and CF ligaments. B: Overlap and imbricate the ligaments.
Position the patient supine with a bump beneath the ipsilateral hip. With the ankle in plantarfexion, make a 15-cm longitudinal incision centered over the prominence of the lateral malleolus and extending toward the base of the fifth metatarsal.

Protect the sural nerve, which lies in the posterior portion of the incision. Open the peroneal tendon sheath and identify the peroneus brevis tendon running anterior to the peroneus longus at the ankle. Traction on the peroneus longus causes the hallux metatarsal to flex in a plantar direction. Dissect the muscle of the peroneus brevis from the anterior two thirds of the peroneus brevis tendon, splitting the tendon longitudinally to its attachment to the base of the fifth metatarsal (Fig. 95.8A). Place a whipstitch (#2 nonabsorbable suture) tapering the free end of the graft to ease passage through the bony tunnels.

Make bony tunnels in the calcaneus, fibula, and talus with a 4.5-mm drill bit. Make a transverse tunnel at the calcaneal insertion of the CF ligament. Maintaining a 1-cm bony bridge, start both tunnels at 45° angles to converge beneath the cortical bridge. Connect and enlarge the drill holes with a curette. Now, at the fibular origin of the calcaneofibular ligament, drill a tunnel from posterior to anterior that exits at the origin of the anterior talofibular ligament. Next, drill a vertical tunnel on the neck of the talus at the insertion of the anterior talofibular ligament.

Before passing the tendon graft, imbricate the anterior talofibular and calcaneofibular ligaments as described in the section on delayed primary repair. Pass the tendon graft sequentially through the calcaneal, fibular, and talar tunnels (Fig. 95.8B). Coating the tendon with mineral oil and using a commercially available curved suture passer are helpful in passing the graft.

Position the ankle in neutral and the foot in near maximum eversion. Tighten the peroneal tendon graft. First, suture the graft (#0 absorbable suture) to the calcaneofibular ligament origin and insertion. Tighten the graft again and suture the free end of the graft to the anterior talofibular ligament (Fig. 95.8C). Check that ankle and subtalar motion are preserved. Repair the peroneal tendon sheath at the level of the lateral malleolus (2-0 absorbable suture). Release the tourniquet, obtain hemostasis, and close the subcutaneous layer. Close the skin with interrupted 3-0 nylon mattress sutures. Apply a well-padded posterior splint.

**Postoperative Management**

At 1 week remove the sutures and immobilize the ankle and foot in a short leg cast, allowing weight bearing as tolerated. At 6 weeks discontinue immobilization and start rehabilitation using the same schedule as for delayed primary repair. Patients can return to sports at 6 months. An ankle brace or orthosis is used for the first year of activity.

**SYNDESMOSIS SPRAIN**

Often initially misdiagnosed as a lateral ankle sprain, injury to the syndesmosis can have significant ramifications including prolonged recovery from injury, ossification of the syndesmosis, and diastasis of the ankle mortise if complete ligament rupture occurs (S). Diastasis, lateral or frank, can cause symptoms of instability, loss of power with push-off, and eventually arthrosis of the ankle joint (T). A.

**CLINICAL ASSESSMENT**

Initially, swelling is supramalleolar but eventually spreads to involve the entire ankle. Tenderness is present over the anterior inferior tibiofibular ligament just above the ankle joint margin and may extend to the posterior aspect of the distal tibiofibular joint but does not extend to the inframalleolar region laterally. Tenderness along the deltoid ligament medially in the absence of tenderness of the lateral ankle ligaments should raise suspicion of a syndesmosis injury. Compression of the malleoli and squeezing of the midcalf (S), compressing hematoma within the injured syndesmosis, are quite painful. The usual ankle laxity tests are negative.

**RADIOGRAPHS**

Obtain AP, lateral, and mortise views. If proximal tenderness is present, include the entire tibia and fibula to avoid missing an extensive syndesmosis rupture with associated proximal fibula fracture. On the AP view, the fibula should overlap the tibia by 42% of the width of the fibula, and on the mortise view the separation of the tibia and fibula should not exceed 5 mm (T). A comparison view is helpful (Fig. 95.10). Radiographic evidence of lateral talar shift in the absence of a fibula fracture confirms combined rupture of the deltoid ligament and syndesmosis (Fig. 95.10). If lateral diastasis is suspected, obtain a stress AP or mortise view by applying external rotation to the foot and ankle.

---

- Repair the peroneal tendon sheath and the joint capsule with 2-0 absorbable suture. If additional support for the repair is desired, mobilize the inferior extensor retinaculum from the sinus tarsi and imbricate it to the fibular periosseum proximal to the ligament repair (S). This maneuver requires placing the foot in maximum eversion.
- Close the skin with interrupted 4-0 nylon sutures and apply a short-leg, well-padded U-shaped splint to maintain the ankle and foot in neutral position.

**Postoperative Management**

Prescribe protected weight bearing until 10 days postoperatively, at which time remove the splint and sutures. Apply a short-leg walking cast or have the patient use a CAM walker for an additional 5 weeks. Start rehabilitation to regain active ankle and subtalar motion. As motion is regained, add resistive exercises for the peroneals and dorsiflexors of the ankle together with a tilt board for proprioceptive conditioning. Once motion is restored and strength is 90% of that of the normal ankle, begin functional exercises including running and pivoting. The patient usually returns to activity by 3 to 4 months. Taping or use of an ankle orthosis is recommended during the first year after surgery.

**Reconstruction of the Lateral Ankle Ligaments**

Reconstruction of the lateral ankle ligaments requires precise placement of the tendon graft to replicate normal anatomy, thereby avoiding the limitation of subtalar motion that occurs with the traditional Watson Jones and Chrisman Snook procedures (T). Anatomic reconstruction yields similar success in stabilizing the ankle (85%) without limiting subtalar motion (T) (refer to Fig. 95.8).

---

**Figure 95.8.** Anatomic reconstruction for chronic lateral ligament laxity. A: Anterior half of peroneus brevis is harvested, leaving distal insertion intact. Drill holes are made in the calcaneus, fibula, and talus as described in the text. B: Split tendon is passed through the drill holes in the calcaneus and fibula. C: Tendon graft is passed through talus neck drill holes and sutured to itself.
NONOPERATIVE TREATMENT

In the absence of diastasis and instability, the keys to successful early resolution are to keep the limb immobilized and have the patient keep weight off it. Between sessions for range-of-motion exercises and therapeutic modalities, immobilize the injury in either a bivalved short leg cast or a CAM walker. Do not allow weight bearing until the ankle is nonpainful and the patient is able to walk unprotected without a limp—usually 3 to 4 weeks but possibly up to 6 weeks. Thereafter, treatment is similar to that of a lateral ankle sprain.

OPERATIVE TREATMENT

- If diastasis is present, either frank or latent, surgery is necessary.
- Anatomic reduction of the fibula into the sulcus on the tibia in both the medial–lateral and anteroposterior planes is essential. Fixation can be done using closed percutaneous technique, or the syndesmosis can be opened if reduction is uncertain or the injury is old and interposed scar tissue prevents reduction. Maintain closed reduction of the syndesmosis by a positional, nonlagged 3.5-mm cortical screw. In large men, a 4 to 5-mm cortical screw may be necessary to prevent breakage. Placed 2 to 3 cm above the tibiotalar joint, the screw should engage both fibular and tibial cortices.
- Postoperatively, use a well-padded U-splint for 1 week and then start ROM exercises and peroneal and dorsiflexor strengthening. Allow protected weight bearing for 3 to 4 weeks. If desired, remove the screw before return to sports at 2 to 3 months, although breakage is not likely.

POSTINJURY SEQUELAE

Following a syndesmosis sprain, persistent pain and weakness with push-off during running and jumping are not uncommon. These symptoms may last for more than a year in the high-performance athlete. Stiffness of the ankle may develop as a result of ossification of the syndesmosis ligaments. After ossification, patients experience a greater incidence of inversion sprains of the ankle. Excision of the ossification is usually not necessary, however.

SPRAINS OF THE DELTOID LIGAMENT

Isolated sprains of the deltoid ligament on the medial side of the ankle are much less common than lateral injuries. Rupture of the deltoid ligament commonly accompanies fractures of the lateral malleolus because of external rotation-eversion or abduction injuries. These fractures are usually treated with internal fixation. Exploration and repair of the deltoid ligament is rarely required unless interposition prevents reduction or an osteochondral fracture is suspected.

Isolated sprains are characterized by an external rotation or ankle eversion injury with medial ankle pain. Physical examination usually provides the diagnosis, as there is localized tenderness and swelling directly over the ligament. Grade I tears are anterior and progress posteriorly as the tear increases in severity. Radiographs may be necessary to rule out a fracture. Other conditions that may mimic a deltoid ligament tear include injuries to the posterior tibial tendon or spring ligament.

Treat all grades of deltoid ligament tear nonoperatively. Stable injuries can be treated as described for lateral ligament sprains. More severe sprains that are very painful or are unstable may require use of a short leg walking cast or CAM walker for 3 to 4 weeks.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic article; and +, clinical results/outcome study.

Stress fractures are most often encountered in athletes and military recruits. Runners, basketball and American football players, dancers, and aerobic fitness enthusiasts are those at significant risk for injury (6,13,16,17,25,27). The overwhelming majority of stress fractures occur in the lower extremity with 50% of cases involving the tibia and fibula (11,13,14,16,19). An increased incidence of stress fractures in women has been noted (3). Although most of these injuries heal uneventfully with only rest from the precipitating activity, certain stress fractures pose a challenge to achieve and maintain union. Among these, fractures of the fifth metatarsal proximal diaphysis, tarsal navicular, anterior tibial diaphysis, and femoral neck frequently require surgical treatment.

ETIOLOGY

A stress fracture is the bony expression of an overuse injury. Of the numerous inciting factors that have been described, the most common are rapid increases in the frequency, duration, or intensity of an athletic activity. Anatomic and alignment factors such as tibia vara, pronation, cavus, limited joint motion, and decreased vascularity may be contributing factors in stress fractures of the lower leg and foot (16,26,27) (See Chapter 19).

PATHOPHYSIOLOGY

Stress fractures develop as the result of repetitive loads that exceed the remodeling capability of the involved bone. Cyclic loading above the threshold level disrupts normal bone remodeling, and osteoblastic activity becomes outpaced by osteoclastic resorption. Li et al. have described the histologic changes in an experimental model (15). Initially, vascular congestion occurs, followed by osteoclast-mediated bone resorption in the haversian canals and interstitial lamellae. Small cracks appear at the cement lines of the haversian systems, which propagate into microfractures. Simultaneously, new bone formation occurs as a result of increased periosteal osteoblastic activity.

DIAGNOSIS

Pain on exertion is the hallmark of a stress fracture. Typically, the onset of pain is vague and insidious. This may follow a recent increase in activity or a change in shoes or running surface. Usually, symptoms subside with rest; without interruption of activity, however, pain intensifies, performance is impaired, and overt fracture can occur.

The most consistent physical finding is tenderness on palpation. Pain often can be elicited by percussion over a distant site of the involved bone. Especially in the foot, soft-tissue swelling can be seen. A stress fracture of the tarsal bones or tibia should be suspected in the foot with pronation just as a stress fracture of a metatarsal should be considered in the cavus foot.

Diagnosis is usually suspected on the basis of the history and physical examination; confirmation requires radiographic studies. Routine radiographs may be unremarkable for as long as 3 weeks after the onset of symptoms and may never demonstrate an abnormality (20). The technetium diphosphonate bone scan, although not specific for diagnosis, is an extremely sensitive test for excluding a stress fracture (22,23 and 24,26). Rarely, pain may antedate a positive scan, and if symptoms continue, a repeat scan is recommended (18). If the bone scan demonstrates focal activity, tomography, computed tomography, or MRI can be used to anatomically define the stress fracture.

PRINCIPLES OF TREATMENT

Depending on fracture location, treatment varies from rest to surgical stabilization. Most stress fractures of the lower extremity respond to avoidance of impact loading for a period of 4 to 8 weeks. During this time, aerobic conditioning can be maintained by bicycling, swimming, or water running. A graduated return to impact activity is started after resolution of pain. The most common fractures involving the proximal and distal tibia, fibula, calcaneus, and central metatarsals readily respond to this regimen.

Other measures, however, may be necessary. Refraining from weight bearing is mandatory if nonoperative treatment is selected for a stress fracture of the femoral neck. Immobilization and avoidance of weight bearing are usually required for successful treatment of a nondisplaced fracture of the tarsal navicular.

As discussed in the following sections, surgical treatment is needed for certain fractures:

- Femoral neck
- Anterior tibia
- Tarsal navicular
- Fifth metatarsal (Jones)

TREATMENT OF SPECIFIC INJURIES

FEMORAL NECK STRESS FRACTURES

The treatment of a femoral neck stress fracture is based on the prevention of displacement (1). If displacement occurs, nonunion, varus deformity, and osteonecrosis can result (5). A complaint of groin pain associated with activity requires investigation and treatment without delay to avoid these potential sequelae. Physical examination demonstrates pain with movement of the hip and often a reduction in range of motion.

If the initial radiographs, consisting of an anteroposterior (AP) pelvis and frog lateral view of the hip, are unremarkable, a bone scan is required. Evidence of a cortical infraction or uptake along the superior aspect of the femoral neck indicates a tensile-type fracture, which has a significant risk of displacement (6). Internal fixation to prevent this is recommended as soon as possible (5,8). The method of internal fixation of the femoral neck is described in Chapter 19.

Callus or scintigraphic uptake occurring on the inferior aspect of the femoral neck indicates a compression fracture that may be amenable to conservative treatment (6). If, however, a compression fracture is seen with a fracture line that extends toward the superior cortex, immediate internal fixation is advisable. Treatment of the stable compression-type femoral neck stress fracture consists of avoiding weight bearing and serial radiographs to ensure that displacement is not occurring and that healing
is progressing. Fracture healing may require up to 2 months from the time of diagnosis. Return to activity requires resolution of pain, a full range of motion of the hip, restoration of muscle strength and endurance, and radiographic evidence of a healed fracture.

**ANTERIOR TIBIAL STRESS FRACTURES**

Stress fractures of the middle anterior diaphysis of the tibia are uncommon. First described in ballet dancers by Burrows, this injury typically presents with localized pain associated with jumping (6). On physical examination, there may be tenderness and palpable, irregular thickening of the anterior cortex. Radiographs demonstrate diffuse anterior cortical thickening containing one or more horizontal infractions (Fig. 96.1A, Fig. 96.1B).

**Figure 96.1.** Stress fracture of the anterior mid-diaphysis of the tibia. Notice the extensive cortical hypertrophy in addition to the transverse infraction (A) and the multiple horizontal translucencies (B). C: Immediately after IM nailing. D: Healed fractures with extensive anterior cortical thickening.

A significant number of these injuries progress to nonunion or complete fracture despite rest and prolonged immobilization, which are the initial recommended treatment (12). Two factors may be responsible for this phenomenon: fracture distraction as a result of tensile forces that are concentrated along the anterior cortex and relative hypovascularity of the fracture area.

As reported by Rettig, use of noninvasive electrical stimulation can be successful in achieving union (21). Electrical stimulation is combined with immobilization in a patellar tendon-bearing (PTB) cast. The coils of the pulsed electromagnetic field’s system are incorporated in the cast to overlie the fracture site. The stimulator is used approximately 12 hours each day for 4 to 6 months (4). A bivalved, removable cast facilitates nonimpact exercises of the lower extremity, including swimming.

If this regimen is unsuccessful, and the patient remains symptomatic, surgical treatment is indicated. If a single fracture exists, excision of the fracture site with cancellous bone grafting can be used, but for multiple fracture lines, intramedullary nailing is preferred (Fig. 96.1C, Fig. 96.1D) (2). In the athlete, avoid the patella-splitting approach to minimize the potential for patellar tendonitis. Intraoperative nailing is described in Chapter 24.

**Excision and Grafting**

- Perform the procedure using a tourniquet and image intensifier.
- Make a longitudinal incision centered over the fracture, immediately lateral to the anterior tibial crest. Longitudinally incise the crural fascia adjacent to the tibial crest, and partially elevate the tibialis anterior to expose the fracture area. Elevate periosteum medial and lateral to the crest.
- Using sharp osteotomes, remove the fracture and adjacent callus en bloc.
- Use cancellous bone harvested from the iliac crest to fill the defect.
- Reapproximate the periosteum with interrupted stitches (0 absorbable). Position a 3-mm closed suction drain superficial to the reapproximated periosteum and bring it out through a separate proximal skin incision. Loosely reapproximate the fascia and close the subcutaneous tissue and skin in an atraumatic fashion using an Allgöwer stitch. Apply a well-padded splint to the lower extremity, and admit the patient overnight for observation.

**Postoperative Care** Apply a long leg cast 1 week postoperatively at the time of suture removal. Incorporate a noninvasive electrical stimulation unit to overlie the fracture area. Weight bearing is allowed as tolerated. A PTB cast can be applied at 8 weeks. Continue cast treatment until tenderness is absent and there is radiographic evidence of healing. A return to vigorous jumping activity or contact sports is not allowed until there is complete radiographic union. This may require 6 to 9 months.

**STRESS FRACTURES OF THE TARSAL NAVICULAR**

Diagnosis of a stress fracture of the tarsal navicular is frequently delayed because of the insidious onset, vague complaints of pain on the dorsomedial aspect of the foot, and the frequency with which routine radiographs do not demonstrate the injury (27,28). Torg observed several factors associated with the injury, including limited ankle dorsiflexion, limited motion of the subtalar joint, shortening of the first metatarsal, metatarsus adductus, and hypovascularity of the central one third of the navicular (27). Diagnosis is made with scintigraphy and tomograms in the AP plane (Fig. 96.2).

**Figure 96.2.** A: Delayed bone scan indicating focal increased uptake in the region of the navicular bilaterally. B: Anteroposterior tomogram demonstrating navicular fracture.

The initial treatment of nondisplaced navicular stress fractures is avoidance of weight bearing and immobilization in a short leg cast for 8 weeks. Surgical treatment is indicated for fractures that are displaced at initial presentation or fail to heal with immobilization. The preferred method of surgical treatment is open reduction and internal fixation with lag screws.

**Lag Screw Fixation**

- Under tourniquet control, make a dorsal incision centered over the navicular between the interval of the tibialis anterior and extensor hallucis longus tendons. Retract the deep peroneal nerve and dorsalis pedis artery laterally.
- With image intensification, approximate the fracture edges, and from a medial or lateral approach, insert two parallel 2-mm guide wires.
- Insert 4.0-mm cannulated lag screws of appropriate length, making sure that no threads cross the fracture site. If the fracture involves the extreme lateral third of the navicular, it may be necessary to cut off excessive screw threads. Occasionally, only one screw can be inserted.
- Cancellous grafting is not necessary unless the fracture edges are not compressed.
- Perform routine closure of the wound, and immobilize the ankle with a well-padded posterior or U-splint.
Postoperative Care

At 10 days, remove the sutures and immobilize the ankle in a non-weight-bearing short leg cast for 4 weeks. A controlled ankle motion (CAM) walker allows protected weight bearing over the next 4 weeks. After 8 weeks, remove the cast and begin rehabilitative exercises for the foot and ankle, allowing progressive weight bearing. Radiographic healing is required before resumption of running or jumping. Tomography may be necessary to document radiographic union. A return to full activity requires a minimum of 3 months (usually 4–6 months) following surgery.

**FRACTURES OF THE PROXIMAL DIAPHYSIS OF THE FIFTH METATARSAL**

Proximal fifth metatarsal fractures have two patterns: avulsion injuries of the tuberosity (dancer's fracture) and fracture of the proximal diaphysis (Jones fracture) (Fig. 96.3). Whereas avulsion injuries usually heal without the need for surgical treatment, fracture of the proximal diaphysis often requires operative treatment, especially in the active patient. Although stress fractures of the fifth metatarsal may present as an acute injury, there is usually a history of discomfort antedating the traumatic event.

*Figure 96.3. Patterns of proximal fifth metatarsal fractures. Peroneal brevis and tertius insertions (A), dancer's avulsion fracture (B), and Jones fracture of the proximal diaphysis (C).*

Diagnosis is suggested by the finding of localized pain and tenderness over the lateral and plantar aspects of the proximal diaphysis. This injury occurs frequently in basketball and American football players and is not associated with any specific foot configuration. At the time of presentation, routine radiographs can demonstrate the fracture. As Torg described, intramedullary sclerosis and widening of the fracture can be useful in diagnosing remote injuries that have progressed to delayed union or nonunion (Fig. 96.4) (26). Successful treatment must take into account the activity level of the patient and the chronicity of the fracture.

*Figure 96.4. Nonunion of the fifth metatarsal with intramedullary sclerosis and fracture widening.*

In a recreational athlete with an acute injury, successful treatment can be achieved by cast immobilization combined with strict avoidance of weight bearing for 6 to 8 weeks. In the high-performance athlete, refracture after conservative treatment is not unusual, and therefore, intramedullary screw fixation can achieve early and persistent union with minimal morbidity and an early return to activity (7). If a fracture has progressed to delayed union or nonunion, intramedullary screw fixation or medullary curettage and inlay bone grafting can be successful (26).

**Intramedullary Screw Fixation**

- Select regional, epidural, or general anesthesia, and position the patient on an operating table that allows intraoperative use of the image intensifier. The lower extremity should be internally rotated to provide access to the lateral border of the affected foot.
- Under tourniquet control, palpate the lateral base of the tuberosity of the fifth metatarsal, and make a longitudinal incision from this point extending proximally for 3 cm. Divide the subcutaneous tissue, protecting the branches of the sural nerve and the insertions of the peroneus tertius and peroneal brevis at the base of the tuberosity. Adduction of the forefoot increases exposure of the metatarsal base.
- Under image intensification, introduce a 3.2-mm drill in line with the axis of the metatarsal. If necessary to prevent penetrating the cortex of the shaft, reposition the drill. Insert a 4.5-mm malleolar screw into the hole, making sure that the screw remains intramedullary and that the threads completely pass distal to the fracture site (Fig. 96.5). The hole should not be countersunk to allow maximal compression. If the canal is large, and adequate purchase is not obtained with the 4.5-mm screw, redrill using a 4.5-mm drill bit and insert the appropriate length 6.5-mm cancellous screw. If desired, a cannulated screw system that allows insertion of an initial guide wire can be used.

*Figure 96.5. Jones fracture after insertion of a malleolar screw*

- Close the skin with interrupted sutures, and apply a well-padded splint to the foot and leg.

**Postoperative Care**

As soon as swelling subsides, apply a short leg cast for 2 weeks, limiting weight bearing. After this period, remove the sutures and fit the patient with a CAM walker, allowing progressive weight bearing for an additional 3 to 4 weeks. Restorative exercises can be started during this period. Resolution of pain and radiographic healing usually occur by 8 weeks postoperatively. No further protection is necessary after return to activity.

**Combined Intramedullary Screw Fixation and Inlay Bone Grafting**
With the patient positioned as above, make a straight 5-cm incision along the lateral border of the fifth metatarsal, centered over the tuberosity.

- Identify and protect sensory branches of the sural nerve, and retract the peroneous brevis dorsally to expose the inferior aspect of the tuberosity. Expose the fracture by incising the periosteum.

- Use a curet and rongeur to trim the sclerotic ends of the fracture. Outline and remove a small rectangular cortical segment (2 × 1 cm) from the lateral and inferior area centered over the fracture (Fig. 96.6A, Fig. 96.6B).

- Using a template, obtain a corticocancellous block oversized by 2 mm in each direction from the iliac crest along with cancellous graft.

- Pack the fracture area and intramedullary canal with cancellous graft and press-fit the corticocancellous-block into the trough bridging the fracture.

- If additional stability is desired, insert an intramedullary screw as described above. This achieves a "belt and suspenders" method of fixation (Fig. 96.6C).

- Close the skin and apply a well-padded splint as previously described.

**Postoperative Care**

Remove the sutures at 10 days and use a cast or CAM walker for protected weight bearing for 6 to 8 weeks. Return to activity usually takes 3 to 4 months.

CHAPTER 97

ADOLESCENT SPORTS INJURIES

Letha Y. Griffin and Xavier A. Duralde

In the United States, it is estimated that 25 million scholastic athletes (202) participate in sports on a regular basis each year and 35 million nonscholastic athletes participate in community programs (196). All in all, sports account for 36% of the injuries of all kinds seen in children and adolescents in the United States yearly. Injuries are more frequent in boys than girls at a ratio of 1.8:1 and increase with age (20), a statistic that reflects lower levels of training intensity in the younger age group (78,193). Injuries tend to be sport specific and are more common in collision sports (26,192,223), with 40% to 80% of football players sustaining an injury yearly (196). Although catastrophic injuries do occur (156) the majority of injuries are minor (77,196). A full 25% of youth football players, however, require five days off during the season for sports-related injuries (77). Unorganized sports are associated with a higher rate of injury than organized athletics (49,223), a fact that underscores the importance of adult supervision in youth athletics.

OVERUSE INJURIES

Overuse injuries are those caused by repetitive minor trauma that overwhelms the individual’s healing capacity. Two scenarios have been blamed for the occurrence of overuse injuries in children: an inadequately trained athlete experiences high musculoskeletal demands (83) or an extremely fit athlete overtrains (197). Children rarely develop stress injuries during unstructured play, but under the pressures of coaches, parents, or occasionally, peers, they will press past pain into injury (192). With greater emphasis on excelling in a single sport, children have begun training for many hours a day at very young ages. The young runner runs 10 to 15 miles a day, an elite swimmer strokes up to 400,000 times in a 10-month season (196), a gymnast spends 4 to 6 hours a day in the gym, and a dancer dances a similar amount of time. Few studies have explored the ability of immature musculoskeletal tissue to adapt to increased physical stresses or the influence of factors such as psychological stress, hormonal fluctuations, and nutrition. Table 97.1 lists commonly reported risk factors for overuse injuries in children and adolescents.

Table 97.1. Risk Factors for Overuse Injuries in Children and Adolescents

To minimize overuse injuries, children should be encouraged to limit practice hours; use good-quality, properly fitted equipment; cross train; and participate in conditioning programs to develop strength and flexibility. Overuse injuries in children most commonly affect the bone or its physis (stress fractures), cartilage at the attachment of tendons (nonarticular osteochondroses), or cartilage and bone at the joint surfaces (primary and secondary osteochondroses).

STRESS FRACTURES

Stress fractures are less common in children than in adolescents and less common in adolescents than in adults (132,204,214). Before the advent of organized sports for children, stress fractures in this age group were rare; however, with emphasis on serious sports training at earlier ages, the incidence has increased (84). These fractures are most commonly reported in the tibia (50%), fibula (20%), pars interarticularis (15%), and femur (3%) (185). Sports most commonly associated with stress fractures are running (24%), basketball (13%), gymnastics (21%), football (9%), and ice skating (15%) (132). Upper extremity stress fractures are seen in baseball, tennis, swimming, and gymnastics.

CLINICAL EVALUATION AND PRESENTATION

The clinical evaluation of a young athlete with a stress fracture is similar to that of an adult. Unlike the pain associated with soft-tissue overuse injuries, stress fracture pain is minimal or absent on arising in the morning, progressively gets worse with activity, and is relieved with rest. In certain sites where the bone is palpable directly
beneath the skin, such as the tibia, fibula, or distal radius, the athlete may be able to localize the pain to the specific site of involvement. At other sites—hip, femur, or humerus—pain localization may not be possible; the athlete vocalizes only that the limb “hurts” with increased activity. On physical examination, stressing the injured bone either by taping or applying digital pressure or angular or rotational stresses generally reproduces symptoms. There may be localized tenderness, warmth, or discoloration at the fracture site, but these findings are more typically seen after the athlete has been symptomatic for a while and may not be present in the early stages of injury. Young children may have a low-grade fever.

**IMAGING**

Plain radiographs in the early stages of bone injury may be normal. Radiographic findings may take several weeks or months to develop. In fact, if the athlete ceases activity when the symptoms first begin, the injury may never be seen radiographically (132). However, technetium-99M phosphate bone scans are positive within 6 to 72 hours of injury (65,132). The degree of uptake depends on the rate of bone repair and local blood flow. Uptake is typically localized, but diffuse uptake patterns may occasionally occur. Although they are highly sensitive, bone scans are not specific because other conditions, including infection and tumor, result in positive scans. Periostitis associated with inflammation at the origin of the posterior tibial muscle (shin splints) may be associated with a diffuse linear uptake pattern, which can be confused with a stress fracture. Imaging studies must be correlated with the clinical history and physical exam. Computed tomography (CT) scanning is less sensitive.

Magnetic resonance imaging (MRI) is extremely sensitive to early stress reactions presenting as edema—that is, areas of low-intensity signal on T-1 weighted images that increase on T-2 weighted images. In advanced stress reactions, T-2 weighted images demonstrate low intensity bands continuous with the cortex, presumably representing fracture lines (10). *Figure 97.1* presents Anderson and Greenspan’s imaging algorithm (15) for suspected stress fractures.

**TREATMENT**

The philosophy of treating stress fractures in athletes is to decrease stress to the injured area while maintaining a conditioned state. The intact soft-tissue envelope (skin, muscle, tendon, and ligament) provide support for the injured bone. Therefore, crutches or a cane to decrease weight-bearing stress to the injured extremity rather than a cast may be all that is needed. The key phase in the treatment of stress fractures is to increase the stresses to the bone gradually within the limits of comfort, advancing from non-weight-bearing, nonimpact activities to weight-bearing, nonimpact activities, and finally, to weight-bearing impact activities *(Fig. 97.2)*. Progression of each new activity should be done as in *Figure 97.3*. As part of the treatment for a stress fracture, try to identify and correct any causative factors.

**DIFFICULT-TO-HEAL FRACTURES**

Although most stress fractures in children heal uneventfully, anterior midtibial cortical stress fractures and pars interarticularis fractures of the spine may take a prolonged time to heal (86). The former occur primarily in jumping sports (86,161). Some have recommended debridement and bone grafting for these fractures if union is delayed (10), whereas others have recommended electrical or ultrasound stimulation (172). Fractures of the pars interarticularis should always be considered in the differential diagnosis of the young growing athlete with low back pain, especially if the athlete is involved in sports requiring repetitive hyperextension of the lumbar spine, such as football, dancing, skating, and gymnastics (183). On clinical examination, the athlete may not have pain on palpation of the area of injury despite complaining of unilateral low back pain with lumbar hyperextension. If radiographs are normal at the time of diagnosis, early prolonged protection in an antilordotic orthosis may result in healing in 4 to 6 months (54). This isthmic spondylolysis infrequently progresses to severe spondylolisthesis (185).

**PHYSEAL STRESS FRACTURES**

Physeal stress fractures are unique to children (33). Sites of involvement have included the distal radius in gymnasts (41,127), the proximal tibia (40) and distal femur (82) in runners, and the distal ulna in break dancers (78).
As in most overuse injuries, pain is insidious in onset. The diagnosis is made on the basis of history and physical examination. For distal radial fractures, the most common physseal stress fractures, the patient is typically a young male or female gymnast performing at a high intensity with no history of a single traumatic event but gradually increasing wrist pain. There is tenderness to palpation over the distal radius. Initially, range of motion may be full, but as the symptoms progress, range of motion decreases.

Wrist radiographs may at first appear normal, but widening of the growth plate with cystic changes and marginal irregularities, typically seen on the metaphyseal side of the plate, can be seen in those athletes who continue to participate despite pain (41,127).

Cahill et al. (37) described stress fractures of the proximal humerus in Little League pitchers who presented with vague pain during pitching. Radiographs, which were initially normal, soon demonstrated a widened proximal humeral physis and finally show callus with progressive healing. Complete healing took approximately 6 weeks.

OSTEOCHONDROSES

The osteochondroses are a group of growth cartilage abnormalities that occur at the apophysis, at the joint surface, and at the physseal plate. They have been defined by Siffert (189) as “idiopathic conditions characterized by disorderliness of endochondral ossification, including both chondrogenesis and osteogenesis that comes upon a formerly normal growth mechanism” (Table 97.2). Some researchers believe that repetitive stress (microtrauma) is the primary precipitating factor (145) or at least a major contributing factor (64). However, the etiology of the osteochondroses is still debatable; vascular, hormonal, genetic, and metabolic factors as well as infections have all been proposed as precipitating or contributing causes. These conditions may merely represent abnormalities of maturation. Because diagnosis typically depends on radiographic confirmation (64,159,169), many of the osteochondroses carry the name of the individual who first described their radiographic appearance.

</tr>
</thead>
<tbody>
<tr>
<td>The nonarticular osteochondroses are summarized in Table 97.3. They typically occur during periods of rapid growth, are generally self-limited, and resolve without residual impairment (107). Symptomatic treatment is appropriate in young athletes to try to minimize morbidity and enhance recovery. Outcome studies justifying the expense of such treatment are lacking, and one could argue, as did Voltaire, that “the physician entertains the patient while nature cures the disease.”</td>
</tr>
</tbody>
</table>

Table 97.3. The Nonarticular Osteochondroses ("The Apophysites")

<table>
<thead>
<tr>
<th>PRIMARY ARTICULAR OSTEOCHONDROSES</th>
</tr>
</thead>
<tbody>
<tr>
<td>Primary articular osteochondroses have been defined as “diseases of the growth or ossification centers in children that begin as a degeneration or necrosis followed by regeneration or recalcification” (26).</td>
</tr>
</tbody>
</table>

Pathophysiology

Primary articular osteochondroses progress through three stages (46,159). Stage 1 is reactive edema of the articular tissues and active hyperemia of the metaphysis leading to decreased diffusion of nutrition to cells of the epiphysis. Thrombosis and trabecular microfracture further compromise the epiphysis, resulting in epiphyseal irregularities and thinning at the subcortical zone (stage 2). Peripheral ingrowth of the capillaries and mesenchymal cell differentiation are responsible for repair with
gradual replacement of necrotic tissue (stage 3).

**Treatment**

Treatment focuses on activity modification and protective immobilization of the injured area until symptoms resolve and radiographic recovery is evident. In some cases, surgery is needed to correct residual anatomic abnormalities that prevent normal function. Two of the more common primary articular osteochondroses seen in young athletes are Freiberg's and Panner's diseases (Table 97.4).

**SECONDARY ARTICULAR OSTEOCHONDROSES**

Secondary articular osteochondroses are characterized by involvement of the articular epiphyseal cartilage as a consequence of loss of support from destroyed subchondral bone (183). Included in this category are Legg-Calvé-Perthes syndrome, Köhler's disease, and osteochondritis dissecans, which in adolescent athletes occurs most commonly in the knee, ankle, and elbow (186) and can significantly implicate participation. Osteochondritis dissecans (OCD) has been characterized as an "isolated segment of epiphyseal and articular cartilage–covered necrotic bony centrum" occurring in diarthrodial joints. The etiology remains obscure, but OCD is believed to be unlikely to be an inflammatory condition, even though its name implies that it is (164). Many authors favor a traumatic etiology, either a single traumatic event or repetitive stress, resulting in either vascular compromise to a bony segment or a subchondral fracture that fails to heal and therefore goes on to develop avascular necrosis (39,52,75). Some believe that a vascular insult in the absence of trauma may occur (65). Metabolic, hormonal, or genetic factors may enhance the vulnerability of certain individuals to OCD. Age may also be a predisposing factor, and a familial tendency has been found (74,135,208). Bilaterality has been reported as high as 33% in one series (87). Although the etiology of this entity remains obscure, there is agreement that the reparative process is more likely to occur before cessation of skeletal growth, and in fact, repair is the likely outcome in children; it may occur in adolescence, but it is rare in adults.

**Pathophysiology**

The affected bony fragment is typically located at the superficial joint surface. Focal avascular necrosis is followed by reparative osteogenesis consisting of revascularization, granulation tissue invasion, osteoclastic of necrotic fragments, ingrowth of osteoid, and finally, remodeling of new bone. In the early stages of the lesion, the overlying articular cartilage is normal, but later it becomes softened, discolored, fibrillated, and fissured. Finally, from lack of support of the underlying subchondral bone, it eventually separates, leaving a bare area of bone that will ultimately fill with fibrous tissue. Even before the fragment separates completely, if the subchondral bone fails to heal but instead remains avascular, fibrous tissue may develop beneath the fragment. If a healing response occurs before cartilage collapse, the subchondral bone is characterized by active cellular processes with vascular ingrowth and active osteogenesis, providing once again a viable structural foundation for the overlying articular cartilage.

**OSTEOCHONDritis of the Knee**

Osteochondritis of the knee, named by Koenig in 1887 (36), was really first described in 1866 by Sir James Pagent, who termed it "quiet necrosis," a name that perhaps more typifies its pathophysiology than does Koenig's term.

**Clinical Evaluation**

The clinical presentation of the athlete with OCD of the knee is variable and nonspecific. The lesion may be noted in asymptomatic athletes on review of radiographs taken for an unrelated problem, may cause minor symptoms such as an ache in the knee aggravated by activity, may result in a slight effusion, or if the fragment separates, may cause frank locking or catching. The symptomatic individual may recall a precipitating traumatic event, often minor and not resulting in loss of time from sports or may recall no such event, but typically patients have been active in sports and exercise (39,175). The age of onset is between 5 and 50 years (175,179), with the greatest incidence during the adolescent decade (175).

On physical examination, pain may be elicited by flexing the knee 90° and palpating for tenderness along the condyle. There may be slight swelling, but no instability is present. Typically there is a near full range of motion unless a fragment has become loose, resulting in mechanical locking of the knee. Thigh muscle atrophy and externally rotated gait may be noted. Pain may be elicited by flexing the knee to 90° and, with the tibia externally rotated on the femur, slowly extending the knee to approximately 30°. Internally rotating the tibia rapidly relieves this pain (Wilson's sign) (219).

**Classification**

Various classification schemes exist for OCD, each with implications for treatment and prognosis. These include

1. Age or, more specifically, status of the physis at the time of diagnosis (164)
2. Scintigraphic appearance of the lesion, as correlated with radiographs (Fig. 97.4) (36)
3. Location on the femoral condyle (Fig. 97.5) (39)
4. Appearance on imaging studies with contrast (MRI or CT) (112).
5. Intactness of the articular mantle and mobility of the fragment, as noted surgically (Fig. 97.6).

The status of the physis at the time of the diagnosis of OCD seems most critical in predicting outcome. Juvenile OCD, which occurs in children or young adolescents with open growth centers, has a higher probability of healing without the development of degenerative changes than does adult-onset OCD (36,120). The prognosis and course of OCD diagnosed in late adolescence is similar to that in adults.

**Imaging**

OCD classically occurs on the lateral aspect of the posterior portion of the medial femoral condyle and is frequently visible on routine radiographs of the knee. Tunnel views may be required to enhance visualization. The lesion's appearance is that of a well-circumscribed area of subchondral bone, which may be sclerotic or fragmented and is often separated from the femoral condyle by a crescent-shaped radiolucent line.

In 80% to 85% of patients, the lesions occur in the medial femoral condyle, with 15% to 20% in the lateral femoral condyle (Fig. 97.7). Bone scans that measure osteoblastic activity and regional blood flow can be used to evaluate the potential for fragment healing (39,124). However, Paletta et al. (162) demonstrated that although quantitative bone scanning with technetium-99M has a 100% predictive value for prognosis in patients with a open physis, it is less reliable in predicting healing in adolescents with a closed physis. Unfortunately, it is in the group of adolescents with a closed physis in whom outcome is unpredictable, and predictability by bone scans would be extremely helpful were it more reliable.

**Treatment**

The algorithm for treatment of OCD, like its etiology, remains controversial. Most would agree, however, that the ultimate goal is to promote recovery of the subchondral bony defect while preserving the intactness of the overlying cartilage. Early literature is confusing because outcomes were not related to the age of the patient at the time of onset (a major determinant of prognosis).

The classification schemes previously discussed are extremely helpful in trying to formulate a treatment plan. Many agree that for symptomatic children with an open physis (juvenile osteochondritis dissecans [JOCD]) in whom contrast arthrography demonstrates an intact articular surface, nonoperative care is reasonable (87,119,179,198). For this group of patients, Cahill (36) recommends activity modification initially using crutches for non-weight bearing or partial weight bearing. He does not recommend braces or casts. When acute symptoms subside, discard crutches and institute recreational cycling, swimming, and lower extremity strengthening exercises. Perform serial bone scans every 4 months; the lesion is considered healed when bone scans revert to stage II lesions (Fig. 97.4). Cahill's reported average time to healing is 10 months. Schenck and Goodnight (154) support this scheme but would recommend splint, cast, or an immobilizer during the early stages of treatment to increase compliance. They suggest following healing with plain radiographs or occasionally serial MRI in lieu of bone scans (36). The success rate with JOCD treated conservatively has been reported to be 50% (36). However, Pappas (164) stated that if all JOCD patients are subclassified into Pappas category I and II (Table 97.5), successful treatment in category I (children and young adolescents) is usually ensured without surgery.
Operative treatment in JOCD is indicated when conservative care fails to show progressive healing of the lesion on serial bone scans or when the cartilage mantle becomes disrupted, indicating instability of the fragment. How long conservative care should be pursued if symptoms persist without improvement or radiographs remain unchanged is debatable. Schenck and Goodnight (184) suggest 6 to 12 months of conservative care before considering surgical intervention.

Cahill (36) published a treatment algorithm for JOCD (Fig. 97.8), noting “with the exception of earlier surgical intervention, the principles of surgical treatment of OCD are identical to those for JOCD”.

Operative Technique

Principles of operative treatment for osteochondritis dissecans of the knee are to (1) preserve the articular cartilage, especially on the weight-bearing areas; (2) enhance the blood supply; and (3) ensure stability of the bony fragment.

If a lesion is stable at the time of surgery and has an intact cartilage mantle, perform antegrade (7) or retrograde drilling under image visualization (90,198) to enhance the vascularity of the fragment (Fig. 97.9). Cahill (36) believes that the intactness of the cartilage mantle is not critical, and even if there is a partial articular defect, if the fragment is stable with probing, no internal fixation is needed. Postoperatively, with stable lesions that are drilled, progress weight bearing as tolerated.

If the lesion is unstable or partially detached, remove the fragment from its base and curet the base of the fragment as well as the base of the lesion to debride all fibrous tissue. If there is a soft-tissue bridge at the insertion of the posterior cruciate ligament on the femoral condyle, preserve this potential vascular bridge by elevating the fragment on this as a hinge rather than removing the fragment. Drill the dense bone of the crater to enhance vascularity before replacing the fragment. In a partial or totally detached lesion, crater fragment mismatch may exist either because the fragment, nourished by joint fluid, grows larger than the crater or, because with the loss of subchondral bone, the fragment is too small. If the fragment is too large, sculpt it to fit the crater; if the crater is too large, graft the crater's base with local bone from the metaphyseal area of the tibia to provide support for the fragment (36,184,187). Take care to match the crater to the fragment as accurately as possible because inadequate reductions of the articular surface yield poor results (87).

Various devices exist to fix the fragment rigidly, including screws and pins (123) (biodegradable and nonbiodegradable) as well as bone pegs (Fig. 97.10 and Fig. 97.11) (79,103). Cahill (36) believes that metallic fixation devices may adversely affect the cartilage surface and prefers smooth pins over screws. Initially a sterile synovitius was observed with biodegradable self-reinforced polylactide rods and polylactic acid pins. This has not been seen with the newer biodegradable pins and screws made of the slower absorbing polylactide (133).
Figure 97.10. Bone peg fixation of OCD lesion. A: Make two anteromedial skin incisions. B: Expose the lesion on the medial condyle. C: Place drill holes in the fragment across the lesion. D: Harvest bone graft from the tibia and fashion bone pins. E: Insert bone pins into the fragment to fix it. (Redrawn with permission from Gillespie HS, Day MD. Bone Peg Fixation in the Treatment of Osteochondritis Dissecans of the Knee Joint. Clin Orthop 143:126;1979, with permission.)

Figure 97.11. Authors’ preferred method for treating unstable partially detached lesions of the medial femoral condyle. A: Visualize and probe lesion. If unstable, hinge open lesion, preserving intact cartilage rim. B: Curet base of lesion and drill or pierce retrograde with arthroscopic awls or picks, taking care to perforate but not destroy subchondral plate. C: Replace lesion using bone if needed from femoral condylar region obtained percutaneously or with a hollow core drill from proximal tibial metaphysis. D: Stabilize the lesion with K-wire drilled antegrade until just piercing the articular cartilage surface, cutting pins beneath the skin or stabilized with PDS pegs by Johnson & Johnson placed retrograde under arthroscopic visualization. Postoperative care: Immobilize the knee for 3 to 5 days and then brace to allow full range of motion and begin strengthening exercises. No weight bearing is permitted for 8 to 10 weeks until radiographic healing is apparent.

Fixative devices are adaptable to either arthroscopic or open procedures. The decision of which technique to use depends on the ability of the surgeon to approach the fragment arthroscopically.

- If nonbiodegradable pins are used for fixation, they are generally removed at 3 to 8 weeks postoperatively (36,123). Postoperative care includes early range of motion, with strict adherence to non-weight bearing until the fragment is healed.
- Consider removal of only small fragments (134), fragments on the non-weight-bearing articular surface (36), or fragments that pose a significant fragment-crater mismatch. Treatment of the crater remains controversial. Doing nothing but fragment removal has yielded poor long-term results, even though short-term outcomes are generally good (8).
- The defect can be drilled or “picked” with arthroscopic awls (28) used to create microfractures in the subchondral bone to enhance vascularity of the bed and thus promote the development of type I fibrocartilage.
- Stabilize the edges of the defect by trephining (80) or spongialization (187) rather than saucerization (Fig. 97.12).

Figure 97.12. Methods of dealing with articular cartilage defects. (Redrawn from Clanton TO, DeLee JC. Osteochondritis Dissecans—History, Pathophysiology, and Current Treatment Concepts. Clin Orthop Rel Res 167:50;1982, with permission.)

- Other options include filling the defect with a paste of mortilized autologous cartilage and bone taken from the joint (Construct Chondral Repair System by DePuy [207]), core autografts harvested with one of the several commercially available systems (MosaicPlasty by Smith and Nephew [92], OATS by Arthex [30], and COR System by Innovasive), or autologous cell culture grafting using the Genzyme technique (34).

Consider osteochondral allografts only for OCD lesions larger than 20 mm in diameter (47).

OSTEOCHONDritis DissecANS OF THE TALUS

Kappis (206) as described by Stone was the first to use the term OCD for lesions in the ankle. Whether the ankle lesion is the same pathologically as that in the knee is debatable.

Pathophysiology

In 1959, Berndt and Harly (21) reviewed the literature on osteochondral lesions of the talus (191 lesions in 183 patients) and concluded that these lesions, whether they appeared on the medial (57%) or the lateral (43%) side of the talus, were trauma-induced transchondral fractures. Canale and Belding (62), in their survey of 31 lesions, found all lateral lesions were secondary to trauma, whereas only 9 of 14 medial lesions were associated with trauma.

Prognostically, lateral lesions have more persistent symptoms and a greater association with later degenerative changes. Roden et al.’s (179) data reinforced Canale and Belding’s observation that medial talar lesions can heal spontaneously, have few symptoms, typically are not associated with degenerative changes, and may not all be trauma related, whereas lateral lesions are by and large all traumatic (69,131).

Classification

Berndt and Harly’s (21) radiographic classification (Table 97.6) remains popular. Prisco et al. (179) correlated this system with a grading scale related to the arthroscopically observed intactness of the articular surface (Fig. 97.14) and concluded that the radiographic stage did not necessarily correlate with the severity of
hyalin cartilage injury (arthroscopic grading). They recommended using the arthoscopic rather than radiographic appearance for treatment decisions.

**Figure 97.14.** Berndt and Harty Classification of OCD of the talus (see table 97.6).

---

**Imaging**

Osteochondritic lesions can generally be seen on a plain radiograph. A mortise view taken in plantar flexion highlights posteromedial lesions, whereas anterolateral lesions are best seen if the mortise view is done in dorsiflexion (206). Anderson et al. (9) recommends bone scans on patients in whom osteochondral lesions are suspected but routine films are negative.

CT and MRI, particularly if enhanced with contrast, provide accurate information on fragment size and location, and correlate fairly well with arthroscopic evaluation of cartilage congruity and fragment stability (9, 86).

**Treatment**

Canale and Belding (42) use the classification scheme of Berndt and Harty (21) as the basis for their treatment decisions (Table 97.6).

Procedures described to treat OCD include drilling intact lesions; open reduction internal fixation of detached lesions; and fragment excision and curettage, abrasion, or drilling of the base. Recently, autologous bone grafting techniques developed for osteochondritis of the knee have been tried for OCD lesions of the ankle. Lateral lesions are fairly easy to approach arthroscopically, whereas approaching medial lesions arthroscopically may pose some difficulty (66, 170). Some authors prefer a medial malleolar osteotomy for visualization of medial lesions.

**Operative Technique**

Ankle arthroscopy for OCD (Fig. 97.13) of the talus proceeds as follows:

**Figure 97.13.** Ankle arthroscopy for osteochondritis dissecans of the talus. (From Stone JW. Osteochondral Lesions of the Talar Dome. *J Am Acad Orthop Surg* 1996;4:63, with permission.)

- Prep and drape the extremity as for diagnostic ankle arthroscopy using the strap ankle distracter and 2.7 mm 30° and 70° arthroscopes.
- Inspect the joint, looking in all gutters as well as anteriorly and posteriorly for loose bodies.
- For anterolateral lesions, place the scope in the anteromedial portal, inserting instruments through the anterolateral portal. Probe the lesion to examine the intactness of its edges and base. Trephine the edges and debride the base of the crater with a ring curet. Use 0.062-inch smooth K-wires to drill the lesion.

**Figure 97.15.** Berndt and Harty Classification of OCD of the talus (see table 97.6).
For anteromedial lesions, place the scope through the anterolateral portal and visualize the lesion through the anteromedial portal. The lesion may be difficult to reach for curetting and drilling if it is located far posteriorly. However, with plantar flexion of the foot, most lesions are accessible.

If the lesion cannot be reached through the anteromedial portal for drilling, visualize the lesion arthroscopically, but insert the K-wires through the medial malleolus down into the lesion while plantarflexing and dorsiflexing the foot to aid in visualizing and drilling the lesion. This technique does violate the intactness of the ankle's articular surface.

Alternatively, while watching arthroscopically, use a drill guide to drill transtalarly into the lesion, entering from the sinus tarsi into the talus in its nonarticular portion anterior to the anterior talofibular ligament insertion area.

Postoperatively, Stone (206) advises immobilizing the ankle for 6 weeks and then beginning active and passive motion exercises. Others immobilize the ankle for only 7 to 10 days and then start active range of motion and strengthening exercises, with weight bearing being delayed for 6 to 8 weeks. See section on ankle arthroscopy for additional procedures.

OSTEOCHONDROSIS DISSECSANS OF THE ELBOW

OCD of the elbow (found most frequently in the capitellum but occasionally also seen in the radial head) is part of the injury complex popularly termed “Little League elbow.” This term was originally used by Brodgon and Crowe (35) to describe clinical and radiographic changes on the medial side of the elbow in young baseball pitchers, but was expanded by Adams (3) to all the pathologic processes that occur about the elbow secondary to the stresses of pitching or throwing (Fig. 97.16), including not only medial tension injuries but also lateral compression and posterior fossa injuries. Repetitive medial tension forces on the growing youth's elbow include medial apophysitis, avulsions of the medial condyle, accelerated growth, or fragmentation of the medial epicondyle. Repetitive lateral compression forces are thought to be responsible for the development of OCD of the capitellum and radial head. The valgus position of the elbow as it is forcefully propelled forward by the shoulder with the wrist in a supinated position during the acceleration phase of pitching is the mechanism blamed for the development of these tension and compression loads (5) (Fig. 97.17). Children who pitch with a side-arm delivery are therefore more likely to develop symptoms (197).

Clinical Evaluation

The child with Little League elbow is typically between 11 and 16 years of age and may complain only of decreased throwing performance but more typically complains of pain with activity that improves with rest. If the athlete continues to play with pain, the pain may last after playing hours. Night pain is rare. The pain may be diffuse but is generally limited to medial, lateral, or posterior aspects of the elbow. There may be a lack of full extension, and this may be the only complaint. Flexion is rarely limited.

On physical examination, in addition to a loss of extension, there may be a mild effusion or localized swelling over the medial epicondyle. Crepitation with motion can be present if there are loose bodies.

Injuries to the posterior fossa of the elbow occur from the posterior medial shear force, which develops during late cocking and from the hyperextension that develops during follow-through. Such forces result in posterior medial spurs, olecranon spurs, stress or avulsion fractures of the olecranon apophysis (see the section on nonarticular osteochondroses), and traction spurs of the coronoid process.

The incidence of Little League elbow in the adolescent has been reported to be from 23% to 70% (190). Changes similar to those that occur in Little League elbow have been found in other throwing athletes (javelin throwers and tennis players) as well as gymnasts, the latter presumably from weight bearing on an extended valgus elbow.

Classification

Bianco’s (25) classification system for osteochondritic lesions (Table 97.7) is based on the integrity of the cartilage mantle as noted by contrast imaging or arthroscopy.
Table 97.7. Treatment Options for Osteochondritis Dissecans of the Capitellum Based on Bianco’s Classification System

Imaging

In most circumstances, the lesion of OCD appears as a rarefaction in the subchondral capitellum, often with a well-defined sclerotic border (Fig. 97.18). Loose bodies may or may not be identified. In the symptomatic athlete with normal radiographs or in the athlete whose lesion is seen on routine radiographs but in whom there is a question regarding the integrity of the cartilage mantle or the presence of loose bodies, arthrotomography or contrast MRI may be extremely helpful. In chronic cases of Little League elbow, routine films may also show an enlarged or beaked medial epicondyle, fragmentation or separation of the medial apophysis, an enlarged radial head, or fragmentation or widening of the olecranon epiphysis.

Figure 97.18. Radiograph of 15-year-old pitcher. Note osteochondritis lesion of the capitellum.

Treatment

For the symptomatic thrower whose x-ray study demonstrates an intact lesion, treat with cessation of the offending activity; range-of-motion exercises; and stretching and strengthening the muscles of the shoulder, arm, forearm, and wrist. Give particular attention to stretching the anterior elbow capsule. A cast or a splint may be needed for several weeks to enhance compliance with ceasing activity. Limit resistance weight training for 6 to 12 weeks. When radiographic revascularization and healing is evident on repeat serial x-ray studies, begin a gradual return to a throwing program, with emphasis on proper technique (Fig. 97.19).

Figure 97.19. An example of gradual return to throwing program.

As in all children's and adolescents' throwing programs, place limits on the number of pitches thrown both in practices and games. A change of position for pitchers is advised, even if only on a temporary basis. The prognosis is favorable for adolescents who have lucent subchondral defects with intact overlying cartilage. Return to sports typically occurs within 6 months to 1 year but may be earlier based on resolution of symptoms and radiographic healing.

There is not unanimous agreement on how to treat Bianco's type II lesions (25). Some authors (121,164) recommend arthroscopic or open pinning of type II lesions in situ using unthreaded K-wires placed antegrade into the lesion and through the lateral condyle. The K-wires are left either under the skin or just above it to be removed in 6 to 8 weeks. Others (152,190) recommend surgery only for loose fragments that cause locking or catching. The three options available for treating loose fragments are

1. to replace the fragment using bone graft if needed,
2. to remove the fragment and either drill (or drill and curet) the base (most authors [136,164,190] recommend preservation of the subchondral plate when curetting), and
3. to simply remove the fragment (152,221).

Those favoring the second option argue that replacing the lesion yields poor results and 85% of those treated with a well-structured rehabilitation program following excision and drilling (or drilling and curetting) are able to throw successfully in 6 months to a year (136). Younger patients typically have a more favorable outcome no matter what stage of the lesion they have at the time of diagnosis.

Operative Technique

McManama et al.’s (136) treatment of osteochondritis dissecans of the capitellum is as follows (Fig. 97.20):

- Make a lateral incision by beginning 1 to 2 cm proximal to the lateral epicondyle of the humerus. Extend the incision distally over the epicondyle and along the posterolateral surface of the forearm for 4 to 5 cm. Proximally, the deep incision should enter through the triceps posteriorly and the brachioradialis and extensor
AVULSION OF THE MEDIAL EPICONDYLE OF THE ELBOW

AVULSION OF THE MEDIAL EPICONDYLE OF THE ELBOW

Avulsion fractures in children and adolescents were previously thought to be rare but are now more common and occur almost exclusively during athletic activity (171). Secondary ossification centers remain open in different parts of the skeleton between 14 and 25 years of age, and the unification time for each particular apophysis correlates with the average age of occurrence of avulsion fractures at their respective locations (216). Longitudinal bone growth stimulates muscle tendon growth, resulting in a period of relative inflexibility of these soft tissues relative to the adjacent skeletal tissue. This occurs during or immediately after periods of rapid growth and also coincides with periods of relative weakness at the physes. This relative inflexibility is particularly a problem for muscle-tendon units that cross two joints, such as the rectus femoris, sartorius, hamstrings, gastrocnemius, iliotibial band, and iliofemoral. The great majority of avulsion fractures occur in children who are constitutionally tight and have just finished a growth spurt (146,149). Avulsion fractures are seen most commonly in ballistic sports such as soccer, track, and field, and jumping sports in which a sudden violent contracture of a muscle tendon unit can lead to avulsion of the apophysis (118,146,149). Adolescent athletes who participate in running or jumping sports tend to be less flexible than age-matched controls, and flexibility is gained slowly (119). The mechanism of avulsion tends to result from either excessive stretching or a violent contraction (65) of the adjacent muscle tendon unit. Although conservative management is often successful, these fractures must be differentiated from neoplasms or normal sesamoid bones.

AVULSION OF THE ANTERIOR SUPERIOR ILIAC SPINE

Avulsion fractures from the pelvis are usually related to sports (67) and occur secondary to eccentric muscle contraction associated with rapid deceleration or acceleration (Figs. 97.21) or excessive passive stretching such as by a cheerleader doing a split. Only rarely are these fractures due to a direct blow (198). The amount of displacement seen in these avulsion fractures is related to the degree of initial injury and to the soft-tissue attachments that may tether the avulsed fragment. The anterior superior iliac spine avulses secondary to extensive pulling of the sartorius, usually with the hip extended and the knee flexed (177). There is pain and swelling over the anterior superior iliac spine, and the average age of presentation is 15 years (178). Radiographs show displacement of the anterior superior iliac spine apophysis. Treat with bed rest, followed by progressive weight bearing on crutches for approximately 4 weeks. Surgery is rarely required, even if displacement is noted, and the athlete may return to sports after 2 to 3 months as pain allows (45).

AVULSION OF THE ANTERIOR INFERIOR ILIAC SPINE

The anterior inferior iliac spine may avulse secondary to excessive traction by the direct head of the rectus femoris, usually with the hip hyperextended and the knee flexed (Fig. 97.21). This injury typically occurs in kicking sports such as soccer, rugby, and football (215). This avulsion is much less common than that of the anterior superior iliac spine and occurs in a younger age group, averaging 13 years, reflecting the earlier age of fusion of this apophysis (171,216). Pain from this lesion is often difficult to localize (67), but patients will commonly be most comfortable in a position that relaxes the rectus femoris by keeping the hip flexed and knee extended. Radiographs may reveal minimal displacement of the anterior inferior iliac spine, and this fragment must be differentiated from an os acetabulare or acetabular epiphysis (215). Further displacement of this fragment is typically limited by the tethering effect of the reflected head of the rectus femoris. These respond well to bed rest, followed by progressive mobilization on crutches, with a fairly rapid return to sports as pain allows (44,45).

AVULSION OF THE ISCHIAL TUBEROSITY

Avalusion of the ischial tuberosity occurs secondary to rapid traction on the hamstring muscles either with violent contraction or a sudden excessive passive stretch (1,22,55,108,149) (Fig. 97.21). This epiphysis is not ossified until 15 years of age and often is not united with the pelvis until 25 years of age (106). This fracture occurs in an older age group averaging 15 years of age and is usually sports related. Patients present complaining of acute-onset of pain in the ischium or chronic pain with a sudden exacerbation of symptoms (190). Origin of the extensor mechanism can be elicited by passive straight leg raising or abduction of the hip. Patients often notice pain when sitting, and radiographs show a variable amount of displacement of the ischial apophysis. Wide displacement tends to be limited by the sacrotuberous ligament. Treatment of this lesion is controversial because wide displacement of the ischial tuberosity can lead to excessive callous formation, which causes pain when sitting (22). This problem rarely requires excision (190) but has led some authors (145,148,149) to recommend open reduction and internal fixation to avoid fibrous union, pain, and prominence. The vast majority of these cases can be treated successfully with conservative management with a period of bed rest, followed by progressive ambulation on crutches and slow advancement to sport as pain allows (108). In the absence of a characteristic history, periosteal reaction and callous formation in the area of the ischium must be differentiated from neoplasm or infection, and biopsy must be considered (84,86).

AVULSION OF THE MEDIAL EPICONDYLAR LESION OF THE ELBOW

Pathophysiology

The elbow is the most frequent area of complaints by adolescent baseball players (89,212), and avulsion fractures of the medial epicondyle represent almost 12% of all fractures about the elbow in children. The peak age of occurrence is between 11 and 12 years, and boys outnumber girls 4 to 1 (6,10). This injury can follow a pronate of medial elbow pain from apophysitis and overuse or may follow a single violent injury to the elbow. Ossification of the medial epicondyle occurs between 5 and 7 years of age, and the epicondyle continues to enlarge and finally fuses to the humerus at approximately 14 years of age in girls and 17 in boys (165). This is the last secondary ossification center to fuse in the distal humeral metaphysis. Two mechanisms for medial epicondylar avulsion have been proposed: Avulsion can occur by (1) violent contraction of the flexor pronator mass or (2) elbow dislocation associated with valgus stress in which the ulnar collateral ligament provides the avulsion force. Fracture by direct blow to the elbow is thought to be extremely rare. In younger children, a fall on the outstretched hand with the wrist extended tightness the flexor pronator mass and may result in this avulsion (Fig. 97.22). In the older adolescent athlete, the most common cause is throwing a baseball with sudden...
contracture of the forearm muscles.

Figure 97.22. The usual mechanism for avulsion of the medial epicondyle in the child is a fall on the outstretched hand with the elbow in extension and wrist held in hyperextension. The flexor pronator mass, which inserts on the medial epicondyle, avulses this fragment of bone. Adapted from ref. 178.

Classification

There are two types of medial epicondyle fractures (220), and they are age dependent. Type I fractures with avulsion of a large fragment involving the entire epicondyle occur in younger children. This fragment may be displaced and malrotated. In the older adolescent patient, a small fracture fragment of medial epicondyle occurs and may be associated with avulsion of the anterior oblique portion of the medial collateral ligament. This fragment can be displaced distally and incarcerated in the joint. Medial epicondylar fractures can be either nondisplaced, minimally displaced (less than 5 mm displaced), significantly displaced (greater than 5 mm displaced), or entrapped, in which case the fracture fragment is typically seen at the joint line on x-ray study (178) (Fig. 97.23).

Figure 97.23. A: Intraarticular displacement of the medial epicondyle and entrapment within the joint after reduction of dislocation of elbow. B: Intraarticular effusion at the elbow joint will lead to displacement of anterior and posterior fat pads, which is often easily visible on the lateral x-ray study of the elbow. 1. Normal fat pads. 2. Displacement of anterior and posterior fat pads. 3. Isolated displacement of anterior fat pad.

Clinical Examination

With a medial epicondyle fracture, the elbow is painful and swollen with ecchymosis over the medial epicondylar region and decreased motion due to pain and effusion. Point tenderness is noted at the flexor origin over the medial epicondyle, and significant valgus instability may be present. Check for function of the ulnar nerve (136,220).

Imaging

Anteroposterior and lateral radiographs of the distal humerus may reveal only widening or irregularity of the apophyseal line. A displaced fragment is difficult to visualize on radiographs but may be missing from its usual location. The fat pad (Fig. 97.23B) sign is typically not seen because in older children this fragment is extra-articular, and in younger children this fracture is associated with rupture of the capsule and the dissemination of the joint effusion into the soft tissues. Fracture of the medial condyle, which is an intraarticular injury, is less common and can be ruled out on radiographs. Radiographs taken with the arm held in an abducted supinated position, which causes a valgus force at the elbow, will show any instability (180) (Fig. 97.24).

Figure 97.24. The weight of the forearm exerts a gentle valgus stress on the injured elbow and reliably demonstrates valgus instability secondary to ulnar collateral ligament injury or medial epicondylar avulsion.

Treatment

Treatment of minimally displaced and nondisplaced fractures of the medial epicondyle consists of a period of immobilization for several weeks, followed by gradual resumption in range of motion and return to throwing as pain allows (23,136). Incarcerated fragments require open reduction and internal fixation. This surgery usually results in closure of the growth plate, but because this epiphysis does not contribute to longitudinal growth of the humerus, growth disturbances are not significant. Treatment of displaced fractures of the medial epicondyle are controversial, and operative management is recommended primarily in throwing athletes (220). Nonoperative management in other children usually has good results despite the fact that fibrous union may occur (17,23,71). Ulnar nerve symptoms represent another indication for operative exploration. Even patients with minimally displaced fragments should be reevaluated for valgus instability 6 weeks following injury because fixation may be required in cases in which valgus stability is important.

Operative Technique

The surgical technique for open reduction and internal fixation of medial epicondyle fractures is as follows (Fig. 97.25):
A: Position arm on a radiolucent table. B: Expose the medial epicondyle through a longitudinal incision. C: Identify the fracture and reduce it. D: Fix the fracture with one or more K-wires.

- Place the patient supine on the operating table, with the affected arm abducted onto a hand table (Fig. 97.25A).
- Incise the skin along the medial aspect of the elbow centered at the elbow joint (Fig. 97.25B).
- Identify the fracture fragment and remove fracture hematoma (Fig. 97.25C).
- Reduce the fracture and fix temporarily with K-wires. Fixation with one 3.5 mm screw is adequate if the bone fragment is large enough. Multiple K-wires can be used for smaller fragments. Lysis of adhesions around the ulnar nerve may be performed, but ulnar nerve transposition is typically not required (Fig. 97.25D).

TIBIAL TUBERCLE AVULSION

Pathophysiology

Tibial tubercle avulsion is fortunately a rare injury. It can follow a long history of apophysitis or occur as an acute injury (154). The average age of presentation of tibial tubercle avulsion is 14 years, with a strong male predominance. Because this injury may occur near the age of physiologic epiphysiodesis, growth problems following treatment are rare. Whereas Osgood-Schlatter disease is usually insidious, with mild symptoms creating partial disability, tibial tubercle avulsion typically occurs as an acute injury with marked pain and swelling and inability to stand or walk. Fractures are usually displaced, requiring surgical intervention. Avulsion of the tibial tubercle by the patellar ligament occurs with violent contraction of the quadriceps against the fixed tibia, as in jumping, or by acute passive flexion, as in landing, and accounts for the fact that this injury is most commonly seen with jumping or running sports (57,72,109). Children with tight hamstrings, pre-existing tibial apophysitis, and patella baja are at risk for this injury.

Clinical Examination

Physical findings include the following:

- Acute swelling and tenderness is present, often associated with a kind effusion or tense hemarthrosis.
- A freely movable fragment at the tibial tubercle, and proximal patellar displacement is usually present.
- With a type I fracture, active knee extension may be possible, but in more displaced fragments, straight leg raising is not possible.
- A lateral radiograph of the knee is diagnostic and guides both classification and further treatment.

Treatment

Treat minimally displaced fragments closed with casting in extension and molding over the proximal pole of the patella to decrease stress on the tibial tubercle. Minimal displacement, however, is rare, and displaced fractures of the type II or type III variety require open reduction and internal fixation, usually through a vertical incision. Larger fragments require the use of a screw, and small fragments can be treated with multiple pins with repair of the periosteal rupture (Fig. 97.26).

Operative Technique

Open reduction and internal fixation of tibial tubercle avulsion fractures is as follows:

- Place the patient supine on the operating table and make a vertical incision centered over the tibial tubercle along the medial or lateral border.
- Remove any soft-tissue interposition at the fracture site and reduce the fracture fragment.
- If the fragment is large enough, fix this fragment with a cancellous screw extending through the tubercle and into the metaphysis.
- If comminution of the fragment is encountered, use multiple threaded Steinmann pins and reinforce these using periosteal sutures.

Postoperatively apply a well-fitting cylinder cast molded on either side of the tibial tubercle and proximal patella to reduce tension at the fracture site. Allow the patient to walk full weight bearing in a cylinder cast for the first month. Allow gentle range-of-motion exercises and quadriceps-strengthening exercises after a month with continued protected ambulation, and add resistive exercises when the tibial tubercle is no longer tender and healing is noted on x-ray study.

Complications

The prognosis for treatment of this injury is excellent, with a return to sports possible in the vast majority of patients. No significant deformity usually results in acute cases (24,109,128). Although genu recurvatum can occur in skeletally immature athletes, tubercle avulsion usually occurs close to skeletal maturity, so this complication is rare. Loss of knee flexion and persistent quadriceps atrophy occurs rarely (178).

ANTERIOR CRUCIATE LIGAMENT INJURIES

The true incidence of ligamentous injuries about the knee in children and adolescents is unknown (200) but considered rare. Reports of the incidence of anterior cruciate ligament (ACL) injuries in those younger than 14 to 15 years of age vary from 3.4% (122) to 10% (59), but the number or injuries appears to be increasing as children and young adolescents become more competitive in sports. The reported incidence of meniscal lesions associated with ACL injuries in children and adolescents is also variable. McCarroll et al. (134) reported a 60% rate of meniscal injury, and Staninski (203) reported a 47% incidence, but others (12,58,63) have
found the meniscus less frequently injured in ACL injuries in children than in adults.

Clinical Evaluation

For a detailed discussion, see Chapter 89.

Because of the difficulty in obtaining an adequate evaluation in children, some authors have recommended early evaluation under anesthesia. However, others believe that if adequate time is taken to win the confidence of the injured adolescent or child, a reasonable evaluation can be accomplished.

In adolescent girls, a history of a twisting injury associated with a pop and severe pain followed by knee swelling and lack of extension can also be consistent with an episode of patella subluxation. Therefore, palpate the medial patella retinaculum for tenderness and manipulate the patella in the trochlear groove, noting its degree of movement and the patient's apprehension during the examination.

For preoperative planning, also assess prepubescent youngsters with an ACL injury for maturity by noting chronologic age, bone age as determined by left-hand anteroposterior (AP) radiographs in comparison to known standards, sexual development (e.g., Tanner classification; Table 97.8), growth remaining via assessment of parents' and siblings' heights, patient's projected height on basis of prior growth chart data (if available), and the extent of physeal closure on routine radiographs.

Table 97.8. Tanner's Stages of Sexual Development*

Imaging Studies

Take radiographs of the knee to assess the status of the physeal and to exclude associated fractures or osseous congenital variations. Obtain stress radiographs as needed to rule out physeal injuries. MRI may be helpful in determining the extent of injury to the ligament and the status of other intraarticular structures (58,82). Take care in interpreting meniscal tears on MRI because a high incidence of false-positive results in children has been described (201).

Treatment

Injury to the ACL in the preadolescent and adolescent is a difficult management problem. Most natural history studies of ACL injuries in children have deficiencies (12,32,83,104,168,195). Associated meniscal injuries are frequently not documented, and the maturity of the child is infrequently noted (14,83). Some authors have reported reasonable results following conservative measures (12-50), but most authors have reported a high incidence of reinjury (83,106,195).

Initially, protect the knee to allow secondary restraints and areas of cartilage contusion to heal. Identify associated meniscal injuries and treat as in adults with repair or resection. Implement a well-structured rehabilitation program to restore range of motion and strength as well as develop balance skills and proprioceptive feedback pathways. Teach youngsters proper jumping and landing techniques to prevent future reinjuring (19). Although it has not been well documented to eliminate instability, bracing can be clinically useful.

Operative Technique

Criteria for electing to proceed with surgical reconstruction of the anterior cruciate ligament and the type of procedure chosen for the adolescent who is nearing growth completion (Tanner's stages 3, 4, or 5 with closing physes) follows guidelines established for adults. In the child or preadolescent (Tanner's stages 1 or 2 with widely open physes), the decision becomes more difficult because premature femoral or tibial physeal closure can result in a significant leg length discrepancy, especially in a young child.

The long-term outcome of the conservatively treated unstable ACL-deficient knee in the child is often poor. Recurrent episodes of pivoting result in meniscal and articular cartilage injury, often leading to early degenerative changes (63,135,134,150,191,187). However, placing hardware or even drilling tunnels across an open physeal carries the risk of causing premature closure (65,132,134).

Primary reconstruction of the torn ACL has poor results in children, just as it does in adults (82,157). Extra-articular reconstructions also yield poor late results (125,135,157). Bergfeld, in an attempt to use an intraarticular reconstruction but avoid the physeal plate, developed what has been called the “tomato stake” procedure (187), which is performed as follows (Fig. 97.27):

- Make a midpatella tendon incision.
- Isolate the middle third of the patella tendon, leaving it attached at the proximal tibia.
- Pass the tendon over the front of the tibia, beneath the transverse ligament, through the knee, and around the top of the femur.
- Fasten the tendon to the femur above the physeal with a staple; do not violate the physeal with the staple.
- The stump of the ACL can be used to augment the reconstruction.

Parker et al. (167) modified this technique by creating a groove in the tibia and femur to make the tunnel more isometric and also added an extraarticular iliotibial band tenodesis. Brief (52) developed a procedure similar to that of Parker et al. but prepared the groove and passed the graft arthroscopically (Fig. 97.28). He reported using hamstring graft, but his technique can also be adapted for patella tendon graft. Brief's technique, incorporating the “groove” in the tibia suggested by Parker et al. (167)...
Parker et al.'s (extraarticular repair is not intended to create a stable knee for high-risk activities but is merely used as a time-buying procedure for those who have failed conservative treatment within several days and advance over the next 6 to 8 weeks. Do not permit running for 3 to 4 months, and require brace protection for return to low-risk pivotal activities. This is postoperatively, permit limited range of motion as described earlier, advancing from 30° to full flexion within 2 weeks. Begin close kinetic strengthening exercises in the first week. Parker et al. (167) have reported complications with drilling across the physis, as long as the fixation device does not cross the physis. In their series, only one patient had premature physeal closure, and this was attributed to placement of a fixation staple across the physis.

Smith and Tao (194), by using hamstring grafts put through standard tibial and femoral tunnels for adolescents within 1 to 2 years of skeletal maturity, reported no complications. For younger children who failed a well-structured conservative program, hamstring tendon grafts placed through standard tibial holes in the over-the-top femoral position was advised. McCarroll et al. (134) recommend activity modification, functional bracing, frequent follow-up, and delayed definitive hamstring reconstruction for the child with wide open physes who is several years from skeletal maturity. In contrast, Fowler (70) recommends a hamstring or patella-quadiceps tendon graft placed through small (6 mm) tibial tunnels and in the over-the-top position on the femur. In reviewing 29 young adolescents treated in this manner, he found no leg length discrepancies. All youngsters returned to their preoperative activity levels. The use of Achilles tendon or fascia lata allografts (7 mm) placed through a tibial tunnel and in the over-the-top position in the femur to replace the ACL in skeletally immature patients has been reported (11) on a limited series (eight patients) with good early results (58 months).

Author’s Preferred Treatment

Initially, we treat nonoperatively a tear of the ACL in the child with widely open growth centers who is in Tanner’s stage 1 or 2 and who has taller siblings and parents. We use MRI to help evaluate intraarticular structures, provide early protection until acute symptoms subside, and correct meniscal pathology if such exists. We then prescribe a well-structured rehabilitation program stressing range of motion, strength, proprioceptive skills, and guided return to functional activities.

We treat like adults adolescents in Tanner stages 3, 4, and 5 with radiographs demonstrating little growth remaining in their physes. We prefer quadruple hamstring tendon grafting with fixation above and below the physes.

In patients who fail conservative care but who have significant growth remaining, we use a modification of an extraarticular reconstruction (either DeLee’s or a modified Andrew’s), until the physes are closing and the athlete is in Tanner’s stage 3, at which time an intraarticular reconstruction procedure can be done. DeLee’s reconstruction (Figs. 97.28A) is as follows:

- Isolate a 2.5 cm wide strip of iliotibial band, 15 cm in length. Leave the iliotibial band attached to Gerdy’s tubercle (Fig. 97.29A).
- Pass the strip beneath the fibular collateral ligament.
- Create an osteoperiosteal tunnel proximal to the physeal plates.
- Fix the graft in the tunnel with a ligament screw and washer (Fig. 97.29B).
- Next, pass the iliotibial band back distally beneath the fibular collateral ligament (Fig. 97.29C) and fix the ligament with a screw and washer to Gerdy’s tubercle (Fig. 97.29D).

The Andrews procedure is as follows:

- Place a tourniquet high on the thigh and the knee in a leg holder immediately below the tourniquet, leaving most of the distal thigh exposed.
- Prep and drape the extremity in the typical fashion for arthroscopy.
- Inflate the tourniquet, tighten the knee holder, and perform a diagnostic arthroscopy, correcting any intraarticular pathology found.
- With the knee bent 90° in the knee holder and the foot hanging free, make a lateral incision in the distal thigh beginning approximately 8 cm above the knee joint and extending down to just above Gerdy’s tubercle. Extend the incision through the subcutaneous tissue, exposing the iliotibial band.
- Longitudinally divide the iliotibial band to create a strip approximately one third the width of the band, situated 2 to 3 cm from its posterior border.
- Retract the remaining iliotibial band anteriorly and, using a periosteal elevator, denude the soft tissue and peristeum from the area of the femur at the lateral intermuscular septum just proximal to the beginning of the femoral condyle and above the physis. Use an osteotome to fish scale this area.
- Place a modified Kessler stitch with a 2-0 Polydec suture through the strip of iliotibial band, going distal to proximal.
- With tension on the iliotibial band through traction on the previously placed suture, staple the iliotibial band to the previously prepared bed on the femur.
- Close the wound in layers. Apply a sterile dressing and a limited motion brace from 30° to 90°.

Postoperatively, permit limited range of motion as described earlier, advancing from 30° to full flexion within 2 weeks. Begin close kinetic strengthening exercises in several days and advance over the next 6 to 8 weeks. Do not permit running for 3 to 4 months, and require brace protection for return to low-risk pivotal activities. This extraarticular repair is not intended to create a stable knee for high-risk activities but is merely used as a time-buying procedure for those who have failed conservative care in order to enhance stability for low-risk activities. The rehabilitation protocol is much like that used for nonoperative management.

Parker et al.’s (167) arthroscopic modification of Bergfeld’s “tomato stake” procedure may be a reasonable alternative; however, this reconstruction is not ideal because
it uses a prime source of autologous graft material (patellar or hamstring tendon), which is placed in a nonisometric position, thereby subjecting it to failure over time. One needs to take care in grooving the over-the-top femoral tunnel not to groove the physis, which is only 2.5 cm proximal to the ACL’s attachment (19).

**TIBIAL SPINE FRACTURES**

In the past, it was believed that before closure of the physis, the intercondylar eminence offers less resistance to traction forces than the ACL, making it more commonly injured than the ACL in children (173,210). Recently, with the increased emphasis on competitive sports in children, increasing numbers of ACL midsubstance tears are being seen. In the athletic population, such injuries may be more frequent than eminence fractures (135,194).

**Pathophysiology**

A fall or collision in sport, a fall from a bike, or a collision with a car are the most likely events resulting in a tibial eminence fracture (84). The mechanism of injury has not been well defined. Wiley and Baxter (218) suggest that injuries occur when, with the foot planted on the ground, the extended knee is axially loaded simultaneously with outward rotation of the femur on the tibia. Hyperflexion is another potential mechanism of injury.

Meyers and McKeever (142) reported that tibial eminence fractures in children were often the result of less violent injuries than those resulting in proximal tibial fractures in adults and were typically an isolated injury. In contrast, DeLee's (158) more recent review of this injury led him to conclude that this fracture was often associated with collateral or meniscal injury.

The tibial eminence is the area between the two tibial plateaus, consisting of the two tibial spines and the bony attachments for the anterior and posterior horns of the medial and lateral menisci (218). The ACL is partially attached to the medial spine (Fig. 97.30). Spine fractures in children occur through the cancellous bone beneath the subcortical plate. The fracture fragment typically includes the ACL and a variable-sized portion of the intermeniscal area (208). The ACL receives its blood supply from the middle genicular artery but can atrophy if it remains detached at one end due to a nondisplaced avulsion fracture (143).

**Classification System**

The classification system of Meyers and McKeever (142,143) (Fig. 97.31) is still used to make treatment decisions. Zaricznyj (224) added a fifth category, type IV or III C, consisting of comminuted displaced eminence fractures.

**Clinical Evaluation**

The child with a tibial eminence fracture typically presents with a large hemarthrosis. Because this injury is often associated with high-velocity trauma, look for associated neurovascular or collateral ligament injuries and assess the entire lower extremity.

**Imaging**

The tibial spine fracture typically can be seen on standard radiographs of the knee, although tunnel and oblique views in nondisplaced fractures may be helpful. The avulsed bony fragment may be small compared with the cartilaginous fragment, making radiographic identification more difficult.

**Treatment**

Nondisplaced type I fractures require only protection with a cast or a hinged knee brace locked in extension. Type II fractures can frequently be reduced by aspirating the joint, instilling local anesthetics, and then gently extending the knee. As the knee comes into full extension (the last 5° are critical [58,174]), the femoral condyle impinges on the fragment, resulting in its reduction. Following reduction, immobilize the knee in full extension by cast or brace until healing at 6 to 8 weeks. Note that Meyers and McKeever (143) and Medler and Jammason (138) recommend immobilization in 20° of flexion because in full extension, the ACL can exert tension on the fragment.

For types III and III + fractures as well as type IV fractures, we recommend arthroscopic or open reduction of the fragment with fixation using absorbable or nonabsorbable sutures, pins, or screws (Fig. 97.32 and Fig. 97.33). If left displaced, the eminence will likely block full extension and result in laxity of the ACL.

The open procedure for reduction of tibial eminence type III or irreducible type II fractures is as follows:
MENISCAL TEARS

The incidence of meniscal tears is rising in the adolescent athlete primarily due to increased sports participation (24,185). This lesion represents one of the most common injuries seen in youth sports (67). Although rarely seen in children younger than 9 years of age (111,153), meniscal tears must be suspected in adolescents older than 12 years of age with signs of internal derangement of the knee following a twisting injury in sports (706). Menisci in children are more vascular, suggesting a greater ability to heal following injury (53). In adults, vascular channels are present in the peripheral third of the menisci, whereas in children, these vascular channels often extend up to or even beyond the halfway mark (73). The pattern of meniscal tearing in children also differs from that in adults in that the younger the patient, the more peripheral the meniscal tear tends to be (111).

Evaluation of children with internal derangement can be more difficult than in adults because they are poorer historians, but typically a more significant injury is required to tear the meniscus and it is often associated with tears of the ACL. Radiographs are typically normal. Consider MRI if tenderness and pain persist beyond 2 weeks. Beware of false-positive results (79).

Long-term results of total meniscectomy in adolescents is poor, with a large number of patients developing advanced degenerative changes in the knee (68,128,223). On the other hand, healing of meniscal repairs in adolescents is superior to that in adults (79,91,96,153).

The techniques used for meniscal repair in children do not differ from those in adults, and are described in Chapter 85.

DISCOID LATERAL MENISCUS

Pathophysiology

Disoid meniscus is a congenital anomaly resulting in an enlargement of all or part of the meniscus (79). Lateral disoid meniscus is more common than the medial type and occurs in approximately 2% of the population (79).

Arthroscopic treatment of fractures of the tibial spine proceeds as follows:

- After examination of the knee under anesthesia, elevate the leg and inflate tourniquet. Place the leg in leg holder and prep and drape the extremity in the usual sterile fashion.
- Examine the joint arthroscopically, correcting any associated injuries.
- Clean the fracture area of all loose and unstable tissue.
- Perform a trial fracture reduction using the probe to guide the fragment into position.
- Make an anteromedial proximal incision over the tibia and carry it down to bone.
- Place two drill-tipped guide wires through the tibia and through the fracture fragment (Fig. 97.33A).
- Insert spade-tipped guide pins through the drill holes and through the bony fragment using a probe or small rasp to hold the fragment reduced while passing the guide wires and pins.
- Use the Accufex suture passed from the shoulder set to pass a #1 PDS through a 7 mm cannula in the anteromedial portal (Fig. 97.33B).
- Thread the suture through the islet of the spade-tipped pins and bring it back through the same portal with a grasping instrument. Repeat this procedure for the other pins.
- Remove both pins from the knee, bringing the double strands of sutures with them.
- Tie the sutures protruding through the anteromedial portal and pull them back into the joint, creating a loop that snugly ties down the avulsed fragment.
- Tie the two loops together over the small bony bridge as they exit from the anterior tibia.
- Close wounds in a routine fashion.

Although most authors (52,73,142,151) report good to excellent results following open reduction and internal fixation with no laxity after healing of the fracture, others (218,224) report mild laxity without functional disability. The lack of significant functional disability despite evidence of mild to moderate clinical laxity has been attributed to either intact proprioceptive mechanisms or increased stability from enlargement of the reduced fragment secondary to the increase in its blood supply during healing (218). In contrast, Smith (185) and Gronkvist et al. (68) found residual symptoms and clinical instability in a significant number of patients, indicating that a reevaluation of treatment protocols was needed.

Figure 97.32. Meyer and McKeever’s method of fixation of tibial eminence fractures. Note the use of absorbable sutures placed through the fragment and sutured to the anterior horn of the medial meniscus, which are used in lieu of screws, pins, or transitional sutures (52,142,43).

Figure 97.33. Arthroscopic treatment of fractures of the tibial spine. (From Medlar RG, Jansson KA. Arthroscopic Treatment of Fracture of the Tibial Spine. Arthroscopy 1994;10:292, with permission.)
Classification

Discoid meniscus is a common cause of knee symptoms in children and adolescents (61,62). Discoid meniscus has been categorized into three major types by Watanabe et al. (214) (Fig. 97.34). Type I, the most common variety, is a complete disk-shaped semilunar type with a thinner center. Type II consists of an incomplete semilunar type with a concave or convex free edge. Type III is a hypermobile or Wrisberg-type, which lacks a posterior tibial attachment. Although the Wrisberg-type is the most rare, it is most likely to lead to symptoms because of its hypermobile nature. Types I and II discoid menisci are often asymptomatic, although athletes with these types are susceptible to a greater frequency of tears because of the relatively poor vascularity and thickness of the discoid meniscus (93). In the Wrisberg-type discoid meniscus, there is no posterior attachment to the tibial plateau, resulting in a hypermobile posterior horn that displaces into the intracondylar notch with extension because of traction on the lateral meniscal femoral (Wrisberg) ligament. This results in the often-symptomatic “snapping knee syndrome,” which is notable due to the audible clicking when the knee is moved (78).

Clinical Examination

Adolescent athletes typically present with this disorder between 12 and 15 years of age and often complain of the classic meniscal symptoms of limited extension, snapping, locking, and pain. Physical examination may reveal loss of extension, quadriceps atrophy, and a variable effusion.

Imaging

Radiographs may be normal but often show widening of the lateral joint space and squaring of the lateral femoral condyle. In addition, hypoplasia of the lateral tibial spine with tilting of the lateral tibial articular surface and apparent elevation of the fibular head may be noted. MRI reveals the presence of abnormally thickened meniscal tissue interposed into the central intercondylar zone, which may be limited to only one portion of the meniscus (79).

Treatment

As with the treatment of tears of normal menisci in children and adolescents, the focus in treatment of symptomatic discoid lateral menisci is preservation of as much normal meniscal tissue as possible. A course of conservative management is indicated initially, but if symptoms persist, arthroscopy is indicated. Small loose fragments can be removed and peripheral tears may be considered for repair. Menisectomy has been recommended to reduce the thickness of the discoid meniscus and prevent recurrent tears. Hayashi et al. (93) advise leaving a rim of 6 mm in the complete type discoid meniscus and 8 mm in the incomplete type. This allows the remaining meniscus to participate in weight bearing (Fig. 97.35). The pattern of the meniscal tear will sometimes dictate the amount of meniscus to be resected. Several reports (20,62,93) have documented good results following total meniscectomy for discoid lateral meniscus. Total excision, however, should be the last resort to avoid the possibility of progressive degenerative arthritis.

PATELLOFEMORAL JOINT PROBLEMS

Complaints relative to the patellofemoral joint in the child and adolescent athlete are extremely common and can be categorized as either patellofemoral stress syndrome, characterized by pain, or patellofemoral instability, with symptoms of subluxation and recurrent dislocation. Although laxity does play a part in both of these problems, it is one small part of an overall malalignment syndrome, which may include tissue imbalance, muscle weakness, angular and rotational deformities, and dysplastic bone (Fig. 97.36). Evaluation and treatment of these problems therefore must take into account the overall configuration of the patellofemoral joint so that treatment can be directed toward the specific pathology (217).

Figure 97.34. Watanabe classification of discoid menisci. Type I, stable complete discoid meniscus. Type II, stable incomplete discoid meniscus. Type III, unstable discoid meniscus secondary to lack of a complete meniscotibial ligament.

Figure 97.35. Menisectomy by resection of the central portion of the discoid meniscus reduces the thickness of the meniscus to prevent recurrent tears.

Figure 97.36. Patellofemoral biomechanics. The patella depends on muscular, soft-tissue, and bony factors to maintain stable alignment in the patellofemoral joint.
Factors that increase the lateral pull on the patella or decrease the medial restraining mechanism will lead to lateral tracking of the patella with associated pain and instability (79,128,168,218) (Table 97.9). The cause of pain appears to be excessive tension and rotational forces on the peripatellar soft tissues (152) as well as excessive pressure on the lateral patellar facet (69). Patients typically present reporting diffuse generalized anterior knee pain that is exacerbated when weight bearing is performed on the bent knee with such activities as descending stairs and squatting. Patients may complain of associated instability, but true locking of the knee is uncommon, although a catching sensation is reported (79). Pain is often present after a period of prolonged sitting with the knee flexed. A history of sudden increase in training or in training errors is commonly obtained from these patients (102).

The force required to produce patellar dislocation is inversely related to the degree of malalignment and dysplasia encountered. Patients present usually between 16 and 20 years of age (61,48,97,116) following a single twisting maneuver involving the knee. Football, baseball, and basketball are commonly involved, but cases have been reported in gymnastics as well as cheerleading. Just as with patellofemoral stress syndrome, girls are more commonly affected than boys, and in almost one quarter of cases, a positive family history for patellofemoral instability is elicited (31). Dislocations frequently reduce spontaneously, and the adolescent athlete presents with diffuse knee pain and swelling. Physical examination may reveal an effusion, diffuse parapatellar tenderness, a positive apprehension test for patellar dislocation, and a palpable defect in the VMO insertion into the patella. Patients should be evaluated for signs of other ligamentous injury about the knee, which can occur with the same mechanism. Look for other sources of pain referred to the knee. Reduce persistent dislocations of the patella immediately with intravenous sedation and an intraarticular anesthetic if needed. As hamstring spasm resolves, the knee can be brought gently into extension, and spontaneous reduction usually occurs. Radiographic evaluation of the acutely injured knee includes AP and lateral x-ray studies, and this can be supplemented with a CT scan if these studies are nonconclusive. Osteochondral fragments may be noted in the joint, and bone fragments along the medial patellar margin, which are not free floating, may be evident.

Aspirate a tense hemorrhotis, if present. Immobilize the knee in extension up to 6 weeks (48). During this time, straight-leg raises for progressive strengthening are beneficial in reestablishing the pull of the VMO. Osteochondral fractures, which occur in approximately 10% of cases of patellar dislocation, require immediate surgery. Fragments larger than 5 mm may require repair, whereas smaller fragments can be excised (79). Approximately 75% of patients obtain acceptable results following closed treatment of patellar dislocation (48), but only 50% become asymptomatic. Risk factors for redislocation include osteochondral fragment, age younger than 14 years, participation in athletics, palpable medial defect, contralateral evidence of knee dysplasia, patellar hypermobility, prior dislocations, positive family history for dislocations, and patella alta (48). Recurrent dislocations can be treated conservatively as well with vigorous quadriceps strengthening, but patients with high-risk factors may benefit from early surgery. Surgery should be tailored to the pathology encountered, and the previously mentioned dysplastic features should guide the surgical approach (89). Options include lateral retinacular release and distal realignment procedures (15,48,95,127,141). Bony distal realignment procedures such as the Elmslie-Trillat procedure lead to an overall good result in more than 80% of cases (79) but are contraindicated in younger patients with open growth plates (95,128). Soft-tissue procedures such as medial plication, hemitransfer of the patella tendon, and semitendinosus transfer to the distal pole of the patella (15) have also enjoyed success. Results tend to be worse in children and adolescents with ligamentous laxity, and in younger children, surgery may be unpredictable and require a tibial tubercle transfer after skeletal maturity has been reached. Figure 97.37 shows the potential steps in patellar realignment in the growing child. Lateral release is nearly always necessary. Medial plication is usually required. Medial transfer to the lateral half of the patellar tendon is sometimes required. Tenodesis of the semitendinosus tendon to the patella is required for severe deformity in which the other three steps are inadequate.
GENERAL CONDITIONING AND REHABILITATION PRINCIPLES

The phases of a rehabilitation program for a child or adolescent are no different from those of an adult, although generally the child progresses through these phases more rapidly. A typical program may be divided into five phases:

- phase I—decreasing inflammation
- phase II—improving range of motion
- phase III—improve strength and proprioception
- phase IV—return to functional skills
- phase V—return to sport

One must master 75% to 80% of the goals of each phase before progressing to the next phase. Providing youngsters with short-term and intermediate goals will help maintain their interest and enthusiasm. One must also remember that children have short attention spans, and therefore, exercises need to be brief, simple, and fun. Incorporate range-of-motion, proprioception, and strengthening exercises into games using a variety of colorful equipment. During adolescence, exercising with peers often results in greater compliance.

Conditioning is as beneficial for children and adolescents, especially those involved in highly competitive sports, as it is for adults, and just as in adults, proper conditioning in children and adolescents is associated with a decrease in injury rates (118).

Strength training for children and prepubescent adolescents is appropriate provided the equipment is sized appropriately. (Hence free weights are frequently better than machines built for adults.) Although this age group lacks adequate androgen to develop muscle bulk, weight-training programs have been found to develop tone and strength and enhance performance (119).

A common misconception among coaches is the belief that all youngsters are flexible and do not need to stretch before and after practice and play. Particularly during periods of rapid growth, when young bones may be growing faster than the surrounding muscles, warming up and stretching is important in preventing overuse injuries such as the traction apophysites. (See section on nonarticular osteochondroses in this chapter.)

WATCH OUT FOR THE MASQUERADERS

When evaluating children and adolescents who report pain with sports activity, one must always keep in mind that other systemic problems can masquerade as sport injuries. For example, a persistently swollen ankle in an 11-year-old may not be secondary to landing wrong while practicing a basketball drill but may be the first sign of juvenile rheumatoid arthritis; a swollen tender tibial tubercle or iliac crest may not be an acute traumatic apophysitis, but the inflammation may be secondary to infection (56); the first sign of leukemia may be fatigue with activity; and the early stages of osteogenic sarcoma may be confused radiographically with a healing stress fracture.

Beware also of the youngster who presents with symptoms far more severe than the objective findings or who frequents the physician's office with a variety of minor problems over a brief period of time. This adolescent, although strongly verbalizing his desire to "play through any pain," may in reality be trying to use his "injury" as an "acceptable way out" of sports. Such a scenario is not infrequent during teenage years, when adolescents may no longer wish to continue to spend the long hours in training that has been required of them but instead may wish to spend more time socializing with friends. However, these adolescents fearing rejection and chastisement from disappointed parents, cannot admit to them that they just do not want to participate anymore. Often the physician must "read between the lines," gain the athlete's confidence, and help the athlete deal with the situation in an acceptable manner.

CHAPTER 98

USE OF LASERS IN ORTHOPAEDIC SURGERY

Kenneth B. Trauner

K. B. Trauner: Department of Orthopaedic Surgery, University of California, Davis Medical Center, Sacramento, California, 95817.

PRINCIPLES

Over the past twenty years, laser technologies have been developed for endoscopic applications in many surgical disciplines. More recently, arthroscopic laser systems have been introduced in orthopaedic surgery as low-profile cutting tools. Initial orthopaedic studies used existing commercial and surgical laser systems, which were poorly suited for arthroscopic use. These lasers resected torn meniscal tissue but increased perioperative morbidity and required changes in surgical technique. Pulsed near-infrared systems later allowed delivery of high-power laser light to the joint tissues through small fiber optics and more convenient instrumentation. These near-infrared systems are now used in shoulder, knee, and spinal surgery. Several recent cases of osteonecrosis in laser-treated knees, however, have generated controversy regarding the safety of these devices (21, 23, 34, 59).

LASER PHYSICS

The term laser is an acronym for light amplification by stimulated emission of radiation. The laser is a device that produces high-intensity light energy with three unique properties. It is (a) monochromatic—the light has a single wavelength, (b) coherent—the light waves are in phase with one another, and (c) directional. These characteristics allow laser light, at high energies, to be transmitted through fiber optics, waveguides, or articulated arms to tissue. The light energy, for surgical applications, can then cut, coagulate, or ablate tissue.

Laser systems have four essential components (Fig. 98.1). The laser medium—a solid, liquid, or gas—determines the wavelength of the laser light. The resonator cavity sandwiches the medium between two mirrors—one partially reflective and the other fully reflective. The excitation source pumps high-energy electric or optical energy into the laser medium. A cooling system removes excess thermal energy from the resonator cavity to prevent damage to optical components.

Figure 98.1. The laser system is composed of a laser medium placed between two mirrors, one of which is partially reflective. Energy delivered to the medium produces light energy that is amplified between the two mirrors. Light escaping the output coupler has the unique properties of being monochromatic, directional, and in phase.

When light or electrical energy is released into the laser medium, the absorbed photons are stimulated into higher energy levels. The collapse of the electrons to their ground states releases photons of a specific wavelength. These photons are reflected between the two mirrors of the resonator cavity. High-intensity light eventually escapes through the partially reflective mirror.

The wavelength of the output light and the choice of laser medium characterize surgical laser systems. In the United States, most surgical systems produce visible, near-infrared or infrared laser energy. Ultraviolet systems have been approved for ophthalmic use but are not currently Food and Drug Administration (FDA)-approved for surgical applications. The standard media include CO₂ and argon gases, and yttrium aluminum garnet (YAG) crystals doped with heavy metals including holmium (Ho), erbium (Er), thulium, and neodymium (Nd).

The output light energy has two primary forms—continuous wave (CW) and pulsed. CW lasers produce a continuous beam of light energy similar to a flashlight. The conduction of heat that occurs during the use of a CW system may produce large peripheral zones of thermal damage. Pulsed laser systems produce high-intensity light over short time intervals. The high peak power of each laser pulse may produce explosive ablation of target tissues. The time between pulses allows for dissipation of thermal energy and prevents excessive damage due to thermal conduction.

For CW systems, the surgeon selects the average power to be delivered through the handpiece, in a manner similar to that seen in electrocautery. For a pulsed laser
system, the surgeon sets the energy per pulse and the repetition rate. The flow of light is controlled by a hand- or foot-switch. The focus (or defocus) of the light energy at the tissue level controls the light intensity and affects the zone and depth of laser-induced damage.

LASER–TISSUE INTERACTION

The optical properties of tissue and the wavelength of the laser light are major determinants in controlling the effect of the laser light on the treated tissues. Light striking tissue reflects, refracts, scatters, or is absorbed by the tissue. All tissues have characteristic properties for each of these parameters, which vary as a function of wavelength. Most existing surgical laser systems target either the water within the tissue or selected chromophores—tissue pigments such as hemoglobin, hemosiderin, or melanin.

MECHANISMS OF TISSUE ABLATION

Three mechanisms of action characterize laser ablation of tissue:

- Photoablation: Absorption of light energy creates molecular vibrations and heat. Heating water above 100°C causes vaporization. Pulsed infrared lasers deliver high peak powers of laser light in short time periods of less than a fraction of a second. Tissue ablation occurs by the explosive release of the vaporized tissue contents (Fig. 98.2). Heating tissues below the vaporization threshold produces thermal changes if collagen is heated above its phase transition temperature of 62°C.

- Photochemical: Ablation occurs when absorbed photons directly dissociate molecular bonds. If the energy of ultraviolet photons is greater than the energy of molecular bonds, photon absorption may directly disrupt the molecules for nonthermal cutting of tissue. The so-called cold excimer lasers operate by this mechanism.

- Photomechanical: When light energy is rapidly deposited in tissues, the thermal energy and rapid expansion of vaporization contents creates high shear stresses within the tissue. Photoacoustic shock waves may create damage at large distances from the site (73). The process may occur for any pulsed laser system operating throughout the ultraviolet, visible, or infrared spectrum (16,60).

ORTHOPAEDIC LASER SYSTEMS

Initially, the choice of lasers for orthopaedics was determined by availability. Modification of existing surgical systems allowed passage of light energy into joint cavities. The earliest systems, using CO₂ laser media, varied considerably in their configurations. Both CW and pulsed systems were evaluated, with variable tissue effects. Ablation of cartilage produced excessive charring and thermal damage with all devices. As 10.6-micron light energy cannot pass through standard optical fibers, all CO₂ systems required large, cumbersome devices for light delivery to the joints. The requirement for joint distention with gas, the lack of proven benefit, and the limited availability of awkward instrumentation led to the early abandonment of the CO₂ laser arthroscopic devices.

Additional industrial and surgical systems also proved poorly suited for arthroscopic use. Solid state Nd:YAG surgical lasers are used in both CW and pulsed formats. The Nd:YAG lasers produce light (at 1.06 and 1.32 microns) that is readily transmitted through standard silica optical fibers. The Nd:YAG light is strongly absorbed by pigmented or darkly stained tissue but not well absorbed by most intra-articular tissues. Because of its low tissue absorption, at high energies the light deeply coagulates tissue before producing changes at the tissue surface. Cutting effects vary significantly as desiccation or charring of the tissue surface substantially increases the light absorption characteristics.

Functionally, a Nd:YAG laser can coagulate and cause necrosis of tissue to a depth greater than 1 cm before any apparent cutting effect occurs at the tip of the instrument. A contact sapphire tip Nd:YAG laser system received limited use as an arthroscopic cutting tool for meniscectomy and occasional chondroplasty (44,49). Multiple cases of osteonecrosis have been reported with this laser system (23,34). However, it has been largely abandoned because of concerns about effectiveness and safety.

The excimer laser is an ultraviolet laser system that ablates and cuts tissues via nonthermal mechanisms. Tissue effects occur when ultraviolet light energy is absorbed by carbon–carbon double bonds of organic chromophores. Efficient light absorption limits the light penetration to within microns of the tissue surface. The high power density of the absorbed light generates precise and effective tissue-cutting effects with minimal thermal damage (3,5,17,22,63). Unfortunately, ultraviolet light energy cannot be transmitted down standard optical fibers, and development of convenient arthroscopic delivery systems has proven difficult. Only the 308-nanometer xenon chloride excimer laser can be delivered fiberoptically through expensive, nonflexible zirconia fluoride fibers.

The system itself uses toxic gases as a laser medium. Excimer arthroscopic systems have received limited use, and that has been largely in the European market (24,29). Nuss et al. (48) reported on the use of the 308 nm excimer laser in a prospective, randomized clinical trial of 70 patients with chondral degeneration. After a 6-month follow-up, the authors found a significant reduction in pain and in reactive synovitis in laser compared with control groups. No differences in level of disability or function were noted between groups.

Ho:YAG LASER

The Ho:YAG laser is the most widely used arthroscopic laser system. It was specifically developed for arthroscopic use and has now been adapted for use in multiple surgical disciplines. The device produces pulsed 2.1-micron-wavelength laser light, which is readily transmitted down conventional optical fibers into low-profile handpieces. The Ho:YAG laser effectively cuts, coagulates, and ablates well-hydrated intra-articular tissues (74,75,76 and 77). The laser is used in contact or near contact mode.

Use of the device has been controversial. FDA approval for meniscectomy was granted in the late 1980s. Fanton et al. reported decreased postoperative symptoms and recuperation time following laser meniscectomy (19). No prospective, double-blind, randomized clinical studies have validated the original claims.

The Ho:YAG laser is the most widely used arthroscopic laser system. It was specifically developed for arthroscopic use and has now been adapted for use in multiple surgical disciplines. The Ho:YAG laser effectively cuts, coagulates, and ablates well-hydrated intra-articular tissues (74,75,76 and 77). The laser is used in contact or near contact mode.

Use of the device has been controversial. FDA approval for meniscectomy was granted in the late 1980s. Fanton et al. reported decreased postoperative symptoms and recuperation time following laser meniscectomy (19). No prospective, double-blind, randomized clinical studies have validated the original claims.
Multiple studies have documented that the healing response of articular cartilage following laser irradiation is consistent with that following mechanical instrumentation (13, 54, 75). Partial-thickness defects do not heal, and full-thickness defects are characterized by fibrocartilaginous repair, which is less durable than the host tissue (75).

Loss of cellularity and necrosis in subchondral bone is found consistently at the border of treated regions in an equine model (13).

APPLICATIONS

MENISCETOMY

Meniscectomy is the primary arthroscopic application for which the laser was originally developed. The laser offers the theoretical advantage of less iatrogenic damage to articular surfaces when treating poorly accessible, posterior horn meniscal tears. Whereas mechanical instruments may abrade or inadvertently gouge chondral surfaces, the low-profile laser handpieces may be used in limited noncontact mode to ablate and cut the damaged posterior structures. Limited literature is available to substantiate these claims (19, 66). Rather than minimizing damage, the laser, when used in an unsafe manner, may play a role in producing osteonecrosis in subchondral bone.

OSTEONECROSIS

In the last five years, there have been multiple reports of osteonecrosis following laser arthroscopy with either the Nd:YAG or the Ho:YAG laser systems (21, 23, 34, 59). Early laser tissue interaction studies suggested that thermal damage would be limited to the optical penetration of the tissue, which is approximately 300–500 microns. The studies, performed with low laser repetition rates on cartilage (13, 54, 63, 72, 75, 77), did not address the tissue effects at the clinically relevant higher repetition rates. Studies suggest that osteonecrosis, in many cases, may be preexisting and may not relate to the use of the laser (33).

Additional animal studies suggest that the laser produces extensive subchondral damage if used to drill into articular surfaces (73). If the laser energy penetrates subchondral bone, the expansion of the vaporization bubble may produce a fluid wave within the confined space (Fig. 98.4). High shear stresses may tear blood vessels and produce hemorrhage several centimeters deep within the subchondral bone. Additional data suggest that less than 25 J of energy may induce this deleterious effect. These studies suggest that inadvertent direction of the laser energy into the articular cartilage with penetration of the calcified cartilage can cause damage, which may lead to osteonecrosis. Avoid drilling articular cartilage with any laser system.

ANNEALING

The Ho:YAG laser produces a zone of nonablated, thermally altered tissue when applied to either meniscus or articular cartilage. The laser can thermally alter tissue if the energy striking the tissue is less than the tissue ablation threshold. If held remotely from the tissue, the laser can deliver sufficiently low amounts of light energy to thermally alter the tissue without vaporization. At 62°C, collagen undergoes a phase transition from a triple helix to an amorphous gel. Due to gross structural changes, ordered collagenous tissues such as capsule or tendon “shrink” in length, whereas surfaces of meniscus or articular cartilage coagulate or “anneal.” In using the laser for meniscectomy, surgeons routinely produce smooth residual rims of meniscus (Fig. 98.5; see color Fig. 98.5). The durability and the long-term clinical value of the annealing treatment is unknown. Tissue tensile properties, long-term healing response, and short-term histopathologic effects of the annealing treatments have not been adequately characterized. Annealing should be considered experimental at this time.

LATERAL RETINACULAR RELEASE

The Ho:YAG laser offers the theoretical advantage of limited hemostasis when performing cutting or ablative procedures. Two investigators have evaluated the
LASER-INDUCED CAPSULAR SHIFT (TIGHTENING)

Recognition of the thermal effects of the laser on shoulder joint capsule has led to the development of arthroscopic laser and radiofrequency techniques for treating excess capsular laxity (20,27,30,55,70). Symptomatic inferior and multidirectional instability is based on two factors in varying proportions: (a) the inherent laxity of the shoulder capsule, and (b) the activities of the patient (45). In cadaveric specimens, temperatures at or above 65°C cause significant shrinkage of glenohumeral joint capsular tissue (28). The shrinkage is achieved with use of nonablative laser energy without detrimental effects to the viscoelastic properties of the tissue (25).

Ultrastuctural alteration of collagen fibril architecture caused by the thermal effect of laser energy is probably the dominant mechanism of laser-induced tissue shrinkage (27). Studies have demonstrated that remodeling of capsule is unimpeded following treatment (25). In cadaveric specimens, laser anterior capsulectomy acutely reduces anterior and posterior translation (70). Studies have demonstrated variable consistency and durability of the thermal effects (55). The depth of the thermal effect and potential damage to surrounding structures has been questioned.

Recently, additional nonlaser thermal devices have been developed for thermal shrinkage procedures (15,43,50). Bipolar (Mitek, Arthrotec) and radiofrequency devices (Oratec) function by applying electrical or microwave energy to the collagenous tissues by direct contact. The radiofrequency device also incorporates temperature control by monitoring the temperature at the thermal field. A bipolar probe, in contrast, is capable of delivering current to or leads positioned at the tip to a grounding surface on the edge of the handpiece, whereas the radiofrequency device transmits energy directly into the tissue. The radiofrequency-induced thermal effects vary with the impedance of the tissues. Equivalent tissue effects have been reported for treating capsular tissues with laser and with nonlaser thermal devices (50).

LASER DISCECTOMY

Many different laser systems have been evaluated for the development of laser discoscopy techniques. The first discoscopy study used the CO2 laser on a canine model (17). This study and others using multiple animal models (41,52,80) demonstrated equivalent healing following cervical discoscopy performed with either mechanical or CO2 laser tools. Laser and mechanical tools both produced lower mean intradiscal pressures (11,52,80) due to a bulk modulus effect (78).

In vitro laboratory studies with many newer laser systems demonstrate the ability to remove intradiscal tissue (10,11,39,44,58). Ho:YAG, Nd:YAG, and potassiumdihydrogenphosphate (KTP) all create defects greater than 1.5 cm in diameter with up to 1,200 J of energy. The greatest temperature elevations occur with the Nd:YAG laser (39). Temperatures remain within safe limits, however, in the region of the posterior longitudinal ligament adjacent to the nerve root.

Both the Ho:YAG (69) and the KTP lasers (69,79) are FDA-approved for discoscopy procedures in the United States. No clinical results with the KTP system have been reported. The Ho:YAG system demonstrated no difference between treatment and nonoperative control groups in a nonrandomized study of lumbar discoscopy (65). Most clinical laser discoscopy procedures have been performed in Europe. Choy et al. reported clinical results of outpatient laser discoscopy performed with continuously tuned Ho:YAG laser systems (10). Laser energy was delivered by 400-micron optical fiber through a fluoroscopically placed 18-gauge spinal needle. Fair or good results were noted in only 78% of patients, with gross failure in 22% and one complication of discitis. The system is not currently available for use in spinal procedures in the United States.

The indications for laser discoscopy remain controversial. Results have been comparable to other percutaneous techniques such as chymopapain injection (41). Use has been restricted to prolapsed or extruded discs but not sequestered discs. Laser ablation of subligamentous extruded nucleus pulposus has been noted to be ineffective. Indications for use remain restricted until further clinical and basic science studies can demonstrate spinal laser use to be both safe and effective.

Future developments in endoscopic and laser instrumentation may increase the indications for laser use. Lasers are currently being used experimentally in Europe for foraminal decompression and debreadment of extruded discs. While lasers offer promise, future controlled clinical trials will be required before they attain an expanded role in spinal surgery.

SURGICAL TECHNIQUES

ARTHROSCOPIC MENISCOTOMY

The Ho:YAG laser is available from several manufacturers, with either rigid or flexible handpieces. Check the laser system for proper function before starting the procedure.

- Prepare and drape the knee in the usual fashion. After creation of standard arthroscopic portals and introduction of the arthroscope, carry out diagnostic arthroscopy in standard fashion.
- Identify intra-articular pathologies including meniscal tears. Choose a laser handpiece. I prefer to use a 30°-bend, recessed-tip device, which usually provides access to all regions of the joint. Plug the optical coupler attached to the handpiece into the laser system. Turn the system on and place it into standby mode. During laser use, wear protective laser goggles. Program laser parameters into the system. For meniscotomy, a power of 2 J per pulse and a repetition rate of 10 Hz are recommended.
- Place the laser handpiece into the joint with the tip in contact with the meniscal tear. Activate the laser with a foot pedal. Debride flap tears. If desired, also debride or anneal remnants of frayed meniscus. Conventional mechanical instruments may supplement laser treatments.
- The laser may also be used to coagulate bleeding vessels in a noncontact mode. After completion of debridement, place the laser in standby mode. Remove the instruments and close the wounds in the usual fashion.

SYNOVECTOMY

Its hemostatic properties make the laser suitable for arthroscopic debridement of hypervascular rheumatoid synovitis. The procedure is indicated for patients with marked preoperative monarticular synovitis with no radiographic evidence of joint degeneration. Treatment of synovitis secondary to hemophilia has also been advocated (46).

- For synovectomy, set the laser at 2 J per pulse and a repetition rate of 10-20 Hz. Hold the laser 2-3 mm from the tissue to thermally necrose and coagulate synovium in a noncontact manner. With use of accessory posterior portals, extensive debridement of posterior compartment synovitis can be performed with minimal bleeding and improved visualization.

SHOULDER ARTHROSCOPIC DEBRIDEMENT

Because of its ablative, thermal, and hemostatic properties, the laser has been used extensively for debridement of torn intra-articular tissues including superior labral anterior and posterior (SLAP) tears and other labral lesions. The use of the Ho:YAG laser for the debridement of rotator cuff lesions and biceps tendon tears is contraindicated because of the risk of damage to adjacent normal tissues.

- Place the patient in either a beach-chair or lateral decubitus position. Examination under anesthesia is performed preoperatively. Sterilely prep and drape the shoulder. Create standard anterior, mid-lateral and posterior portals and carry out diagnostic arthroscopy on the glenohumeral joint and subacromial bursa.
- If you identify a labral tear that requires debridement, turn the laser on and insert a 30° angled laser handpiece through the anterior or posterior operating portal that affords best access to the lesion. Laser parameters of 2 J per pulse at a repetition rate of 20 Hz (20 watts) are routinely used for debridement.
- Place the laser in active mode. Put the laser tip in contact or near contact with the tissue and activate the laser by foot pedal. Ablate the damaged tissue. As the energy is delivered, you can focus and defocus the beam by controlling the distance between the probe and the tissue.
- After completion of the debridement, place the laser in standby mode before removal of handpieces from the joint. Close wounds in routine fashion.

SUBACROMIAL DECOMPRESSION

With use of mechanical tools for subacromial decompression, substantial bleeding is frequently a problem. It limits visualization, prolongs the procedure, increases fluid extravasation, and leads to increased perioperative morbidity. Use of the arthroscopic pump often is supplemented with epinephrine within the irrigation solution to limit extravasation, and leads to increased perioperative morbidity. Use of the arthroscopic pump often is supplemented with epinephrine within the irrigation solution to limit
bleeding. The laser’s hemostatic properties in a “defocused” mode make it useful in subacromial decompression procedures.

- After completion of glenohumeral arthroscopy as previously described, visualize the subacromial space with the arthroscope placed in the posterior portal. Place cannulas in the anterior and lateral mid-deltoid portals.
- Debride the subacromial bursa with a mechanical shaver according to standard technique. Use of the mechanical tools is faster for removal of larger tissue volumes and can be supplemented with use of the laser in defocused, noncontact mode to achieve hemostasis.
- Set the laser initially at 2 J per pulse and a repetition rate of 20 Hz (40 W), and use it after completion of the bursal resection to create a hemostatic field. Deliver the laser probe through the lateral portal. Expose the anterior and lateral margins of the acromion by laser debridement of the undersurface periosteum. Then reset the laser to a higher repetition rate of 30 Hz at a total average power of 60 W. Identify the coracohumeral ligament and resect it off the anterior edge of the acromion with the laser. Bleeding that is frequently encountered from the acromial branch of the thoracocapsular artery can be coagulated in noncontact mode with the laser. A mechanical shaver may complete the debridement and remove the remnant of the ligament. The subacromial periosteum is coagulated with the laser.
- Perform arthroscopic debridement and defocused laser, with the laser as previously described. Maintain the laser in standby mode when the handpiece is removed from the joint. Close wounds in routine fashion. Postoperative rehabilitation is identical to that of nonlaser procedures.

**SHOULDER CAPSULORRHAPHY—LASER-ASSISTED CAPSULAR SHIFT**

- Perform examination under anesthesia to confirm the magnitude and direction of the glenohumeral instability. Position, prep, and drape the patient, and perform diagnostic arthroscopy as previously described. After treating the intra-articular pathology according to standard arthroscopic technique, turn attention to the capsule.
- For the capsular treatments, use the 30° angled laser probe with laser settings of 1 J per pulse and a repetition rate of 10 Hz. For patients with anterior instability, introduce the laser through the anterior portal, with the arthroscopic placed posteriorly. The laser is activated 5 mm from the tissue and advanced until shrinkage is observed without tissue ablation (Fig. 98.6). The laser probe energy is applied radially in brushstroke fashion from the edge of the glenoid laterally. The process is repeated sequentially.

**Figure 98.6.** Capsular shrinkage procedure. Ho:YAG laser energy is applied to anterior shoulder capsule in a noncontact mode. The two figures demonstrate the capsule pretreatment (A) and after application of laser energy (B). Note the contracted band of tissue at the tip of the device that appears after application of laser energy.

- Do not make repeat passes over treated areas; nearly all shrinkage occurs with the initial laser treatment. Additional laser energy may increase thermal damage beyond the capsule. Initiate the treatment posteriorinferiorly, bring it into the axillary region, then to the region of the anterior inferior glenohumeral ligament.
- Advance the arthroscope for improved anterior visualization. Then treat the anterior capsule, and the anteroinferior, middle, and superior glenohumeral ligaments.
- Treat unidirectional posterior instability with similar technique, but place the arthroscope in the anterior portal with the laser probe in the posterior portal. The posterior structures are thermally treated starting in an anteroinferior location and advancing posteriorly.
- In the case of multidirectional instability, the capsule and ligaments are treated circumferentially. Visualization is improved if the posterior structures are treated first, in a manner similar to that described for posterior instability. The arthroscope and laser probe then exchange portals prior to treatment of anterior tissues.
- Tailor rehabilitation to the age of the patient and the direction of instability. For unidirectional anterior instability, keep older patients in a sling for 1 to 2 weeks, and younger patients, 2 to 3 weeks. Encourage patients to attain 90° of abduction and limit them to 45° of external rotation by 6 weeks. Rotation and abduction are then advanced as tolerated, limited motion to the final 15° of abduction and external rotation until 12 weeks. Allow patients unrestricted return to sports and overhead throwing at 3–4 months, depending on strength, conditioning, and endurance.
- After posterior stabilization, stabilize the arm in 30° of external rotation for 4 weeks. Start glenohumeral and scapulothoracic exercises at that time, avoiding full internal rotation for 12 weeks.

**EXPERIMENTAL TECHNIQUES**

**REMOVAL OF POLYMETHYL METHACRYLATE**

Removal of polymethylmethacrylate (PMMA) remains a difficult challenge for revision total joint surgeons. The laser offers the potential advantage of selective ablation of redundant cement adjacent to host bone. The laser is activated at 2 J per pulse and a repetition rate of 20 Hz (40 W). PMMA strongly absorbs infrared and near-infrared light energy. In the infrared region, the water within tissue absorbs light energy and the dry components of bone have minimal optical absorption. By using wavelengths of light that do not correlate with the absorption peaks for water, many researchers have documented efficient cement removal with infrared laser systems.

Clinically, laser cement removal techniques have not been widely adapted or developed because of concerns about safety, efficacy, and convenience. Vaporization of PMMA produces highly toxic byproducts that must be removed from the operating room with high-powered evacuation systems to prevent injury to personnel. Vaporization products are flammable and may ignite during the laser process. The infrared laser light cannot be transmitted through fiber optics, and cumbersome delivery systems are required.

Light produced by the CO2 laser system, while effective at ablatting cement, is nonselective and may also perforate and ablate host bone. Desiccation of the tissues in the surgical field may produce extensive charring. Visualization within the femoral canal is difficult and the interface between host bone and PMMA becomes difficult after use of the laser has been initiated. Access to the distal canal is often difficult with the free-beam CO2 laser.

Intermediate success has been achieved with use of a laser waveguide, which pumps a nitrogen or CO2 gas into the laser field. The gases reduce the oxygen content in the plume and dilute the vaporization contents, reducing the risk of ignition. The waveguide is also less cumbersome than the articulated arm handpieces for the CO2 laser. Distal removal of cement from the femoral canal has proven difficult with these devices. Few surgeons are currently using the laser clinically or experimentally for cement removal in revision joint arthroplasty.

**LASER OSTEOTOMY**

Lasers theoretically offer the advantage of cutting easily through calcified tissues with minimal trauma to the host tissues. Multiple laser systems, both CW and pulsed, at high peak powers efficiently ablate bone (32–35,42,47,48). Cutting through bone at rates comparable to mechanical tools requires larger, more expensive laser systems. In contrast to mechanical tools, the lasers can thermally damage the osteotomized bone. In vivo studies demonstrate delayed healing after ablation with near-infrared Er and Ho systems in rat tibial and calvarial bone (7,18). The lack of a readily adaptable high-powered lasers for osteotomy, the increased cost, the effectiveness of current mechanical tools, and concerns about impaired healing result in limited indications for laser osteotomy at this time.

**TISSUE WELDING**

Tissue welding refers to techniques for joining severed collagenous connective tissues. The two primary welding mechanisms under investigation are based on thermal and photothermal mechanisms. The laser-based techniques use light energy to “melt” the end of the collagenous structures. The melting occurs as light disrupts collagen crosslinks and, in turn, the organized collagen triple helical structure. The collagen phase transition, and resulting “molten” mass, occurs within a narrow temperature range bridging 62°C (38). Tissue welding occurs when the molten uncrosslinked tissues are mechanically apposed, then recrosslinked. Limited success
has also been achieved with use of fibrin solders [67].

Photochemical techniques use light-activated chemicals to directly crosslink collagen of severed tissues. Experimental naphthalimide dyes have produced high-strength welds of menisci and articular cartilage. Preclinical studies with Barbados sheep have demonstrated healing and retention of articular cartilage welds for longer than 12 months [31,36,37]. Photochemical techniques are early in development. Toxicity, safety, and efficacy studies will need to be done before the techniques are put to clinical use in humans.

BIOSIMULATION

Biosimulation is a controversial field of study in which low-level light energy is used to induce therapeutic effects. The theory is based on observations that low-level light energy increases cellular metabolism. Multiple endogenous chromophores within cells produce multiple complex in vitro cellular effects. The cellular effects are dependent on both wavelength and light dose [1,41].

Researchers postulate that patients can derive clinical benefit from low-level light treatments if the metabolic effects can be induced broadly throughout tissues. Studies have assessed the influence of low-level light on both fracture and wound healing in animals [2,14,31]. Clinical trials in the United States currently evaluate biosimulation for the treatment of low back pain and carpal tunnel syndrome. No systems are currently approved for use in the United States.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) is a new treatment modality in which light-activated chemicals are used to treat a variety of pathologic conditions. The FDA has currently approved the photosensitizer Photofrin for the treatment of lung cancer and multiple other applications. Additional dyes are in later-stage clinical trials. As both drug and light must reach the target tissue to induce therapeutic effects, PDT offers the potential for selective drug toxicity. The difficulty in delivering light energy to opaque solid musculoskeletal tumors has prevented the adoption of PDT techniques in orthopaedic oncology.

In orthopaedics, PDT has been most extensively evaluated for the treatment of inflammatory arthritis (Fig. 98.7; see color Fig. 98.7) [56,57,71,74]. The hypervascular proliferative synovium of rheumatoid arthritis can be targeted and destroyed with PDT. Photosensitizers are delivered systemically or via intra-articular injection.

![Figure 98.7](image) (See also color Fig. 98.7) Photochemical treatment of a rabbit model of rheumatoid arthritis. Light delivered percutaneously to the anterior knee joint activates photochemicals that destroy the proliferative synovium.

Percutaneous optical fibers of transcutaneous techniques deliver light energy to the inflamed synovium. The light-activated dyes, or photosensitizers, are large multiconjugated structures that produce reactive oxygen species after absorbing the light energy of a specific wavelength. The singlet and triplet oxygen reacts locally to disrupt cellular and nuclear membranes inducing both necrosis and apoptosis. Direct occlusion of tissue neovasculature indirectly produces synovial necrosis. Activation of multiple photosensitizers with a variety of light-delivery systems produces synovial necrosis without apparent damage to the adjacent chondral or soft tissues. Development of these techniques remains at the preclinical research level.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

As much as 10% of the population of the United States is disabled by arthritis. Although arthritis has many causes, the common end result is deterioration of joint surfaces and progressive loss of joint function. The cause determines the clinical characteristics and the rate of deterioration for a given arthritic condition. Septic arthritis is often characterized by rapid deterioration, but primary osteoarthritis is characterized by a slow, insidious deterioration.

The national impact of osteoarthritis and rheumatoid arthritis is enormous. Musculoskeletal diseases account for more than 40% of all patients referred for vocational rehabilitation. Arthritis is the second most frequent cause of outpatient complaints among patients with chronic diseases. Musculoskeletal diseases account for 20% of all Medicare hospital costs. The number of days of work lost annually as a result of rheumatoid arthritis and osteoarthritis is staggering.

One of the most difficult problems that patients with arthritis and their families face is accepting that the disease is chronic, with little likelihood of spontaneous remission. People with arthritis must live with their disease, because they will not die of it. Therefore, accurate diagnosis and early appropriate comprehensive management are critical.

Approximately 50 years ago, only a handful of causes of arthritis were identified. We now recognize more than 100 causes. Although we may congratulate ourselves on the tremendous advances in diagnosis and treatment of patients, we have only begun to scratch the surface. Answers to the management of arthritis are likely to remain elusive in the near future.

It is important to identify as early as possible the patients who need more intensive treatment than others and the patients who are more likely to develop functional disability. Involvement with social services or peer support groups and consultation with other disciplines are crucial to the care of the patient. Do not allow a patient to become seriously functionally disabled before suggesting vocational rehabilitation. Several identifiable work factors are important in maintaining employment. The most important factor is having the autonomy to control the pace and content of work activities. Accessibility of the workplace is also an important consideration. We tend to lose sight of the young mother with arthritis and morning stiffness who is unable to dress her children for school, of the worker who loses his job because of recurrent absence, and of the marital breakdowns that are almost twice as frequent among arthritis patients as in the general population. The financial and social hardships are substantial.

After the clinical and functional evaluation, develop a management plan that addresses specific medical measures to control the arthritic process. Include the use of appropriate regimens of rest, exercise, and the various available physical and surgical modalities to relieve pain and maintain musculoskeletal function. If appropriate, encourage the use of assistive devices to further these goals and allow the patient to remain as independent as possible.

A critical feature of all management programs is the education of the patient about the disease process, the modalities of treatment, and the principles of joint protection and energy conservation. Many educational pamphlets and books are available from the Arthritis Foundation (4, 28, 67, 69). If the patient understands the process and rationale for treatment, he or she is more likely to comply with the therapeutic regimen. Provide information about reasonable therapeutic goals and limitation of activity according to the patient's functional level. Suggest suitable modifications of the living and working environments and tasks. Relatively minor physical modifications may make major differences in the patient's independence.

GENERAL PRINCIPLES

Arthritic conditions can be classified as low-inflammatory or high-inflammatory types. Patients with the low-inflammatory type have low leukocyte counts in the synovial fluid and laboratory findings consistent with low-level inflammatory activity; the affected joint often shows focal degeneration. Those with the high-inflammatory type have high leukocyte counts in the synovial fluid, laboratory findings consistent with high-level inflammatory activity, and usually show a more diffuse degeneration of the involved joints (Table 99.1).

Table 99.1. Interpretation of Synovial Fluid Findings in the Setting of Undiagnosed Arthritis

As the classic types of low-inflammatory disease are primary osteoarthritis, produced by intrinsic degeneration of articular cartilage, and posttraumatic arthritis. The
classic type of high-inflammatory arthritis is rheumatoid arthritis. Other types include gout, arthritis of psoriasis, lupus erythematosus, ankylosing spondylitis, arthritis associated with bacterial infection (11), Reiter's syndrome, and arthritis of ulcerative colitis. There are some arthritic diseases that fit into neither category and that have unique characteristics, such as aseptic necrosis, "frozen" shoulder and other joint-stiffening conditions, as well as neuropathic joints.

ARTHRITIC PAIN

The most common symptom of arthritis is pain in the joints. The pain may arise from soft tissues about the joint that are under tension or muscles that are in spasm, or from subchondral bone that is undergoing destruction as a result of the arthritic process. Other common and significant symptoms and signs of arthritis are loss of joint motion, instability of joints, and deformity. Many of the normal components of gait are significantly altered, including walking speed, step length, cadence, lateral motion of the pelvis, pelvic tilt, and transverse rotation of the pelvis.

HISTOLOGY

The histologic characteristics of any given arthritic condition vary with the stage of the disease, and often these changes do not differentiate specific causes. Low-inflammatory and high-inflammatory arthritis may show chronic inflammation of the synovium, diffuse articular cartilage damage with fissures and subchondral cysts, and pannus extending across the articular surface. The pathology report often reads, “compatible with, but not diagnostic of, high-inflammatory arthritis.”

There is a mechanism of joint destruction in arthritis that is associated with the immune response. Antibodies produced by lymphocytes and plasma cells of the synovial membrane combine with antigens in the synovium (i.e., locally produced and altered IgG or an unknown antigen, “X”). In systemic lupus erythematosus, desoxyribonucleic acid (DNA) antigens are the most important finding. Some or all of these complexes may fix or activate complement, causing chemotactic substances to be produced. Ingestion of complexes by polymorphonuclear leukocytes leads to vacuole formation and release of lysosomal enzymes, which cause the destruction of articular cartilage and cell death.

BIOCHEMISTRY

In arthritis, the major destructive process at the biochemical level is thought to be enzymatic degradation of the articular cartilage [38]. In the various types of arthritic conditions, there is a decrease in the concentration of chondroitin sulfate, and the existing chondroitin sulfate has a decreased chain length. The enzymes thought to be responsible are hyaluronidase, which breaks down mucopolysaccharides, and collagenase, which breaks down proteins such as collagen.

These enzymes, called cathepsins, are responsible for cartilage degradation and may be found in the synovium, the synovial fluid polymorphonuclear cells, or the chondrocytes themselves. With the breakdown of matrix components, the production of new components by the cells increases in an attempt to repair the damage. With disease progression, however, the balance favors articular cartilage degradation. The mechanical and lubricating functions of cartilage are lost, and joint collapse progresses [7,59,75].

IMMUNOCHEMISTRY

In high-inflammatory and low-inflammatory types of arthritis, IgG, IgM, and IgA levels are elevated in the synovial fluid. Rheumatoid factor, an IgM (19S) antibody that reacts with degraded IgG (7S) immunoglobulins, is found in 70% to 80% of adults with rheumatoid arthritis. For this reason, arthritis is considered one of the immune complex diseases (6). Rheumatoid factor is not specific to rheumatoid arthritis, because it is also found in approximately 25% of patients with systemic lupus erythematosus, scleroderma, and polymyositis. If this factor is found in high titer, however, it is characteristic of rheumatoid arthritis; usually the serum and synovial fluid levels of the factor are correspondingly elevated.

DIAGNOSIS

The diagnosis of late-stage disease is usually obvious. A given arthritic condition, such as rheumatoid arthritis, usually creates a characteristic clinical picture that is not difficult to differentiate from other types of arthritis. The problem of diagnosis arises when the presenting symptom of a patient with arthritis is an acutely swollen joint or joints. A history of trauma at this point is often helpful for diagnosis of the condition, but if such a history is lacking, the diagnosis is best approached by turning to radiological and laboratory examinations.

The characteristic radiographic features of low-inflammatory osteoarthritits, arthritis secondary to trauma, or other conditions in which normal joint mechanics have been disrupted are the irregular narrowing of the joint surface and the appearance of osteophytes (Fig. 99.1). The radiograph is characterized by hypertrophic changes about the joint rather than the atrophic changes seen in high-inflammatory types of arthritis. It is common for cysts to form along the weight-bearing surfaces in the lower extremities. It is rare that a patient's presenting symptom is an acute attack of arthritis in a joint affected with osteoarthritits, unless he or she had a fall or other traumatic episode that aggravated a pre-existing abnormality. In these cases, a radiograph of the joint is helpful in determining the contribution of degenerative joint disease to the traumatic episode.

![Figure 99.1](image1.png)

**Figure 99.1.** A: The drawing depicts degenerative arthritis, which is characterized by focal narrowing of the surface cartilage with subchondral sclerosis on each site of the narrowing. Occasionally, there are subchondral cysts in this area. B: The radiograph shows a cyst in the acetabulum of a hip with degenerative arthritis in a 77-year-old female.

The characteristic radiographic features of high-inflammatory arthritis (i.e., rheumatoid arthritis, septic arthritis, and gout) include diffuse narrowing of the entire joint surface and the appearance of periarticular cysts (Fig. 99.2). The cysts are thought to be caused by erosion from the inflamed synovium at its reflection near the insertion of the joint capsule. The margins of the cysts are often "fuzzy" during the acute stage and sclerotic during the chronic stage. The uniform narrowing of the joint space is thought to be due to enzymatic digestion of the entire cartilage surface. Another radiographic feature common to high-inflammatory types of arthritis is osteoporosis of the bones near the joints.

![Figure 99.2](image2.png)

**Figure 99.2.** The drawing depicts a high-inflammatory arthritis, which is characterized by diffuse narrowing of the entire joint surface. A: Occasional, periarticular
cysts are seen near the reflection of the synovium. B: The radiograph shows these changes in a 65-year-old woman with rheumatoid arthritis affecting the right hip.

Perhaps the most important diagnostic procedure in the evaluation of the patient with the first episode of an acutely painful joint is arthrocentesis and synovial fluid analysis. The indications and contraindications for arthrocentesis are illustrated in Table 99.2. The technique of arthrocentesis involves infiltration of the skin with a local anesthetic by using a 25-gauge needle, followed by introduction of a 20-gauge needle into the joint. Joints that contain large amounts of fluid are the most successfully aspirated, but even these joints may have hypertrophic synovial folds that can block the needle tip, resulting in an unsuccessful aspiration. Approaches to various joints for arthrocentesis are illustrated in Figure 99.3.

Figure 99.3. Sites for introduction of a needle for arthrocentesis of various joints. Some joints are more difficult to aspirate (such as the hip, shoulder, elbow, and ankle) and should be examined with fluoroscopy. The needle is introduced into the subcutaneous tissue, and the fluoroscope is used to ensure that it is on target.

A synovial fluid analysis usually helps the diagnosis, but synovial biopsies and cartilage biopsies are often not diagnostic. A few exceptions to this principle are synovial biopsy in tuberculosis or sarcoidosis, which show the familiar Langhans' giant cells and central fibrinoid necrosis; a synovial biopsy in coccidioidomycosis that demonstrates the characteristic endospore; and a synovial biopsy from pigmented villonodular synovitis that differentiates this tumorous condition from arthritis.

Subject the extracted synovial fluid to several laboratory tests: gross appearance and the “string” test, mucin clot, leukocyte count and differential, microscopic examination of a wet preparation, polarized light examination, compensated polarized light examination, Gram stain examination, glucose content, and culture and sensitivity tests. Compare the glucose value of the synovial fluid with that of the serum glucose levels. These tests often confirm the diagnosis and can be carried out with only a few drops of synovial fluid (Table 99.3). Gout can often be diagnosed by the finding of negatively birefringent crystals in the fluid; pseudogout is characterized by positively birefringent crystals, and infection can be diagnosed by the identification of bacteria by Gram stain.

The serum rheumatoid factor is positive in 70% to 80% of adult rheumatoid arthritis patients. It is rarely positive in juvenile rheumatoid arthritis. The lupus erythematosus test demonstrates a polymorphonuclear cell filled with antinuclear antibody (ANA) complexes. More frequently used tests are the fluorescent ANA tests, the results of which are classified as homogeneous, shaggy, or speckled. Homogeneous, the most common ANA pattern, is seen primarily in lupus erythematosus but occurs in other diseases as well; shaggy (peripheral or rim) is more specific to lupus erythematosus and is often associated with increased disease activity; speckled is characteristic of mixed connective tissue disease. In lupus erythematosus, the titer is higher than those in other rheumatic conditions.

Another helpful test is the HLA-B27. Of those patients with ankylosing spondylitis, 90% have the gene for the HLA-B27 antigen, a histocompatibility complex antigen controlled by a gene on chromosome 6. Other arthritic conditions, such as the arthritis of inflammatory bowel disease, appear to have an increased association with a positive HLA-B27 test if the arthritis is localized to the spine.

Synovial biopsy is usually unnecessary in diagnosing arthritis. However, if the history, physical findings, radiographic findings, and synovial analysis does not reveal the diagnosis, consider a synovial biopsy.

PRINCIPLES OF NONSURGICAL TREATMENT

Treatment of arthritic conditions may be divided into nonsurgical and surgical approaches. Surgery should not be considered as a last alternative to nonsurgical treatment but rather as an adjunct that may be appropriate at any stage in the treatment of the disease. The treatment goals in arthritis are to prevent and correct deformity, preserve function, restore function, and relieve pain. The nonsurgical treatment primarily consists of drugs, physiotherapy, rest, and use of orthotic devices.

DRUG TREATMENT
Of the drugs most commonly used, nonsteroidal anti-inflammatory drugs (NSAIDs) remain the first line of therapy in the treatment of arthritis, and they should be administered in a dose sufficient to control pain and relieve stiffness (14). Individualized dosage and emphasis on compliance are necessary. These drugs are best given after meals or after antacids to prevent gastrointestinal irritation. The most frequent side effects of NSAIDs are gastrointestinal irritation and bleeding.

Gastrointestinal bleeding from NSAIDs is particularly a problem for people older than 60, those who smoke, and those with a history of gastrointestinal ulcer. All COX-1 NSAIDs can potentially induce gastrointestinal bleeding.

The use of NSAIDs has changed dramatically. The Food and Drug Administration has approved two new NSAIDs that are selectively inhibitory for cyclooxygenase-2 (COX-2). It was discovered approximately 10 years ago that there were two forms of cyclooxygenase. Both forms were inhibitory for the production of prostaglandins and, therefore, could potentially help in inflammation. Inhibition of COX-1, however, also led to the loss of the protective effects of prostaglandins on the mucous membrane of the gastrointestinal tract, which led to an increase in gastrointestinal ulceration. Inhibition of COX-2 leads to protection from inflammation but does not produce the harmful side effect of gastric ulceration. Until recently, all NSAIDs have been COX-1 inhibitors. The first two of the new class of drugs, celecoxib and rofecoxib (44,70), became available in 1999. Celecoxib, in particular, is indicated in both osteoarthritis and rheumatoid arthritis and appears to spare the GI tract. It also does not inhibit platelet function. The use of Celecoxib has changed clinical practice and has made the use of COX-2 inhibitors a standard of care.

Gluconolactone and chondroitin sulfate have been advocated as oral agents designed to stimulate aggrecan formation as well as hyaluronic acid formation. Aggrecan is the major proteoglycan (PG) in cartilage. It has a PG in the core, chondroitin sulfate and keratin sulfate sidechains attached to it. Hyaluronic acid (hyaluronan) is made of alternating acetylgalactosamine and glucuronic acid building blocks. It is the core molecule that aggrecan binds to through the link protein, forming the large PG block. It is thought that oral administration of the building blocks chondroitin sulfate and glucosamine will stimulate increased formation of the larger molecules. The glucosamine molecules reach the cellular machinery of the chondrocyte without being altered by intestinal absorption, chondrolysis, or other metabolic influences, and the chondroitin sulfate preparations undergo partial degradation. In vitro studies (tissue culture) have shown that both chondroitin sulfate and glucosamine will stimulate glycosaminoglycan (GAG), PG, and collagen synthesis. In vivo studies have not demonstrated an anti-inflammatory effect on the cyclooxygenase system or the prostaglandin generation of metalloproteases, and there is little effect on bradykinin, serotonin, or histamine-mediated inflammation. However, there appears to be blockade of leukocyte esterase, hyaluronidase, and superoxide radical generation. Thus, these drugs might be considered "anti-reactive" as opposed to anti-inflammatory (21).

Several double-blind studies have addressed the safety and efficacy of glucosamine sulfate. In one study, 80 patients with focal or general osteoarthritis were randomized to glucosamine 500 mg three times daily versus placebo for 30 days (14). Symptoms were reduced in 72% of patients in the glucosamine group and 36% of patients in the placebo group. Improvement was noted in most by 20 days. Another study of 24 outpatients with osteoarthritis showed significant improvement in the scores for joint pain, tenderness, and swelling in 80% of patients in the glucosamine group versus 20% of patients in the placebo group (61).

Another important study compared glucosamine sulfate with ibuprofen in osteoarthritics of the knee (59). Two hundred inpatients were randomized to glucosamine 500 mg orally three times daily versus ibuprofen 400 mg orally three times daily for 4 weeks. No other analgesics, NSAIDs, or corticosteroids were allowed. Efficacy was measured by Lequesne's pain index and global assessment. Ibuprofen response was faster; 69% responded within 1 week, compared with 28% of the glucosamine treated groups. It should be noted that it takes 1 to 2 months for glucosamine sulfate to take effect. The overall response rate was equal: 52% versus 48%. Lequesne's severity index improved equally: ibuprofen (severely index = 16) to glucosamine (severity index = 10), respectively. Adverse effects were significantly higher in the ibuprofen group (35% ibuprofen versus 6% glucosamine), and the adverse event-related dropout rate was 7% for ibuprofen and 1% for glucosamine. Similar results were found in another study (47).

Chondroitin sulfate has also been studied, but not as extensively. In a trial comparing chondroitin sulfate (400 mg three times daily) with diclofenac (50 mg three times daily), adverse responses were few and equal in both groups (55). The response to diclofenac was prompt but was not sustained after withdrawal. The response to chondroitin sulfate response was slower, but ultimately greater and sustained 3 months after withdrawal.

Gold salts are second-line drugs for the treatment of rheumatoid arthritis. Chrysotherapy requires careful supervision because of the possible side effects of nephrotoxicity, blood dyscrasias, and gold allergy. Gold can be administered parenterally or orally. Methotrexate is becoming widely used for severe rheumatoid arthritis, and its use requires monitoring of blood counts and liver function tests.

Another class of drugs to be considered are steroids (e.g., prednisone). In rheumatoid arthritis, 5 to 10 mg of prednisone daily in divided doses can give good relief from pain, swelling, and inflammation. At these low levels, the side effects of cataracts, decreased resistance to infection, poor wound healing, psychological changes, acne, and diabetes are minimal. Higher doses of steroids, however, are associated with lower body weight, nausea, fluid retention, edema, and high blood pressure. Recovery from the catabolic effects of high-dosage steroids is generally quick, and the doses can be slowly reduced to 10 to 20 mg daily. Patients should be warned of the possibility of psychological changes and advised to limit alcohol consumption.

Another class of steroids that is often used is prednisolone. Prednisolone is a long-acting corticosteroid that is converted to prednisone in the liver. It is absorbed well on oral administration and is available in oral tablets. The adverse effects of prednisolone are similar to those of prednisone, except that there is less fluid retention and edema. Dosage should be started at 40 to 60 mg per day and reduced gradually as the condition improves. The majority of patients with rheumatoid arthritis require dosage levels of 20 to 40 mg per day. These patients are also at risk for osteoporosis. The risk of osteoporosis can be reduced by providing adequate calcium and vitamin D to maintain bone mass. Adequate dietary calcium and vitamin D intake should be encouraged, and patients should be monitored for signs of osteoporosis.

Another newer drug for the management of moderate to severe rheumatoid arthritis is Etanercept (Enbrel, Immunix, Seattle, Washington), which is a soluble, injectable tumor necrosis factor receptor that has been engineered to resemble human IgG1. Patients with moderate to severe rheumatoid arthritis self-administer 25 mg two times per week. The responses in some patients have been dramatic, particularly in those patients who have failed with other disease-modifying agents. It is expected in the next several years that similar products will likewise be approved. The overall goal is to selectively down-regulate the inflammatory response at the molecular level.

Hyaluronic acid as an injectable, large, linear GAG has now been studied in a double-blind fashion. There are two preparations now available, hylan G-F20 (Synvisc, Ortho-McNeil, Warren, New Jersey; and Hyalgan, Hyalgen, New York, New York); both are processed from rooster comb. Synvisc has a molecular weight of 6 million and Hyalgan has a molecular weight of 730,000, as compared with naturally occurring hyaluronic acid with a molecular weight of 10 million. Because of the difference in molecular weight, Synvisc is recommended that it be given every three times, 1 week apart; and Hyalgan recommended five times, 1 week apart. Both Hyalgan and Synvisc have been shown to be significantly better than saline controls (1,13,45,46). The functional improvement was noted within 2 months after injections and was sustained for at least 1 year. No significant difference was noted in radiographic progression.

Another study compared Synvisc to NSAIDs and found no significant difference at 12 weeks, but there was significant improvement of Synvisc over the anti-inflammatory drugs by 26 weeks (2). It was noted that Synvisc plus NSAIDs were superior to Synvisc alone or NSAIDs alone. Finally, a study comparing Synvisc to intra-articular steroid injections showed no significant difference by 6 months (39).

Local steroids are of limited use, but they are of definite benefit and must be used selectively (20). They are often helpful in the early rehabilitation of an acute rheumatic flare. They also provide temporary relief of an acute flare of chronic synovitis. They should not be used more than two or three times per year, and at least 2 weeks should pass between repeat injections. If there is a question of infection, they should not be used, and the results (particularly the culture) of the synovial analysis should be examined before a steroid injection is given. The main limitation of repeated local steroid injection is the risk of infection and destruction of articular cartilage. It is mandatory that the steroid mixture not be injected directly into a tendon, for example, when treating patella tendinosis, achillis tendinosis, or rotator cuff tendinosis, but rather into the tendon sheath around the tendon.

PHYSICAL THERAPY

Physical modalities act as counterirritants to reduce pain, and are not capable of significantly increasing deep tissue temperatures or local circulation. Superficial heat or localized cold may relieve pain sufficiently to permit exercises. Therapeutic exercises are designed to increase muscle strength, reduce joint contractions, and maintain range of motion.

In using physical therapy, patients should avoid heavy loading exercises that compress the joint. For this reason, the majority of muscle-strengthening exercises are best done isometrically in a position of the joint that does not cause pain. On the basis of clinical experience, we found that redundant and intense exercise produces pain that lasts for longer than 10 to 15 minutes after the activity, the activity is not advised. Passive range-of-motion exercise within pain tolerances is acceptable, but forceful, painful stressing must be avoided. Assisted and active range-of-motion and isotonic-muscle-strengthening exercises are highly recommended. Swimming, adaptive physical education, and activities of daily living are sometimes more appealing to the patient than a boring, structured exercise program.

Avoid prolonged bed rest, although periodic daily rest periods are essential. Resting with removable splints or braces that permit limited function of the limb may prevent deformity that would otherwise occur as a result of pain. Resting night splints may be applied to stretch out contracted joints, if the deformity is not too severe. A dynamic walking aid or other assistive devices may be used to permit continuation of the exercise program and, in conjunction with rest, to relieve pain and correct or prevent deformity. Complicated dynamic braces are of little value.

Avoid using cylindrical, nonremovable plaster, or braces. Wielding of cylinder casts to overcome flexion deformity is usually ill advised. The use of orthotic shock absorbers in shoes can decrease joint impact in the lower extremity by as much as 40% (79). New developments in continuous passive motion devices appear
Roentgenographic changes vary with progression of the disease. Early joint space narrowing may occur in the knee, with relatively minor changes seen at arthroscopy.

The synovial fluid white cell count is less than 1000/mm³. The laboratory tests are usually normal, and are performed to rule out other arthritides. The erythrocyte sedimentation rate is normal in most patients, and the tests are positive in about 30% of patients. The maximum joint space narrowing. The joints most frequently involved are the hands, knees, hips, feet, and spine. The distal interphalangeal joints of the hands have been pathologically involved, usually with erosion of the articular surface, and this leads to sclerosis that may be seen radiographically. Appositional growth of bone at the joint margins leads to osteophytes, or “spurs.” Spurs, along with thickening of the joint capsule, leads to limitation of motion.

In the early stages of osteoarthritis, there is actually an increase in thickness owing to increased water content (swelling) and an increase in the net rate of synthesis of PG. This is an attempt to repair articular cartilage, and may last for years in humans (62,63). With disease progression, the joint surface thins and the PG content decreases. Progressive fibrillation of the cartilage occurs, and eventually, the underlying bone is exposed. There is increased bone formation in the subchondral bone, and this leads to sclerosis that may be seen radiographically. Appositional growth of bone at the joint margins leads to osteophytes, or “spurs.” Spurs, along with thickening of the joint capsule, leads to limitation of motion.

Cartilage loss is the central process in osteoarthritis. After the initial attempts at repair with increased synthesis of collagen, PG, and hyaluronan, the catabolic activity at the biochemical level becomes high. Lysozyme proteases (cathepsins) and neutral metalloproteinase such as stromelysin, collagenase, and gelatinase account for much of the loss of cartilage. The concentration of collagenase increases with advancing disease, and matrix collagen decreases. Similarly, despite an increase in hyaluronic synthesis, there is a reduction in hyaluronan. A specific hyaluronidase has not been identified in cartilage, but several lysosomal enzymes can lyse hyaluronic acid and chondroitin sulfate. The cartilage loses aggrecan (49), which results in a loss of compressive stiffness and elasticity as well as an increase in fluid permeability. This may be due to a deficiency in link protein. The cells in osteoarthritic cartilage divide more actively than in normal cartilage, and the resultant cells are very metabolically active. However, the new cells do not produce a normal extracellular matrix due to biochemical deficiencies, which leads to further cartilage deterioration. Tissue inhibitors of metalloproteinase and plasminogen activator inhibitor can be secreted by chondrocytes to inhibit the degenerative process, but the balance appears in favor of the degradative enzymes.

PRINCIPLES OF SURGICAL TREATMENT

Before considering surgery, perform adequate diagnostic procedures to determine whether the problem is due to tendon contractures, ligament or capsular contractures, bony deformities, or joint surface deterioration. Also important, consider the social disabilities suffered by the patient: What is it the patient cannot do that he or she would like to be able to do? After considering these factors, devise the treatment plan. Particularly in late-stage disease, surgery often can help improve the arthritic patient. Rarely can a cure be obtained.

The procedures available may be divided into two main categories: soft-tissue procedures and bone and joint procedures. The soft-tissue surgeries include synovectomy, capsulotomy and capsuectomies, tendon transfers, and other tendon procedures. The bone and joint procedures include arthroplasty, osteotomy, arthrodessis, excision of osteophytes and loose bodies that cause locking or mechanical joint damage, articular resection, chondroplasty to stimulate repair fibrocartilage, and biologic resurfacing using autograft or allograft cartilage. These techniques are discussed in Chapter 70, 71 and 72 (Hand), Chapter 86 (Chondral Injuries) Chapter 101, Chapter 102, Chapter 103, Chapter 104, Chapter 105, Chapter 106, Chapter 107, Chapter 108 and Chapter 109 (Arthroplasty, Osteotomies, and Arthrodesis of the Major Joints), Chapter 117 (Foot), Chapter 125 (Osteonecrosis), and Chapter 153 and Chapter 154 (Spine). Conditions that almost always require surgery include unstable luxation of the cervical spine, ankylosis of the temporal mandibular joint with risk of starvation, severe ankylosis of both elbows in extension, severe deformities of the hips and knees, and deformities that cause severe compression of nerves or imminent or actual tendon ruptures. Table 99.4 summarizes the common surgical procedures and their indications.

Table 99.4. Surgical Procedures Commonly Used in the Treatment of Arthritic Conditions

COMMON ARTHRITIC DISEASES AND THEIR TREATMENT

For a discussion of neuropathic joint disease, see Chapter 124. For information on septic arthritis, see Chapter 134 for adults or Chapter 176 for children.

OSTEOARTHRITIS

Osteoarthritis is the most common joint disease and is, for the most part, a noninflammatory form of arthritis.

- It is characterized by progressive loss of articular cartilage, appositional new bone formation in the subchondral trabecular bone, and formation of new cartilage and new bone at the margins (osteoephytes). Clinical features can include pain in the involved joint, which is frequently aggravated by activity and relieved by rest. Stiffness after periods of immobility is common. Advanced stages are characterized by enlargement of the joint, instability, limitation of motion, and functional loss.

**Epidemiology**

More than 80% of those older than 75 years of age suffer from some degree of osteoarthritis. The prevalence increases with age, and age is the most important predictive risk factor. Osteoarthritis is a major cause of disability, and the knee is involved more commonly than the hip. There are also racial differences, with whites having a higher incidence than Chinese, South African blacks, East Indians, and Native Americans.

Fewer than one half of those with radiographic evidence of osteoarthritis have significant symptoms; therefore, treatment is predicated on symptoms rather than on the degree of pathology. The damaged joint may be due to degenerative joint disease due to wear and tear, or it may be secondary to a previous traumatic episode. There is some evidence that there is a genetic predisposition (42). The presence of Heberden’s nodes signifies a predisposition toward the development of osteoarthritis, and this may potentiate the effects of local etiologic factors, such as trauma or instability. For example, patients with Heberden’s nodes who have meniscal tears are more likely to develop posttraumatic arthritis of the knee after meniscectomy (12). Other predictors of osteoarthritis are obesity, increased bone density, trauma, and repetitive stress (67).

**Pathogenesis**

In the early stages of osteoarthritis, there is actually an increase in thickness owing to increased water content (swelling) and an increase in the net rate of synthesis of PG. This is an attempt to repair articular cartilage, and may last for years in humans (62,63). With disease progression, the joint surface thins and the PG content decreases. Progressive fibrillation of the cartilage occurs, and eventually, the underlying bone is exposed. There is increased bone formation in the subchondral bone, and this leads to sclerosis that may be seen radiographically. Appositional growth of bone at the joint margins leads to osteophytes, or “spurs.” Spurs, along with thickening of the joint capsule, leads to limitation of motion.

Cartilage loss is the central process in osteoarthritis. After the initial attempts at repair with increased synthesis of collagen, PG, and hyaluronan, the catabolic activity at the biochemical level becomes high. Lysozyme proteases (cathepsins) and neutral metalloproteinase (such as stromelysin, collagenase, and gelatinase) account for much of the loss of cartilage. The concentration of collagenase increases with advancing disease, and matrix collagen decreases. Similarly, despite an increase in hyaluronic synthesis, there is a reduction in hyaluronan. A specific hyaluronidase has not been identified in cartilage, but several lysosomal enzymes can lyse hyaluronic acid and chondroitin sulfate. The cartilage loses aggrecan (49), which results in a loss of compressive stiffness and elasticity as well as an increase in fluid permeability. This may be due to a deficiency in link protein. The cells in osteoarthritic cartilage divide more actively than in normal cartilage, and the resultant cells are very metabolically active. However, the new cells do not produce a normal extracellular matrix due to biochemical deficiencies, which leads to further cartilage deterioration. Tissue inhibitors of metalloproteinase and plasminogen activator inhibitor can be secreted by chondrocytes to inhibit the degenerative process, but the balance appears in favor of the degradative enzymes.

**Clinical Findings and Diagnosis**

Osteoarthritis is usually not a systemic disease, and the symptoms remain localized to a joint. Clinical correlation of patient complaints with objective findings usually show a positive correlation, but the discrepancy between symptoms and pathological findings may be striking. The findings are usually local and may or may not be bilateral. There is progressive loss of motion and pain in the joint with physical activity, and the pain is usually relieved by rest. Acute inflammatory flares may be precipitated by trauma or exercise. The entire joint will be swollen, tender, and stiff. After the acute flare resolves, the tenderness will be localized to the area of maximum joint space narrowing. The joints most frequently involved are the hands, knees, hips, feet, and spine. The distal interphalangeal joints of the hands have characteristic spurs and lateral deviations called Heberden’s nodes.

The laboratory tests are usually normal, and the tests are performed to rule out other arthritides. The erythrocyte sedimentation rate is normal in most patients, and the synovial fluid white cell count is less than 1000/mm³. Roentgenographic changes vary with progression of the disease. Early joint space narrowing may occur in the knee, with relatively minor changes seen at arthroscopy.
Rheumatoid arthritis is a systemic disease, and generalized malaise and fatigue are common. Significant involvement of other organ systems, however, is usually subluxations of the metaphalangeal joints are common. The subtalar joint is also frequently involved, and an everted foot is common. In the cervical spine, erosions of deformity, hitchhiker’s thumb). Shoulder involvement with rotator cuff tears and mechanical instability are common. In the feet, clawing of the toes and dorsal but not distal interphalangeal joints), and the carpal articulations. In the hands, deformities due to erosion of ligaments are common (swan-neck deformity, boutonnière)

Rheumatoid arthritis has a predilection for the large joints (knees, hips), the small joints of the hands (metacarpophalangeal joints and proximal interphalangeal joints, the radiocarpal, and the radioulnar articulations). The most commonly involved small joints are the metacarpophalangeal joints of the fingers and the proximal interphalangeal joints of the thumbs. The wrist and the ankle are also common sites of involvement.

The characteristic early finding is an inflammatory synovitis. This must be documented by synovial analysis showing a leukocytosis of 2,000 cells/mm³. Animal studies have shown that they are found when prolonged hypergammaglobulinemia is found, such as in chronic infections. They may help host defense mechanisms by cleaning small antigen-antibody complexes, but they may secondarily harm host structures by increasing deleterious inflammation. Certain polymorphonuclears of the variable and constant regions of the rheumatoid factor kappa light chain are associated with an increased risk of rheumatoid arthritis, indicating that immunoglobulin genes, in addition to the major histocompatibility locus DR4, may influence disease susceptibility.

Rheumatoid factors are immunoglobulins (IgM) that react with the Fc portion of the IgG molecule. They are detected in about 3% of the normal population but are common in high titers in rheumatoid arthritis. Animal studies have shown that they are found when prolonged hypergammaglobulinemia is found, such as in chronic infections. They may help host defense mechanisms by cleaning small antigen-antibody complexes, but they may secondarily harm host structures by increasing deleterious inflammation. Certain polymorphonuclears of the variable and constant regions of the rheumatoid factor kappa light chain are associated with an increased risk of rheumatoid arthritis, indicating that immunoglobulin genes, in addition to the major histocompatibility locus DR4, may influence disease susceptibility.

Rheumatoid synovium is characterized by a massive tumor-like expansion of stromal connective tissue cells, primarily fibroblast-like cells and new blood vessels. The fibroblast-like cells are typically immature and highly invasive (forming a tissue called pannus). They appear more like transformed cells and express activation markers such as photo-oncogenes c-fos and c-jun and metalloproteinase such as collagenase and trans/in/stromelysin (67,80). These cells are not malignant but are stimulated by factors such as platelet derived growth factor (PDGF), fibroblast growth factor (FGF), Interleukin-I (IL-1), and tumor necrosis factor (TNF) to express the abnormal phenotype. It appears that the rheumatoid factor containing immune complexes precipitate out in the superficial layers of cartilage and stimulate further pannus invasion. The result of the multifaceted process is continuous pain, progressive deformity and disability.

The primary cause of rheumatoid arthritis is unknown. Investigations of the etiology have focused on interrelationships of infectious agents, genetics, and autoimmunity. It is known that rheumatoid arthritis has a higher incidence in those patients with an HLA-DR4 locus containing the amino acid sequence common to the DR1, Dw14, or Dw15 hypervariable region. It has been suggested that the third hypervariable regions of the beta chains of HLA-DR4 may influence the susceptibility to disease by binding arthrogenic peptides; that they trigger disease by expanding or deleting particular T-cell populations; or both.

Rheumatoid factors are factors that react with the Fc portion of the IgG molecule. They are detected in about 3% of the normal population but are common in high titers in rheumatoid arthritis. Animal studies have shown that they are found when prolonged hypergammaglobulinemia is found, such as in chronic infections. They may help host defense mechanisms by cleaning small antigen-antibody complexes, but they may secondarily harm host structures by increasing deleterious inflammation. Certain polymorphonuclears of the variable and constant regions of the rheumatoid factor kappa light chain are associated with an increased risk of rheumatoid arthritis, indicating that immunoglobulin genes, in addition to the major histocompatibility locus DR4, may influence disease susceptibility.

Rheumatoid synovium is characterized by a massive tumor-like expansion of stromal connective tissue cells, primarily fibroblast-like cells and new blood vessels. The fibroblast-like cells are typically immature and highly invasive (forming a tissue called pannus). They appear more like transformed cells and express activation markers such as photo-oncogenes c-fos and c-jun and metalloproteinase such as collagenase and trans/in/stromelysin (67,80). These cells are not malignant but are stimulated by factors such as platelet derived growth factor (PDGF), fibroblast growth factor (FGF), Interleukin-I (IL-1), and tumor necrosis factor (TNF) to express the abnormal phenotype. It appears that the rheumatoid factor containing immune complexes precipitate out in the superficial layers of cartilage and stimulate further pannus invasion. The result of the multifaceted process is continuous pain, progressive deformity and disability.

Clinical and Laboratory Findings

The characteristic early finding is an inflammatory synovitis. This must be documented by synovial analysis showing a leukocytosis of 2,000 cells/mm³ to 50,000 plus cells/mm³, biopsy proven synovitis, or characteristic periarticular erosions on x-ray study. Another diagnostic feature is the evolution of the disease process to bilaterally symmetric arthritis.

There is no one laboratory test, histologic test, or radiographic finding that is definitive for rheumatoid arthritis. Rheumatoid factor is present in 85% of patients with rheumatoid arthritis, and is frequently a predictor of the severe and unremitting form of the disease. The erythrocyte sedimentation rate is elevated with flares of the disease, as is the C-reactive protein level.

Structural damage to the joints usually begins between the first and second year of the disease. The synovitis tends to come and go following a sine wave pattern, but the structural damage tends to follow a straight line related to the amount of prior synovitis. Patients who undergo remission within the first year can become virtually asymptomatic. However, once structural damage occurs, there will be permanent disability.

As the disease progresses, the patient will manifest symptoms due to the structural deformity and recurrent synovitis. It is important to recognize the difference, because recurrent synovitis is usually treated pharmacologically, whereas structural deformity requires activity restriction, or reconstructive surgery. Morning stiffness (lasting 1 hour or more) is present with inflammatory flares, and usually disappears when a remission occurs. Structural damage is characterized by pain that occurs with activity but is relieved by rest, deformity, and joint space narrowing on radiographs in addition to periarticular cysts and diffuse subchondral osteopenia (3). Shoulders involvement with rotation cuff tears and mechanical instability are common. In the feet, clawing of the toes and dorsal subluxations of the metatarsophalangeal joints are common. The subtalor joint is also frequently involved, and an everted foot is common. In the cervical spine, erosions of the transverse ligament of C-1 can result in subluxation of C-1 on C-2, and eventually superior misalignment of C2.

Rheumatoid arthritis is a systemic disease, and generalized malaise and fatigue are common. Significant involvement of other organ systems, however, is usually
limited to those patients with rheumatoid factor in the serum. Awareness of complicating conditions such as rheumatoid nodules and vasculitis, ocular manifestations, intestinal lung disease, pericarditis, neuropathies related to cervical spine instability, nerve entrapment, hyperchronic-microcytic anemia, and Felty's syndrome are important to be aware of, but discussion of these conditions is beyond the scope of this chapter. Further details can be found in larger rheumatoid texts (67).

The course of this disease varies considerably. About 10% of patients undergo spontaneous remission (69), and most long-term remissions occur within the first 2 years of the disease. Factors that are predictors for the more severe chronic form of the disease are the presence of rheumatoid factor, nodules, and the HLA-DR4 phenotype. Close to 90% of joints ultimately involved in a given patient are evident on clinical examination during the first year of the disease (65).

Treatment

The general principles of nonoperative treatment previously outlined apply to rheumatoid arthritis. Soluble gold salts and methotrexate often give some relief in rheumatoid diseases but not in other arthritic processes (41). Corticosteroids have an important place in the treatment of rheumatoid arthritis. They are often helpful in low doses given over a long period, a regimen that avoids most of the systemic side effects seen with high doses. Biologics, such as tumor necrosis factor and receptor, will be more and more applicable for the treatment of rheumatoid arthritis. Prevent deformity by using spints on an alternating basis with range-of-motion exercises. Preserve rest in the position of function during periods of acute inflammation and exacerbation of the disease. The position of function for the upper extremity is with the elbow at 90°, the forearm across the abdomen, with the wrist slightly dorsiflexed and the finger joints slightly palmarflexed. The position of function for the lower extremity is with the hip and knee fully extended, and the ankle at 90° to the tibia.

Synovectomy to reduce inflammation and slow cartilage erosion, and capsulotomy to increase motion, are used in rheumatoid arthritis much more frequently than in other arthritic conditions (60). To be effective, perform synovectomy before significant articular cartilage damage has occurred. Synovectomy is usually performed in the shoulder before rupture of the rotator cuff, in the wrist preferably before and after rupture of the finger or thumb extensor tendons, and in the knee before loss of articular cartilage and attenuation of the knee ligaments. Capsulotomy is often used as an isolated procedure, particularly about the knee to correct surgically joint deformities that are resistant to bracing and other forms of physical therapy. Capsulotomies are also used with arthroplasties.

Surgical treatment and reconstruction of the rheumatoid hand is complex, demanding, and often required (see Chapter 70). The shoulder, elbow, hip, and knee are the most common joints undergoing total joint arthroplasty, whereas fusion is most useful in the wrist and ankle. See Chapter 101 (shoulder), Chapter 102 (elbow), Chapter 70, Chapter 71 and Chapter 72 (hand and wrist), Chapter 105 (hip), Chapter 107 and Chapter 108 (knee), and Chapter 117 (foot). Distal ankle arthroplasty is becoming more accepted due to new prostheses.

In rheumatoid arthritis, C1–C2 subluxations can result from attenuation and rupture of the transverse odontoid ligament (71). The condition varies in symptoms and severity. The patient may be asymptomatic and show only mild tenderness at the upper cervical spine on physical examination, or he or she may have headaches and neck pain. A cervical collar may give temporary symptomatic relief. Rarely, there are patients with long-tract neurologic signs in whom spine fusion may be indicated (see Chapter 154).

JUVENILE RHEUMATOID ARTHRITIS

The three major subgroups of juvenile rheumatoid arthritis are defined by their extent at presentation: Still's disease (systemic onset), polyarticular onset, and pauciarticular onset (67). All are characterized by chronic synovial inflammation, but the disease must be present for more than 6 months before subclassification is possible.

Epidemiology and Clinical Presentation

It is estimated that juvenile rheumatoid arthritis affects 65,000 tp 70,000 children in the United States. Juvenile rheumatoid arthritis exhibits many of the radiographic features of adult rheumatoid arthritis, including periarticular osteoporosis, articular erosions, and joint deformities. Additional features that are almost pathognomonic for this condition include a periosteal reaction and joint ankylosis, particularly affecting the apophyseal joints of the cervical spine. Growth retardation due to involvement of the epiphysis is a major problem in children with rheumatoid arthritis and is readily apparent on radiographs.

Systemic Onset

About 10% of patients have a systemic onset. Boys and girls are equally involved, and the onset may be at any age. Spiking temperatures associated with an evanescent, salmon pink rash may occur at any time during the day but most often during the late afternoon. Diffuse lymphadenopathy, hepatosplenomegaly, pericardial effusions, and pleural effusions are common. Systemic attacks are usually self-limited and rarely life threatening, and may recur after months to years, unexpectedly. About 50% of patients develop severe, chronic arthritis, which continues after systemic manifestations have subsided (19).

Polyarticular Onset

Arthritis in five or more joints occurs in approximately 40% of children with juvenile rheumatoid arthritis. Malaise and weight loss are common. Polyarticular involvement may occur at any time and has a 3:1 predilection for girls. Three fourths of the patients have systemic involvement.

Pauciarticular Onset

This subtype occurs in about 50% of children with juvenile rheumatoid arthritis. This group has arthritis affecting four or fewer joints within the first 6 months of their disease, and about 50% only have one joint involved, usually the knee. Although synovitis may be chronic, the prognosis for joint function is often good. Iridocyclitis develops in 10% to 50% of children with pauciarticular juvenile rheumatoid arthritis. An ophthalmology consult is important.

Diagnosis

Rheumatic fever may be difficult to differentiate from juvenile rheumatoid arthritis in younger patients. The presence of a streptococcal infection and positive serologic tests for Streptococcus help in making the differential diagnosis. Rheumatic fever usually is self-limiting and has a relatively short course compared with juvenile rheumatoid arthritis. Differentiating rheumatoid arthritis from osteoarthritis is rarely a problem, because osteoarthritis occurs in the older age group and the presence of Heberden's node is often helpful in making the diagnosis. The sedimentation rate is rarely elevated in osteoarthritis. With septic arthritis, there is usually a single joint involved, and high fever, leukocytosis, and positive cultures are evident. Systemic lupus erythematosus may present a difficult diagnostic problem, but the positive ANA test and lupus erythematosus prep test are characteristic of systemic lupus erythematosus and are not noted in the juvenile form. In juvenile rheumatoid arthritis, the test for rheumatoid factor is usually negative.

Laboratory and X-ray Findings

Rheumatoid factors are detected in only 15% to 20% of patients. ANAs are detected in 40% to 60%. Children who are consistently rheumatoid factor positive have more erosions, nodules, and vasculitis. Destructive arthritis occurs in about 50% of those with rheumatoid factor positive disease as compared with 10% in rheumatoid factor–negative disease. Radiographs show osteopenia about the affected joints. There is diffuse narrowing of the joint surfaces, and subluxation or dislocation may be evident.

Treatment

The immediate goal for juvenile rheumatoid arthritis is relief of symptoms, maintenance of joint range of motion, and muscle strength. Although juvenile rheumatoid arthritis is often chronic, the prognosis for most children is good. At least 75% enter long remissions and have no residual deformity (69).

Aspirin is acceptable for treatment but causes Reye's syndrome (persistent vomiting and mental alterations), although this usually occurs more commonly when treatment is delayed for fever accompanying viral infections. Ibuprofen, tolmetin, naproxen, and fenoprofen are frequently used as alternative treatments. Gold and hydroxychloroquine are occasionally used as slow-acting therapy in resistant cases, but steroids are discouraged. An ophthalmology consult for the treatment of iridocyclitis is important.

Synovectomy usually does not benefit juvenile rheumatoid arthritis. Total joint replacement may greatly improve joint function in longstanding diseases but must wait...
4% of the adult population have articular pseudogout at the time of death and that the incidence increases with age. The incidence of clinically symptomatic disease is specific identification of calcium pyrophosphate crystals in synovial fluid and on cartilage characterize the condition called pseudogout. Pathologic surveys indicate that pseudogout is most common in the hands, wrists, knees, and elbows. The condition is characterized by recurrent episodes of joint pain and swelling, which may be accompanied by fever, chills, and rigors. The pain is usually worse at night and may mimic gout. Treatment includes nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, and colchicine. Gout is a metabolic disorder in which deposition of crystals of monosodium urate results in one or more clinical presentations including: a) acute gouty arthritis, b) chronic tophaceous gout, c) uric acid stones in the urinary tract, d) gouty tophi in the articular, osseous, and soft tissues, e) hyperuricemia, which may occur in the absence of gout.

GOUT

Gout is a metabolic disorder in which deposition of crystals of monosodium urate results in one or more clinical presentations including:

- Gouty arthritis, which is characterized by recurrent attacks of acute severe or chronic articular and periarticular inflammation
- Accumulation of gouty tophi in the articular, osseous, and soft tissues
- Gouty nephropathy, which can lead to renal impairment
- Uric acid stones in the urinary tract

Hyperuricemia is the common denominator leading to these clinical syndromes, but hyperuricemia may occur in the absence of gout.

Epidemiology

Gout occurs most frequently in adult men, with a peak incidence in the fifth decade. It is the most common inflammatory arthritis in men over the age of 30 years. It rarely occurs in men before adolescence or in women before menopause. Hyperuricemia occurs in approximately 13% of hospitalized adult men, but fewer than one in five will develop clinically evident urate crystal deposits.

Pathogenesis

The catabolism of purines produces uric acid, and the lack of the enzyme uricase, which makes uric acid soluble in body fluids, can lead to the crystalline deposition of uric acid. There are many environmental and genetic influences on uric acid formation, transport and disposal, including: body weight, diet, lifestyle, social class, and hemoglobin level. The familial occurrence of gout is well known. Hyperuricemia occurs in 25% of first-degree relatives of patients with gout.

Urate crystallizes as a monosodium salt in saturated joint tissues. The decreased solubility of sodium urate at lower temperatures explains the predilection of the toes and ears for deposition. The histopathology of tophi shows a chronic foreign body granuloma surrounding monosodium urate crystals. The inflammatory reaction consists primarily of mononuclear cells and giant cells.

Clinical Findings

The evolution of gout can result in presentation as asymptomatic hyperuricemia, acute gouty arthritis, and chronic tophaceous gout. Acute arthritis is the most common early clinical presentation. The metatarsal phalangeal joint of the great toe is involved most often and is affected at some time in three quarters of patients. Other common joints involved include the ankle, tarsal joints, and knee. Gout usually begins with abrupt onset in a single joint, often at night so that the patient awakens with severe unexplained joint pain and swelling. Attacks tend to dissipate spontaneously in 3 to 10 days without treatment, resulting in desquamation of the skin over the affected joint. Subsequent episodes may occur more frequently, involve other joints and persist longer.

Chronic tophaceous gout affects the helix of the ear and the periarticular tissues of the hands and feet. Secondary degenerative arthritis can develop as a result of erosion of the cartilage and subchondral bone. Tendons and the carpal tunnel may be involved.

Radiologic Findings

During the initial attack, radiographs may only show soft-tissue swelling surrounding the affected joint. Later, irregular, asymmetric soft tissue swelling and calcification of tophi can occur. Bony erosions tend to be round or oval in shape with a sclerotic margin and interarticular or periarticular erosions showing a thin overhanging edge of displaced bone at the margins of the articular cartilage.

Laboratory Findings

The diagnosis is best made on joint fluid analysis, in which rod- or needle-shaped crystals 3 to 20 µ in size are seen. Under a polarizing microscope, these show birefringence and bright yellow crystals parallel to the axis of slow vibration. Synovial fluid leukocyte counts can vary from 20,000 to 100,000. Serum uric acid levels may or may not be elevated.

Treatment

Historically, colchicine has been the drug of choice but its use remains controversial due to its side effects. Up to 80% of patients can be expected to experience significant relief of pain within 48 hours when treated with oral colchicine. Gastrointestinal toxicity consisting of nausea, vomiting, diarrhea, and cramping abdominal pain can occur in up to 80% of patients and can be severe, leading to dehydration and electrolyte imbalance. Intravenous colchicine avoids the gastrointestinal symptoms and can result in response within 30 minutes, however, improper use of colchicine has led to serious toxicity and death.

For oral administration give 0.5 mg tablets hourly until one of three events occurs: (1) There is significant improvement of pain and inflammation, (2) Gastrointestinal toxicity occurs, or (3) a total dose of 8 mg has been received, assuming the patient has normal renal and liver function.

For intravenous therapy, a single intravenous dose should not exceed 3 mg and the total cumulative dose for a given attack should not exceed 4 mg in a total 24-hour period. Do not administer oral colchicine for at least 7 days after a full intravenous dose. Reduce the dose in older patients and those with renal or hepatic disease. Intravenous colchicine is contraindicated in combined renal and hepatic disease, when the glomerular filtration rate is less than 10 mm per minute or there is extra hepatic biliary obstruction.

NSAIDs started at their recommended maximal dose at the first sign of an attack may be successful and are less toxic than colchicine, but they are not without their gastrointestinal side effects as well. Many physicians prefer indomethacin for acute gout. Oral corticosteroids and adrenocorticotrophic hormone can be effective when colchicine and NSAIDs are contraindicated. Administer 20 to 40 mg doses of prednisone or its equivalent daily for 3 to 4 days and then gradually taper over 1 to 2 weeks.

Prophylactic treatment of interstitial gout is not indicated until an established pattern of frequency occurs. One 0.5 mg colchicine tablet twice daily effectively lowers the frequency of attacks. Efforts to reduce hyperuricemia are indicated in some patients. Limit foods with high purine content. Uricosuric drugs such as probenecid can be given at a dose from 0.5 g per day up to 1 g twice daily, until a targeted urate level is reached. Common side effects are rash and gastrointestinal upset. Xanthine oxidase inhibitors such as allopurinol are useful in patients in whom there is urate overproduction, nephrolithiasis, or other contraindications to uricosuric therapy.

Surgical treatment is usually not required except for the excision of tophi that are interfering with function, threaten to rupture tendons or erode through the skin, or which have eroded through skin and become infected. Because of infiltration of the tophaceous material throughout the connective tissues, excision can be difficult. Care must be taken to maintain the function of affected structures.

PSEUDOGOUT

Specific identification of calcium pyrophosphate crystals in synovial fluid and on cartilage characterize the condition called pseudogout. Pathologic surveys indicate that 4% of the adult population have pseudogout at the time of death and that the incidence increases with age. The incidence of clinically symptomatic disease is...
If a microfracture and drilling procedure fails, other considerations are a perichondral or periosteal autograft (passive motion (CPM) for 6 to 8 hours per day. After the initial rehabilitation, it is best if the patient gives up running, cutting, and jumping sports and concentrates on joint replacement. The commitment is a major one, however, because the postoperative regimen requires 2 to 3 months of partial weight bearing and continuous of choice after failed shaving or abrasion chondroplasty. Many patients gain long-term improvement and do not require osteotomy, open biologic resurfacing, or total replacement, but in whom short term improvement is desired.

The current mainstay of the arthroscopic procedures is debridement and drilling or microfracture through the subchondral bone of chondral defects. It is the procedure until more definitive procedures are required. Debridement may also be considered in the older patient who is medically unable to undergo a total joint replacement alone is often beneficial in obtaining significant relief for a short period of time (6 months to 1 year). It is recommended as a temporizing procedure until more definitive procedures are required. Debridement may also be considered in the older patient who is medically unable to undergo a total joint replacement.

Joint inflammation and joint degeneration may coexist. Frequently inflammation will occur early and later manifest as degeneration. The knee is the most frequent joint presenting with an acute attack. Trauma may preclude the attack as well as surgery, similar to gout. About 50% of patients will have progressive degeneration of multiple joints, with the knees most frequently involved, followed by the wrists, metacarpophalangeal joints, hips, shoulders, and elbows. However, most joints with radiologically evident CPPD calcification are not symptomatic.

The radiologic appearance of punctate and linear densities in articular hyaline or fibrocartilaginous surfaces is helpful and is called “chondrocalcinosis.” In the early phases, there is no joint space narrowing or degeneration. The inflammatory response appears to be related to a dose related response to crystals being shed from the joint surface. The joint aspirate will show rod-shaped crystals, frequently in leukocytes, and they will test out with positive birefringence.

**Treatment**

Unlike gout, calcium phosphate crystals cannot be removed from joints. Acute attacks can be treated by aspiration of the joint and injection of steroids. Whether or not crystalline removal over time would prevent chronic degenerative joint disease is not known at this time.

**ANKYLOSING SPONDYLITIS**

Ankylosing spondylitis (i.e., Marie-Strümpell disease) is an arthritic condition characterized by primary involvement of the sacroiliac joints and spine, leading to a full-blown bony ankylosis of the entire spine at the end stage of the disease. In approximately 25% of patients, there is involvement of the proximal joints of the limbs. It is predominantly a disease of young men, and the cause is unknown.

**Etiology and Diagnosis**

Because there is a high incidence of the HLA-B27 antigen (about 95%) in patients with the disease, there may be a genetic predisposition. Making the correct diagnosis is often difficult in the early stages of the disease, but it is rarely difficult in the end stage. In the early stages, it may present as a lower lumbar disc degenerative condition, and there is usually sacroiliac joint involvement. Another diagnostic feature during early disease is a decreased chest expansion (<3.8 cm). In end-stage disease, the sacroiliac joints are fused, and the radiographic appearance of the spine is that of a complete fusion with a bamboo spine appearance. The patient often walks in a stooped position and has essentially no motion in the spine. Rheumatoid factor and serologic tests for other types of arthritis are usually negative.

Patients may exhibit extra-articular features, including iritis, cardiac conduction defects, aortic incompetence, spinal cord compression, and amyloidosis. The radiographic hallmarks of ankylosing spondylitis include squaring of the vertebral bodies and the development of delicate syndesmophytes.

**Treatment**

Institute physical therapy, including hydrotherapy, and advise patient to sleep flat (without the use of pillows) to help prevent seriously flexed fusions of the neck. Pharmacologic treatment is essentially nonspecific, using anti-inflammatory drugs such as salicylates and NSAIDs. The orthopædic surgical procedures involve spinal osteotomy in the cervical region and the lumbar region to correct severe flexion deformities of the spine (Figs. 99.5). These operations are major surgical procedures with considerable risk, and should not be undertaken lightly (see Chapter 153). Hip arthroplasty often is necessary if there is severe hip disease (see Chapter 105). The possibility of spinal fusion should be excluded in any patient with advanced ankylosing spondylitis who complains of neck or back pain after even mild trauma. Computed tomography is helpful in making the diagnosis.

**POSTTRAUMATIC ARTHRITIS**

Many types of injury can lead to disabling arthritis because of involvement of the joint surfaces (48). Fractures involving the joint surfaces that do not heal in an anatomic position can produce arthritis. If ligamentous injuries do not heal in a satisfactory manner, a chronically unstable joint results, and the joint frequently develops degenerative arthritis as a result of chronic subluxation. In addition, many heritable disorders and developmental disorders can lead to mechanical malalignment and eventual arthritis (multiple epiphyseal dysplasia, slipped capital femoral epiphysis, congenital dislocation of the hips, neuropathic arthropathy, hemophilic arthropathy, acommegalic arthropathy, and Paget's disease of bone) (68). The histologic changes are similar to those described for degenerative arthritis. These conditions can be relatively mild, and conservative measures, such as decreased activity and decreased mechanical stress, are satisfactory. The symptoms also frequently occur in the thirties and forties after an injury in the twenties, but the disability may not be severe at any age.

**Treatment**

Isometric exercises are beneficial for posttraumatic arthritis, and considerable improvement can be gained. Anti-inflammatory medication is also important and should be used for short periods when the joint is relatively asymptomatic.

Arthroscopic debridement alone is often beneficial in obtaining significant relief for a short period of time (6 months to 1 year). It is recommended as a temporizing procedure until more definitive procedures are required. Debridement may also be considered in the older patient who is medically unable to undergo a total joint replacement, but in whom short term improvement is desired.

The current mainstay of the arthroscopic procedures is debridement and drilling or microfracture through the subchondral bone of chondral defects. It is the procedure of choice after failed shaving or abrasion chondroplasty. Many patients gain long-term improvement and do not require osteotomy, open biologic resurfacing, or total joint replacement. The commitment is a major one, however, because the postoperative regimen requires 2 to 3 months of partial weight bearing and continuous passive motion (CPM) for 6 to 8 hours per day. After the initial rehabilitation, it is best if the patient gives up running, cutting, and jumping sports and concentrates on an isometric anaerobic exercise with bicycling or swimming for aerobic exercise. The surgery is relativelyatraumatic compared with the demanding postoperative regimen, but only with such a rehabilitation program can a long-term durable repair be expected.

If a microfracture and drilling procedure fails, other considerations are a perichondral or periosteal autograft (15,30,31,32,35,38,43,59,73,74,81), mosaicplasty (shell

![Figure 99.5](image-url)
allografts) (23,24 and 25), or osteotomy (3, 9, 10, 18, 27, 28, 33, 34, 51, 57, 59, 64, 77, 79). A modification of the periosteal graft has been described, in which autologous
cultured chondrocytes are injected under the periosteum (6). Normal joint cartilage is necessary on the other side of the joint if osteotomy is considered. If the lesion is
small or involves a small joint in the hand, a perichondral autograft or periosseal autograft may be appropriate. Ostearticular shell autograft plugs are also reasonable
for small lesions, although their efficiency is not well proven. This is best in locations where there is little joint space narrowing or mechanical collapse. The subchondral
bone must be intact; otherwise, an osteoarticular allograft should be considered.

If there is little joint space narrowing and no asymmetric mechanical collapse of the joint, an osteochondral allograft is a good consideration (17,52,53). This is
particularly useful if multiple defects must be grafted in a joint, requiring a fairly large graft surface. In addition, when the subchondral bone is disrupted (for example,
after a biaxial plateau fracture), an allograft is quite useful. When multiple defects occur in a joint that is malaligned, then an osteotomy should be performed in
combination with the allograft procedure (see Chapter 9).

Osteotomies are indicated primarily in the hip and the knee, and occasionally in the ankle to shift weight-bearing forces from arthritic areas of the joint to more normal areas. If there is significant subchondral bone loss in the joint then a shell allograft should be performed together with the osteotomy, or a prosthetic arthroplasty
performed.

Some young patients do not desire multiple biologic resurfacing procedures for their chondral defects, but their symptoms are severe. It is not advisable to do a total
joint replacement in young patients, however, a total joint replacement is a predictable means of providing a joint with minimal pain and adequate stability. Therefore, it
is one reasonable alternative for a patient to choose, as long as he or she understands that the joint replacement will most likely wear out or become loose in 10 to 15
years. The patient should also understand that the scenario of multiple joint revisions involves increased risks of surgery and that the longevity of the subsequent joint
revision will decrease. The patient should be advised that a joint replacement is not an end to the multiple biologic resurfacing procedures that he or she has been
considering, but rather it is an opportunity to have a decent joint for 10 to 15 years before having a revision or salvage procedure. The patient is “buying” a good joint
for his or her younger years but accepting the disability of a fusion or resection arthroplasty during the older years. A second alternative—and usually the one advised
by the surgeon—is to use a cane and live with the disability during the young and middle years, and put off having a total joint replacement until the patient is retired. A third alternative is to have a fusion or resection arthroplasty after the failure of one or two biologic resurfacing procedures.

HISTORICAL DEVELOPMENT

Among the earliest methods for treating arthritis was interposition arthroplasty using soft and flexible materials, but the strength of these materials was inadequate. Rigid materials such as metal and glass in the form of condylar shapes attached to one of the joint surfaces provided some success, but there was still a problem with the opposing joint surface. In the knee, geometric inaccuracy leading to poor kinematics and abnormal soft-tissue tensions was also a problem. An interesting finding with condylar components, such as cup arthroplasty of the lateral process of the patella, was the formation of a fibrous membrane adjacent to the component, with a new bone plate beneath. This tissue modeling is now recognized to develop due to interface micromotion and to the stresses acting on the exposed trabecular ends. Even now, implants are designed with relatively smooth surfaces interfacing the bone; however, there is a higher incidence of pain, migration, and loosening with these implants compared with the more rigid methods of fixation. The success of more invasive components with uncemented intramedullary stems, such as hemiarthroplasties and knee hinges, depended largely on obtaining an acceptably low level of stem–bone micromotion and interface stresses on the bone.

Modern-day joint replacement began in the early 1960s, when Charnley introduced cemented metal-polyethylene components for the hip, and in the late 1960s, when this technology was transferred to the knee by Gunston. The principles proposed by Charnley were rigid fixation of the components to the bone, resurfacing of both joint surfaces, and the use of materials with low friction and wear. These principles, embodied in cemented metal-on-plastic components, have stood the test of time to this day.

PRESENT STATUS

In the 1970s, there was a rapid expansion in the number of total joints used. A number of other hip designs were introduced that were fundamentally based on the Charnley design. An exception was the use of metal-on-metal in the McKee-Farrar design. There was a great deal of attention to surgical technique, especially obtaining good cement–bone apposition with high shear strength. Some total knees proved to be successful in the long term, but others fell by the wayside because of the lack of recognition of the kinematics, the role of the cruciates, the patellofemoral mechanics, and the requirements for adequate fixation. Most of the design forms used today, namely unicompartmentals, condylar replacements with or without cruciate retention, mobile bearing knees, stabilized condylars, and fixed and rotating hinges, were all introduced before the end of the decade. Ceramic-on-polyethylene and ceramic-on-ceramic replacements for the hip had been introduced before 1980.

The 1980s saw two substantial areas of development: more sophisticated instrumentation, especially for the knee, and uncemented components with porous coatings intended for indefinite fixation. In the knee, improved consistency of surgical technique was achieved as a result of more accurate alignment and soft-tissue balancing. Concerning porous coating, those designs in which rigid initial fixation was achieved obtained sufficient bone ingrowth for long-lasting results. Certain uncemented designs of hip stem, acetabular component, and femoral component of the knee have shown survivorship values superior to those of cemented components. A hydroxyapatite (HA) coating has similarly shown high durability from 5 to 10 years follow-up. The situation today is that a number of designs of hips, knees, and other joints have been shown to have a survivorship of greater than 90% at 10 years, such that the large majority of elderly patients can be treated confidently.

Today’s hip and knee systems offer a large variety of sizes and modular augments to deal with virtually every situation encountered in primary and revision surgery. The instrumentation systems are elaborate, usually well engineered, and often too complex, but they allow the surgeon to achieve accurate component placement and limb alignment.

FUTURE DIRECTIONS

The main limitations of total hip and knee replacements are excessive wear of the ultra-high molecular weight polyethylene (UHMWPE) and loosening. These two problems are related to some extent in that the accumulation of small particles causes a tissue response that, in turn, produces bone resorption. However, it is now evident that wear can be reduced in a number of ways. The main problem has been that gamma-irradiation of UHMWPE in air, followed by gradual oxidation either on the shelf or in the patient, has led to a degradation of mechanical properties and an increase in the wear rate.

Components that have been directly molded from UHMWPE have shown a reduced susceptibility to oxidation, which has resulted in reduced surface wear and a much lower incidence of the destructive delamination seen in total knee replacements (TKRs). Gamma-irradiation and storage in an inert atmosphere, as well as enhanced cross-linking and stabilization to minimize subsequent oxidation, have resulted in reduced wear rates. For the hip joint, ceramic-on-UHMWPE can reduce wear by as much as 50%, whereas ceramic-on-ceramic and metal-on-metal produce minimal wear debris. If such improved bearings are combined with superior cement techniques or porous and bioactive coatings, much greater durability can be expected compared with that achieved in the past 2 decades.

In the knee, however, delamination due to high subsurface stresses is still a threat. Computer modeling of this process has shown how appropriate surface geometry can substantially reduce the likelihood of delamination without compromising the freedom of motion. New advances will undoubtedly be made in the performance of TKR, especially for younger patients. The mobile bearing concept is one such approach for minimizing wear and improving function. However, further advances are likely in the form of guided motion knees providing optimal muscle lever arms and high flexion ranges. The superior functional performance of unicompartmental replacement performed on one or both sides of the joint opens up the possibilities of minimally invasive surgery, with the option of using...
computer-assisted technologies. The boundary between biologic treatments and total joints will become an issue, and with both approaches improving and developing, the relative merits and applications will become an area for extensive research and evaluation (58,70,72,79,141,142,152,162,165,177).

**APPLIED MECHANICS AND MATERIALS**

This section is not intended to be analytical but to provide a definition of engineering terminology and to convey the concepts of biomechanics and biomaterials relevant to joint replacement (158). The Standard International (SI) system of units (Table 100.1) is now in widespread use.

**MOTION OR KINEMATICS**

The motion in a single plane is first considered. Figure 100.1 shows the knee schematically with an origin A fixed in the femur and a contact point B on the tibial surface. The knee is set in a global axis system ZY with origin O (the X axis is used for the lateral-medial direction for a right knee). The femur is first given a rotation F about A. The femur is next given a displacement or translation p in the negative Z direction. Finally, the femur is given an additional displacement d along the negative Y direction. The tibia has remained fixed with respect to the global axes, and the femoral motions could be described with respect to an axis system fixed in the tibia. The values F, p, and d are vectors in that they have magnitude and direction, often denoted with a line above or in bold type.

![Figure 100.1](image.png)

**Figure 100.1.** Motion in a plane. Global axes, axes in the femur, and axes in the tibia are defined. In this case, three successive motions of the femoral axes relative to the global axes are shown: F, p, and d.

From a kinematics point of view, the final position of the femur can be obtained by a single rotation F about an axis D (Fig. 100.2). An instant center of rotation (207) is defined for small motions. The centers for a succession of small motions is the instant center pathway, not to be confused with the geometric centers of local radii of curvature. If the instant center is at the center of curvature, the motion at the contact point is called pure sliding (124). If the center is at the contact point, the motion is pure rolling (31). A center in between the two produces sliding and rolling combined.

![Figure 100.2](image.png)

**Figure 100.2.** Any two successive positions of a body in a plane can be obtained by a rotation about a single point.

In general, to visualize motion, it is usually easier to define rotations and displacements with respect to axes, rather than using centers of rotation (238) by the following principles:

- Define a global axis system.
- Define axes in each bone.
- Define each component of motion of one axis system relative to the other.
- Define the order in which the motions take place.

The importance of these principles is seen in visualizing three-dimensional (3-D) motion. In Figure 100.3, the femur is shown in its initial position on the tibia at zero flexion with contact points L and M. The femur is first rotated by 90° (flexed) about a transverse axis through A. Next the femur is rotated about a vertical axis through A fixed relative to the tibial axes. The lateral contact point moves posteriorly by a and the medial anteriorly by a. The femur is next translated posteriorly by a. The lateral contact point has now displaced posteriorly by a total of 2a, but the medial condyle is in its original position. In orthopaedic terms, as the knee has flexed, there has been an internal rotation of the tibia and a posterior translation of the femur.

![Figure 100.3](image.png)

**Figure 100.3.**
Figure 100.3. Three-dimensional knee motion described by successive rotations and displacements. The figure depicts “average” knee motion from the extended to the flexed position.

Note that, depending on the order of the motions, the posterior displacement of the lateral contact point can occur on an unrotated or rotated tibia, producing a slightly different end result. The entire motion could have been achieved by a single rotation about and a displacement along a screw axis, but this is more difficult to visualize conceptually than the sequence of rotations and displacements described. In addition, the internal rotation and posterior displacement could have been achieved by a rotation about a vertical axis through the medial tibial condyle. Hence, it is important to define the method of describing the motion and which axes are used, to avoid misunderstanding and confusion.

For the hip joint, the origin of the femur is the center of the femoral head and the vertical axis is through the center of the knee (Fig. 100.4). The anteroposterior (AP) and mediolateral (ML) axes are self-evident, and all axes are mutually perpendicular. The axes in the acetabulum and femur are conveniently defined as being coincident with the hip in the neutral position. The motion of the femur is defined in relation to a fixed acetabulum as follows:

1. Flexion-extension about the XA axis.
2. Abduction-adduction about the ZA axis.
3. Internal-external rotation about the YF axis.

The importance of the orders of the rotation can be seen by reversing the order of the first two.

The motion of the knee is more complex in that it involves six degrees of freedom—three rotations, and three translations (Fig. 100.5). The transverse axis in the femur can be chosen through the epicondyles. The other two axes are mutually perpendicular. For convenience, the axes of the tibia in the initial reference position at zero flexion can be taken to be the same as for the femur. Ordered motions are defined for the femoral axis system relative to the tibial axis system.

1. Flexion-extension about XT.
2. Varus-valgus about ZT.
3. Internal-external rotation about YT (this can also be regarded as rotation of the tibia about YT).
4. AP displacement along ZT.

A modification in the way the axes are defined has been used to define a set of order-independent motions of the knee. This is the Grood-Suntay system, which has the advantage of ease of visualization.

For a joint with uniaxial motion, such as the elbow, it is useful to define the axes with respect to the axis of rotation, rather than using the long axes of the bones. The description of the motion can then be simplified to a single degree of freedom by the choice of the axis, which bisects the carrying angle (Fig. 100.6). This axis becomes a common axis in the humerus and ulna, the other two axes being mutually perpendicular as shown. In this case, the long axes of the bones are not coincident with the reference axes.
FORCES AND FORCE ANALYSIS

Forces, like motions, are vector quantities. In this case, they have magnitude, line of action, and point of application. Exactly the same axis systems used for the bones can be used to define the forces. For the hip in the neutral position, there are three components of force along each of the three axes, which can be combined into a single resultant force (Fig. 100.7). The forces on the femoral head are exactly equal and opposite to those on the acetabulum. If the femur is now moved to any arbitrary position, the resultant forces on the femoral head and in the acetabulum will still be equal and opposite. However, the three components of force along each of the femoral axes are now different from those along the acetabular axes. Hence, when defining the forces across a joint, it is important to specify the axis system to which the forces are referred. In reality, of course, the resultant force is representative of the pressure acting over a large surface area.

In the knee, to represent the forces acting on the joint surfaces as well as along the axes, a moment in the frontal plane can be considered (Fig. 100.8). A moment has the units of force × distance, for example, N/m or N·mm. In the case shown, the main force is axial compression FY acting in the negative YT direction. An anterior shear force FZ is shown acting along positive ZT, and a varus moment MZ is shown acting about ZT. This set of forces and moments is shown distributed to the upper tibia. The compressive force and the varus moment produce a larger resultant force on the medial condyle than on the lateral condyle. The forces themselves are representative of the contact pressures and act at the center of pressure of each contact area. The shear force is transmitted to the tibia by the contact areas being on the upward anterior slopes of the tibial plateaus and by a force in the posterior cruciate ligament (PCL).

A method for the analysis of forces is shown in Figure 100.9, in which the problem is to calculate the forces on the face of the glenoid with the arm abducted and a weight in the hand (174). The steps are:

Figure 100.9. To calculate the unknown forces at the joint, the forces are drawn and the arm is isolated as a “free body,” shown by the dotted line.
Define axes in each bone. The humeral axes are not drawn here because only the forces with respect to the glenoid are considered.

Define the forces on the glenoid. In this example, only the forces in the scapular plane FY and FX are considered.

Draw the other forces on the arm, namely the muscle forces FM, and the external forces WA (weight of the arm) and WH (weight in the hand).

Define the arm as a free body by drawing a boundary around it and showing the forces that act across the boundary.

Assuming that the geometry is known (e.g., from radiographs), there are three unknowns, namely FX, FY, and FM. Three equations are thus required to obtain a solution.

Resolve the forces along the negative YG direction:

\[ FY + WA + WH - FM \sin \theta = 0 \]

Resolve the forces along the negative XG direction:

\[ FX - FM \cos \theta = 0 \]

Take moments in the clockwise direction about the center of the humeral head:

\[ FMr - WAp - WHq = 0 \]

(Note that FX and FY pass through the center of the humeral head, so their moments are zero.) The individual values are then solved from these three equations. This concept of isolating a defined entity as a free body and analyzing the forces across the boundary can be applied to numerous force analysis problems in the body. As with motion, the changing pattern of forces during activities is important.

PRESSURES AND STRESSES

Even though the resultant forces across joints are depicted with lines of action, in reality the forces are transmitted across areas on the joint surfaces. This results in a contact pressure, or contact stress, acting on the surface. The density of the subchondral bone plate will provide an indication of the pressure distribution.

**Mean Contact Pressure = Residual Force / Contact Area**

The units of pressure are pascals, equal to newtons per square meter (N/m²). Because this is such a small quantity, mega-pascals (MPa), equal to newtons per square millimeter (N/mm²) are used. Whereas static analysis, as shown in the previous section, can be used to calculate resultant forces, to calculate pressures and stresses in an implant-bone system, more complex analyses are required. For simple geometries, elasticity (e.g., hertzian) equations can be used to calculate the contact areas and stresses in terms of the radii and the elastic properties of the materials. However, for realistic bone and implant shapes, finite element analysis (FEA) is the most appropriate technique.

If a sphere is loaded onto a flat surface, a circular contact area is formed due to deformation of both surfaces. The pressure distribution is hemispherical, with the maximum pressure at the center being 1.5 times the mean pressure. The same situation occurs if the lower surface is flat, a convex spherical surface, or a concave spherical surface.

![Figure 100.10. Three types of contact in joints: spherical, cylindrical, and toroidal.](image)

The contact area increases as any one or a combination of the following conditions occurs:

- Higher force.
- Lower elastic modulus (stiffness) of the materials.
- More conforming surfaces.
- Longer time the force is acting (due to "creep," defined later).

The contact pressure increases as any one or a combination of the following conditions occurs:

- Higher force.
- Higher elastic modulus.
- Less conforming surfaces.
- For a stiff layer under a relatively soft layer.

The conformity has a major influence on the pressure, the relevant parameter being the relative radius of curvature \( R \) defined by:

\[ \frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} \]

where \( R_1 \) and \( R_2 \) are the radii of curvature for the two surfaces, and the radius of curvature is taken as positive for convex surfaces and negative for concave surfaces.

Thus, any two surfaces can be represented by a surface with radius \( R \) on a flat surface. The average contact pressures calculated for a given force (1000 N) and material properties (metal-on-plastic) are shown in Table 100.2. This table shows how the relative radius and the contact pressure change dramatically as the surfaces approach full conformity. The range covers a nonconforming knee to a hip joint with a small femoral–acetabular clearance (15). Note, however, that the standard hertzian equations lose accuracy when the contact radius \( R_2 \) approaches the surface radius \( R_1 \). Another factor is that the contact pressure does not necessarily predict the wear rate, which is so often assumed.
A cylinder on a flat surface (with an infinite radius of curvature) has a much larger contact area than does a sphere on the same flat surface (Fig. 100.10). Examples of arthroplasties with such contacts include some knees, elbows, ankles, and fingers. Today, most geometries in condylar knees are toroidal, between spherical and cylindrical, producing elliptical contact areas. This has the advantages of reducing contact stresses and avoiding “dipping-in” at the sides if tilting occurs. The stresses beneath the surface in all types of contacts are extremely important in both natural and artificial joints, in terms of producing subsurface damage.

High pressures can act across implant–bone interfaces (39) (Fig. 100.11). (Note that the word “stress” can be substituted for the word “pressure” in this context.) In the case of metallic cemented or uncemented hips, the contact pressures are highest in the proximal-medial region but with high pressures distal-lateral also. The magnitudes of the pressures depend also on stem geometry and head offset. For uncemented stems, in which a “perfect” metal–bone fit is not achieved, local contact pressures can be very high due to the stiffnesses of the materials. An additional interface effect is due to friction between the metal and the bone, causing shear forces to act as shown in Figure 100.11 (101,198). If there is bonding across the interface from cement or from a porous or HA coating, the shear forces will be higher, decreasing the interface contact pressures. The interface shear stress is defined as:

\[
\text{strain} = \frac{\text{change in length}}{\text{original length}} = \frac{(L_1 - L_0)}{L_0}
\]

In designing implant components for whatever location, the design goals for the interface stresses are:

1. Positive contact pressures at those interfaces that usually experience compression (e.g., acetabulum, upper tibia).
2. Minimum contact stresses on interfaces that usually do not experience compression (e.g., intramedullary canal).
3. Minimum shear stresses (e.g., acetabulum, upper tibia, intramedullary canal).

The implications of goals 2 and 3 are to minimize or avoid intramedullary fixation, or to design the component to minimize tension and shear.

On the outside surface of a structure on which no direct forces are acting, in general, there will be stresses acting in the plane of the surface (Fig. 100.12). If a small square is drawn on the surface, there will be one direct stress (tensile or compressive) acting on opposite faces and another direct stress acting on the other pair of faces. There will be a single value of shear stress acting to distort the square. If the square is now rotated, an orientation can be found at which the shear stress is zero. The direct stresses acting at this orientation are called the principal stresses. One of these is the maximum and the other the minimum. Tension is taken to be positive; compression negative. However, the principal stresses can be both negative, both positive, or one negative and one positive, depending on the loading conditions around the square of surface. The maximum shear stress is at 45° to the principal stresses.

In three dimensions, the general principles are the same. Here, a small cube of material is taken, which has three direct stresses and three shear stresses. At a certain orientation, the shear stresses are zero and the direct stresses are again called the principal stresses.

Stress calculations of bones and implant components often quote values of Von Mises stress. This term is convenient in that it describes the stress state at a point with a single number. In fact, it is calculated from the three principal stresses, and is a value that quantifies the likelihood of yielding, synonymous with the yield stress in direct tension.

Another often-used quantity is strain energy density, which is the amount of energy (force × distance) stored in the material due to the applied stresses deforming the material. This quantity is considered to be relevant to bone remodeling, whereby the response of osteoblasts within the bone material is proportionate to the amount of deformation and hence strain energy density. This is an “elastic” quantity recoverable on removal of the stresses, but yielding of the material is an additional consideration.
MATERIAL AND STRUCTURAL PROPERTIES

Material properties relate only to the material itself and not to the shape of the object, whether it be a bone or an implant component. A fundamental property is modulus of elasticity $E$, which can be determined by a simple tensile or compressive test on a cylinder (Fig. 100.13).

$$E = \text{stress} \div \text{strain} = \sigma e$$

where stress = force ÷ area = $F/A_0$, and $A_0$ is the original cross-sectional area.

The change in a linear dimension is described by strain:

$$\text{shear stress} = \text{shear force} \div \text{contact area}$$

For stiffer materials, such as bone and metals, the strain is small, usually measured in microstrain. A typical strain value for the cortex of a long bone under peak load is on the order of 2000 to 3000 microstrain. For materials such as cartilage and ligament, however, the strain can be 10% or more, and hence the true stress after load application must be related to the deformed area $\sigma_1 = F/A_1$, where $A_1$ is the area with the force applied. Poisson’s ratio $n$ defines the strain in directions perpendicular to the longitudinal strain:

$$n = \left( \frac{D_0 - D_1}{D_0} \right) \left( \frac{L_1 - L_0}{L_0} \right) = \varepsilon_1/\varepsilon_2$$

For metals $n$ equals 0.3, for plastics $n$ equals 0.3 to 0.4, and for an incompressible material such as a fluid or rubber, $n$ equals 0.5.

For metals, the stress-strain relation is linear (Fig. 100.14A). The elastic modulus, defined as the slope of the stress-strain curve, is constant. Ligament and tendon are strain stiffening due to the straightening of collagen fibrils (86). This means that the elastic modulus is not constant but increases steadily with strain. Rubbers usually exhibit strain stiffening also. Conversely, materials such as polyethylene exhibit strain-softening behavior, in which the elastic modulus appears to reduce with strain. For these nonlinear materials, modulus of elasticity has to be defined as a tangent modulus at a particular value of strain, as shown in Figure 100.14A.

For viscoelastic materials, there is a residual displacement and a hysteresis loop. A viscous material, such as synovial fluid, does not recover the strain (or only a very small amount) after force removal.

Materials for which the strain recoveries immediately on removal of the force are called elastic (Fig. 100.14B). If there is a time delay in recovery and a hysteresis loop is formed, the material is defined as viscoelastic, and some energy is absorbed in the cycle. A viscous material, such as synovial fluid, does not recover the strain (or only a very small amount) after force removal.

In some materials, if a force is applied suddenly, there is an immediate strain, followed by a continued strain at a decreasing rate, reaching an asymptotic level (Fig. 100.14C). The behavior is called creep or cold flow. When the force is removed, the reverse process occurs. Polyethylene behaves in this way, as does articular cartilage, tendon, and ligament. Stretching exercises before a sporting activity put such tissues through viscoelastic and creep cycles. Acrylic cement, when subjected to sustained loading in a fluid environment at 37°C, shows some creep, and this may be relevant to the slight sinkage of polished hip stems over time.

Materials for which the properties are the same in all directions are called isotropic. Most artificial materials used in joints are of this type, although a number of experimental composite materials consisting of aligned fibers embedded in a polymeric matrix are nonisotropic. These materials are called orthotropic if a property such as modulus or strength is much greater in only one particular direction. Most biologic materials are orthotropic, which results from their structure, either aligned collagen fibers in the case of ligament and tendon, or aligned osteons in the case of bone (128). Articular cartilage is a special case with complex properties due to its triphasic composition of collagen fibers, mucopolysaccharide matrix, and fluid. The values of modulus of elasticity for the materials discussed cover a wide range (Table 100.3), and consequently, the transfer of forces between different structures is complex and can involve regions of stress concentration.
Material failure in a single load episode can occur in either tension, compression, or shear. In general, tensile failure is the most common. If a material is stretched and fails suddenly, that is termed brittle fracture. Ceramics and acrylic cement behave in this way. Metals and polyethylene, on the other hand, are ductile in that there is a region of plastic deformation whereby the material elongates at essentially the same applied load. If the load is released, there is a permanent deformation, but the material can continue to be structurally useful in that condition. Permanent deformation in plastic tibial and patellar components is an example. Tendons and ligaments behave as if they were numerous fascicles in combination (41, 241), with rupture of the tightest fascicles occurring first. If the load is released and sufficient fibers are intact, the structure can still function. Bone is close to being brittle, although there is some plastic deformation due to pull-out of osteons from the matrix (58, 128, 159).

Failure of a material can occur at stress levels below the level at which single cycle yield or fracture occurs due to repetitive cycling of forces, a process known as fatigue. This process has been observed on many orthopaedic devices including hip stems (93) (Fig. 100.15), tibial trays (1), and plastic liners (Fig. 100.16). The fatigue strength or fatigue limit is the stress below which no failure would occur no matter how many cycles of loading occurred (Table 100.3). This value is generally about two thirds of the failure stress for a single-load application. Fatigue failure initiates at the location of the highest stresses, and the crack gradually propagates through the section until the stress reaches the level at which complete failure occurs at a single load. The starting point of the crack can be a small defect in the material structure, such as an intergranular defect in metal or plastic (205). Even a reference number of a component etched onto a metal surface in a highly stressed region has been the initial location of a fatigue crack. Such defects are called stress concentrations or stress raisers in that they raise the stress level above the overall average level in that region (106). Sharp edges, corners, or grooves in implant components are common sites of stress concentration. Even defects just within the material, such as small bubbles in cement, can act as stress concentrations in the same way. Generally, biologic materials do not experience fatigue failure because the resting periods between loading episodes allow for restoration and remodeling. However, one theory for the development of osteoarthritis has been advanced: healed trabecular microfractures, failed in fatigue, produce an overly stiff supporting structure to the articular cartilage.

Table 100.3. The Modulus of Elasticity and the Fatigue Strength of Biological and Artificial Materials
In the normal intact hip, there are forces on the femoral head and in the abductors, such as to produce both compression and bending in the upper femur [34] (Fig. 100.18). This can be depicted at a level just below the lesser trochanter, where there is a resultant compressive force C acting down the center, together with a moment M. Force C produces a mean compressive stress of $C/A$ at the section, where $A$ is the area of bone. Moment M produces tensile stresses on the lateral half of the femur and compressive stresses on the medial half. These are called bending stresses. These two stress distributions are combined to produce the resultant stresses. The bending stresses usually dominate over direct stresses such that the lateral side is still in tension and the medial side is in increased compression.

![Figure 100.18](image)

Figure 100.18. The stresses in the bone at a section just below the lesser trochanter, for the intact femur, and after insertion of a hip stem. See text for details.

In a total hip replacement, a composite structure, the hip stem, and the bone act in parallel. It is assumed that the forces $F$ and $G$ are the same before and after hip replacement. At the section shown in Figure 100.18, compressive force $C$ and bending moment $M$ are now shared between the bone and the stem. For $C$, the proportions are $A_F E_F A_G E_G$, where $A_F$ and $A_G$ are areas and $E_F$ and $E_G$ are the elastic moduli of the bone and stem, respectively. For $M$, the proportions are $E_F I_F E_G I_G$ where $I_F$ and $I_G$ are the second moments of area or section moduli of the bone and stem, respectively. For a circular stem diameter $D_I$, $I_I = \pi D_I^4 / 64$. For a hollow femur with outer and inner diameters $D_o$ and $D_i$, respectively, $I_I = \pi (D_o^4 - D_i^4)/64$. The important effect of diameter can be seen. The product of $EI$ is called the bending stiffness. In practice, a hip stem has a much higher $EI$ value than the bone for a narrow cortical thickness and large canal diameter. In this case, the proportion of the bending carried by the stem is high, and the bone can be seriously stress protected. At the other extreme, with a thick cortex and a narrow canal, the bone carries a high proportion of the bending.

Friction, Lubrication, and Wear (Tribology)

Tribology is concerned with the science of rubbing surfaces and is thus fundamental to the functioning of joints [62]. Human joints are different from most bearings in engineering in that they operate under low sliding speeds and are expected to last a lifetime. Furthermore, they are constructed of a thin soft layer on a relatively hard layer, carry out motions in multiple directions, and are not necessarily fully conforming. The way in which they function so effectively is in maintaining a layer of viscous fluid between the cartilage surfaces such that direct rubbing of cartilage on cartilage occurs infrequently [227]. A number of different lubrication mechanisms known in engineering have been found to apply to human joints, but their behavior is so complex that there is no direct analogy. The coefficient of friction, defined as the ratio of the frictional shear force to the compressive force, ranges from about 0.001 to 0.01. This means that, for a typical compressive force of 3 body weight (BW) (2000 N) on a hip or knee, the shear force is a mere 10 N. In contrast, a metal-polyethylene joint would have a shear force of at least 10 times that. Although friction is usually associated with sliding between two surfaces, a frictional shear force can also be transmitted during rolling, up to the level determined by the dynamic friction coefficient. The motion in that case is termed inductive rolling.

The lubrication mechanisms believed to occur during normal joint function are as follows [218,227]. During a lightly loaded swing phase, synovial fluid is drawn in between the joint surfaces. On applying a force at the start of stance, a fluid film is maintained by a squeeze film mechanism, whereby the large surface area and the viscosity of the fluid mean that leakage of the film occurs at a very low rate. As movement begins, the film is further maintained or even enhanced by elastohydrodynamic lubrication, by which the area of contact is maintained due to the deformations of the bearing surfaces and fluid is pressurized as it is drawn into a thin converging wedge between the surfaces. In addition, as the cartilage surfaces are deformed, fluid is exuded between the surfaces (this has been termed squeeze film lubrication) and at the leading edge of the contact area. Fluid becomes trapped in small undulations in the cartilage surfaces, a mechanism called trapped pool lubrication, and a higher concentration of hyaluronic acid can result in a more viscous layer of synovial fluid, by so-called boosted lubrication. The hyaluronic acid protein complex chemically binds to the cartilage surface so that even if sliding occurs when there is minimal film thickness, boundary lubrication is provided.

In metal-polyartificial joints, fluid film lubrication mechanisms are ineffective because of the hardness of the materials and the limited surface areas, so that surface-to-surface rubbing takes place during sliding. At each step, it is estimated that millions of submicron-sized plastic particles are released into the joint. The effect of wear on particles and osteolysis of the bone around the interface, as well as the mechanical effects of the change in geometry, are major limiting factors in the durability of artificial joints [83].

The first wear mechanism is termed adhesive wear, visualized as the sticking of a tiny region of the plastic surface on to the metal surface such that a fragment of plastic is pulled away (Fig. 100.19). It is now thought that such a mechanism may require multiple passes to build up sufficient strain energy in the asperity (a local high point) before it is released. A variation of this mechanism occurs when the adhesion results in a small fibril of plastic being stretched from an asperity and eventually released. The next mechanism is abrasive wear [63]. In two-body abrasive wear, small sharp asperities on the metal surface, such as scratches, cut into the plastic surface. Crisscrossing of scratches on the plastic due to variations in motion paths accelerate this type of wear. Three-body abrasive wear occurs due to the entrapment of small particles between the sliding surfaces [51]. In artificial joints, these particles can be plastic, acrylic cement, bone, HA, or metal debris from rough or sprayed surfaces. If such particles embed into the plastic surface, they can accelerate the wear locally. All of these mechanisms produce particles in the range of 0.1 μm to a few microns. The particle shapes are granules, fibrils, or flakes (47,48). For ceramic-on-ceramic or metal-on-metal joints, the wear mechanisms are similar but the rates of volumetric wear are much smaller than for metal-on-polyethylene joints, and the particle sizes are also smaller.

![Figure 100.19](image)

Figure 100.19. A representation of different wear and damage mechanisms from a plastic surface: adhesive wear (A), two-body abrasive wear (B), three-body abrasive wear (C), delamination (D), and fretting (E).

A damage mechanism that has been particularly destructive in knee joints is delamination (62,205). This is a fatigue process whereby shear stresses at about 1 mm beneath the surface change in direction as sliding and rolling take place, initiating and propagating cracks in the material [178]. When the cracks reach the surface, fragments of plastic are liberated. A surface once disrupted fragments at a rapid rate. It is noted that, because delamination is affected by subsurface stresses, it can occur due to rolling as well as sliding, although the stress magnitudes are slightly higher in sliding. Pitting is another fatigue damage phenomenon caused by tensile cracks initiating at the surface. The effect is usually local, seen as pits about 0.5 to 1.0 mm in diameter. The severity of both delamination and pitting depend on the...
fatigue properties of the material, which, in turn, may depend on time-dependent phenomena such as oxidative degradation (62, 77, 135, 180, 182). The basic equations for steady-state wear, excluding time-dependent damage such as delamination, are:

\[
\text{wear rate} = \text{wear factor} \times \text{load} \times \text{sliding velocity} \\
\text{i.e., } \dot{w} = k \times W \times v \\
\text{wear volume} = \text{wear factor} \times \text{load} \times \text{sliding distance} \\
\text{i.e., } w = k' \times W \times s
\]

The wear factor may be a constant for a given pair of materials, but it can change over time if:

- The material properties change (e.g., due to yield, surface heating, in vivo oxidation, chemical effects).
- The surface of an initially polished hard material becomes scratched.
- Transfer films occur (e.g., due to surface heating, degraded joint fluid).

Another type of wear, not due to sliding in a bearing itself, is fretting (36). This occurs due to cyclic shear stresses across an interface between two parts intended to be statically fixed together. Examples are a modular femoral head on a taper and a plastic insert in a metal backing. The shear stresses can be generated due to elastic deformations from cyclic loading, including the Poissons effect. The latter occurs, for example, when the plastic of a tibial component becomes squeezed radially outward from a contact area. The motion due to the interface shear stresses can be submicron or even up to a millimeter in a loose snap-fit connection.

HIP REPLACEMENT

HIP MECHANICS

Typical angular rotations at the hip joint for a walking cycle are shown in Figure 100.20 (120). On heel-strike, there is about 30° of flexion, and at toe-off, about 10° of extension. The other two rotations are approximate because of the difficulty of separating femoral from pelvic motion. However, the range of abduction to adduction is about 11°, and for internal-external rotation, the range is about 8°. These rotations produce motions of individual points on the femoral head that traverse curved paths in the socket and cross over one another. This aspect is discussed further in the section dealing with hip-simulating machines.

The forces acting across the normal intact hip have been determined indirectly by using gait analysis and directly in total joints by using telemetry (20, 21, 187). The latter is more applicable to the subject of this chapter. These forces have been depicted as acting on the femoral head during different activities. Figure 100.21 shows that the line of action of the force during level walking changes much less than the angles of motion of the femur relative to the acetabulum. The projection on the acetabulum of these forces during walking results in a similar pattern but with larger angles of excursion. This means that the force vector moves somewhat more with the femur than it does with the acetabulum (74, 75). The reason for this is that approximately two thirds of the hip force is produced by the abductors (10), which tend to apply their force parallel to the long axis of the femur (74, 75).

Figure 100.20. Representative values for the rotations occurring in the hip joint during normal walking. (Data from Inman VT, Ralston HJ, Todd F, eds. Human Walking. Baltimore: Williams & Wilkins, 1981.).

The directions of the resultant force on the joint are important to the function of total hips. For this purpose, it is useful to consider the forces relative to axes based on the long axis of the femur. In the frontal plane, the force makes an angle of 15° to 27° to the long axis of the femur during stance. This produces axial compression, a varus moment, and a medial-to-lateral force. In the sagittal plane, there is an important component peaking at approximately 0.75 BW acting from an anterior to posterior direction on the femoral head, which results in torsion (21, 89). The latter is considered to be an important contributor to the compressive failure of trabecular bone in un cemented stems, and results in stem fractures initiating from an antero-lateral corner.

The peak forces during a range of different activities are shown in Figure 100.22. The exceedingly high force of 8 BW encountered accidentally in a stumble is important because a single force such as this, along with its torsional component (21), could lead to debonding at the implant-bone, cement-bone or cement-stem interfaces, or to cracking of the cement mantle (22,150, 210). A factor that influences the mechanics of the hip is the offset of the femoral head from the femoral axis (187, 184). This is frequently reduced from normal in a total hip replacement (THR). The effect is an increase in the force required in the abductors (10), leading to a higher resultant joint force, a more vertical resultant, and sometimes a gait abnormality. An increase in offset reduces forces but causes an increase in the bending moment on the stem. Failure to achieve the normal anteversion of the head and neck increases the axial torsion, which is undesirable (21).
Cemented femoral components have changed relatively little since the original Charnley design, although paradoxically, even a small change in design can result in a major change in performance. Fundamentally, the stem shape parallels the canal shape (107), leaving space for a cement mantle of 2 to 4 mm in thickness. In early designs such as the Charnley, Exeter, Stanmore, Mueller, and T28, the cement was not intended to bond to the stem. In contrast, at the cement–bone interface, these designs aimed for an intimate mechanical contact with rough bone or trabecular bone. Compressive, shear, and tensile stresses are transmitted to the bone surface (113), an unnatural situation, but one that is tolerated for long time periods.

It is well known that the stresses in the femur are changed from normal due to the presence of the stem, especially proximomedially, where the longitudinal compressive stresses are reduced to 20% to 30% of normal levels (110,223) (Fig. 100.23). Progressing distally, the stresses become closer to normal, reaching normal levels below the level of the stem tip. The reduction in a stress parameter, such as the Von Mises stress, particularly when it results in a reduction of bone density or volume, is called stress protection or stress shielding (30). Over a time period of approximately 5 to 10 years, this results in longitudinal removal of bone at the neck cut level, osteopenia, and resorption of bone away from the cement. If this process becomes extreme, the interface stresses around the remaining stem become excessive (150), leading to “clinical” loosening (84). In addition, wear particles can be more easily transported down the interface, producing lysis at locations all around the stem, especially distally (98). A further consequence of proximal bone loss is that the stem is only rigidly fixed in its distal half, increasing the bending stresses and increasing the possibility of fatigue fracture (94).

Dual energy x-ray absorptiometry (DEXA) scanning has now become the standard method for measuring and monitoring changes in bone density over time (201,202). In this technique, in the frontal plane, for example, an x-ray beam is scanned across the field, and measures of x-ray absorption are made, giving a measure of bone mass at a matrix of points in the field. Major changes in bone mass usually occur slowly, and it has been found that bone loss may be only 10% to 20% at 2 years, but that this loss can increase to as much as 50% in the proximal-medial region at 5 years.

The allowable level of stresses at the interface are known only approximately, but the goal is to minimize these stresses and to avoid local stress concentrations. Stresses within the bone should be as close to normal as possible. Cement and stem stresses, especially tensile, should be minimized and should not exceed the fatigue limit under normal loading conditions. All of these goals cannot be obtained simultaneously, but a number of guidelines for hip stem design exist:

- Stem bending stiffness should be much lower than that of the bone to minimize stress shielding.
- Avoid excessively flexible stems that elevate interface tensile and compressive stresses and produce excessive micromotion.
- Ensure that the cement mantle thickness is a minimum of 2 to 3 mm (122) (can be achieved using centralizers).
- Avoid corners or any other feature on the stem that would cause stress concentrations in the cement or in the stem itself (22).
- Create smooth contours but with sectional shapes that will not twist within the cement mantle.
- Provide features such as proximolateral projections (e.g., “cobra” design) to provide a greater connection between stem and cement, a net increase in compressive stresses, and a reduction in tensile stresses.
- Provide a means of centralization, especially proximomedial and distal, to avoid close metal–bone proximity, where lysis frequently occurs.
- Use third-generation cementing techniques, including cleaning the canal, distal plugging, pressurizing, and minimizing porosity (12,145).

Concerning the ideal surface finish for a stem, long-term clinical data suggest that a smooth surface or a near-smooth surface, in which there is no direct stem–cement bonding, produces successful results. The use of rough surfaces, or rough surfaces with a precoating of cement to obtain stem–cement bonding, has not been uniformly successful. It appears that shear and tensile stresses at the interface can cause progressive debonding and interface micromotion (150). The latter can then generate metal and cement debris, which enter the joint space, followed by accelerated wear of the UHMWPE liner. Evidence of stem–cement micromotion in all types of stem is frequently seen in retrievals and produces fretting wear of both stem and cement (Fig. 100.24).
The stem material for cemented components is important, and forged cobalt-chrome or stainless steel is usually preferred. Titanium alloys have been prone to surface wear or even crevice corrosion and are not in general suitable for cemented application. The ideal combination for a cemented stem with a modular head is to use cobalt-chrome alloy for both owing to the minimal corrosion on the taper connection (31) and reduced scratching of the femoral head over time. Other head materials are discussed later in this chapter. Because of its success in elderly patients, and even in younger patients (12,71,145) (although studies are variable on this issue), it is unlikely that the design of the standard cemented stem for primary cases will change substantially in the foreseeable future. Long-term cemented components are used in revisions, but the cement penetration and shear strength are likely to be inadequate owing to the loss of most of the cancellous bone from the previous implant (146).

Standard cemented acetabular components consist of a solid UHMWPE hemisphere, or just greater than a hemisphere, with grooves on the outer surface for keying to the cement. A metal wire is usually embedded on the outside to measure the wear relative to the femoral head on radiographs. The range of motion (ROM) between the femoral neck and the socket before impingement occurs is important because it affects the potential for dislocation as well as loosening. It is notable that, as wear proceeds, the ROM steadily reduces, and this process can lead to problems for 22 mm heads in the long term. The factors affecting ROM are:

- ROM increases with head diameter. (However, there is an increase in volumetric wear with diameter.)
- ROM increases with decreasing neck diameter. (This is especially applicable to flexion-extension, in which the neck can be elliptical.)
- ROM decreases with a short neck if collar-socket impingement occurs.
- ROM decreases with "skirted" femoral heads, which increase head height and offset.
- ROM decreases in certain planes if the socket and stem are malpositioned.

Overall, the best compromise appears to be a head diameter of the range in the 26 to 28 mm with an elliptical neck of minimum diameter for strength. In practice, the most widely used diameters are 28 mm and 22 mm. To obtain sufficient plastic thickness the minimum outer diameters of the acetabular component recommended for a 28 mm diameter head are 44 mm for plastic and 48 mm for metal-backed plastic. Below those diameters, a 22 mm head is recommended.

The principles of acetabular fixation (158) are the same as those for stems, notably intimate contact of the cement with a rough bone surface and penetration within the trabeculae. There is still uncertainty regarding removal of the subchondral plate (161) and the size and number of key holes (Fig. 100.25). Although retention of a subchondral plate is attractive for force transmission, areas of relatively smooth bone are prone to interface micromotion, bone resorption, and particle ingress. The loosening mechanism of cemented acetabular components is the peripheral regions become infiltrated with UHMWPE debris, leading to bone resorption, followed by a creeping process that eventually involves the entire interface (192). This process has been conceptualized as a progressive increase in the "effective joint space." Mechanical factors are also likely to play a role due to higher than normal stresses occurring in the trabecular bone (65). Steady migration of sockets into the acetabular bone is common, and acetabular component failure usually occurs at a higher rate than for stems in follow-up examinations after more than 10 years. The use of metal backing (115), which reduces the incidence of interface radioopacity in tibial components, has not been successful in cemented acetabular components. Simple finite element models indicated a more uniform stress distribution across the interface, but more complex 3-D models, which included the exact shapes, bone densities, and forces acting (64), have shown otherwise. This has highlighted the care needed in formulating and interpreting finite element models and the conclusions that may be drawn from them.

![Figure 100.25](image)

**Figure 100.25.** Density of the subchondral bone in the acetabulum for two different ages. Assuming that the density reflects load transmission, in youth (left), there is more even distribution, which gradually converts to more localized superolateral load transmission over time (right). (Data from Müller-Gerbl M. The Subchondral Bone Plate, Vol 141. Advances in Anatomy, Embryology and Cell Biology. Berlin: Springer-Verlag, 1998.)

### UNCEMENTED COMPONENTS

In the 1950s and 1960s, thin polished metal hemispherical shells were interposed between reamed surfaces of the femoral head and acetabulum in the expectation that new cartilaginous surfaces would form between the metal and the bone. The tissue formation, however, was unpredictable, consisting of localized islands of fibrocartilage and hyaline articular cartilage. There will be possibilities for this type of approach if the type of tissue formation can be controlled to a greater degree. The Austin-Moore and similar hemiarthroplasties, generally with rectangular sectioned stems, were moderately successful with regard to fixation and pain relief, although most of the patients had limited functional requirements. Subsequently, many such uncemented stems with "satin" or smooth interface surfaces have been introduced in total hip stems, but have all been subject to bone resorption, interface micromotion, and migration, leading to unsatisfactory results.

Successful fixation of uncemented components depends on achieving tolerable stresses at the implant–bone interface and minimizing interface micromotion to approximately 50 μm or less over most of the interface. These conditions depend on the surface of the stem, the sectional shape, and the overall geometry. The major factors are:

- **Stem Surface.** Smooth or satin stem surfaces are unsatisfactory and become surrounded by a thin layer of fibrous tissue and a bony shell, which is linked to the cortices with trabecular struts. Rough surfaces have been successfully used in designs such as the Zweymüller (PLUS, Endoprothetik AG, Switzerland) in cases in which rigid mechanical fixation with the diaphysis has been achieved at surgery. In suitable stem designs, porous surfaces have shown at least 25% of the surface area ingrown by bone, which has proved to be adequate for long-term fixation (42,80). The rate of bone ingrowth and the percentage of area ingrown are enhanced with HA or HA-tri-calcium phosphate (TCP) coating (203). Such coatings superimposed on rough or macrogrooved surfaces have demonstrated enhanced bone growth around the periphery of the stem, but bone has been sparse when gaps have been greater than approximately 1 mm (90,203). In all of the abovementioned cases, the strongest bone attachment and areas of new bone formation have been where the implant was in contact with cortical bone or strong cancellous bone, in regions where high forces are transmitted (42,80,193).

- **Stem Sectional Shape** (Fig. 100.26). Circular or elliptical sections have the least potential for bone attachment, except where an initial interference fit is achieved and the stem is rough or coated. Corners that cut into the bone have been successful, but again only for certain surfaces and where the overall stem geometry has avoided excessive stresses at the stem corners. Grooves cut into the stem provide little benefit unless they are provided with a bioactive coating such as HA.

On the other hand, multiple cutting flutes, especially when combined with a rough surface, provide stable fixation, particularly in torsion (232). A useful application of such flutes is in revision stem design (131).

![Figure 100.26](image)

**Figure 100.26.** The shape and orientation of the normal diaphysal canal is shown. The most rigid fixation of stems occurs when the corners of a rectangular
stem or longitudinal cutting flutes cut into the cortical bone. Osseointegrated straight stems provide rigid fixation at the expense of proximalmedial stress-shielding and difficulty of removal. The lateral flare provides rigid fixation and allows for a shorter stem, especially when designed anatomically in the ML view.

- Overall Stem Geometry. In the frontal view, most stems are either straight or have a lateral flare (Fig. 100.26). Generally, it has been found that reliable long-term fixation is obtained when rigid initial fixation has been achieved and most of the stem is rough or coated to promote subsequent bone apposition or ingrowth. Two examples are the Zweymüller and the AML (DePuy, Inc., Warsaw, IN). The main disadvantage of this approach, especially when the stem is both porous coated and long, occurs when removal of an ingrown stem becomes necessary. The lateral flare designs with a high neck cut attempt to maximize proximal fit-and-fill such that the stem can be of reduced length. This is possible because the proximal shape reduces the bending moment on the stem and also provides rigid axial load support. The stems are usually anatomic in shape, as seen in the ML view, to maximize the proximal fit. A question with uncemented stems is the number of sizes needed to provide adequate fit both proximally and distally in the large majority of cases. Some designs address this by using modular distal sleeves (50). Collars are an effective way of increasing the compressive stress component in the proximal femur, but this can be achieved reliably only if there is osseointegration into the underside of the collar (67,71).

It is often assumed that an uncemented stem will cause more proximal stress shielding than a cemented stem owing to its larger cross-sectional area (38,80). Laboratory tests have shown that this is not necessarily the case because the stem becomes tightly wedged in the femur, producing high circumferential tensile stresses as well as up to 50% of the axial compressive stress component (226). Where proximal bone ingrowth has been achieved, bone has been well preserved over time, based on DEXA-scanning data. However, serious proximal bone loss has occurred under the following conditions:

- Rigid distal fixation and inadequate proximal fixation.
- High bending stiffness of stem compared with bone (80) (i.e., thick stem, thin cortex)
- Excessive stem length.

Uncemented stems have an important application in revisions. The major goals in the design of a revision stem are to maximize axial and torsional stability, and to preserve or enhance the remaining bone. To achieve these goals, the following features are an advantage:

- A stem with distal longitudinal cutting flutes and a bone attachment surface (e.g., rough or HA-coated) to provide torsional, axial, and bending stability; if necessary, the long stem inserting into the diaphysis past the level of the previous stem.
- A proximally filling stem with cutting fins and grooves, and a bone attachment surface to attach to and load the proximal bone.
- A lateral flare to enhance axial stability, increase proximal bone loading, and reduce the bending moments on the distal stem.
- A “platform collar” with a bone attachment surface to increase proximal bone stresses and increase axial stability.

Because of the extreme range of conditions of the bone, as well as patient factors, a graduated implant system is logical, basing the design decision on a hierarchy of factors (Fig. 100.27). Modular systems using separate proximal “plugs” and distal stems, or using a hollow proximal sleeve with a stem that locks within it (as in the S-ROM [DePuy-J&J, Warsaw, IN] system) (48) are useful approaches in dealing with these variations in an off-the-shelf system. A fragile or detached greater trochanter is problematic and can be handled by hooks or wires. Circumferential bone wiring reduces hoop stresses on surgical insertion but may cause stress concentrations in future years. The most difficult revision situation occurs when the diaphysis below the level of the failed stem is thin. Here, the choice is between impaction allografting (51), with a risk of migration, or a very long uncemented or cemented stem affixing in the femoral condyles. The long stem can even be rigidly attached to a knee replacement in those cases in which both the hip and knee need revising or replacing.

SPECIAL HIPS—CUSTOM AND CONSERVATIVE DESIGNS

From a scientific point of view, a strong case can be made for providing a custom hip for every case, provided the surgery is suitably precise (14). For a cemented hip, there must theoretically be an ideal thickness and shape of cement mantle and an ideal stem length. For an uncemented hip, there must be an ideal fit and stem length to minimize femoral micromotion (109) and produce the ideal combination of interface and bone stresses (109,232). In all cases, the ideal position of the femoral head can be obtained. However, the issue is complex, and separate considerations apply to cemented or uncemented, primary or revision (49,131). Some of the factors that are noted in the argument against the widespread adoption of custom stems are as follows:

- The stem design itself is only one part of the total operative procedure. Larger variations in clinical results may occur owing to technique variables rather than owing to the stem design. This point includes the fact that custom stems are not necessarily positioned in the intended location in the femur. However, a “Robodoc” type of approach (computer-controlled milling of the femoral canal based on preoperative computed tomographic [CT] imaging) might provide the eventual answer to this problem (14,171).
- Long-term deterioration of fixation, such as bone resorption and “clinical loosening,” may be dominated by biologic factors at the interface, including the effect of wear debris.
- There are no validated theoretical models for determining the ideal shape for a hip stem for any particular femoral geometry. Hence, the nearest fit from an off-the-shelf system may be as favorable as a custom design if the latter is designed by nonvalidated rules.
- Achieving an accurate fit-and-fill of a stem to the cortical bone (or an exactly uniform cement mantle) may not produce the ideal conditions for long-term success (181). This has been demonstrated for a closely fitting stem, but one without a surface that provided osseointegration, such as porous or HA coating.
- There are insufficient randomized and well-documented studies demonstrating that for routine use, a custom stem system produces better long-term results compared with an off-the-shelf system of comparable design features. Furthermore, the clinical measures—other than outright failure, which requires long follow-up and large numbers—are insufficiently sensitive to distinguish between two stem designs.
- The variations in femoral geometry are contained within a sufficiently narrow boundary that a multizone off-the-shelf system, in combination with reamers and rasps that can modify a given femur shape, can achieve an accurate fit in the large majority of cases.
- The logistics of producing custom hips involve additional technological steps to determine the 3-D geometry of the femur, such as scaled radiographs (119), CT reconstruction, or even direct shape determination at surgery (160,181), such that there is a significant increase in the cost and administrative steps required, and there may be excessive delay in producing the custom hip.
- It might be found at surgery that the custom hip was an unsatisfactory fit, so that an off-the-shelf system was needed as a back-up.

However, even accounting for the above-mentioned problems, there is still a justification for using custom hips in primary cases and even more so in revisions. It has been shown that very low rates of loosening, even superior to that obtained with cemented stems, can be achieved by using fully porous-coated or HA-coated stems that are fixed tightly into the diaphysis by appropriate reaming. However, proximal stress shielding is an undesirable consequence with this system. If the more preferred proximal stem fixation is required, the fit requirements are more stringent. In this situation, custom hips have an advantage. There is considerable empirical data that interface micromotion is the major cause of pain and bone resorption, and laboratory data have shown that micromotion can be minimized by implants with a close fit to cortical bone (48). Hence, in a large series of cases, custom stems should reduce the incidence of pain and interface radiolucency compared with an off-the-shelf hip design with the same design features (Fig. 100.28). Even if an off-the-shelf hip is used for the more “normal” anatomies, custom stems may still be used for abnormal situations. For revision hip replacements, the variations in the proximal shape after removal of the original stem, the diameter and curvature of the diaphysis below that region, and the required location of the femoral head are so great that a custom approach has a strong justification. Indications for custom hip
replacements are:

- Congenital dislocated hip (CDH), in which the femoral anteverision is in the range of approximately 30° to 60°. The custom stem is designed to fit the canal closely and to restore the normal 15° to 20° of anteverision.
- CDH in which the femoral anteverision is in excess of approximately 60°. Here, a subtrochanteric osteotomy is performed, the upper femur is rotated correctly at surgery, and the custom stem is designed with longitudinal cutting flutes to provide torsional stability across the osteotomy site (Fig. 100.28).
- CDH, juvenile rheumatoid arthritis (JRA), or other conditions in which the hip is exceptionally small or has severely abnormal anatomy (Fig. 100.28).
- In hips that are extremely large, or with large canals, for which the custom hip is made hollow or slotted to reduce the bending stiffness.
- After osteotomy, trauma, or other conditions, with abnormal geometry, sometimes requiring an osteotomy at surgery to restore normal geometrical relations.
- Canals with extreme bowing in either the AP or ML views or with an overhanging greater trochanter, requiring a "banana-shaped" stem.
- In revisions due to the wide range of bony conditions, proximal shape and bone loss, stem length required, anterior bow, distal diameter, and relation between the proximal and distal dimensions. A graduated approach is especially appropriate for revision hip replacements, as described earlier (Fig. 100.27).

In order to design and manufacture a custom hip stem (223), accurate determination of the 3-D canal shape is required (160). The most accurate method is by the use of CT scans (116,184). A number of commercially available software packages can be used to contour the inside and outside cortical bone boundaries, from which a 3-D model of the bone can be generated. The internal contouring requires definition of a suitable Hounsfield number (a value signifying bone density, where 100 equals water and 1000 equals cortical bone) distinguishing the boundary between cancellous and cortical bone. For purposes of reaming and rasping, a value of 500 to 600 has been shown to be suitable. Another method for determining the shape of the femoral canal that is more direct and less expensive but is restricted to femurs of relatively normal shape is to use scaled AP and ML radiographs (119). The canal outlines are digitized and then a 3-D computer model of the "average femur" is numerically distorted so that its canal outline fits that of the specific femur. This method has been shown to be accurate to better than 1 mm in the regions where a close stem fit is required.

Given the shape of the femoral canal, special software is needed to design the stem to a particular scheme. For example, it can be assumed that distal reaming and proximal rasping are performed to produce a more geometric shape for ease of manufacture and surgery. The general principle is such that the major load transmission occurs proximally (116), which results in the following ideal features:

- Medial, lateral, and anterior flares.
- A collar with a coating for osseointegration.
- A close-fitting proximal stem with an osseointegration coating.
- Proximal macrogrooves to minimize micromotion and provide additional bony stability should there be any deterioration of an HA coating.
- A relatively short and smooth distal stem to restrict its function to controlling bending rather than transmitting axial forces.

For economy, convenience, and speed of manufacture of custom hip replacements, prewritten computer numerically controlled (CNC) software is required. This software provides instructions to a milling machine to produce the stem from a bar of preformed material. The end result is an integrated software package that covers both the design and manufacturing stages.

One approach for assessing the relative value of a custom hip system compared with an off-the-shelf system is to assume that accuracy of fit is the single criterion for comparison, and then to determine how many off-the-shelf sizes would be needed to fit the general population of femurs to a given accuracy. This requires that the most ideal set of sizes for the off-the-shelf system be synthesized. The problem can be solved in the following way:

- Produce a "training set" of approximately 100 successive osteoarthritic cases for which custom hip replacements have been produced, excluding shapes that clearly are outliers.
- Define the shape of the stem by p geometric variables, such as coordinates of numerous key points around the stem periphery.
- Use "principal component analysis" to reduce the variables, using linear combinations of the variables that best express the p-dimensional scatterplot of the original variables.
- Synthesize an n-sized system such that if n = 1, that is the geometric mean, and if n > 1, the sizes synthesized provide the best fit for the largest number of the training set.

If such a process is carried out, data such as those shown in Figure 100.29 can be produced. If an accuracy of fit of 0.5 mm or better between the stem and the bone were required, then a 40-sized system would achieve this in just under 50% of all cases. However, if a 1 mm accuracy were satisfactory, a 20-sized system would deal with more than 80% of all cases. Virtually all cases could be dealt with using a 10-sized system if only 1.5 or 2 mm accuracy were required.

**Figure 100.28.** Examples of custom hips used in primary cases, in which the anatomy ranged from normal to grossly abnormal. **Top left:** A custom hip used for normal anatomy. **Top right:** Subtrochanteric osteotomy in a 90° anteverision congenital dislocated hip using longitudinal cutting flutes across the osteotomy. **Bottom:** Grossly abnormal geometry for which CT scans were used to design a tongue-shaped stem and a stereolithographic plastic model was made for preoperative trials.

**Figure 100.29.** Principal component analysis was used to synthesize best fit off-the-shelf hip systems with different numbers of sizes in the system. The percent of cases in the general population fitted to the specified accuracy is shown.
Wear and Friction Measurement and cancellous bone contact. Nevertheless, provided the model is appropriate to the intended question, the FEA method is invaluable for comparing different stems, behavior. Indeed, many models are idealized, showing, for example complete stem–bone contact when, in reality, there is a variable mixture of gaps, as well as cortical situation. An initial proposal for a stem shape can be successively modified to minimize an objective function of the stresses at the interface and in the bone itself. The bone are changed to reflect the local stresses where a region of stem causing a stress concentration is smoothed away. The FEA is then rerun, and the process is iterative analysis, in which the material properties or a stem shape are changed as a result of the first stress analysis. The bone remodeling (such as around the entire distal stem or on the lateral and medial flares. From a practical point of view, contact can be considered to be within a defined values of around 2 to 3 mm from distal to proximal. For uncemented stems, the goal is to achieve stem–cortical contact at those areas determined by the design philosophy, such as around the entire distal stem or on the lateral and medial flares. From a practical point of view, contact can be considered to be within a defined tolerance level such as 0.5 or 1.0 mm (119). In actual evaluations of this type on typical uncemented stems, it has been found that there is only a small percentage of contact with cortical bone.

Migration and Micromotion Studies Typically in migration and micromotion studies, the component is fitted into a plastic or cadaveric bone, cyclic forces are applied to the femoral head in a test machine, and the stem–bone motion is measured over time (193). It has been found that the stem subsides progressively, usually reaching an asymptotic limit after a few hundred cycles. The total subsidence is called “migration.” Thereafter, there is a cyclic elastic deformation between the stem and the bone, termed “micromotion.” The values of micromotion are usually in the range of 10-200 µm (109). It is estimated that a value of about 50 µm is acceptable before interface bone resorption would occur. Generally, better fit, a more anatomic stem, the presence of a lateral flare, and more cortical contact produce less migration and micromotion. To compare different stem designs, use of the same artificial femurs (although it provides reproducibility) might prejudice the results by being a better fit for one particular design; hence, a range of femoral shapes is preferable. The use of cadaveric bones is ideal for realistic geometry and bone properties, but large numbers are needed for statistical significance unless a small number of stems can be successively implanted into the same femur without prejudice.

Finite Element Analysis FEA has the major advantage that the stresses and strains in the entire system can be determined. The data can then be used to predict bone remodeling (201,230), interface failure, stem crack, cement-stem debonding (210), and other factors (113). A relatively recent advance is analytical, in which the material properties or a stem shape are changed as a result of the first stress analysis (114). For example, the elastic modulus values for the bone are changed to reflect the local stresses where a region of stem causing a stress concentration is smoothed away. The FEA is then rerun, and the process is repeated until a steady state is reached. Using this technique, the bone remodeling over time can be simulated, predicting the amount of bone loss in the steady-state situation. An initial proposal for a stem shape can be successively modified to minimize an objective function of the stresses at the interface and in the bone itself. The consequences of progressive cement debonding can be studied. However, there is still considerable skepticism concerning the ability of FEA to predict actual in vivo behavior. Indeed, many models are idealized, showing, for example complete stem–bone contact when, in reality, there is a variable mixture of gaps, as well as cortical and cancellous bone contact. Nevertheless, provided the model is appropriate to the intended question, the FEA method is invaluable for comparing different stems, using such criteria as the stresses, strains, or strain energy density in the system (185).

Methods used to characterize hip stems and to compare stems with each other can be divided into laboratory studies and clinical evaluations.

**Laboratory Evaluation Methods**

**Fit-and-fill Geometric Evaluation** Fit-and-fill geometry involves evaluating the frontal view, sagittal view, and the sectional fits, from a given stem size range, in a representative selection of femurs. The goal with cemented stems is to achieve a uniform cement mantle thickness around each cross section, as well as minimum values of around 2 to 3 mm from distal to proximal. For uncemented stems, the goal is to achieve stem–cortical contact at those areas determined by the design philosophy, such as around the entire distal stem or on the lateral and medial flares. From a practical point of view, contact can be considered to be within a defined tolerance level such as 0.5 or 1.0 mm (119). In actual evaluations of this type on typical uncemented stems, it has been found that there is only a small percentage of contact with cortical bone.

**Clinical Evaluation Methods**

Wear and Friction Measurement Wear and friction measurement is discussed in the next section on clinical evaluation methods.
Clinical Evaluation Methods

Apart from “standard” clinical and outcome studies, clinical evaluation methods (43,123) include migration studies, DEXA scanning, and measurement of wear from radiographs.

Migration Studies The most accurate migration study method is roentgen stereophotogrammetry (RSA), developed by Selvik in Sweden in the 1970s (196). The method involves placing small tantalum beads in the bone at the time of surgery, identifying landmarks in the component, and taking biplanar radiographs through a calibration grid. The juxtaposition of the points to obtain coordinates allows the 3-D position of the component relative to the bone to be calculated to a high degree of accuracy, approximately 0.3 mm and 0.3°. As well as being used for migration over periods of several years, the “inductive” displacement at a particular time has been measured when the patient relaxes and then loads the leg. These data give an idea of the rigidity of the implant-bone interface.

The RSA method must be carried out prospectively. To use retrospective data, where radiographic and clinical data are available for a long follow-up time (e.g., 10 years), simpler methods have been developed using landmarks on the bone and component. In some methods, accuracy is enhanced using mathematical corrections for different x-ray orientations, as well as by using boundary-detection methods. Accuracies of 0.5 mm and 0.5° can be achieved. A typical example of migration curves using such a method is shown in Figure 100.32. It is important to specify when the initial (time zero) measurement was taken because even the first few steps of weight bearing can cause as much migration as in the subsequent 6 months.

From studies of numerous designs of cemented and uncemented hips, it has been found that the migration behavior in the first 2 years correlates with loosening and radiolucency in the longer term (133,222). In particular, stems that are “continuous migrators,” that is, those for which the migration rate at 2 years has not reduced to a very small value to “clinical loosening” on the femoral side. Hence, the method is invaluable for evaluating new hip designs in a short time period. However, it must be recognized that longer term effects such as socket wear, wear of the stem surface, fracture of the cement mantle and of the stem itself, and corrosion or fretting at interfaces are not addressed in such a short study.

DEXA Scanning DEXA scans are usually taken in the AP view to measure the total bone mineral surrounding the implant, the proximomedical region being of particular interest. The method is sensitive, unlike radiographic data from which only general impressions of bone density, or relative density, can be obtained (201). Great care is needed in the interpretation of DEXA data. Bone density can decrease in the postoperative months owing to the patient’s a low activity level, and drugs can also have an effect. Large bone density changes are often apparent only after several years, although 2-year data would identify an implant with severe changes. Another factor is that whereas subsequent changes in bone density can depend on the initial stresses, calculated, for example, by FEA, if radiolucency subsequently develops due to interface problems, the stress distribution on and in the bone can change as a result.

Measurement of Wear from Radiographs At this time, the accumulation of wear debris and the subsequent osteolysis and loosening are the major limitations to durability of total hip replacements (69,86). Literally millions of particles are released on every step. The particles consist of granules released from the tops of asperities and ridges, or fibrils pulled away as small filaments. Particle size ranges from 0.1 to 1 µm. The method is quantitative, unlike radiographic data from which only general impressions of bone density, or relative density, can be obtained (201). Great care is needed in the interpretation of DEXA data. Bone density can decrease in the postoperative months owing to the patient’s a low activity level, and drugs can also have an effect. Large bone density changes are often apparent only after several years, although 2-year data would identify an implant with severe changes. Another factor is that whereas subsequent changes in bone density can depend on the initial stresses, calculated, for example, by FEA, if radiolucency subsequently develops due to interface problems, the stress distribution on and in the bone can change as a result.

Measurement of Wear from Radiographs At this time, the accumulation of wear debris and the subsequent osteolysis and loosening are the major limitations to durability of total hip replacements (69,86). Literally millions of particles are released on every step. The particles consist of granules released from the tops of asperities and ridges, or fibrils pulled away as small filaments. Particle size ranges from 0.1 to 1 µm (137). The wear rates, measured as the linear penetration into the socket, have averaged 0.05 to 1.0 mm per year for 22 mm joints, but the ranges in given series have varied considerably (96). Determining the effect of different variables on wear rate is difficult. In the laboratory, the test conditions are greatly simplified, but aging effects of the materials that occur in the bone are not easily reproduced. In vivo, there are numerous variables, many of which cannot be accurately quantified. The main factors that affect the wear factor and the rate of wear in total hip replacements are the diameter (149), surface finish, and material of the femoral head, as well as polyethylene processing and patient factors.

- The Diameter of the Femoral Head. From the basic wear equations:
  \[ \text{wear rate} = \text{wear factor} \times \text{load} \times \text{sliding velocity} \]
  \[ \text{wear volume} = \text{wear factor} \times \text{load} \times \text{sliding distance} \]

  the volume of wear is proportional to the diameter, and the penetration is inversely proportional to the diameter of the femoral head. Penetration into the socket itself is not a problem except when it begins to cause impingement, which can then loosen the socket or result in dislocation. For 22 mm heads, these problems may occur in long follow-ups in heavy and active patients if the wear factor is unusually high. It is noted that the wear equations assume that the wear rate is independent of both surface area and contact pressure, which may be a reasonable assumption for the ranges encountered in hip joints (148,149).

- Surface Finish of the Head. Metallic femoral heads are manufactured with an exceedingly high polish of Ra value 0.01 to 0.02 µm. Ra is the mean value of the peaks and troughs with respect to a mean line (82). In a new head, asperities, projecting from the surface, are not present, except those made of materials such as cast cobalt-chrome. Hard carbides at grain boundaries can resist polishing and be slightly prominent. However, at surgery, the head can become scratched owing to the impingement of instruments or hard particles embedded in the impactor. In the patient, the head can become scratched by hard particles from a number of sources: The UHMWPE can have contaminants; the cement can release barium sulfate; the stem surface can shed metallic debris or HA from coatings (26); or bone particles can be present from surgery. The head itself can release hard particles due to rubbing. As well as becoming temporarily trapped between the bearing surfaces, particles can embed in the plastic, causing multiple scratches on the head. The end result is that the number of scratches on the head can accumulate over time. Typically, the Ra value of retrieved heads compared with new heads is two to three times higher for cobalt-chrome, higher still for stainless steel, and highest for titanium alloy. In contrast, the Ra value of ceramic heads changes little over time. Scratches with cutting edges above the mean are the most damaging, however. Over time, the wear factor K will increase due to the scratching. However, the penetration rate into sockets over time may still approximate to linear if the patient gradually reduces his or her activity level.

- Femoral Head Material. In general, the harder and more wearable the material, and the better the initial surface finish, the less the wear. Alumina ceramics against UHMWPE have had a long history of clinical use and have shown wear rates approximately half those of metal on UHMWPE, which has been confirmed in hip simulator studies (237). Zirconia ceramics have a similar record, although with shorter follow-up at this time. However, zirconia is tougher than alumina and would probably be recommended over alumina. Alumina ceramic-on-ceramic bearings have shown exceedingly low wear rates, one to two orders of magnitude lower in calcium than for metal or ceramic on UHMWPE. Zirconia-on-zirconia is not viable. The main drawbacks of ceramics are that stringent tolerances are required for the trunnions and for the bearing geometry itself, and a number of breakages of ceramic heads have been reported, although the incidence is well below 1%. Overall, the use of ceramic bearings from proven sources offer definite advantages, especially for younger and more active patients. Metal-on-metal bearings, using cobalt-chrome alloys, have likewise shown exceedingly low volumetric wear over long time periods. The reservations against more widespread use of these alloys are the unknown long-term linear systemic effects of metallic ions, although no adverse effects have yet been demonstrated in McKee-Farrar hip replacements, which have had more than 2 decades of follow-up. Metal-on-metal components can be designed with thin sections, which is an advantage for surface replication.

- Processing of Polyethylene. In recent years, a great deal has been learned about the effects of gamma irradiation, most notably molecular chain scission and cross-linking (81). The latter can be due to oxidation over time when components are stored for several years before use or in service conditions. This factor, in turn, causes an increase in density, a degradation of mechanical properties, and a reduction in wear resistance. In such cases, retrieved sockets have shown a “white band” of degraded polyethylene at or just below the surface. In laboratory tests, the wear factor increases progressively with oxidation level. At this time, when gamma-irradiation is used for sterilization, the irradiation, together with the packaging, is carried out in an inert atmosphere to avoid the effect of oxygen. Other sterilization methods, such as ethylene oxide (ETO) and gas plasma, avoid chain scission and oxidation, and evidently reduce the wear factor. However, more recently, methods for minimizing the progress of oxidation have been developed. The free radicals produced by gamma-irradiation or by electron beam irradiation have been cross-linked by various postirradiation treatments such as controlled heating. The reductions in the wear factor have been dramatic, as measured in hip-simulating machines. However, with some processing methods, there is a reduction in mechanical properties so that suitable fatigue testing of
components is needed.

- Patient Factors. The wear rate will increase with the weight and activity level of the patient, and even the type of activity might have an effect. However, in radiographic studies of wear penetration, or studies of retrieved sockets, obtaining significance for a particular variable has proven difficult because of the effects of many other variables and the unknowns involved. Care must be taken to distinguish between wear factor K, which is a constant for that bearing (as long as the bearing does not change); wear rate, which depends on weight and activity level; and wear volume, which is the average wear rate times time.

Hip-Simulating Machines

Hip simulators have been used for more than 30 years to measure wear rates. Today, data from such machines are a requirement for the introduction of a new bearing combination. The proposed test method by the International Organization for Standardization (ISO) includes

- A physiologic single-axis force cycle in a direction fixed in the acetabulum.
- Three independent motion curves applied to the femur: flexion-extension, inward-outward rotation, and abduction-adduction (Fig. 100.4 and Fig. 100.20).
- Twenty-five percent calf serum at 37°C.
- Tests run at 1 Hz for 5 million cycles.
- Dimensional and weight changes measured at intervals.

The major goals in specifying such a standard are to provide a method that produces results sufficiently representative of in vivo conditions and to allow for comparative data between different laboratories. No single test can, for practical reasons, reproduce physiologic conditions, which involve a range of activities and a host of other variables. The wide range of conditions in the patient population means that the results of a test must be viewed statistically and not in an absolute sense. A comparative test of a new bearing against a known standard is therefore necessary. Another factor is that, as with all wear tests, there can be a wide spread of results from nominally the same bearing, which has led to the requirement for multichannel machines (Fig. 100.33).

Figure 100.33. A multistation AMTI-Boston hip simulating machine for long-term hip wear testing. The machine includes computer monitoring of the input forces and motions as well as other test parameters. (Photo courtesy Advanced Medical Technology, Inc., Watertown, MA.)

As hip simulators have evolved over the past two decades, several different mechanical configurations have been developed:

- The femur and acetabulum are either anatomically positioned (ideal for particle transport) or inverted (easier experimentally).
- The force is applied relative to the socket or to the femur (in reality, the force is more closely aligned with the femur).
- Independent motions about one, two, or three axes are applied. To assess this motion, the paths of multiple points on the femoral head traversing over the plastic socket can be mapped (211). Only for three independent motions do the patterns of the points resemble the physiologic patterns, namely loops that cross over each other. This is embodied in the present AMTI (Advanced Medical Technology, Inc., Watertown, MA) machine. However, two motions, as long as they are not in phase, will produce crossing loops but of different shape that can achieve similar wear rates. This type of motion applies to the McKellop and to the recent Leeds machines. Single-axis motion is inadequate in that straight or curved tracks are produced that do not cross over one another, and hence the wear rates are too low.

In recent years, it has been recognized that in addition to carrying out tests under ideal conditions, more adverse conditions need to be addressed. The effect on the wear rate of scratches on the femoral head or of hard particles introduced into the fluid are particularly important.

KNEE REPLACEMENT

KNEE MECHANICS

The general conception of normal knee motion is usually derived from the measurements of "passive motion" of knee specimens when the external forces are small (228). The tibia has either been passively flexed and held at successive flexion angles, or a small flexion moment has been applied, balanced by a force in the quadriceps (97,183). The motion itself has been described in several different ways, which has led to a number of misunderstandings. The "contact points" are defined as the common tangent of the femoral and tibial outlines, as seen on radiographs (although in reality only the bone outlines and not the cartilage outlines can be seen). These contact points displace posteriorly, with the lateral contact point moving much more than the medial (134,183) (Fig. 100.34). If the actual contact areas were plotted, however, although the areas would follow the same trend as the "points," it would be difficult to define a point directly from the areas because the areas are of irregular shape and occur on both the cartilage and the menisci (2). Motion can also be described by defining axes in the femur, the transverse axis being through the centers of the lateral and medial posterior femoral condyles, or the epondyляр line. If the motion of the femoral origin at the center of the femur were plotted as a function of flexion, it, too, would move posteriorly with flexion, whereas the transverse x-axis would tilt slightly. This rigid body motion would not be the same as that determined from the contact points. For example, in a total knee replacement (TKR) seen in the sagittal view, it can readily be observed that if the tibial surface is too low, the femoral origin at the center of the femur would move posteriorly (Fig. 100.34). As the knee is flexed from 0° to 120°, there is a posterior femoral displacement and internal tibial rotation about its y-axis. There is also a valgus rotation of the femur as the lateral femoral condyle moves down the slope of the tibial plateau. This motion is governed by the shape of the condylar surfaces, the different mobility of the menisci on the lateral and medial sides (219), and the locations and stiffnesses of the cruciate and collateral (especially the medial) ligaments (5,41,88,89,183,199,207,241). This "passive motion" of the knee is useful for

Figure 100.34. Three methods for describing passive knee motion. Top: The contact points defined by the common tangent. Center: The contact areas. Lower: Rigid body motion of the femur relative to the tibia, based on axes defined in the femur and tibia. (Data from Rovick JS, Reuben JD, Schrager RJ, Walker PS. Relation Between Knee Motion and Ligament Length Patterns. Clin Biomech 1991;6:213.)

The passive motion of the knee can now be summarized in rigid body terms, with the axes as defined in Figure 100.34. As the knee is flexed from 0° to 120°, there is a posterior femoral displacement and internal tibial rotation about its y-axis. There is also a valgus rotation of the femur as the lateral femoral condyle moves down the slope of the tibial plateau. This motion is governed by the shape of the condylar surfaces, the different mobility of the menisci on the lateral and medial sides (219), and the locations and stiffnesses of the cruciate and collateral (especially the medial) ligaments (5,41,88,89,183,199,207,241). This "passive motion" of the knee is useful for
describing a middle path of knee motion for reference purposes.

Three effects will change this motion path considerably:

- An AP force or an internal-external torque is applied to the tibia about its y-axis at a given flexion angle (88.229) (Fig. 100.35). This produces displacements and rotations, which are termed laxity (108.123). The laxity is reasonably constant from about 30° to 120° of flexion but reduces as the knee is extended from 30°. An envelope of passive motion, defined as the boundaries within which the knee position can lie (24.25), is thus obtained.

![Figure 100.35. The torque-rotation curves at different flexion angles describe the rotational laxity of the knee. A composite of the rotations describes the envelope of knee motion. Note that the x-axis represents the neutral rotation at that angle of flexion. The neutral positions relative to zero flexion change at subsequent flexion angles.](image)

- An AP force is applied to the tibia along its z-axis, and then an internal-external torque about the y-axis is applied. The rotational laxity is reduced. Similarly, if the torque is applied first, the AP laxity is reduced. This is termed coupled motion (143.172). In the extreme positions, the laxities can be reduced to very small values.

- A compressive force is applied along the tibial y-axis. The laxities are now reduced, AP laxity (158) more so than rotational laxity (157). The mechanism is that the dishing of the joint surfaces and the deformation of the surfaces require that the joint displace upward to move from its neutral position, thus requiring energy input. In the normal knee, frictional effects due to the compressive force are small.

In functional activities (7.73.132), the knee motion occurs within the envelopes of laxity. An infinite number of motion paths is possible; these paths are likely to vary even between successive steps (184). The major factors that determine the actual motion path are the external forces and the muscle forces (138). Whereas the principal force direction across the knee is along the long axis of the tibia, the combination of the applied forces results in shear forces and torques (Fig. 100.36).

These force components have been calculated using measured values of the foot-to-ground force, the limb segment kinematics, and electromyography (EMG) data of muscle action, input to a knee model (136.155.156 and 157). In a recent study, telemetry data from an instrumented distal femoral replacement was used (206). During walking, there are three peak forces of 2 to 3 BW. The shear forces act in both anterior and posterior directions, with posterior being predominant, in a direction so as to tense the PCL. The torque is predominantly internal, the effect being to move the lateral tibial plateau forward. The forces do not increase dramatically for ascending and descending stairs, the largest increase of about 15% in the compressive force occurring in descending stairs (156). The patellofemoral forces are just less than half BW in walking but reach approximately 1 BW or more in rising from a chair or climbing stairs. The axial torques in level walking and on stairs are in the range of 6 to 8 Nm.

![Figure 100.36. The flexion angle, forces, and moments acting across the knee during normal walking, as specified in a current ISO-proposed standard for knee-simulating machines. These forces are distributed to the joint surfaces and to the ligaments.](image)

**CONDYLAR REPLACEMENTS—FIXED BEARING**

The most obvious form for a TKR is a replacement of the bearing surfaces using metal and plastic components, positioned so as to restore the neutral alignment of the knee and achieve the correct tensions in the ligaments (121). The simplest form is a compartmental type (a “uni”), which is applicable if the patellofemoral surfaces do not require replacement (65). Most often, only the medial side is required, but replacement of both sides as an alternative to a TKR has been used extensively in some centers. Some of the issues concerning compartmental knees are the following:

- When both the anterior cruciate ligament (ACL) and PCL are present and the components are correctly sized and positioned, the function is close to normal (231).
- When the ACL is absent (19), abnormal motion and even instability occur (92).
- Most designs have had a close-to-flat tibial surface, with a high sensitivity to the slope in the sagittal plane.
- The flat tibial surface, thin plastic, and metal backing have led to severe wear problems in some designs.
- Molded polyethylene flat components that are not metal backed have survived for long periods (up to 20 years) without serious wear (102).
- Loosening has been a problem, especially when the subchondral bone has been removed and there has been excessive AP sliding.
- Surgical placement has been difficult in the absence of a precise instrumentation system.

On the basis that the AP movement of the contact point on the medial side is small, it appears logical to provide a dished tibial surface, which would alleviate a number of the above problems. Improved designs and instrumentation, coupled with small incisions, present an important opportunity for outpatient surgery in the appropriate indications.

One-piece tibial and femoral components covering both compartments are able to provide stable fixation, are self-aligning, and incorporate the patellofemoral surfaces; for these reasons, such designs are the most frequently used. A fundamental principle of condylar replacement is that the artificial surfaces are designed such that, in combination with the remaining joint structures, the laxity and stability characteristics are similar to those of the normal intact knee (144). In general terms, if all of the ligaments are preserved, the tibial surface requires only shallow dishing (Fig. 100.37). If the ACL is absent, posterior curvature is required (although in most designs there is insufficient curvature to compensate for the ACL). If both cruciate ligaments are absent, posterior and anterior curvatures are required (85).
The AP shear force is shared between the cruciate ligaments and, to a lesser extent, other ligaments and soft tissues, and the reaction forces at the joint surfaces (19). The ACL is more tense in early flexion, and the PCL is more tense in high flexion (183). The fraction of the shear force carried by the cruciate ligaments depends on the tibial surface geometry, the location of the "bottom of the dish," and the placement of the components. Even modest dishing of the tibial surface (e.g., sagittal radius, 70 to 80 mm) provides considerable stability, especially when high compressive forces of 2 to 3 BW are exerted (144,214). In TKRs in which the PCL is preserved, the fraction of the shear force carried by the PCL depends on the curvature of the tibial surface, the curvature of the interfacing femoral surface (which depends on the angle of flexion), the location of the bottom of the tibial dish, the tightness of the PCL (which depends on the surgery), and the angle of flexion (69). In practice, the PCL, especially the anterior fibers, carry an increasing proportion of the anterior shear force with flexion (129). The different schemes for condylar TKR design have advantages and disadvantages:

- Combined ACL and PCL preservation (assuming the knee has both) requires condylar shapes and surgical placement within approximately 2 mm of ideal to be effective. The tibial component must leave space for both ligaments, and surgical exposure is more restricted.
- PCL preservation alone may result in an abnormally posterior contact point in early flexion (68), and there is no mechanism for producing anterior displacement of the femur as the knee extends.
- ACL and PCL sacrifice requires condylar shapes (or cams) with excessive rotational constraint under weight-bearing conditions. The AP displacement is limited, although an intercondylar cam may produce posterior femoral motion in high flexion.

A valid and reproducible method is needed for the bone cuts and for performing ligament releases to achieve ideal kinematic and stability characteristics. This condition applies more especially when one or both cruciate ligaments are preserved.

The basic principles of the stability and laxity of a well-designed TKR, as embodied in the original Total Condylar (Howmedica, Rutherford, NJ) (213,215,228) and in a number of other later designs, is shown in Figure 100.37. If there is a compressive force V acting down the long axis of the tibia, the femoral component locates at the bottom of the tibial dish. If a shear force S is superimposed, the femoral component displaces anteriorly such that the reaction force at the contact point exactly balances V and S. The contact point displacement is greater than the rigid body displacement. A torque applied to the tibia is equilibrated by an anterior displacement of one side of the knee and a posterior displacement of the other. The torque Q carried by the surfaces is $Q = S \times BS$, where BS is the bearing spacing. The total condylar type of design thus provides both stability and laxity, and has the advantages of moderate conformity for low wear, simplicity, and ease of surgery.

An interesting variation of a standard total condylar concept is an evolution of the Freeman and Freeman-Samuelson (Protek) designs (86). The medial side is almost fully conforming, whereas the lateral side has low conformity. This has the potential advantages of achieving physiologic motion and reducing wear on the more heavily loaded medial side.

In coupled motion, when AP displacement and internal-external rotation are combined, the laxity curves of a TKR are complex (Fig. 100.38). In neutral rotation, an AP laxity test, in which an anterior shear force is applied to the femur followed by a posterior shear force, produces anterior and posterior femoral displacements. As shown in Figure 100.38, when there is greater conformity anteriorly, the anterior femoral displacement is less. When rotation is superimposed, one condyle moves more than the other. The torque Q carried by the surfaces is $Q = S \times BS$, where BS is the bearing spacing. The total condylar type of design thus provides both stability and laxity, and has the advantages of moderate conformity for low wear, simplicity, and ease of surgery.

Another important effect on kinematics is friction between the femoral and tibial surfaces (188) (Fig. 100.39). The coefficient of friction for metal on polyethylene surfaces is 0.05 to 0.1. For a condylar prosthesis implanted in a knee, without friction, the laxity curve would be strain stiffening (Fig. 100.14) with a hysteresis loop. However, owing to friction when a compressive force is acting and the shear force direction is reversed, as occurs during the gait cycle, there is a "stick" period without motion. In function, this will result in some erratic behavior of the motion, with combinations of rolling, sliding, and stick.
Based on the above-mentioned factors, it can be seen that the geometric parameters of a TKR play an important role in determining function and durability. The geometric considerations can be broadly categorized as being in the sagittal plane or the frontal plane.

**Sagittal Plane**

Geometric considerations in the sagittal plane consist of the following:

- The profile of the patellar flange replicates normal to produce correct quadriceps lever arms (7). Gait abnormalities (19) have been associated with profiles that are too prominent distal-anteriorly (8).
- The distal radius of the femoral component is larger than the posterior radius to provide greater stability and larger contact areas in early flexion.
- If the posterior-distal transition angle (PDTA) is about 20°, the large distal radius contacts the tibia during the stance phase of gait, maintaining relatively low contact pressures. However, this will result in a tendency for anterior sliding of the femur after 20° (Fig. 100.38).
- The posterior radius is similar to the anatomic radius (approximately 20 mm average) to maintain correct soft tissue lengths. This will result in increased laxity in flexion compared with extension, as in the normal knee.
- When the femur locates at the bottom of the tibial dish the radius in early flexion, the femur and tibia are in the correct anatomic relation to ensure normal patella and soft-tissue mechanics.
- As the knee moves to zero flexion and into slight hyperextension, the contact point rolls anteriorly to provide an increased lever arm for the hamstrings and gastrocnemius.

**Frontal Plane**

Geometric considerations in the frontal plane consist of the following:

- The bearing spacing (Fig. 100.40) determines the varus-valgus moment before lift-off, and affects the feasibility of interchangeability between different sizes in TKR systems. A larger BS value is preferable.
- The inner femoral radius (RIF; Fig. 100.40) is determined by the requirement to provide an anatomical patellar groove.
- The outer femoral radius (ROF; Fig. 100.40) needs to be between approximately 25 mm and the sagittal tibial radius, which is 55 to 80 mm in contemporary designs. This is required to avoid the outside of the femoral condyles digging in during internal-external rotation.
- A femorotibial radial clearance of only 1 to 2 mm produces elliptically shaped contact areas with relatively low contact stresses.
- For a given clearance between the femoral and tibial radii, larger outer radii (ROF, ROT; Fig. 100.40) have the advantage of a larger area of contact and reduced contact stresses.
- When lateral lift-off occurs, the contact point for large radius surfaces will roll medially, counteracting further lift-off. In extreme cases, there may be some tendency to ML slipping. For a given clearance, there is a critical varus angle at which digging in occurs.
- When lateral lift-off occurs, the small radius surfaces rotates about the center of curvature and the contact point remains constant. ML stability is maintained.
- For a given clearance between the femoral and tibial radii, surfaces of larger radius provide increased rotational laxity.

Experience with some condylar designs in the past 25 years (11) has shown satisfactory function and a survivorship of better than 95% at 10 years (78,130,178). However, other designs have shown serious problems, such as instability (including ML), tibial baseplate fracture, excessive wear and deformation, patella subluxation, limited flexion, and component loosening. In many cases, the problems have been related to unsatisfactory geometric features of design; in other cases, alignment has been the main problem (169,208).

**STABILIZED OR GUIDED-MOTION DESIGNS**

In the total condylar type of knee prosthesis, stability is provided by the articular surfaces and the retained ligaments. The motion of the femorotibial contact point is hence determined by these factors, in response to the external forces and the muscle forces. As indicated previously, designs with shallow tibial surfaces and preservation of both cruciate ligaments have the theoretical capability of reproducing normal kinematics. Fluoroscopic techniques have been used to record relative tibial and femoral knee motion during a range of activities. The method involves sequential high-resolution fluoroscopic images obtained in the sagittal plane. If the 3-D shape of the femoral and tibial components is known and input to the computer, then the computer image can be moved into a 3-D orientation so as to match the radiographic image. In this way, the relative 3-D position of the femur on the tibia can be determined throughout the activity. The accuracy of such methods is now better than 1 mm and 1°. Interestingly, this method was originally developed for the military to identify high-flying aircraft.

Fluoroscopic studies of TKR patients (13,68,204) have shown the following:

- The smooth AP and rotation patterns measured in passive knee motion are not reproduced during weight-bearing activities, such as deep-knee bends and step climbing.
- The AP motion between the femur and the tibia is strongly influenced by the ground-to-foot and muscle forces.
- There are considerable differences in the AP motion between different individuals. Even the same individual produces variable AP motion for the same activity at different times.
- TKRs with high femorotibial conformity in the sagittal plane show more reproducible AP motion.
- Condylar lift-off, mostly medial, occurs often, and it is more frequent and of greater magnitude with PCL-resecting devices and when the BS (Fig. 100.40) is low.

There is thus a rationale for designing condylar knees that control relative femorotibial motion in a more predictable way, at least during part of the flexion range. One scheme for controlling the kinematics is by the use of intercondylar cams.

Two cam types have been used since the 1970s. The first is embodied in the Kinematic (now the Kinemax) Stabiliser (Howmedica, Rutherford, NJ) (79) (Fig. 100.41), which consists of cam surfaces that are in contact throughout flexion and produce a progressively posterior movement of the femorotibial contact point with increasing knee flexion. The second type is used in the Posterior Stabilised Knee (Zimmer, Warsaw, IN), in which the cams interact only after about 70° flexion (233), thereafter producing a large posterior displacement of the contact point. The aims of these particular designs were to:
Figure 100.41. Examples of early guided-motion knees, in which certain phases of the AP motion are controlled by intercondylar cams. Top: Kinematic (now Kinemax) Stabiliser (Howmedica, Rutherford, NJ). Bottom: Posterior Stabilised Knee (Zimmer, Warsaw, IN).

- Increase the quadriceps lever arm at high flexion angles.
- Increase the range of flexion by preventing posterior impingement of bone and soft tissues
- Prevent posterior tibial subluxation in flexion under the action of the hamstrings

Important mechanical criteria concerning the cam design are as follows:

- The height of the contact points on the plastic cam should be minimized to minimize the rocking moments on the tibial component, and to reduce the possibility of fracture of the plastic post and component loosening.
- The cam should be shaped to allow internal-external rotation without digging in at the corners
- The amount of elevation of the femoral component before dislocation occurs ("hop height") should be maximized.

However, if cams or guide surfaces, in combination with the condylar bearing surfaces themselves, are to provide ideal knee kinematics, the following criteria can be added:

- The device should control the location of the femorotibial contact points in the AP direction and internal-external rotation throughout the flexion range but allow some laxity about these contact points.
- The device should guide the contact points posteriorly with flexion (especially on the lateral side) and anteriorly with extension.
- The device should produce internal tibial rotation progressively with flexion and external rotation with extension.

The rationale is to provide optimal muscle lever arms and soft-tissue tensions to restore optimal function as closely as possible. By using special computer programs (225), the designs shown in Figure 100.41 and other types of intercondylar guide surfaces with different patterns of motion control can be synthesized (Fig. 100.42).

Another useful configuration occurs when the femoral guide surface is an eccentric circle and the tibial guide surface is a saddle (225). This can provide AP motion control in different parts of the flexion range (Fig. 100.43). By defining and varying geometric parameters of the above-mentioned types, different AP control patterns can be achieved. In another design using intercondylar guide surfaces (69), the saddle moved the contact from anterior to posterior during flexion, the second part of flexion using a ball-in-socket. In another design (76), the saddle shape was such as to induce pure rolling during flexion and extension.

Other designs have been introduced in which anterior femorotibial contact in early flexion and posterior contact in late flexion have been achieved using separate pairs of bearing surfaces. The TRAC (Biomet, Inc., Warsaw, IN) uses intercondylar guide surfaces, shown at the lower left of Figure 100.42, to transfer the contact from the first pair of bearing surfaces to the second. The Bi-Articular (Kyocera, Kyoto, Japan) uses conventional total condylar bearing surfaces until about 90° of flexion. On further flexion, intercondylar surfaces of spherical shape, which are posteriorly located, interact. The goals are maximum flexion and freedom of internal-external rotation.

MOBILE BEARING DESIGNS

The term “meniscal bearing” is used for a plastic bearing used on one side of the joint (69) (usually medial). A “mobile bearing” is a plastic bearing that includes both the medial and lateral compartments. A “mobile bearing knee” has come to mean any unicompartmental or total knee replacement incorporating a meniscal bearing or a mobile bearing (63). The purposes of a mobile bearing knee (Fig. 100.43) are to minimize the wear of the plastic and to allow relatively unrestrained motion to occur between the femur and the tibia.

Figure 100.43. Schemes for mobile bearing knees: A: unicompartimental (Oxford Knee, Biomet, Inc., Warsaw, IN); B: LCS (Depuy-J&J, Warsaw, IN), or Minns
In concept, the components model the scheme of the natural knee such that nonconforming main bearing surfaces, which allow freedom of motion, have menisci interposed to increase the contact area (2,219). The deformability of the menisci allows for changing femorotibial geometry during flexion while still maintaining a large contact area. The constraint of a mobile bearing knee compared with a natural knee is less on the medial side and more on the lateral side.

There are two schemes for the femorotibial bearing surfaces:

1. Complete conformity throughout the full range of flexion. This is achieved in the Oxford (Biomet, Warsaw, IN) unicompartmental design, using spherical surfaces (53). However, this modular design does not provide for the patellofemoral joint. The Polyziodes Rotaglide (Corin Orthopaedic, Gloucesteshire, United Kingdom) (173) has total condylar type components, but the femoral and tibial bearing surfaces are spherical, giving full contact throughout flexion from just anterior of the bottom of the tibial dish to the posterior tibial surface. There is a normal patellar flange. A recent design that achieves full contact from the anterior to the posterior of the tibial bearing surface is the MBK (Zimmer, Warsaw, IN) (225). This is achieved by notches in the medial and lateral sides of the femoral component (Fig. 100.43). The advantage of this scheme is the larger contact area and the resistance to anterior subluxation of the femur on the tibia.

2. Complete conformity in early flexion but partial conformity at higher flexion. One example is the LCS (DePuy-J&J, Warsaw, IN) (37). The reason for this compromise is to allow for a femoral component design of reasonably anatomic sagittal geometry with a radius that is larger distally than posteriorly. Full conformity is achieved during the major part of a level walking cycle, whereas partial conformity is restricted to the less frequent activities requiring higher flexion.

Until more data are available from knee simulator testing, it is not possible to assert which scheme will produce the least wear and plastic damage over the long term. However, surface wear, pitting, and delamination wear must all be considered in any comparison.

Concerning the design scheme of the meniscal or mobile bearings, there are four fundamentally different arrangements (Fig. 100.43 and Fig. 100.44):

1. The plastic menisci are separate and are free to slide and rotate on their own metal plates (e.g., the Oxford). Even though this allows for the maximum freedom of motion, there is the possibility of bearing dislocation or excessive posterior overhang. In this simple type of design, components with a minimum thickness of 4 mm can be used.
2. The plastic menisci are separate and slide in curved (LCS) (DePuy-J&J, Warsaw, IN) or straight (Minns, Zimmer, Swindon, UK) tracks in a one-piece metal baseplate. Suitable clearances in the slots allow for combined sliding and rotation. The possibility of bearing dislocation is reduced, but overhang is still possible. Because of the slots, the overall component thickness has to be increased.
3. An one-piece mobile bearing is free to rotate about a central pivot. This factor eliminates the uncertainty of rotational placement at surgery and allows rotational freedom in function. However, when rotation occurs, the lateral side moves posteriorly and the medial side moves anteriorly, which does not resemble anatomic motion where the contact on the medial side remains reasonably constant. This problem can be solved by using a medial pivot at the expense of requiring left and right components.
4. A one-piece mobile bearing is free to rotate and free to translate AP. This bearing can accommodate anatomic motion, with an effective center of rotation on the medial side. The posterior displacement during flexion can be provided by a retained PCL or by muscle action. However, as with a fixed-bearing knee with a shallow tibial surface, in early flexion, the femoral component may not be sufficiently anterior.

Additional configurations of the above-mentioned schemes are possible to achieve roll-back with flexion and even roll-forward with extension. A posterior stabilized arrangement can be used, but this would require partially conforming femorotibial bearing surfaces. Guide surfaces, such as those described earlier, can interact between the femoral component and the metal tibial baseplate. This is applicable to either partially or fully conforming bearing geometry.

Comparisons can be made between the fixed and mobile knee bearing types:

- The kinematic analog of a meniscal bearing knee (such as the Oxford used on the medial and lateral sides) is a fixed bearing with shallow or flat tibial surfaces. In this case, the mobile bearing is preferable because the fixed-bearing plastic is liable to excessive deformation and wear in the long term owing to high contact stresses. At the same time, if UHMWPE can be made with enhanced resistance to wear and delamination, the two schemes become comparable.
- The wear in a moderate-high conforming fixed bearing may be comparable with that in a mobile bearing. The fixed bearing, however, is too constrained in AP and rotation, whereas the mobile bearing has increased laxity and a variable neutral position, both of which are advantages.

A final point is that (at the time of writing) there are no reliable data on the wear rates, and the types of particles generated as a function of contact area and contact pressure. Hence, comparisons between different designs must be determined by simulator tests rather than automatically assuming that larger contact areas are an advantage, as has been commonly done in the last decade.

**LINKED DESIGNS**

Over the years, numerous different linked designs have been introduced, which reflects more the opportunity for inventive design rather than extensive need. The largest numbers continue to be used in Europe, whereas in the United States, the tendency is to use the most conservative design whenever possible, even if substantial soft-tissue balancing is required. The characteristics of a linked design are:

- Stability is provided in all degrees of freedom, varus-valgus and hyperextension being particularly important, although there can be some laxity (e.g., rotational) in one or more degrees of freedom.
- A linkage of some type, such as a hinge, provides the stability and prevents subluxation or dissociation
- Intramedullary stems are required for fixation.

The most conservative type of linked TKR is the intercondylar hinge (Fig. 100.45). The linkage is housed in the intercondylar region, preserving the condyles on each side (9). Versions of this type include the Attenborough (9), the St. Georg Endo (Waldemar-Link, Germany) model, the Sheehan (Howmedica, Rutherford, NJ), the Rotaflex (JJ Orthopaedics, Warsaw, IN), and the PFC S-ROM (J&J Orthopaedics, Warsaw, IN). The bearing surfaces can be extended to the full width of the knee, an advantage for reducing varus-valgus bending moments on the linkage. The patellofemoral resurfacing has been absent in some designs but ideally should be included. Advantages of the intercondylar design are:

---

(Zimmer, Warsaw, IN) with separate plastic components in tracks; C: LCS rotating platform; D: MBK (Zimmer, Warsaw, IN) with fully conforming femorotibial surfaces.

---

Figure 100.44. For one-piece plastic components, there are several mechanical schemes for obtaining different femoral-tibial motions. For the axis plus slot, if the medial structures are tighter than the lateral, the axis of rotation can be variable and lie in the region found for the natural knee (shaded).

1. The plastic menisci are separate and are free to slide and rotate on their own metal plates (e.g., the Oxford). Even though this allows for the maximum freedom of motion, there is the possibility of bearing dislocation or excessive posterior overhang. In this simple type of design, components with a minimum thickness of 4 mm can be used.
2. The plastic menisci are separate and slide in curved (LCS) (DePuy-J&J, Warsaw, IN) or straight (Minns, Zimmer, Swindon, UK) tracks in a one-piece metal baseplate. Suitable clearances in the slots allow for combined sliding and rotation. The possibility of bearing dislocation is reduced, but overhang is still possible. Because of the slots, the overall component thickness has to be increased.
3. A one-piece mobile bearing is free to rotate about a central pivot. This factor eliminates the uncertainty of rotational placement at surgery and allows rotational freedom in function. However, when rotation occurs, the lateral side moves posteriorly and the medial side moves anteriorly, which does not resemble anatomic motion where the contact on the medial side remains reasonably constant. This problem can be solved by using a medial pivot at the expense of requiring left and right components.
4. A one-piece mobile bearing is free to rotate and free to translate AP. This bearing can accommodate anatomic motion, with an effective center of rotation on the medial side. The posterior displacement during flexion can be provided by a retained PCL or by muscle action. However, as with a fixed-bearing knee with a shallow tibial surface, in early flexion, the femoral component may not be sufficiently anterior.

Additional configurations of the above-mentioned schemes are possible to achieve roll-back with flexion and even roll-forward with extension. A posterior stabilized arrangement can be used, but this would require partially conforming femorotibial bearing surfaces. Guide surfaces, such as those described earlier, can interact between the femoral component and the metal tibial baseplate. This is applicable to either partially or fully conforming bearing geometry.

Comparisons can be made between the fixed and mobile knee bearing types:

- The kinematic analog of a meniscal bearing knee (such as the Oxford used on the medial and lateral sides) is a fixed bearing with shallow or flat tibial surfaces. In this case, the mobile bearing is preferable because the fixed-bearing plastic is liable to excessive deformation and wear in the long term owing to high contact stresses. At the same time, if UHMWPE can be made with enhanced resistance to wear and delamination, the two schemes become comparable.
- The wear in a moderate-high conforming fixed bearing may be comparable with that in a mobile bearing. The fixed bearing, however, is too constrained in AP and rotation, whereas the mobile bearing has increased laxity and a variable neutral position, both of which are advantages.

A final point is that (at the time of writing) there are no reliable data on the wear rates, and the types of particles generated as a function of contact area and contact pressure. Hence, comparisons between different designs must be determined by simulator tests rather than automatically assuming that larger contact areas are an advantage, as has been commonly done in the last decade.

**LINKED DESIGNS**

Over the years, numerous different linked designs have been introduced, which reflects more the opportunity for inventive design rather than extensive need. The largest numbers continue to be used in Europe, whereas in the United States, the tendency is to use the most conservative design whenever possible, even if substantial soft-tissue balancing is required. The characteristics of a linked design are:

- Stability is provided in all degrees of freedom, varus-valgus and hyperextension being particularly important, although there can be some laxity (e.g., rotational) in one or more degrees of freedom.
- A linkage of some type, such as a hinge, provides the stability and prevents subluxation or dissociation
- Intramedullary stems are required for fixation.

The most conservative type of linked TKR is the intercondylar hinge (Fig. 100.45). The linkage is housed in the intercondylar region, preserving the condyles on each side (9). Versions of this type include the Attenborough (9), the St. Georg Endo (Waldemar-Link, Germany) model, the Sheehan (Howmedica, Rutherford, NJ), the Rotaflex (JJ Orthopaedics, Warsaw, IN), and the PFC S-ROM (J&J Orthopaedics, Warsaw, IN). The bearing surfaces can be extended to the full width of the knee, an advantage for reducing varus-valgus bending moments on the linkage. The patellofemoral resurfacing has been absent in some designs but ideally should be included. Advantages of the intercondylar design are:
this is unlikely, and hence the cone and gaussian patellar components are likely to be stable. When the Q-angle is large enough, the lateral force will decrease. However, as long as both forces are positive, the patella will be stable. At the point where the medial force reaches zero, the patella will become unstable and will be subject to tilting and subluxation. This is calculated to occur at a Q-angle of approximately 12°. If the profile of the patellar flange is a circular arc to match the dome, a retained anatomic patella is a poor fit. If the femoral flange has an anatomic profile (to accept a retained patella), the dome has two local areas of high stress, which are subject to wear and deformation.

Disadvantages of the intercondylar design are:

- The relatively restricted size of the bearing components, with an increased potential for wear and deformation.
- The possibility of condylar fracture on each side.
- The difficulty of linking the components at surgery, and the possibility of dislocation in extreme loading conditions (in some designs).

The least conservative type of linked TKR, in terms of bone resection, is the fixed hinge or rotating hinge. Placement is achieved by resection of about 25 mm from the distal femoral condyles and 10 mm from the upper tibia. An axis is then used to connect the femoral and tibial components, usually with plastic bushings to act as the bearing. The total thickness is determined by the required dimensions of the axle and bushings, and the ideal placement of the axle, which is close to the epicondylar line. A lower, or more posterior, axle location will reduce bone resection but result in abnormal tracking of the patella. It should be noted that the most important requirement in the placement of hinged replacements is that the patella locates at the correct level on the femoral flange with the knee in extension.

The fixed hinge is the simpler design and can be used for patients of low demand who would not overstress the fixation and for whom flexion-extension motion is sufficient. Examples are the Guépar (Benoist-Gerard), the St. Georg (Link), the Blauth (Allopro), and the original Stanmore. The rotating hinge, however, results in a more "natural" feel to the patient and can be more durable in the long term. Examples are the Kinematics and Kinemax Rotating Hinges (Osteonics-Howmedica, Rutherford, N.J.), the Finn (Biomet, Warsaw, IN), the Noiles (J&J Orthopaedics, Warsaw, IN), and the SMILES (Stanmore Implants Worldwide). More bone resection, however, is required to accommodate the extra bearing surface. The rotation can be achieved by a flat polished metal surface pivoted on a flat plastic surface, or by a convex metal surface in a dished plastic surface. The convex metal surface in a dished plastic surface is preferable because it provides a "soft" limit to rotation, reducing the possibility of instability or patellofemoral subluxation. Some medium- to long-term follow-up studies of linked designs have shown durability comparable to that associated with condylar replacements. That fact, coupled with the relative ease of surgery and the immediate stability, makes linked designs an attractive option for selected patients.

PATELLOFEMORAL JOINT

The function of the patellofemoral joint in the normal knee has been studied from many different aspects. The shape of the patella prosthesis surface can be either a dome, a rounded cone, or a gaussian curve. The dome has been widely used in total condylar type designs but has several drawbacks:

- The plastic is thin at the sides, resulting in overall deformation of the component, especially in activities with high flexion.
- If the femoral flange has an anatomic profile (to accept a retained patella), the dome has two local areas of high stress, which are subject to wear and deformation.
- If the profile of the patellar flange is a circular arc to match the dome, a retained anatomic patella is a poor fit.

The cone has increased plastic thickness at the sides and larger contact areas in the form of two "lines" rather than "points." Finally, the gaussian shape further increases both the thickness and the contact area. In all of the designs, a medial offset to the peak is an advantage and eliminates the need to use a smaller size of symmetric design and medialize it. A rotating platform design produces the largest area of contact and potentially the least wear and deformation, at the expense of some extra thickness due to the metal backing and a second bearing surface. An additional factor in area of contact is the shape of the intercondylar cutout on the femoral component, as shown in Figure 100.46.

Regarding stability, there is a perception that the dome is more forgiving in alignment and that the other types are susceptible to tilting and loading on the corners. In the front view, it can be seen that, owing to the angle between the lines of action of the patellar ligament and the quadriceps (the Q-angle), there will be resultant tensile and lateral shear forces on the patella itself. The actual direction of the forces depends on the relative forces in the different parts of the quadriceps. In addition, there will be a compressive force between the patella (whether the natural patella or a plastic replacement) and the patellar flange, which increases with the flexion angle up to about 100° flexion. A 3-D force analysis can be carried out, based on the sectional view shown in Figure 100.47. The resultant compressive force is central, equal resultant acts on the lateral and medial facets. However, in general, the lateral reaction force will be larger than the medial owing to the laterally directed component of the quadriceps and patellar tendon forces. As the Q-angle increases, the lateral force will increase and the medial force will decrease. However, as long as both forces are positive, the patella will be stable. At the point where the medial force reaches zero, the patella will become unstable and will be subject to tilting and subluxation. This is calculated to occur at a Q-angle of approximately 12°. In cases of extreme valgus, this is unlikely, and hence the cone and gaussian patellar components are likely to be stable.
The Q-angle between the quadriceps and patellar tendon forces results in a lateral shear force on the patella. The sectional view treats the patella as a free body, from which the forces, including the lateral and medial facet forces, RL and RM, can be calculated.

The resultant forces between the patellar component and the femoral flange. As the lateral shear component is increased, a critical unstable situation is reached but at a high Q-angle.

**FIXATION**

The methods used to attach TKR components to the bone include cementation, press-fit fixation, porous-coating, and fixation with various macroscopic surface finishes or mesh. Any of the uncemented modes can include HA or other bioactive coating. The goals are to minimize interface micromotion, avoid interface bone resorption, and maintain intimate bone contact. An alternative goal, potentially achievable with press-fit fixation, is to obtain a stable interface with a thin fibrous tissue layer or velour-type material. In cementing at surgery, if the cement is applied in a viscous state with little pressure, the penetration will only be on the projecting trabecular tips, allowing distraction to occur when local tensile stresses are exerted. In contrast, penetration of 2 to 4 mm, such that transverse trabeculae are engaged, results in small interface micromotion and an interface that can remain stable for long time periods. The most uniform penetration over the entire surface is achieved with cement applied by multiple applications of a gun nozzle.

Fracture of the cement mantle has not appeared as a problem in metal-backed components but has occurred with all-plastic components when there has been deformation due to poor or uneven bony support or bone overload from malalignment. Components with coatings, for which long-term fixation relies on ingrowth or apposition of new bone, require initial fixation that is sufficiently rigid for at least 2 to 3 months. Screws have been found to be an advantage for tibial components, whereas for femoral components, a tight AP fit has been adequate. However, the use of screws carries the risk of screw-tray fretting and of providing a track for wear debris particles, which produce osteolytic cavities. Press-fit fixation requires suitable macroscopic features and pegs to maintain a sufficiently low level of interface micromotion. In many cases, a stable fibrous tissue interface above a new subchondral layer has been formed, but so far, press-fit fixation has shown a higher incidence of loosening and pain than cementation.

Fixation also depends on the design of the component and the loading on the bearing surfaces. These factors, in turn, directly affect the stress distribution over the entire interface as well as the stresses in the bone itself. In the sagittal plane, if the contact is less than approximately 25% from the edge, there will be excessive bone stresses beneath the load and tensile stresses opposite to the load. The actual pressure distribution at the interface reflects the foundation stiffness of the trabecular bone, whereas the magnitude of the stresses depends on the surface area of the component. The bone stiffness is modified in arthritic conditions, usually by increased and decreased stiffness on opposite compartments. CT studies show that, after realignment and insertion of a TKR, whereas the strong bone reduces in strength toward normal, the weak side gains in strength more slowly. Except in conditions of extreme edge loading, metal-backed components produce a more normal pressure distribution at the interface. In all-plastic components, there is a high pressure region at the interface beneath the contact area. Nevertheless, there is clinical evidence that plastic components with sufficient thickness (e.g., 10 mm) and a strong central peg are viable in patients with low activity levels and when there are no major bone defects or regions of osteoporosis. Regarding overall pressure distribution, central posts reduce the maximum interface stresses for offset loading, such as varus, as well as being effective against shear forces. Design features located toward the periphery, such as pegs or keels, especially when they are embedded in hard cancellous bone, are effective against internal-external rotation.

Fracture of the cement mantle has not appeared as a problem in metal-backed components but has occurred with all-plastic components when there has been deformation due to poor or uneven bony support or bone overload from malalignment. Components with coatings, for which long-term fixation relies on ingrowth or apposition of new bone, require initial fixation that is sufficiently rigid for at least 2 to 3 months. Screws have been found to be an advantage for tibial components, whereas for femoral components, a tight AP fit has been adequate. However, the use of screws carries the risk of screw-tray fretting and of providing a track for wear debris particles, which produce osteolytic cavities. **Figure 100.51.** Design features to transmit varus moments and axial torques more effectively to the bone.

An invaluable method for the measurement of component fixation in vivo has been RSA (62,105,166,186,196). One millimeter tantalum beads are implanted in the component and in the adjacent bone at surgery. Biplanar radiography at specific time intervals, with mathematical analysis, produce the component–bone movements or migrations over time. Continuous migrators after 1 to 2 years are predictive of future clinical loosening.

Cases with bone loss, including revisions, need special consideration (Fig. 100.52). Augments, such as spacers and wedges, are useful for replacing bone defects and for accurately reproducing the joint line (35). These augments can be screwed or cemented to the main components. For larger defects, space fillers made from metal or plastic are an alternative to bone grafting. Stems are useful for bypassing cavitory defects, for protecting against fractures, for traversing fracture sites or serious cortical defects, or for stabilizing allografts (179). When the TKR design carries varus-valgus moments, intramedullary stems are needed. In older patients, cemented stems are usually preferable, but uncemented fluted stems should be used if there is sufficient cortical thickness, in order to reduce the stress-shielding of the cancellous bone near the joint (206). Empirically, suitable stem lengths for Superstabiliser-CKK types of TKR are 100 to 120 mm, and 120 to 150 mm for rotating and fixed hinges. Revision of a failed cemented stem requires a new stem at least 50 mm longer. In all cases, attention is needed to prevent the stem tip from impacting the cortical wall, which frequently produces osteolysis, penetration, and even bone fracture.

![Figure 100.52](image_url)

**Figure 100.52.** Modular augments including spacers, space fillers, medial wedges (not shown), and stems; they are used in cases of bone loss including revisions. There is some stress protection of the distal femur and proximal tibia due to the stems.

WEAR AND DEFORMATION OF PLASTIC

The basic terminology of lubrication and wear was described earlier in the discussion of tribology. In this section, wear mechanisms applied to TKR are discussed. These mechanisms have been deduced from retrieval studies, principally from components that have failed due to instability or loosening (18,27,28,29,80,61,63,139-234). Examples of wear in a range of retrieved TKR components are shown in Figure 100.53. Deformation frequently occurs in dome-shaped patellar components when they are used in anatomically shaped grooves (Fig. 100.54). For partially conforming condylar replacements, on the application of load, a contact patch is produced on each condyle, the shape depending on the geometry of the tibial and femoral surfaces (151,189,190). Contacts approximating circular are called point contacts, whereas when the surfaces are almost conforming in the frontal plane but only partially conforming in the sagittal plane, a cigar shape called a line contact is formed (Fig. 100.10). The contact area varies considerably, from about 150 mm² for moderate- to high-conformity knees in early flexion, down to 30 mm² for low conformity knees in flexion (Table 100.4). The corresponding maximum compressive pressures are 10 to 50 mPa at the centers of the contact areas, the mean pressure being the maximum divided by 1.5.

![Figure 100.53](image_url)

**Figure 100.53.** Examples of wear on different TKR designs with different types of polyethylene: abrasive wear (A), adhesive wear (B), deformation (C, D), and delamination (E) can all be seen.
The yield stress of UHMWPE is about 15 mPa (135,151,176), above which permanent deformation will occur under the center of the contact area (182). In knees of low conformity, as the femur slides over the plastic surface, a deformed groove up to 0.3 mm deep occurs in the first few months of use, and thereafter the groove is steadily deepened by wear. In knees of moderate to high conformity, the deformed area is relatively small, with a depth of less than 0.1 mm. Within the contact area, there are a multitude of local contact points at a micron level, depending on the microroughness of both the metal and plastic surfaces. There are several mechanisms whereby small particles are released. Some of these mechanisms are fatigue processes requiring numerous cycles of sliding. Multidirectional sliding is also more damaging than sliding, which is predominantly limited to the same direction. The wear processes also depend on whether the kinematics involve rolling, tractive rolling, or sliding (23-29). These wear processes (27,60,81) are as follows:

- Adhesive wear occurs when the local frictional shear force on transverse ripples or asperities of polyethylene causes shear deformation or stretching of a fibril. The fibrils are typically 2 to 5 µm in length and 0.2 to 0.5 µm in diameter.
- Another form of adhesive wear occurs when a plastic asperity accumulates strain energy due to repeated deformations to the point where a crack develops and a surface particle is released. This typically produces granules of plastic 0.1 to 1.0 µm in size.
- A third form of adhesive wear occurs when a surface layer about 0.1 to 0.2 µm in thickness becomes sheared with respect to the underlying material, similar to the formation of a blister. Eventually, the layer fragments to form flakes approximately 2 to 10 µm across.
- A small scratch on the metal surface with ridges will produce direct cutting or ploughing into the plastic. Several passes across a groove in the plastic, especially at angles to previous passes, will release fibrils or granules of polyethylene. This is called two-body abrasive wear.
- If hard particles become entrapped in the contact area, they will also cut grooves in the plastic, causing wear called three-body abrasive wear. Plastic particles themselves can produce this type of wear, but to a much lesser extent than hard particles such as metal, ceramic, or bone.

Scanning electron microscopy of the surfaces of retrieved plastic components illustrates the wear mechanisms (Fig. 100.55). Ripples perpendicular to the sliding direction are typical. Fibrils are seen to be stretched from the crests of the ripples, while there is also evidence of granule formation. Shearing of the surface layer results in fibrils or thin flakes. Fluid samples, after processing, can be filtered to show the resulting particles. They are categorized into granules, fibrils, and flakes (47,48). The types and sizes of particles are indicative of the wear mechanisms that were taking place. In general, smaller particles produce more expression of cytokines from cells.

The above-mentioned phenomena are all related to the surface of the plastic. However, other wear mechanisms are more appropriately called “damage mechanisms.” These mechanisms involve more general breakdown of the surface region of the material, including failure that starts entirely subsurface (235). These damage mechanisms, and other phenomena that involve cracks at and under the surface, are dependent on the component geometry, the sliding conditions, and the type of UHMWPE (61,189,190). To illustrate this point, a typical contact situation is shown in Figure 100.56. Around the periphery of the contact area, radial tensile stresses occur of magnitude 0.13 times the maximum compressive stress (124). As sliding and rolling take place, at a particular location on the plastic surface, the stresses cycle between tensile and compressive. This is equivalent to the stresses in a bar of material subject to repeated bending in opposite directions. As a result, cracks will be produced on the surface, which will progress along the surface and into the material, but because the tensile stresses reduce with depth, the crack depth is limited. However, when the cracks are not perpendicular to the surface and adjacent cracks coalesce, pits are formed with typical dimensions of 0.5 to 2 mm in width and depth. Such pits are commonly seen on retrieved components (18,63,139), from low to high conformities (27), including mobile bearings.

The cyclic stresses, representing a fatigue process, produce cracks, pits, and delamination.
A more severe form of damage occurs when cracks form and propagate beneath the surface. This is termed “delamination.” A typical crack depth is 1 mm, and the initial area affected can be several millimeters across, seen as a white patch (18,27,29). These cracks are associated with regions of maximum shear stress, which occur beneath the center of a contact area at a depth of approximately 0.25 times the contact width, usually 1 to 2 mm. The direction of the maximum shear stress is at 45° to the surface (Fig. 100.56). Beneath the periphery of the contact area in the cross-sectional plane, there are further peaks of shear stress of lesser magnitude oriented at 90° to the surface. The stress directions are opposite at the leading and trailing edges of the contact area. Hence, as the femoral component slides across the plastic, particular points beneath the plastic surface experience shear stresses that change in direction, producing a fatigue situation that leads to crack formation. Once the cracks reach the surface, the consequent disruption of the surface leads to rapid delamination of adjacent areas, eventually covering the entire contact region. Examples are shown in Figure 100.53 and in sectional view in Figure 100.55.

**Wear Models**

To predict the wear of TKR components as a function of the geometry, a number of simplified experimental or theoretical wear models have been used.

**Area of Contact**

The most frequently used measure has been the area of contact, either measured in a loading machine or calculated using FEA (Fig. 100.57). This is based on the assumption that the amount of wear at the surface (adhesive and abrasive wear) and damage within the material (pitting and delamination) are inversely proportional to the contact area or proportional to the contact pressure. There are some data in the literature to support this, based on the testing of specimens in wear test machines, and there is the general impression from retrievals that the wear is more severe in designs with small contact areas, usually cruciate-retaining designs. There is, however, the question as to which angle or angles of flexion should be used to measure the contact area. If the majority of wear is assumed to occur during the stance phase of walking, then areas measured between about 0° and 15° of flexion are relevant. Depending on the posterior-distal transition angle (Fig. 100.40), these areas can differ considerably. There is also the possibility that severe wear occurs at the less frequent activities, which generate higher forces at higher flexion angles. Hence, the use of area of contact as a measure should include values for a range of flexion angles. A weakness of using contact area alone is that it does not account for sliding distance.

**Sliding Distance**

Recalling the basic wear equation:

\[
\text{wear volume} = \text{wear factor} \times \text{load} \times \text{sliding distance}
\]

This equation refers to surface wear only and not to pitting and delamination. If it is assumed that the wear factor and load are the same for all TKRs, then the wear is proportional to the sliding distance, which is related to the femoral and tibial radii in the sagittal plane, in other words, the inherent constraint. Hence a simple indicator for wear is the AP sliding distance of the contact points (not the relative rigid body motion itself) for a typical activity cycle. For purposes of comparison between different TKRs, the sliding distance can be determined based on the data for walking and other activities, which shows that, in stance, along with an axial compressive force, there are both anterior and posterior shear forces. This can be simplified, as shown in Figure 100.58, by applying the compressive force first, followed by the anterior and posterior shear forces. As determined by the triangle of forces, the point of equilibrium is reached at a particular angle q on the plastic surface. This point is entirely dependent on the tibial radius and not the femoral radius, and can be calculated directly from the tibial dimensions. If the tibial articular geometry is shallow, so that the slope cannot be reached, the displacement limit would be from soft tissues, at an assumed distance of approximately 12 mm from neutral. The sliding distance is the distance between the anterior and posterior points. Although this test accounts for sliding distance, it does not account for the effect of contact pressure on the wear factor.

**Damage Function Model**

The damage function model was produced to predict delamination rather than surface wear (189,190). However, the surface wear can easily be included, as will be explained later. As already described, delamination is due to the initiation and propagation of subsurface cracks in the polyethylene. The likelihood of a crack developing and the rate of crack propagation can be described by the strain energy input to an element of material during a complete activity cycle. Calculation of this parameter has been carried out as follows:

1. Specify the input forces, moments, and flexion angles on the knee during activity, and divide this into equal time increments.
2. Use specially written software (a kinematic solver) to determine successive contact point locations on the lateral and medial sides, at each increment, taking surface friction into account (188) (Fig. 100.57).
3. Use FEA to calculate the subsurface shear stresses at a multitude of quadrilateral elements below the surface of the plastic at each increment.
4. For each element, plot a shear-stress versus time curve.
5. By treating this in a manner similar to a force displacement curve, the shear strain energy can be calculated for each element as the areas under the curve.
6. Plot the shear strain energy, called the damage function, for the elements at different subsurface levels.

The result is a plot as shown in Figure 100.59. This plot shows a comparison between knees of different frontal and sagittal geometries, demonstrating the regions of
plastic most likely to generate cracks, and predicts the relative susceptibilities of the different knees to delamination wear.

Figure 100.59. Plots of the damage function for elements of plastic at different levels below the surface for condylar knees of different geometries (Fig. 100.49). High susceptibility to delamination (left) is predicted for small frontal femoral radius, high frontal femorotibial clearance, and small POTA. At the other extreme of condylar geometry, delamination is predicted to be low (right). Also, the large frontal radius allows for adequate rotational laxity. (From Robinson R, Clark JE. Uncemented press-fit total hip arthroplasty using the identifit custom-molding technique. J Arthroplasty 1995;11:247.)

In the study described earlier, the surface wear could also be calculated. The method would be to use the basic wear equation for the incremental steps used in calculating the contact areas (Fig. 100.57). The wear in each increment would be the average load acting times the sliding distance. The wear factor could also be expressed as a function of the contact pressure. However, at this time, reliable data are not available.

The material properties of the UHMWPE have a major effect both on surface wear and on subsurface delamination. This has been discussed already in relation to hips, but there are a number of factors specifically related to knees. When retrieved tibial components are sectioned, the region of highest oxidation is typically 1 to 2 mm beneath the surface, although the zone can extend completely to the surface (18). It is noticeable that oxidation is highest beneath the contact areas, indicating a relation with fluid transport and local stress fluctuations. Such oxidation increases the density and the elastic modulus, and decreases the tensile strength, elongation to break, and toughness. All of these factors make the plastic more susceptible to delamination. Newer processing methods, which reduce oxidation are likely to extend the durability of UHMWPE before delamination occurs (18).

There is evidence from retrieval and laboratory studies that the use of directly molded polyethylene, even in designs of low conformity, avoids delamination almost completely, although surface wear from adhesion and abrasion is still observed (67,29). It is possible that such material is resistant to oxidation and degradation of mechanical properties.

Finally, wear debris can originate from locations other than from the bearing surfaces. "Back-side wear" between the plastic and the metal tray occurs due to micromotion at that interface. Snap-in capture mechanisms, combined with the manufacturing tolerances, can result in considerable motion under shear and torque, even up to 1 mm. If this is accompanied by a rough surface in the metal tray, severe wear can occur. The effects of such wear have been noted particularly in trays with holes for fixation screws, around which osteolytic lesions have developed.

TESTING AND SIMULATORS

Physical tests, like computer models, are simplifications of reality that embody sufficient and appropriate characteristics of the actual situation to address the question being asked. In some cases, simple tests suffice; in other cases, a complex test is required.

Static Tests

A commonly used method for determining the geometric relations and the forces within the knee is to mount the tibia on a base, apply a flexion moment to the femur, and balance the knee at a particular angle using a turnbuckle in the quadriceps. The original apparatus was termed the Oxford rig (67), but the design has since evolved (240) (Fig 100.60). Aspects that have been studied using such a rig include:

- The femorotibial contact point or area locations (111), determined radiographically or using pressure-sensitive film inside the knee.
- The orientation of and forces in the ligaments; the forces have been measured by small turnbuckles or by dissociation of bone blocks.
- The force in the quadriceps and in the patellar tendon using force transducers
- The patellofemoral contact areas and pressures, and the effect of different relative forces in the components of the quadriceps.

Limitations of the method are the low force magnitude, the fact that the force may not simulate the direction of the external force at the knee in the frontal and sagittal planes, and only one muscle being represented. Such factors can be addressed in more sophisticated versions of the rig. An extreme example is the use of a robot to position the femur on the tibia in a known 3-D orientation, which can then be used to study the contributions of different structures to resisting applied forces and moments.

Strength Testing

Each new knee design needs to be tested for strength and wear before it is used in patients. In general, the tests should be carried out on the standard-sized components. The test should replicate as far as possible the physiologic conditions while maintaining mechanical simplicity. The rate of testing can be up to 5 Hz for metal components and up to 2 Hz where plastic is involved.

A number of tibial tray designs have failed in service, although the incidence has been low (1). The adverse design factors have been internal corners, notches, a thin plate, and grooves or coatings. The clinical factors have been patient weight and activity level, and loss of bony support under one condyle. The test proposed by the ISO involves clamping one half of the component and then applying a cyclic force to the unsupported condyle (Fig. 100.61). The test does not reproduce the changing contact point locations during function. Furthermore, it has been found that an appropriate force for testing is around 500 N, whereas forces at physiologic levels in walking of 2000 N or more (or even half this value for one-condyle loading) would cause most existing baseplates to fail in fatigue. In this sense, the test is an exaggeration of reality. A typical number of cycles for such tests is 10 million, although this would represent only 5 to 7 years of use in most patients.
The strength of plastic posts in stabilized designs, the security of fixation of the plastic in the metal tray, and the security of mobile bearing components can be tested using an applied cyclic shear force, possibly accompanied by a compressive force (Fig. 100.62). From a compilation of available force data in the knee, including that from a telemetrized distal femoral replacement, a suitable cyclic shear force is 750 N applied for 10 million cycles, interspersed with a force of 1250 N applied for a total of 0.5 million cycles. The former represents vigorous walking, and the latter represents the extreme forces that could be applied in rapid ascending or descending. In the opposite direction (such that the ACL would be tensed) suitable values are 500 and 750 N.

Designs such as superstabilizers and linked hinges require testing in varus loading (Fig. 100.63). This can be accomplished using a cyclic force that is offset from the centerline and medial to the medial femorotibial contact point. For comparative testing applicable to all designs, the offset distance from the center of the knee and the applied force should be the same. A normal value of the external moment acting at the knee during activity is 3% BW times height, whereas an extreme value is 6.5% BW times height (159). To determine a suitable test force, consider a value of the external varus moment of $5\% \times BW \times height = 67,500 N\cdot mm$ for a typical man. The moment carried by the reaction force of 3 BW on the medial condyle at 22 mm spacing = 44,550 N\cdot mm. Hence, the moment carried by the central post is 22,950 N\cdot mm. This can be applied by a force of $C = 1000 N$ acting at 23 mm from the contact point or 45 mm from the center of the knee. In such a test, superstabilizers with plastic posts show considerable progressive angular deformation, which is reduced but not eliminated by metal reinforcement. Fixed or rotating hinges show only small deformations.

To test the overall mechanical strength of a TKR, a complex knee simulator could be used. However, a uniaxial cyclic load machine can be used to apply multiaxial forces and moments. This is achieved by mounting the component at an angle and applying the force offset (Fig. 100.64). In this way, the following is applied by the single uniaxial force:

![Figure 100.64](image)

- Compressive force.
Such tests have the advantage of revealing weak points in a design not shown by simpler testing, as well as effectively applying several test modes simultaneously.

**Wear Testing**

The most difficult and time consuming testing is measuring wear and deformation in TKRs. If the primary concern is to compare a new plastic or a new metal surface, a pin-on-plate test is appropriate (Fig. 100.65). To produce a model that is simple but a close model to the actual TKR, a metal pin with a spherical surface at the end (femoral) is slid to-and-fro on a flat plastic plate (tibial) (216). To account for internal-external rotation, the pin is rotated cyclically about its own axis. The surrounding medium is 25% to 50% serum at 37°C. The fluid requires changing every 2 days to minimize degradation. The sliding distance is a total of 10 mm. The radius of the spherical end should produce a similar relative radius of curvature to the TKR design envisaged. A static load of 1000 N is applied, representing one condyle. Samples of fluid are collected every million cycles for particle analysis. A suitable characterization is to divide particles into granules, fibrils, and flakes, and measure the size ranges and the percentages of each (47,48). The rate of testing is limited to 1 Hz (2 Hz maximum) to avoid overheating at the contact. It is observed that in the first few hundred thousand cycles, deformation of the plastic predominates over wear, whereas as the contact pressure thereby reduces, deformation reduces and wear predominates. If the objective of a test is to determine the effect of load, contact area, or contact pressure on wear, the above-mentioned configuration can be reversed with a flat-ended plastic pin sliding on a flat metal plate.

![Figure 100.65. A simple test for simulating the bearing conditions of a TKR to assess new materials or surfaces. The motion is a combination of sliding and rotation.](image)

To test a knee for long-term durability when functional load and motion cycles are applied to an actual TKR, a knee simulator is required (40,217). If the goals of the design of a simulator are simplicity, low cost, reliability, and ease of use, then this would result in a machine that applies a constant compression force, only in flexion-extension. However, such a machine does not satisfy the criterion for a close simulation of reality, as previously described for hip Simulators. The input required is replication of a walking cycle, preferably with 5% to 10% of more rigorous inputs representing ascending and descending. This involves the following cyclic inputs:

- Compressive force.
- Varus moment.
- AP shear force.
- Internal-external torque
- Flexion-extension.

There is the inherent assumption that the forces and moments acting across the knee are independent of the type of TKR, no matter what the constraint. This leads to a concept for a knee simulator design called force input (217) (Fig. 100.66). In the test setup, the relative motions between the femur and tibia, except flexion-extension, are unconstrained. However, mechanical springs are mounted between the femoral and tibial holders, to simulate soft-tissue restraint. Although the input force data from the literature have been obtained by indirect means and are therefore uncertain, and accounting for the variations between individuals, estimates of the inputs can be specified to produce a reasonable representation of normal activity. Measurements of the output displacements and rotations show that the patterns are highly dependent on the constraints of the particular TKRs. In turn, the wear will depend on the displacements and rotations, and hence the force-input concept seems justified.

![Figure 100.66. Schematic of the force-input concept of a knee simulator design. The movement of each knee depends on its inherent constraint, with the springs representing soft-tissue restraint and preventing excessive movements.](image)

An alternative scheme, which is less complex mechanically, is a displacement-input machine to which AP displacement and internal-external rotation are applied rather than force and torque (45). For the force-input approach, each knee moves according to its inherent constraint, and therefore, comparative testing would seem valid. For displacement-input, however, a means of specifying the input displacements for each individual knee is required. This could be achieved by using a simple test rig initially. However, fixed displacements and rotations would not allow for changes that might occur over time due to deformation and wear.

Another knee simulator design involves applying external forces, together with forces in the quadriceps and possibly other muscles. There would be some similarity with the scheme shown in Figure 100.60. To produce a dynamic version, however, there would be increased mechanical complexity and high demands on the control systems, but the overall scheme is more realistic and the patellofemoral joint can be tested simultaneously (personal communication: B.M. Hillberry, Perdue University).

It is to be emphasized that simulator tests of a particular knee design need to be compared with tests of an earlier design with known clinical history. Furthermore, the duration of the testing needs to be sufficient (153,165), at least 5 million cycles, to account for early bedding in, fatigue phenomena, and possible material degradation.

**ACKNOWLEDGMENTS**

The author is indebted to the numerous colleagues who have contributed indirectly to this chapter. Thanks are especially due to the staff and associates of the Center for Biomedical Engineering (Faculty of Clinical Sciences, and Department of Mechanical Engineering, University College London), located at the Royal National Orthopaedic Hospital Trust, Stanmore, near London, UK.

**CHAPTER REFERENCES AND FURTHER READING**

The shoulder has a unique capacity for motion because of (a) the stable and painless articulation between the glenoid and the humeral head, (b) a subdeltoid space that is free of restricting structures, and (c) the integrated action of the acromioclavicular, sternoclavicular, and scapulothoracic articulations. The critical contribution of the soft tissues surrounding the glenohumeral joint cannot be overemphasized. The glenoid surface is only slightly curved, and its surface area is about 25% that of the humeral head. Thus, the humeral head rests against the glenoid surface, relying on the surrounding capsule and musculotendinous units for stability as well as mobility. Soft-tissue abnormalities such as scarring, contracture, laxity, muscle atrophy, neurologic disease, or rotator cuff tendinopathy severely compromise normal shoulder function.

The multiple variables of the soft-tissue and bony structures of the shoulder must be recognized in considering the role, indications, technique, and potential benefits and risks of shoulder arthroplasty.

The surgical technique of implant insertion in total shoulder arthroplasty is but a part of a process that also includes proper patient selection; evaluation of the soft tissues, acromioclavicular, sternoclavicular, and scapulothoracic relations; evaluation of the integrity and function of the rotator cuff, laxity or contracture of the capsule and glenohumeral ligaments, and the power of the deltoid muscle; and the ability of the surgeon and patient to interact and cooperate in the rehabilitation essential for successful arthroplasty. If these variables can be handled successfully, pain relief following total shoulder replacement is predictable (38, 51). However, although passive motion may be achieved through technically satisfactory attention to the many intraoperative variables, active motion will depend on the strength of the muscles powering the arthroplasty. Thus, adequate rehabilitation aimed at both motion and strength is essential.

The many arthropathies leading to degeneration of the glenohumeral joint have identifying features that can present unique problems of bone and soft-tissue reconstruction. It is important to recognize some of these features, as they may provide clues to intraoperative pitfalls. As an example, primary osteoarthritis presents the problem of asymmetric, posterior wear on the glenoid. Rheumatoid arthritis may display associated acromioclavicular disease, lower extremity disorders, elbow and wrist involvement, rotator cuff disease, osteopenia, and bone destruction, each of which will affect operative technique, postoperative rehabilitation, and the result. Posttraumatic arthritis often exhibits scarring and soft-tissue contracture, malunited tuberosities, or nerve injury. In rotator-cuff tear arthropathy, excessive wear into the acromioclavicular joint, acromion, and glenoid, combined with severe soft-tissue deficits, make reconstruction uniquely challenging (39). In addition, as the characteristics of each arthropathy influence the long-term results, patients may be better informed preoperatively by a surgeon who recognizes the differences between and stages of glenohumeral arthritic disease.

Thus, it is unrealistic to expect a single operative technique to apply to all patients who require total shoulder replacement. In this chapter, a general guide to the technique of primary replacement arthroplasty is followed by a discussion of some of the features of each arthropathy and its associated surgical reconstruction.

**PRINCIPLES OF TREATMENT**

Prosthetic designs vary in their amount of inherent constraint. Most modern systems are modeled after the classic unconstrained arthroplasty, initially described by Neer (38). The popularity of this prosthesis stems in part from the fact that its insertion requires the removal of only that part of the humeral head and glenoid normally covered with articular cartilage. This minimizes bone removal, allowing duplication of normal anatomy by the implant and leaving some bone stock for salvage through arthrodesis if necessary. The Neer design relies on soft-tissue integrity to stabilize and move the implant because it replicates normal anatomy. Thus, the surgeon must be able to anticipate and treat capsular laxity or contracture and must be able to reconstruct a deficient rotator cuff.

The Neer II design features a proximal humeral component with two head thicknesses (15 and 22 mm), each with the same radius of curvature (Fig. 101.1). There are three different stem diameters (6.3, 9.5, and 12.7 mm) for each head thickness. The most commonly used stem lengths are 125 and 150 mm. An extra-long stem (252 mm) is used in tumor reconstruction or to treat an associated humeral shaft fracture. An extra-short stem (63 mm) is useful in some patients with juvenile rheumatoid arthritis or epiphyseal dysplasia (Fig. 101.2). The proximal humerus prosthesis may be used with or without bone cement for total shoulder arthroplasty. Hemiarthroplasty for traumatic reconstruction generally requires cement fixation to allow the implant to sit proud of the humeral shaft, thus restoring length and avoiding inferior subluxation of the head. Because its radius of curvature approximates the normal humeral head, the implant can be used without the glenoid component if the glenoid is free of disease, as in acute fractures and some cases of osteonecrosis (22).

**Figure 101.1.** The Neer II proximal humerus. There are two head sizes, each with the same radius of curvature. The holes in the fin are for securing the tuberosities in fractures or after tuberosity osteotomy.
The Neer II design has three different stem diameters for each head size. The variable stem lengths allow adjustments in unique situations such as tumor reconstruction or juvenile rheumatoid arthritis.

The standard glenoid component approximates the surface of the average adult glenoid and is made of high-density polyethylene. It has a keel that must be inserted into the neck of the scapula, and a radiographic marker wire (Fig. 101.3). Its radius of curvature matches that of the proximal humeral component (Fig. 101.4). More recently, a metal-backed glenoid was designed to minimize the stress on the polyethylene glenoid in hopes of avoiding implant breakage or prosthetic deformation in a high-demand patient (Fig. 101.5). The metal-backed implant is rarely used, as the all polyethylene components are used routinely.

In recent years, several modular designs have become available. The modular designs are attractive in terms of ease of revision surgery, tensioning of soft tissues, inventory, and fracture treatment (26). The Biomet (Warsaw, IN) modular shoulder has four outer head sizes that each have three or four possible neck lengths. These heads can be used with stems ranging from 6 to 15 mm in diameter and 7 to 19 cm in length. The Kirschner Integrated Shoulder System (Biomet) adds modularity to the Neer design, and the Atlas further increases options by adding humeral modularity (Fig. 101.6).
Because unconstrained implants rely entirely on reconstruction of soft tissue for stability and motion, other prosthetic designs provide more inherent stability if the rotator cuff is deficient. Among the constrained designs are the Stanmore and the Michael Reese models (45). The trispherical prosthesis (Gristina), although constrained, is intended to allow more motion through a double ball-and-socket design. Constrained designs may not permit the forces across the joint to be shared with the surrounding soft tissue, and complications in some series have been high. In some constrained implant designs, the amount of bone resection has been greater than in a nonconstrained implant. As has been the experience with constrained implants in the lower extremity, loosening appears to be a greater problem. Although these designs may be considered in situations where there is no functioning rotator cuff, we felt that they are generally not indicated (48). Their use has been abandoned by most shoulder surgeons.

INDICATIONS AND CONTRAINDICATIONS

The main indication for implant arthroplasty of the shoulder is pain from an arthritic glenohumeral joint that is unresponsive to nonoperative treatment such as rest, anti-inflammatory medications, or an occasional intra-articular injection. It is critical to identify the pain as coming from the glenohumeral joint and not from adjacent structures. Some patients may have mild radiographic arthritic changes, although their predominant pain comes from acromioclavicular joint disease, cervical spine disease, or impingement syndrome. A radiographic finding of mild arthritis in a patient with a recurrent dislocation may suggest that dislocation arthropathy is the source of pain (47), although the pain may originate from continued instability or hardware protrusion into the joint. A patient with rheumatoid arthritis may benefit from acromioclavicular joint resection or bursectomy if the radiographic changes are not severe. In addition, there is a precollapse phase before the development of cuff tear arthropathy when acromioplasty and cuff repair, rather than shoulder replacement, are better advised.

Poor motion is a less common indication for prosthetic replacement, because the gain in active motion with arthroplasty may be less predictable than improvement in pain. Active motion depends to a great degree on the surgeon’s ability to reconstruct and rehabilitate the musculotendinous units moving the implant, which may or may not be limited by the disease. Rheumatoid patients may, in fact, have limited active motion because of associated rotator cuff weakness or rheumatoid myopathy, which implant insertion will not correct. A patient with cuff tear arthropathy may have pain relief following arthroplasty without improved active motion, because the cuff may be irreversibly weakened due to the length of time before treatment or the quality of residual tissue (35). Nevertheless, in some patients (notably those with ankylosing spondylitis or other rheumatic diseases), restricted motion may cause hardship with daily living activities or put undue stress on more distal joints. In this situation, it is reasonable to attempt to gain motion with prosthetic replacement.

Indications for prosthetic replacement are driven by the nature of the disease process. Humeral head replacement alone is indicated in the following situations:

- Four-part fractures, where it is anticipated that the articular segment is completely devoid of soft-tissue attachment and blood supply, making avascular necrosis likely (Fig. 101.7)

![Figure 101.7](image)

Figure 101.7. A four-part fracture dislocation. The humeral head is devoid of soft-tissue attachment, late collapse is likely, and prosthetic replacement is the surgical treatment of choice.

- A head-splitting fracture with destruction of the articular surface
- Recurrent acute or chronic dislocations, where the articular impression fracture of the humeral head is 40% or more of the articular surface
- Osteonecrosis, if the disease has caused collapse or deformity of the humeral head but there is not yet disease of the glenoid
- Some forms of primary osteoarthritis, if the glenoid still has some cartilage remaining, and the glenoid surface is congruent
- Severe disease processes where the glenoid bone stock available for insertion of an implant is limited, such as in some forms of rheumatoid arthritis or revision surgery
- Elderly patients with nonunion of the surgical neck (Fig. 101.8)

![Figure 101.8](image)

Figure 101.8. Painful nonunion of surgical neck in a 78-year-old woman. Prosthetic replacement and tuberosity repair were selected because of the patient’s age and osteopenia of the humeral head.

- Very young patients, if glenoid cartilage loss is not severe
- Some types of tumor reconstruction
- Some patients with rotator-cuff tear arthropathy

Hemiarthroplasty may also be combined with biologic resurfacing arthroplasty of the glenoid. A recent study reported on the short-term follow-up of hemiarthroplasty combined with biologic resurfacing of the glenoid with either capsule or autogenous fascia lata in patients with an average age of 48 years (49). Although the preliminary results are promising, longer follow-up with a greater number of patients is required before this procedure can be advocated for routine use.

Unconstrained total shoulder replacement is an excellent solution for glenohumeral arthritis if attention is paid to the details of surgery and rehabilitation. Following are the most common indications for total shoulder replacement:

- Primary osteoarthritis with destruction of both humeral head and glenoid (Fig. 101.9)
Figure 101.9. AP radiograph of primary glenohumeral osteoarthritis, recognizable by the large, inferiorly protruding osteophyte and subchondral cyst formation.

- Osteonecrosis in which the incongruity of the humeral head has also destroyed the glenoid
- Rheumatoid arthritis, which usually affects the glenoid and humeral head (Fig. 101.10)

Figure 101.10. Rheumatoid arthritis of the glenohumeral joint.

- Posttraumatic arthritis in which joint incongruity or malunion has destroyed the glenoid (Fig. 101.11)

Figure 101.11. Axillary radiograph in patient with posttraumatic arthritis. There is joint destruction, humeral head subluxation, and tuberosity malunion.

- Rotator-cuff tear arthropathy if the cuff is unreconstructible (Fig. 101.12)

Figure 101.12. Rotator-cuff tear arthropathy. There is severe superior migration of the humeral head, and wear into the acromion and the acromioclavicular joint. Severe glenohumeral arthritis is evident.

- Severe arthritis of dislocations, the result of repeated instability of the humeral head or capsulorrhaphy arthropathy (Fig. 101.13)

Figure 101.13. Arthritis of recurrent dislocations. The patient had a previous Bristow procedure.

- Arthritis due to old infection that is quiescent or treated
- Failed prosthetic replacement, humeral head resection, or arthrodesis
Contraindications to total shoulder arthroplasty include the following:

- Active or recent infection
- Paralysis of both the deltoid muscle and rotator cuff muscles
- Neuropathic arthropathy
- Glenoid bone loss that can be reconstructed by bone grafting is not considered a contraindication to arthroplasty

Because the nonconstrained implants rely entirely on the reconstructed rotator cuff tendons and deltoid for power, injury to the axillary and suprascapular nerves or other extensive paralytic processes will so weaken and destabilize the replacement that arthrodesis may be preferable. A Charcot joint is usually a contraindication, although in some neuropathic joints, stiffness and pain predominate and implantation is worth consideration.

Total shoulder arthroplasty is contraindicated in the presence of a rotator cuff tear if the tissue is inadequate for repair or if the muscle degeneration as documented on magnetic resonance imaging (MRI) is too severe to allow the cuff to centralize the head in the glenoid. Inadequate centralization of the humeral head in the presence of a glenoid component may lead to asymmetric loading of the glenoid, which can result in premature loosening (18). If the humeral head is fixed superiorly, it is also unlikely that cuff repair will be successful in the setting of total shoulder arthroplasty. In our experience, however, glenoid resurfacing allows more predictable pain relief. Therefore, we will consider reconstruction of massive rotator cuff tears using residual tendon, tenodesis, or grafting if clinically indicated. Patient considerations also play a role in this decision, as does the technical difficulty of reconstructing a massive tear.

Glenoid bone loss that can be reconstructed by bone grafting is not considered a contraindication to arthroplasty (28), although some patients have such severe erosion and bone loss of the glenoid that insertion of a glenoid component may be impossible, and hemiarthroplasty of the humerus alone can be used.

A final relative contraindication to unconstrained arthroplasty is the patient's inability or unwillingness to cooperate with the extensive rehabilitation necessary for adequate functioning of the implant.

Although young age and vigorous activity level do not preclude shoulder replacement (50), consider alternative methods of treatment in the patient who cannot avoid impact-loading types of physical activity. In the patient with a prior infection, as with other arthroplasties, the joint must be free of infection before implantation.

RESULTS

The implant with the longest track record is the Neer design (10,37). The Mayo Clinic experience with this total shoulder arthroplasty has recently shown the survivorship (defined as no further surgery) to be 93% at 10 years and 87% after 15 years (51). The diagnoses were mainly osteoarthritis and rheumatoid arthritis, with a lesser proportion of posttraumatic arthritis. Other series have also reported good pain relief in patients following total shoulder arthroplasty. In general, pain relief following shoulder replacement is independent of function. Function tends to be related to the diagnosis; soft-tissue adequacy is an important factor for success. Total shoulder arthroplasty in younger patients is not as successful as in the elderly (50). Also, revision surgery generally produces inferior results (44,49).

PREOPERATIVE EVALUATION

Carefully evaluate the patient before surgery for cervical spine disease, acromioclavicular disease, and nerve and muscle deficits. Failure to recognize associated diseases before surgery can preclude a good result.

Carefully evaluate the patient's shoulder radiographically with anteroposterior (AP), lateral, and axillary views. An AP view may reveal the degree of osteophyte formation of the humeral head (Fig. 101.9), the amount of superior head migration, the status of the acromioclavicular joint, the presence of a subacromial spur, the thickness and size of the intramedullary canal of the humerus, and deformity or hardware in the humeral shaft. In the posttraumatic shoulder, it may indicate the position of the tuberosities and humeral head relative to the shaft. The lateral radiograph may indicate the amount of anterior or posterior subluxation of the humerus and the position of the tuberosities.

An axillary radiograph provides an excellent view of the amount and position of glenoid wear, the extent of medial migration, and the position of the humeral head (Fig. 101.11, Fig. 101.14). If there is asymmetric wear of the glenoid anteriorly or posteriorly, plans may include bone grafting at surgery. A computed tomography (CT) scan may be extremely helpful in assessing the position of the tuberosities and the amount of glenoid wear (Fig. 101.15). An axillary view may provide sufficient information regarding the glenoid orientation; however, a CT scan provides a clearer picture and may be useful for surgeons with less experience in shoulder arthroplasty. To avoid component malposition, it is crucial that posterior wear of the glenoid be identified prior to surgery, because glenoid version is difficult to assess intraoperatively.

Figure 101.14. Axillary radiograph showing the loss of joint space and degree of wear of the glenoid in a patient with primary osteoarthritis.

Figure 101.15. CT scan in a patient with severe destructive rheumatoid arthritis. The humeral head has been completely destroyed, and there is marked bone loss of the glenoid.

If there is any suspicion of infection in the shoulder joint based on the history and physical examination, a complete blood count, erythrocyte sedimentation rate, and joint aspiration, as well as technetium and gallium scans, may be helpful in determining the current status of the infection.

Evaluate the patient's general health, and before surgery resolve any medical conditions that could lead to problems at the time of operation. In addition, a physical therapist should meet with the patient preoperatively to plan and explain the therapy program.
The choice of anesthesia depends on the surgeon, patient, and anesthesiologist. General anesthesia or interscalene block are the two most commonly used.

- Position the patient to avoid hyperextension of the neck. Fasten the head securely with tape to either a horseshoe head-rest or the operating table itself. This ensures that extremity movement during surgery will not dislodge the endotracheal tube. Place the patient in a semisitting or beach-chair position, with the hips flexed to 30°. Move the patient close to the table edge to permit hyperextension of his arm when the humeral component is inserted (Fig. 101.16). Because support of the arm will permit more effective posterior retraction of the humerus, secure to the operating table an arm board that can easily be moved into or out of the operating field. This aids exposure and insertion of the glenoid (Fig. 101.17).

**Figure 101.16.** Positioning the patient for total shoulder arthroplasty should enable the arm to be hyperextended for humeral component insertion or for rotator cuff mobilization.

**Figure 101.17.** Glenoid exposure is aided by posterior humeral retraction, made easier by the support of an arm board.

- Place a towel under the medial border of the body of the scapula to stabilize it and ease exposure of the glenoid. Then secure the rest of the torso. Use adherent drapes to outline the area to be prepared and to keep the patient's hair from entering the operating field. Prepare the skin of the upper extremity from the base of the neck to the fingertips. If an assistant holds the wrist during scrubbing of the patient, the arm can be moved into abduction or adduction for ease of skin preparation. The skin preparation includes the lower third of the neck superiorly, the middle of the chest anteriorly, the midscapula posteriorly, and the chest wall at the level of the lower border of the scapula. Secure the drape with towel clips or skin staples, and place iodine-impregnated adhesive plastic draping on the entire operative field.

**Figure 101.18.** Deltopectoral approach. Coracoid, acromion, and clavicle have been marked. The skin incision extends from the clavicle at a point between the coracoid process and the acromioclavicular joint, to the deltoid insertion.

Three surgical approaches have been used in shoulder replacement. The long deltopectoral approach with anterior deltoid detachment from the clavicle and acromion is no longer often used and has been supplanted by an approach that does not detach the deltoid from either the acromion or the clavicle. Sometimes detachment of the anterior deltoid may be necessary for exposure or mobilization of the tuberosities, anterior acromioplasty, or bone grafting of the glenoid. However, it is preferable to maintain the integrity of the deltoid origin to avoid the complication of deltoid detachment. We recommend a series of sequential releases to aid in exposure. Release the deltoid insertion over 1 to 2 cm in a subperiosteal fashion. A portion of the pectoralis major insertion may also be released, which should allow ample exposure. If greater exposure is needed, release the lateral portion of the conjoint tendon. In rare situations, it may be necessary to make a separate posterior approach, in addition to an anterior approach, for mobilization of tuberosities; for mobilization of scarred, retracted, rotator cuff; for glenoid bone grafting; or, in the case of a longstanding fixed posterior dislocation, to remove the humeral head from the posterior glenoid.

**Figure 101.19.** Incision in the deltopectoral interval. Begin the incision at the clavicle, beside the coracoid process and the acromioclavicular joint, and extend it distally to the lateral insertion of the deltoid muscle (about 17 cm). Place skin retractors and obtain hemostasis.

If greater exposure is needed, release the lateral portion of the conjoint tendon. In rare situations, it may be necessary to make a separate posterior approach, in addition to an anterior approach, for mobilization of tuberosities; for mobilization of scarred, retracted, rotator cuff; for glenoid bone grafting; or, in the case of a longstanding fixed posterior dislocation, to remove the humeral head from the posterior glenoid.

- If a long deltopectoral incision has been selected, infiltrate the skin and subcutaneous area with a 1:500,000 concentration of epinephrine. Avoid the axillary skin folds in the incision. Begin the incision at the clavicle, beside the coracoid process and the acromioclavicular joint, and extend it distally to the lateral insertion of the deltoid muscle (about 17 cm) (Fig. 101.18). Place skin retractors and obtain hemostasis.
**Figure 101.19.** Identify the cephalic vein, the guide to the deltopectoral interval. It can be preserved, or ligated and excised.

- Bluntly dissect the deltoid free from adherent underlying bursa or rotator cuff. This is facilitated if the deltoid is relaxed by slightly abducting the arm to find the plane between the deltoid and the bursa. Bluntly dissect between the pectoralis and the clavicular fascia overlying the muscles attaching to the coracoid.
- Then retract the deltoid and pectoralis with blunt Richardson retractors. Gentle abduction of 20° to 25° relaxes the deltoid muscle for ease of retraction. In some pathologic conditions (rotator-cuff tear arthropathy, rheumatoid arthritis), the rotator cuff may at first glance appear indistinguishable from the bursa. Avoid excising what is thought to be inflamed, thickened bursa until it can be clearly distinguished from the tendinous portion of the rotator cuff.
- Incise the clavicular fascia superiorly until the coracoacromial ligament is identified. Then free the subscapularis bluntly from the conjoint tendon of the arm muscles, which should remain attached to the coracoid process to protect the brachial plexus and the musculocutaneous nerve from injury by retraction.
- Cauterize the acromial branch of the thoracoacromial artery, and under most circumstances divide the coracoacromial ligament (**Fig. 101.20**). Release of the coracoacromial ligament facilitates exposure and allows more room for the subscapularis repair at the end of the procedure. However, if the rotator cuff is deficient, do not release this ligament because it may diminish anterosuperior stability of the humeral head, increasing the risk of dislocation.

**Figure 101.20.** Retraction may be rendered less traumatic by release of a small amount of the deltoid insertion. Retract the pectoralis major and muscles attached to the coracoid. Excise the coracoacromial ligament. See the text for important additional details.

- Free the subacromial bursa from any tissue to which it adheres, such as the undersurface of the acromion, before excision. This is more accessible if an assistant places slight traction on the operated arm. Place a blunt retractor, instrument, or finger between the rotator cuff and the bursa so the bursa can be well defined before its removal.
- Assess the integrity of the rotator cuff. Abduction and external rotation enables identification of the subscapularis and assessment of its thickness and integrity. Hyperextension and internal rotation of the shoulder bring the supraspinatus, infraspinatus, and teres minor tendons into the operative field. It is critical to identify the upper and lower margins of the subscapularis tendon. Identify the upper margin by tracing the subscapularis tendon from the coracoid process to the lesser tuberosity or by the rotator interval between the subscapularis and supraspinatus tendons. Identify the lower margin of the subscapularis by the anterior humeral circumflex vessels.
- Then externally rotate the humerus and cauterize the anterior humeral circumflex vessels. Maintaining the humerus in internal rotation during division of the subscapularis will jeopardize the axillary nerve, whereas external rotation and a little flexion help protect the axillary nerve.
- Now evaluate the anterior structures (which were evaluated in the office by examination prior to surgery) under anesthetic. Extensive subscapularis release will allow sufficient external rotation in most cases. However, if the patient is unable to externally rotate to neutral in the operating room under anesthetic, lengthen the capsule and subscapularis tendon. If the shoulder is tight anteriorly, divide the subscapularis tendon and capsule laterally, near the bicipital groove, and mobilize them as a single flap (**Fig. 101.21**). At the conclusion of the procedure, fix the subscapularis and capsule to bone at a more medial location using suture anchors. Repair the medial limb of the subscapularis tendon to the lateral limb of the capsule, effectively lengthening the anterior structures of the shoulder. Alternatively, perform a Z-lengthening of the capsule to the subscapularis.

**Figure 101.21.** Divide the subscapularis tendon and capsule.

- If there is no significant limitation to external rotation, divide the subscapularis tendon 1.5 cm medial to its insertion on the lesser tuberosity adjacent to the bicipital groove. Be certain to divide the subscapularis in its entirety by placing a curved clamp deep to the substance of the subscapularis to help with identification of the most superior and inferior margins during division (**Fig. 101.22,** **Fig. 101.23**). Detaching the subscapularis too close to its insertion on the lesser tuberosity leaves tissue that is inadequate for proper closure. When incising the subscapularis superiorly, divide only this tendon; do not inadvertently divide the biceps tendon in the interval between the subscapularis and supraspinatus. In many instances, the capsule and subscapularis can be divided together, unless preoperative evaluation has determined that tight anterior structures require subscapularis lengthening, as discussed previously.

**Figure 101.22.** Divide the subscapularis from superior to inferior in its entirety.
Division of the subscapularis and capsule provides access to the joint. Avoid the biceps tendon at the superior margin. Cauterize the anterior humeral circumflex vessels at the inferior margin.

- Place several nonabsorbable sutures in the proximal subscapularis tendon for identification, retraction, and reattachment (Fig. 101.24). It is usually unnecessary to detach the muscles attached to the coracoid or to osteotomize the coracoid process. This adds exposure if needed, but take care to protect the musculocutaneous nerve. Mobilize the subscapularis superiorly by sectioning the soft tissue superficial to the biceps tendon in the direction of the base of the coracoid process. The subscapularis may be adherent to the coracoid process. Divide these adhesions for effective subscapularis mobilization and retraction. Although the anterior capsule is divided in its entirety, and even excised if abnormally thick, keep the most inferior capsule intact to protect the axillary nerve, which is at risk from traction and the heat generated during cement polymerization.

- Dislocate the humeral head by gently extending and externally rotating the arm and placing a blunt elevator between the humeral head and the glenoid. Take care with osteopenic bone, as in rheumatoid arthritis, because the shaft can be fractured during dislocation of the head. The humeral head is now ready for osteotomy (Fig. 101.25).

- Before osteotomy of the humeral head, assess for osteophytes (Fig. 101.26), particularly inferiorly, which are common with osteoarthritis. These can mislead you to remove excess humeral neck and jeopardize the axillary nerve. Identification of the circumferential osteophytes enables more accurate identification of the amount of humeral head normally covered by articular cartilage. To remove osteophytes, position flat retractors between the humeral head and the inferior capsule and between the humeral head and superior rotator cuff. Remove the osteophytes with an osteotome or rongeur.

- The articular surface of the humerus is usually in 30° to 40° of retroversion relative to the transverse axis of the elbow. Gauge this by flexing the elbow to 90° and externally rotating the arm 30° to 40°, as required. Hold the trial implant against the humeral head to determine the osteotomy site and the appropriate retroversion of the osteotomy (Fig. 101.27). The usual amount of retroversion should be increased in patients with anterior instability, and decreased in patients with posterior instability. Numerous implants have guides to make the cut more accurate, including the intramedullary guide of the Atlas implant.

- If a resection jig is not used, mark the angle of the osteotomy site with cautery and osteotomize the humeral head with an oscillating or sharp osteotome saw. The three important components of the cut to judge are the neck–shaft angle, the degree of retroversion, and the superior–inferior depth.

- Begin the osteotomy just inside the supraspinatus insertion, at the sulcus between the articular cartilage and greater tuberosity (Fig. 101.28). A surprisingly small amount of bone is removed with the humeral head osteotomy (Fig. 101.29). Save the resected humeral head because it is an excellent source of bone graft.
of the biceps. Resurface and resect the excised humeral head to the level of the superior glenoid and the base of the coracoid. During removal of the soft tissue to expose the base of the coracoid, do not divide the long head of the biceps.

Glenoid Preparation

Adequate muscle relaxation is essential to expose the glenoid. It is usually unnecessary to trim the glenoid osteophytes, although they may distort the normal glenoid anatomy and make orientation of the glenoid slot difficult to judge. For ease of insertion of the glenoid, adjust the arm board to bring the elbow level with the head of the humerus. However, withhold final selection of the humeral component until the glenoid has been resurfaced and the ability to close the rotator cuff is determined.

Selection of the appropriate humeral head implant is critical. Determine the correct head size from the size of the humeral head that has been removed, as well as from an assessment of whether the rotator cuff can be repaired around the implant. In general, a large head size provides a longer lever arm and the potential for more power, whereas a smaller head size makes it easier to close the rotator cuff around the prosthesis. Use the largest stem that fits in the intramedullary canal of the humerus. However, withhold final selection of the humeral component until the glenoid has been resurfaced and the ability to close the rotator cuff is determined.

Use T-handled reamers to prepare the canal of the humerus (top). A glenoid guide may be used for localization of the glenoid slot.

Next, insert the trial humerus prosthesis into the intramedullary canal in about 25° to 35° of retroversion, which can be estimated by positioning the fin on the humeral component lateral and posterior to the bicipital groove. Sometimes it may be necessary to create a small vertical trough for the fin. During the insertion of the humeral prosthesis, keep the arm hyperextended off the side of the table and protect the biceps tendon and supraspinatus with retractors. If the humerus is correctly oriented in the appropriate amount of retroversion, the articular surface of the implant should face directly toward the glenoid with the arm in neutral rotation. Seat the trial implant with a mallet and impactor, then trim remaining osteophytes or protruding bone from around the implant. The depth of the insertion should permit the top of the humeral head to extend slightly above the most superior portion of the greater tuberosity. In addition, proper depth should permit closure of the rotator cuff over the implant. As described earlier, subscapularis lengthening may be required for complete closure of the anterior soft tissues.

Remove the trial prosthesis and use the arm board to position the shoulder for inspection of the joint and preparation of the glenoid. Explore the joint, remove loose bodies, and completely excise the synovium. Completely excise the anterior and posterior labrum. Inspect the glenoid to determine whether it will require resurfacing and whether the quality of bone is sufficient to accept a component. Posterior wear of the glenoid can be difficult to estimate in the operating room and should have been assessed preoperatively on an axillary view of the shoulder or a CT scan. Thoroughly inspect the rotator cuff and biceps tendon. Evaluate the acromioclavicular joint for arthritis and for inferiorly protruding osteophytes, which may cause mechanical impingement. Also, inspect the undersurface of the acromion for an overhanging subacromial spur, which may compromise the result. If necessary, perform an anterior acromioplasty and resect the distal clavicle. If there is a tear in the rotator cuff, mobilization for repair is less difficult once the humeral head has been removed. For even further exposure of a massively torn, retracted rotator cuff, excise the distal clavicle. Note that the humerus is prepared but the permanent implant is not inserted prior to glenoid preparation and insertion. We recommend the routine use of a cemented glenoid prosthesis. Prior to implanting a cementless glenoid component, the risks and benefits as well as the rationale for implant selection should clearly have been explained to the patient.

Adequate muscle relaxation is essential to expose the glenoid. It is usually unnecessary to trim the glenoid osteophytes, although they may distort the normal glenoid anatomy and make orientation of the glenoid slot difficult to judge. For ease of insertion of the glenoid, adjust the arm board to bring the elbow level with the shoulder and support the elbow on operative draping or towels so that the humerus will not fall into hyperextension and obscure the glenoid. Carefully retract the proximal humerus posteriorly with the attached rotator cuff; this is facilitated by placing the ring retractor behind the posterior glenoid (Fig. 101.31). With a flat retractor, expose the inferior glenoid by retracting or excising some of the inferior capsular insertion. A second flat retractor may be needed anteriorly to retract some remnants of the anterior capsule (Fig. 101.31). Remove the remaining glenoid cartilage with a curet, taking care to preserve the subchondral bone. Because the base of the coracoid contains cancellous bone useful for anchoring the glenoid component, it is usually necessary to remove the soft tissue from the area between the superior glenoid and the base of the coracoid. During removal of the soft tissue to expose the base of the coracoid, do not divide the long head of the biceps.
Prepare the glenoid for the keel or peg of the component. The slot for a keel extends along a line from a point immediately below the base of the coracoid to just above the infraglenoid tubercle, and it includes the cancellous bone at the base of the coracoid process (Fig. 101.32). Drill holes at the most superior and inferior aspects of the anticipated slot, and connect them with a burr or drill. Do not widen the glenoid slot excessively, or the component will toggle and secure seating will be difficult. The slot corresponds exactly to the size of the keel. Orient the slot so that it lies directly in the cancellous bone of the glenoid neck. This orientation is often difficult, particularly if excessive wear has occurred anteriorly or posteriorly. With the anterior capsule detached, palpate the anterior glenoid neck to aid proper orientation while the slot is deepened. If excessive asymmetric wear has occurred on the glenoid, orienting the slot and deepening it perpendicular to the flat surface of exposed glenoid can result in perforation of the cortex (Fig. 101.33).

With the initial drill hole and superficial slot made, determine the orientation of the glenoid neck with a narrow curet. The arm must often be rotated internally or externally for optimal glenoid exposure. When this slot has been prepared, and the proper orientation of the glenoid neck has been found, undermine the slot superiorly into the cancellous portion of the base of the coracoid and inferiorly into the inferior glenoid neck (Fig. 101.34). A glenoid guide may be used for this part of the procedure (Fig. 101.35). Remove the remaining cartilage and subchondral bone with your preference of a burr or a reamer. The implant must be supported by subchondral bone.

If, during the preparation of the keel, the posterior or anterior cortex is perforated, pack the defect with cancellous bone before final glenoid insertion. Then use a burr to smooth ridges on the glenoid and ensure solid seating of the prosthesis on the glenoid. Inadequate removal of the peripheral synovium is a common error, particularly at the anterior inferior and posterior inferior aspects of the glenoid.

Drill several holes in the remaining subchondral bone for bone cement penetration, and implant the trial glenoid (Fig. 101.36, Fig. 101.37 and Fig. 101.38). Eliminate any rocking. Several pitfalls exist in seating the trial glenoid that may result in prominence, rocking, or poor fit of the glenoid component (Table 101.1).
Figure 101.36. Make multiple small drill holes in the subchondral bone to help anchor the cement.

Figure 101.37. The trial glenoid is about to be inserted. The trial components for the standard and metal-backed glenoids are of different colors.

Figure 101.38. The inserted trial glenoid. This must be seated securely on subchondral bone. There must not be any anterior and posterior rocking.

Table 101.1. Pitfalls in Seating the Glenoid Component

- As with other arthroplasties that use bone cement to anchor components, cement technique is critical. Irrigate the wound, using the water pick with antibiotic solution to rid the glenoid of clot and fibrous debris. Before cementing the glenoid component, remove all blood and bone fragments from the depths of the glenoid slot. To ensure dry bone surfaces, dry the slot with surgical sponges, and use hydrogen peroxide irrigation, staggered cement insertion if necessary, or even hypotensive anesthesia if a dry field cannot be obtained.

- Use a syringe to ensure penetration of cement into the depths of the prepared glenoid. Insert the glenoid component by hand and hold it until the cement hardens. Remove excess cement, particularly from the posterior recess. Anterior cement may bind the subscapularis and impede tendon closure. Be aware that the cement often adheres to the ring retractor and may make removal difficult.

- Once the glenoid prosthesis has been inserted and cement polymerization has occurred, check the prosthesis for security of fixation (Fig. 101.39). Once the glenoid is cemented and the ring retractor is removed, be careful when delivering the proximal humerus into the wound that the greater tuberosity does not lever against the newly cemented glenoid. It is helpful to place a bone hook in the neck of the humerus, pulling laterally while the arm is gently rotated externally (Fig. 101.40). Ensure adequate clearance of the greater tuberosity by palpation. Check the joint for loose fragments of methacrylate as well as any fragments that may protrude beyond the edge of the glenoid component. Remove them carefully with an osteotome or rongeur.

Figure 101.39. Cement a standard polyethylene glenoid component into place. (From Craig EV. Total Shoulder Replacement for Primary Osteoarthritis and Osteonecrosis. In: Craig EV, ed. The Shoulder. Master Techniques in Orthopaedic Surgery. Philadelphia: Lippincott Williams & Wilkins, 1997:45, with permission.)
With the glenoid implantation completed, expose the humeral osteotomy site. Lateral traction with a bone hook during the external rotation diminishes the likelihood that the greater tuberosity will impinge and lever on the posterior glenoid component. (From Craig EV. Total Shoulder Replacement for Primary Osteoarthritis and Osteonecrosis. In: Craig EV, ed. The Shoulder. Master Techniques in Orthopaedic Surgery. Philadelphia: Lippincott Williams & Wilkins, 1997:34, with permission.)

Soft-tissue balancing is critical for motion, stability, and prosthetic longevity. Before inserting the humeral head, make a final check to ensure that the soft tissue is completely mobilized, especially if the rotator cuff has been torn and retracted. The biceps tendon has a tendency to get caught beneath the humeral head as the component is being inserted, so gently retract it. Check the trial humeral head once again to make sure that the orientation is correct. The humeral component should face directly toward the glenoid with the arm in neutral rotation (Fig. 101.41). The top of the humeral head should be superior to the top of the greater tuberosity, to prevent impingement of the greater tuberosity. The fin of the prosthesis should be just lateral to the bicipital groove (Fig. 101.42).

Reduce the humeral head, and test motion and stability. (From Craig EV. Total Shoulder Replacement for Primary Osteoarthritis and Osteonecrosis. In: Craig EV, ed. The Shoulder. Master Techniques in Orthopaedic Surgery. Philadelphia: Lippincott Williams & Wilkins, 1997:38, with permission.)

Insert the prosthesis in 40° of retroversion from the transverse axis of the elbow. With proper retroversion, the fin of the prosthesis is usually lateral to the bicipital groove, and with the arm in neutral rotation, the center of the humeral component articulates directly with the glenoid.

Check the height of the humeral component so that soft tissues can be closed. There are potential problems associated with leaving the humeral prosthesis too proud. It may not articulate properly with the glenoid, it may abut the undersurface of the acromion, or closure of the subscapularis tendon may not be possible. The dangers of sealing the prosthesis too low are that the prominent greater tuberosity may impinge, the prosthesis may be unstable, or the myofascial sleeve may have inadequate deltoid tension to allow maximum power postoperatively. Check this with the humerus reduced, putting traction on the arm in a longitudinal direction. The prosthesis should not be seated so deeply that the humerus subluxates inferiorly with traction.

Whether to cement the humeral component is a matter of surgical judgment (17). If the humeral component has a secure press fit, and the intact tuberosities prevent rotation, then the component may be used without cement. This is particularly appealing in young patients, in whom the avoidance of methylmethacrylate may be preferred. In addition, if glenoid revision becomes necessary, the uncemented humeral component can be an advantage when removing the prosthesis. The humeral component should be cemented in older patients, in patients with rheumatoid arthritis, in osteoporotic bone, or if doubt exists about rotational stability. If cementing, irrigate the canal and dry with a sponge. Place a sponge temporarily in the glenoid to prevent excess methacrylate from extruding into the glenoid as the humeral component is inserted. A bone plug may be used to contain the cement in the humeral canal.

Component orientation may be difficult to maintain during insertion of the humeral head. Inadvertent malrotation may be prevented by temporarily placing a small, thin curet or Steinmann pin in a hole of the fin of the prosthesis to ensure the exact amount of retroversion until seating of the humeral component is near completion (Fig. 101.43).

When inserting the humeral component, maintain proper orientation, with the arm extended and externally rotated the desired amount (usually 40°).

Reduce the humeral head and bring the subscapularis to its point of division for closure. Test the shoulder for stability in forward elevation, external rotation, and internal rotation. It is particularly important after rotator cuff closure, and before wound closure, to bring the arm into external rotation and forward elevation. Thus, the exact ranges of motion sought in therapy can be observed directly, and any tension on the suture lines can be identified. Soft-tissue contracture must be corrected at surgery. If motion is not obtained intraoperatively, postoperative rehabilitation is not likely to restore it.

Close the subscapularis with a nonabsorbable suture (Fig. 101.44). In some instances, if there is severe contraction, once the joint has been resurfaced it may be difficult to reapproximate the subscapularis. Subscapularis release will often allow direct repair; however, in certain cases, subscapularis tendon lengthening may be performed, as described earlier in this chapter.
Place a Hemovac drain between the deltoid and the rotator cuff, and bring it out through a site separate from the skin incision.

Close the deltopectoral interval with an absorbable suture, and close the wound in layers. Apply a sterile dressing and support the shoulder with a postoperative sling and wrap, with the arm in neutral rotation (Fig. 101.45). Take final radiographs to document the position of the prosthesis (Fig. 101.46).

Figure 101.44. Suture the only detached muscle, the subscapularis, to the site of its detachment on the humerus.

Postoperative immobilization may require modification depending on the conditions encountered intraoperatively. For example, in some patients with rheumatoid arthritis or severe cuff tear arthropathy, an abduction brace may be necessary if the quality of the soft tissue is poor. Patients who have had fixed posterior dislocation and have excessive posterior capsular laxity may need to be kept in an external rotation brace to allow the soft tissues to tighten.

Although this outline is a general guide to performing total shoulder replacement arthroplasty, each case must be individualized, both for intraoperative technique and postoperative rehabilitation. The subsequent sections deal with features unique to each diagnostic category of the disease process.

CONSIDERATIONS FOR SPECIFIC DIAGNOSES

PRIMARY OSTEOARTHRITIS

Primary osteoarthritis of the shoulder can be recognized radiographically by the large circumferential osteophyte (seen on the AP radiograph as an inferior protrusion), the sclerosis on both sides of the joint, and subchondral cyst formation in the humeral head. The axillary view often reveals asymmetrical glenoid wear (erosion posteriorly) with apparent posterior subluxation. It is thus critical to evaluate the shoulder before surgery with at least AP and axillary views (Fig. 101.47, Fig. 101.48 and Fig. 101.49). A CT scan may be useful in assessing the amount of asymmetric glenoid wear.

Figure 101.45. Place the arm in a sling and elastic bandage, with the arm in neutral rotation.

Figure 101.46. Radiographic appearance of the total shoulder arthroplasty.

Figure 101.47. Primary osteoarthritis of the shoulder. A large inferior osteophyte, subchondral cyst formation, and sclerosis on both sides of the joint.
The patient with primary osteoarthritis is the ideal candidate for total shoulder replacement because the rotator cuff is almost always normal. However, several features of primary osteoarthritis may make replacement of the shoulder technically difficult. Loose bodies occur frequently and must be carefully sought intraoperatively. The inferior osteophyte may be quite large and overhang the proximal metaphysis. As previously cautioned, during division of the subscapularis tendon, take extreme care to protect the axillary nerve, which courses close to the subscapularis and capsule and is in jeopardy when trimming the osteophyte. The “macro head” with the large circumferential osteophyte can give the impression that a large amount of articular surface must be resected. The unwary surgeon may remove excessive bone while osteotomizing the head. To guard against this, it is usually helpful to trim the obvious osteophytic excrescences first. The remaining humeral head will more accurately reflect exactly how much bone must be removed. Remove only the area of humeral head normally occupied by articular cartilage. This makes it appealing to use a trial implant to mark the area of osteotomy before beginning head resection.

Exposure is the key to glenoid preparation. This is facilitated by global capsulotomy or capsulectomy. Preparing the glenoid in osteoarthritis may be technically difficult because of uneven glenoid wear. Perforation of the cortex may occur while preparing the glenoid slot if this factor is not considered. Determine the correct orientation of the slot by palpation of the neck of the glenoid or by use of a straight blunt instrument along the anterior glenoid neck. If uneven wear exists, the implant may not rest properly on the subchondral bone, and further reconstruction of the glenoid should be considered. This is usually accomplished by reaming or trimming the glenoid with a burr or rongeur to allow secure prosthetic seating. Although the excessively worn side can be built up with cement, this is unwise, because the excess cement mantle may crack and loosen. If the wear is more severe, bone grafting of the excessively worn side can be accomplished using the humeral head. Excess cement mantle may crack and loosen. If the wear is more severe, bone grafting of the excessively worn side can be accomplished using the humeral head (Fig. 101.50), although this is rarely required.

A few patients with osteoarthritis may have associated disease of the acromioclavicular joint or an associated overhanging anterior acromion. If so, an acromioclavicular joint resection or anterior acromioplasty may be required. It is uncommon to have a rotator cuff tear with osteoarthritis, but if this does exist, repair it at the time of the arthroplasty.

RHEUMATOID ARTHRITIS

Technical problems with the rheumatoid shoulder result from the severe, unpredictable destruction of both bone and soft tissue, which is the hallmark of the disease. Severe medial and superior wear of the glenoid, cuff defects of varying sizes, poor soft-tissue quality, associated acromioclavicular joint disease, osteoporosis, and severe bone loss are among the factors that present technical difficulties.
Figure 101.52. Rheumatoid arthritis with severe superior and medial destruction of the glenoid.

Figure 101.53. In this patient with rheumatoid arthritis, there is a fracture of the acromion from superior migration, wear into the acromioclavicular joint, and severe medial migration of the humerus with glenoid bone loss.

Figure 101.54. Rheumatoid arthritis with severe bone loss in the proximal humerus. The amount of glenoid bone loss precluded insertion of a glenoid component, and a proximal humeral component alone was used.

Considerations in the rheumatoid shoulder include the following:

- Evaluate the acromioclavicular joint preoperatively. If radiographic acromioclavicular arthritis exists, if there is tenderness of the acromioclavicular joint, or if there is bone loss from the distal clavicle, excise the distal clavicle.
- Because there is usually dramatic subacromial bursal disease, carefully excise the bursa. The bursa in rheumatoid arthritis may be confused with the rotator cuff tendons, so the limits must be defined during excision. Extensive synovectomy is almost always needed for exposure.
- In addition to joint involvement, rheumatoid arthritis myopathy may weaken the normal humeral head–depressor effect of the rotator cuff, causing the humeral head to ride upward, even in the absence of a cuff tear. This can sometimes cause secondary impingement and may require an acromioplasty. Myopathy may also limit postoperative strength, despite satisfactory passive range of motion.
- Superior head migration may occur from rotator cuff weakness, a feature often accentuated by the use of crutches or a cane. In this situation, leave the coracoacromial ligament intact to prevent anterosuperior head migration.
- The rotator cuff is torn in about 30% of rheumatoid arthritis patients. Such tears are usually not massive and should be repaired at the time of surgery, with direct suture into bone by the usual methods of cuff closure. More often, the rotator cuff is thin and of poor quality.
- Severe osteopenia can weaken bone and result in humerus fracture during initial head dislocation, and tuberosity fracture at the time of humeral head osteotomy or during retraction of the humerus for glenoid insertion. The glenoid can also be fractured if the retractor is used too forcibly.
- In rheumatoid arthritis, always cement the humeral component because the severe osteopenia will often not permit a secure press fit.
- The glenoid may be severely eroded deep into the neck of the scapula. To assess this, a preoperative CT scan is helpful.
- If the glenoid bone loss is extensive, and bone stock does not allow glenoid component insertion, the humeral head may be used alone as a hemiarthroplasty.
- Postoperative rehabilitation often requires modification in the rheumatoid patient because of contralateral arm, ipsilateral elbow, or wrist and hand disease.

In recent years, there has been concern that a deficient rotator cuff may provide inefficient humeral head depression (16). With a nonconstrained arthroplasty, the head may ride up, impact the superior rim of the glenoid, and asymmetrically load the glenoid. There is concern that this may lead to stresses on the component and potential implant failure (16). For this reason, some authors have argued that if the rotator cuff cannot be reconstructed with functioning tissue, consideration should be given to a humeral head prosthesis alone without a glenoid component (16). The ideal treatment for this most difficult group of patients remains uncertain.

ROTATOR-CUFF TEAR ARTHROPATHY

Cuff tear arthropathy is recognized radiographically by severe destructive glenohumeral arthritis; superior migration of the humeral head because of a nonfunctioning cuff; severe superior and medial wear into the glenoid, the coracoid, the acromioclavicular joint, and the acromion; rounding of the greater tuberosity from mechanical impingement; and variable collapse of the humeral head (Figs. 101.55) (39). There may be an unfused acromial epiphysis. Cuff tear arthropathy combines the difficulty of excessive and longstanding major soft-tissue defect with severe glenohumeral destruction. MRI is useful to evaluate muscle wasting and fatty infiltration of the cuff musculature. For most massive defects, if there is fatty infiltration of the cuff muscles, the restoration of cuff continuity may not be associated with increased muscle power. However, the static superior tenodesis effect may contribute to increased active range of motion or function. Also take patient age and function into account in the decision-making process. The following are technical modifications for cuff tear arthropathy:
Figure 101.55. Cuff tear arthropathy of the glenohumeral joint. There is loss of the acromiohumeral interval; deep wear into the acromion, acromioclavicular joint, and glenoid; and rounding of the greater tuberosity from mechanical impingement wear. This is an extremely difficult reconstruction because of the extensive bone and soft-tissue loss.

- Preserve the coracoacromial ligament to prevent anterosuperior head migration (14).
- Do not perform glenoid replacement for end-stage cuff tear arthropathy, because if the cuff is unable to center the head, a “rocking horse” effect may occur, leading to loosening (19).
- Good results have been reported with hemiarthroplasty for arthrosis associated with massive cuff tears (1,53).

By definition, this syndrome is associated with a massive tear of the rotator cuff. With attention to meticulous surgical planning and details, with patience, and with knowledge of alternative means for coverage, the rotator cuff may be reconstructed around the unconstrained implant (16). This reconstruction is technically demanding. The following technical steps can help provide soft-tissue coverage:

- Before surgery, prepare the thigh for possible use of a fascia lata graft.
- Position the arm near the side of the table so that hyperextension and internal rotation will expose the infraspinatus and teres minor, which have retracted posteriorly. External rotation and slight abduction will expose the subscapularis anteriorly.
- Before excising the subacromial bursa on entering the deltopectoral interval, use a blunt elevator to clear the soft tissue from the undersurface of the acromion to free the adherent rotator cuff.
- Placing sutures in the rotator cuff (rather than clamps) will enable traction to be placed on the cuff for mobilization, while preserving tissue integrity, and will permit tension on the sutures to assess tendon mobility.
- Before cementing the humeral component into place, place drill holes in the greater and lesser tuberosities and pass sutures through them if cuff reconstruction is planned.
- If a larger head is used for stability, rotator cuff closure may be difficult. Thus, a smaller head may be a better choice in patients with cuff tears because available soft tissue will be more easily approximated to the greater tuberosity.

Massive cuff tears usually begin in the supraspinatus tendon, which retracts and is scarred to the base of the coracoid and undersurface of the acromion. The tear then extends to the infraspinatus and teres minor. The tendon of the infraspinatus is pulled inferiorly by the teres minor and is adherent to the posterior inferior humeral head. The following sequential steps in soft-tissue mobilization for later implant coverage are necessary:

- Release the multiple adhesions between the rotator cuff, bursa, and deltoid bluntly by finding the plane between the bursa and the cuff posteriorly, and by rotating the humerus as adhesions are bluntly or sharply divided.
- Perform the humeral head osteotomy first, after which cuff mobilization is easier (Fig. 101.56).

**Figure 101.56.** In cuff tear arthropathy, mobilize the rotator cuff after humeral head osteotomy and before glenoid component insertion.

- Retrieve the infraspinatus tendon (which has been pulled inferiorly by a portion of intact teres minor) by pulling cephalad as adhesions are freed.
- The supraspinatus tendon usually retracts posteriorly, but a portion, pulled by intact subscapularis, may adhere to the base of the coracoid process. Retrieve this by bluntly freeing it from the base of the coracoid process. Although you can safely incise along the lateral edge of the coracoid process to free or retrieve scarred tendon, dissection medial to the coracoid process jeopardizes both the musculocutaneous and suprascapular nerves (Fig. 101.57).

**Figure 101.57.** Cuff tear arthropathy. Early distal clavicle excision aids in exposure of the retracted supraspinatus, which is often adherent to both the base of the coracoid and the undersurface of the acromion. The torn infraspinatus is pulled inferiorly by tension from some intact teres minor fibers.

- The subscapularis is often bound by dense adhesions to the inferior base of the coracoid. Release these adhesions to increase subscapularis mobility.
- Although the biceps tendon is often ruptured, if it is intact, suture other tendons to it. Occasionally, with deficient posterior tendons, the biceps tendon can be moved posteriorly by creating a new bicipital groove. Suture the infraspinatus into the intact biceps tendon.
- The subscapularis can be transferred to make up for an extensive superior defect. Identify the interval between the subscapularis and the capsule. Separate the subscapularis from this underlying capsule. Leave the inferior portion of the subscapularis intact to help act as a humeral head depressor and rotate the superior four fifths of the subscapularis superiorly for coverage or suture it into the biceps tendon (Fig. 101.58).
With severe cuff deficiency, an intact biceps may be moved posteriorly to help provide superior or posterior soft-tissue coverage, and it can be used as a stent into which the mobilized spinatus tendons can be sutured. The upper four fifths of the subscapularis can be moved superiorly for added superior coverage.

- Mobilize the teres minor and infraspinatus tendons from within the joint by making a posterior capsular incision close to the glenoid. This may enable these two tendons, retracted and scarred to the posterior capsule, to be retrieved.
- Dissect the conjoined tendon of the short head of biceps and coracobrachialis from the coracoid process. Flexing the elbow may provide some coverage of the gap in the supraspinatus tendon, although this will not reach to the supraglenoid tubercle. During this mobilization, avoid traction on the musculocutaneous nerve. Usually, little additional coverage is obtained by this maneuver.
- With severe posterior and inferior retraction of the cuff, it may adhere to the posterior glenoid neck, making retrieval extremely difficult. Occasionally, a separate posterior incision may be needed to help mobilize the cuff from this retracted position.
- If there is insufficient tendon to provide coverage after complete mobilization, consider fascia lata grafting, freeze-dried cadaver grafting (such as Achilles tendon allograft), or other methods of additional coverage for large tendon deficits.

**ARTHRITIS OF RECURRENT DISLOCATIONS**

The arthritis of recurrent dislocation can be classified into four groups:

1. **Acute:** In the acute setting, a posterior shoulder dislocation may lead to the loss of a significant portion of the articular surface. If the involvement is greater than 40%, consider hemiarthroplasty, depending on whether the patient is a suitable candidate. Gerber and Lambert (18) described the use of osteoarticular allografts for this condition with a satisfactory outcome.

2. **Chronic:** Dislocation arthropathy associated with recurrent shoulder dislocations is usually the result of anterior dislocation (17). This can be recognized radiographically by osteophyte formation on the humeral head and the presence of a Hill-Sachs lesion on axillary view. There may also be anteroinferior wear of the glenoid from recurrent anterior translation.

3. **Hardware penetration:** Penetration of hardware about the shoulder has been documented to cause premature osteoarthritis of the glenohumeral joint (Fig. 101.59) (7, 56). The use of screws and staples about the shoulder has decreased, which has lessened the incidence of this severe complication (42).

4. **Capsulorrhaphy sequella:** Internal rotation contracture following anterior shoulder reconstruction for instability has been associated with arthrosis (24). Anterior release has been documented to be effective for patients who have suffered from this problem (33, 35). These patients occasionally require total shoulder arthroplasty. If a shoulder replacement is planned for a patient with this condition, prepare for a subscapularis release and lengthening (Fig. 101.60, Fig. 101.61), as described earlier in this chapter.

**Figure 101.59.** Tomogram of the glenohumeral joint in a patient who had a surgical procedure for recurrent dislocation. A staple has penetrated the glenohumeral joint and destroyed the humeral head.

**Figure 101.60.** Subscapularis capsular lengthening. Incise the subscapularis 1.5 cm from its insertion, identify the interval between subscapularis and capsule, and incise the capsule near the glenoid. Then suture the subscapularis to the lateral capsular flap, effectively adding length to the subscapularis.
TOTAL SHOULDER REPLACEMENT FOR POSTTRAUMATIC ARTHRITIS

Posttraumatic arthritis presents unique problems in arthroplasty. Malunion or nonunion of tuberosities, nerve injuries, and shortening of the subscapularis muscle commonly occur. The humeral head has often collapsed and healed in excessive retroversion, anteverision, varus, or valgus relative to the shaft and tuberosities. Prior internal fixation may have to be moved. Identification of the position of the tuberosities relative to the head may be extremely difficult and should be determined preoperatively, either by plain radiograph or CT scan with or without three-dimensional reconstruction. If the relative position of the tuberosities to the shaft is not severely distorted, maintaining the greater tuberosity and attached rotator cuff in continuity with the shaft makes rehabilitation less complicated. If there is severe displacement or malunion, however, the tuberosities must be osteotomized and repositioned. This adds the problems of fixation and union to the other technical challenges.

Additional exposure can be obtained by releasing the deltidoid insertion subperiosteally, the pectoralis major tendon, and the conjoint tendon, in that order, as required. Consider direct visualization of the axillary and musculocutaneous nerves if previous trauma or prior surgery has distorted the anatomy sufficiently to make identification of these nerves uncertain.

PROSTHETIC REPLACEMENT FOR ACUTE FRACTURES

In some fractures of the proximal humerus (head-splitting or large impression fractures), the extent of cartilage destruction may make preservation of the humeral head impractical (21). In four-part displaced fractures, the degree of displacement has almost certainly disrupted blood supply to the remaining shell of the humeral head because of lenuous soft-tissue attachments. Considering that later total shoulder replacement for posttraumatic arthrosis is difficult and unpredictable, because of distorted anatomy, malunited tuberosities, nerve injury, and bone loss, primary arthroplasty is recommended to treat the acute fracture (27). This single operation is usually more successful than a failed open reduction and internal fixation followed by arthroplasty. The technique for proximal humeral replacement alone in acute fractures follows.

- While the patient is being prepared in the operating room, avoid excessive abduction because neurovascular injury can occur from the sharp, bony fragments.
- Make a long deltidoid incision from the clavicle to the lateral deltidoid insertion and develop the deltopectoral interval. The clavipectoral fascia is often disrupted, but if it is not, incise it to the level of the coracoacromial ligament. Retract the coracoid muscles and pectoralis medially, and the deltoid laterally.
- Locate the biceps tendon; it is a reliable guide to location and identification of the tuberosities. It also provides a guide for the amount of soft-tissue tension after insertion of the prosthesis.
- Develop the interval between the supraspinatus tendon and the subscapularis by dissecting the biceps tendon toward its origin. Then remove the fragment or fragments of humeral head and evacuate the hematoma. With anterior fracture–dislocations, the humeral head may be in close proximity to the axillary artery or brachial plexus. Consider an angiogram in elderly patients if there are signs of vascular compromise. Carefully use a tap from the large fragment set as a “cork-screw” to assist in removal of the head if it is difficult to access. Prepare the medullary canal as in standard total shoulder replacement.
- Because rotational stability is usually lost once the tuberosities have fractured, cement the humeral component, retaching the tuberosities to the prostatic fin. Before cementing the prosthesis in place, drill holes in the humeral shaft and the tuberosities, and pass #5 nonabsorbable sutures for later reattachment of the tuberosities. Do not excise the tuberosities; bone healing is essential to ensure continuity of the attached tendons.
- Cement the prosthesis in 30° to 40° of retroversion. The prosthesis must be placed proud enough that tuberosities can be sutured around the fin of the implant, and tension on the soft-tissue myofascial sleeve is preserved. This usually amounts to approximately 1–2 cm, although the distance from the humeral shaft should be assessed in each individual case. Sealing the prosthesis too low on the humeral shaft will make the soft tissues slack, resulting in a weakened deltoid and an unstable prosthesis. In addition, tuberosity prominence can result in mechanical impingement. A slack biceps at the time of the humeral trial is often an indication that the prosthesis has been seated too deep into the humerus. Reattach the tuberosities with #5 nonabsorbable suture. Secure the tuberosities to one another, to the fin of the implant, and to the humeral shaft segment itself. While the tuberosities are being sutured together, hold them securely to the fin with a towel clip.
- If there is severe comminution or bone loss, consider adding bone graft at this time. Close the interval between the supraspinatus tendon and the subscapularis with nonabsorbable suture, copiously irrigate the wound, and place suction drains deep to the deltidoid muscle. Then reapproximate the deltopectoral interval.

Rehabilitation following fracture differs from the rehabilitation after inserting a prosthesis with intact rotator cuff and bone. The tuberosities must heal before active muscle contraction is begun to avoid displacement. Nevertheless, begin passive or assistive exercises in 5 or 6 days. Delay assistive external rotation for 2 weeks to allow some healing of the tuberosities.

PITFALLS AND COMPLICATIONS

Complications can occur during or after total shoulder arthroplasty. Injuries to the brachial plexus and the vascular structures are of particular concern. The reported incidence of neurologic complications following total shoulder replacement in the largest reported series was 4% (34). However, if these, only 1% had deficits that interfered with rehabilitation, and most neurologic deficits resolved.

Fortunately, infection is uncommon following total shoulder replacement (54). As is the case with hip and knee arthroplasty, increased infection rates are seen in patients with host-related risk factors such as diabetes mellitus, rheumatoid arthritis revision surgery, and previous infection (36,59).

Intraoperative humerus fracture has been reported to occur during manipulation of the limb, reaming of the intramedullary canal, broaching of the canal, and insertion of the prosthesis (64). Treat intraoperative humeral fractures with cerclage wire and a long-stem prosthesis (19) or dynamic compression plating. Intraoperative fracture of the glenoid is less common. Treatment of this complication involves the use of bone graft or a revision implant with a wedge to accommodate the defect (54).

Postoperative fracture of the humeral shaft may be treated nonoperatively, but it generally requires surgery (6). The pathologic anatomy of the injury should dictate the choice of treatment. One study of nine periprosthetic fractures suggested that long oblique and spiral fractures be treated nonoperatively, whereas transverse and short oblique fractures be treated with surgery (55).

Shoulder instability is the most common periprosthetic complication of shoulder arthroplasty (13,41). The instability may be secondary to soft-tissue imbalance, component malposition, bony deformity, or a combination of these (43). Instability can be anterior, posterior, inferior, or superior. Anterior instability is most commonly due to subscapularis rupture. Less commonly, this pattern of instability can be due to increased anteverision of the humeral or glenoid components (41). Subscapularis tendon rupture, if not caused by direct trauma, can be repaired directly. Late diagnosis often leads to an irreparable situation, requiring pectoralis major tendon transfer or Achilles tendon allograft to reconstruct the anterior soft tissues.

Increased humeral retroversion can lead to posterior instability. However, posterior glenoid wear, which is common in degenerative arthrosis, may lead to a retroverted glenoid component if this osseous deformity is not noted in the preoperative planning and accounted for at the time of surgery. Soft-tissue imbalance can be dealt with by lengthening the tight anterior structures, tightening the loose posterior structures, revising a malpositioned glenoid or humeral component, or using a larger humeral component if this osseous deformity is not noted in the preoperative planning and accounted for at the time of surgery. Soft-tissue imbalance can be dealt with by lengthening the tight anterior structures, tightening the loose posterior structures, revising a malpositioned glenoid or humeral component, or using a larger humeral component if this osseous deformity is not noted in the preoperative planning and accounted for at the time of surgery. Soft-tissue imbalance can be dealt with by lengthening the tight anterior structures, tightening the loose posterior structures, revising a malpositioned glenoid or humeral component, or using a larger humeral component if this osseous deformity is not noted in the preoperative planning and accounted for at the time of surgery. Soft-tissue imbalance can be dealt with by lengthening the tight anterior structures, tightening the loose posterior structures, revising a malpositioned glenoid or humeral component, or using a larger humeral component if this osseous deformity is not noted in the preoperative planning and accounted for at the time of surgery.
reconstructed at the time of arthroplasty if any deficiency exists (41). Radiographic evidence of resorption around the glenoid component, which suggests loosening, has been shown to occur in 30% to 100% of cases (2,40,45,51). However, the majority of these implants are not clinically symptomatic (45). Lucent lines around humeral components are less common than in the glenoid; however, symptomatic loosening of humeral components is rare in most series (2,40,51,54).

OUTCOME MEASUREMENT

Health-related quality of life is an important part of patient assessment. There has been an increase in the emphasis on outcomes research as expenditures for health care have increased and the justification for resource allocation has become paramount (39). Although detailed review of this topic is beyond the scope of this chapter, some important concepts with respect to outcome evaluation should be mentioned.

Traditionally, orthopaedic surgeons have evaluated the results of surgery with assessments such as radiographs and physical examination. These measures do not take into account the patients’ perspectives. There are many questionnaires available to measure patient outcomes for individuals with disorders of the shoulder. These instruments have been tested for reliability, validity, and responsiveness to clinically significant change (3,4). Scales that are specific to the shoulder and upper limb and that can therefore be used for the assessment of patients before and after total shoulder arthroplasty include the simple shoulder test (32), the shoulder rating questionnaire (31), and the DASH (an acronym for disabilities of the arm, shoulder, and hand) (25). The latter tool is specific to the entire upper limb, allowing comparisons of patients with various disorders, whereas the former instruments are specific exclusively to the shoulder joint.

Generic health-status measures, such as the SF-36, are used to measure overall health. These instruments have a broader perspective, including emotional, social, mental, and physical health, and do not restrict attribution to a particular disorder. Generic health status measures are valuable because they allow comparisons across conditions and treatments. The disadvantage of these questionnaires, however, is that they may not measure clinically important change because an isolated problem may not be reflected in this global measure (5,23). The specific measures are more responsive to change in the phenomenon of interest and may be more relevant (26,43).

Both generic and joint- or region-specific questionnaires should be used to evaluate patients undergoing total shoulder arthroplasty. Investigators should avoid nonstandardized outcome assessment tools in the evaluation of patients who have undergone total shoulder replacement, because this complicates comparison across different groups (3,4). Measures of impairment, such as diagnostic imaging and physical examination, complement health-related quality-of-life instruments and remain an important part of patient outcome assessment.

REHABILITATION

Success of total shoulder replacement is intimately related to postoperative rehabilitation (8). The unique character of the shoulder, where stability and function depend on the surrounding soft tissues, makes it essential that the postoperative focus be on the care of the soft tissues and in particular on the rotator cuff.

Rehabilitation depends on the pathology encountered, the goals of the surgeon and the patient, and the resolution of the intraoperative variables. It can be broadly divided into early and late phases. In the early period, the immediate aim is to maintain the motion achieved in the operating room following bone and soft-tissue reconstruction by preventing adhesions in both the subacromial and the glenohumeral joint spaces. This requires protection of repaired or reconstructed soft tissues.

The operating surgeon must provide direction in rehabilitation. After intraoperatively assessing implant stability and tension in repaired tissue, the surgeon makes the decisions concerning the desired pace toward the short-term goal of improved range of motion. Although passive range of motion can be established through effective bone and soft-tissue surgery, the degree of active range of motion depends critically on the muscle power of the rotator cuff and deltoid muscles. While the early phase of rehabilitation concentrates on establishing range of motion, it is important to add strengthening exercises later for muscle rehabilitation. The timing and progress of rehabilitation must be individualized.

Neer (37) suggested a broad rehabilitation program that is safe, effective, and, most important, easy to understand, so the patient can reliably continue it after discharge. In the first phase after surgery, range of motion is established by a series of exercises aimed at restoring forward elevation in the plane of the scapula, external rotation, and internal rotation. The exercises are all patient-assisted, although more recently Neer emphasized that passive motion can be an effective means of establishing range of motion. A typical rehabilitation program is performed five times daily for 15–20 minutes each session. Rehabilitation after total shoulder arthroplasty is more intense than after hip or knee replacement, and it is the key to success.

The patient begins with a brief warm-up of Codman’s gravity-assisted pendulum exercise by bending at the waist and making circles with the operated arm. This is followed by assistive forward elevation, standing and using an overhead pulley, with the unoperated arm acting to raise and lower the operated arm. External rotation is performed with the patient supine, the arm at the side, and the elbow flexed to 90°, with the arm pushed into external rotation by a stick or cane. Internal rotation is initiated by stretching both arms into extension and cephalad toward the scapula.

Continuous passive motion has been shown to maintain motion comfortably in the early postoperative period, provided there is adequate bone and soft-tissue reconstruction (11). Patients who exercise with continuous passive motion achieve adequate motion more rapidly and can be safely discharged earlier from the hospital without compromising soft-tissue and bony repair. Whether continuous passive motion itself is important or whether it acts merely to deliver passive motion remains to be seen.

Early motion must be instituted after total shoulder replacement to minimize postoperative adhesions. A mechanical (continuous passive motion) device can be used, a physical therapist can be involved, or assistive exercises can be performed by the patient. It is important that progress be monitored closely, as many patients lack the confidence or understanding to carry on with the program by themselves. Where stability of the implant or the quality of the soft-tissue repair is such that early motion is unsafe, modify the basic program just described.

As motion improves and tendons heal, add strengthening exercises. It appears most important to concentrate on the anterior and middle deltoid and the rotator cuff, especially the infraspinatus and teres minor. Therapy for this area is often initiated as isometric exercises, with the later addition of active resistive exercises. One effective means of adding progressive resistive exercises is with an elastic exercise band, a dental dam, or surgical tubing, a portable and inexpensive method that may effectively be used at home.

Rehabilitation following total shoulder replacement continues for at least 1 year, with more resistive exercises added as strength improves.

Table 101.2 shows a typical rehabilitation program for patients with osteoarthritis, in whom the deltoid and rotator cuff are normal and the only muscle detached and repaired is the subscapularis. In patients with a severe soft-tissue deficit, such as cuff tear arthropathy, and in some patients with rheumatoid arthritis, the program might be modified as shown in Table 101.3.

ELBOW ARTHROPLASTY

INTERPOSITION ARTHROPLASTY

Resection and interposition arthroplasty are now infrequently performed with the advent of successful replacement arthroplasty. Resection arthroplasty should be avoided due to the gross instability that results from removal of the distal humerus and proximal ulna. The most common indication for resection arthroplasty is a failed infected total elbow arthroplasty (63). Interposition arthroplasty continues to be used in selected patients with elbow arthritis. The procedure consists of interposing fascia lata or dermis between the humerus and ulna while maintaining the overall shape of these bones to preserve stability.

Indications

The most common indication for interposition arthroplasty of the elbow is incapacitating pain and stiffness due to old sepsis, prior trauma, hemophilia, or inflammatory arthropathy. With improved prosthetic arthroplasties of the elbow, interposition arthroplasty is now most commonly used for young patients with posttraumatic arthritis for which the results of total elbow arthroplasty are less reliable. Patients with more than 50% loss of articular cartilage and joint incongruity should be considered for an interposition arthroplasty rather than a surgical debridement. Interposition arthroplasty can be considered in young patients whose elbows are ankylosed but whose functional demands require motion. Patients must be able to cooperate in the postoperative rehabilitation program, which is an essential part of the success of interposition arthroplasty.

Contraindications

Patients with recent sepsis should undergo staged debridement before interposition arthroplasty. Delay arthroplasty until all epiphyses are closed. Patients with a poor soft-tissue envelope should have flap coverage before any type of elbow arthroplasty. Consider elbow arthrodesis or tendon transfers before interposition arthroplasty for patients with inadequate muscle power for flexion and extension. Avoid interposition arthroplasty in heavy laborers because pain relief is often incomplete. Patients who require ambulatory aids for walking may develop increased elbow instability after surgery, which may impair their ability to ambulate. Accept an ankylosed elbow in a functional position because the results of interposition arthroplasty in such circumstances are less reliable than for other indications.

Operative Technique

A variety of different materials have been employed for interposition arthroplasty. Of these, the most popular have been the use of fascia lata or skin (5, 8, 33, 41, 50, 55, 78). Some surgeons have advocated the use of an articulated external fixator to distract the elbow in the postoperative period to improve the outcome (55). There are no comparative series evaluating the efficacy of adding a distraction device to an interposition arthroplasty. In spite of this, distraction interposition arthroplasty has become increasingly popular because it allows immediate postoperative elbow motion while maintaining stability. Distraction of the joint in the postoperative period may have an additional advantage by allowing the interposition material to become biologically attached to the underlying bone before being subjected to compression and shear loading.

- With the patient supine, prep and drape the arm and inflate a sterile tourniquet.
- Make a midline posterior elbow incision, staying just lateral to the tip of the olecranon (15). Elevate a full-thickness lateral flap and identify the Kocher interval between the anconeus and extensor carpi ulnaris (Fig. 102.1).

![Figure 102.1](image)

A: The Kocher interval is identified between the anconeus and the extensor carpi ulnaris. B: The lateral collateral ligament complex is detached from its humeral origin, and the elbow is subluxated to achieve wide access to the joint. C: The fascia lata is folded onto itself and wrapped over the articular condyles of the distal humerus and secured with nonabsorbable sutures. D: The elbow is reduced, and the lateral ligaments are repaired through drill holes in the lateral epicondyle using nonabsorbable sutures.

- Elevate the common extensor origin off the lateral epicondyle and supracondylar ridge anteriorly. Reflect the anconeus posteriorly.
- Detach the lateral collateral ligament complex from its humeral origin to achieve wide access to the elbow. The triceps may need to be elevated off the olecranon in continuity with the anconeus, and the medial collateral ligament may have to be partially released in some patients to achieve adequate exposure, particularly in those with very stiff elbows.
- Excise the anterior and posterior capsule and remove any osteophytes to improve motion.
- Using a burr, smooth and contour the greater sigmoid notch of the olecranon and the trochlea of the distal humerus. Take care to minimize removal of subchondral bone because this often results in excessive bone resorption in the postoperative period.
- If possible, preserve the radial head to maximize the stability of the elbow. It can be debrided if it is mildly arthritic; however, it should be excised if it is involved...
with advanced disease.

- Make a 25 cm incision over the proximal lateral thigh. Remove a 10 cm wide by 25 cm long portion of fascia lata. Do not close the fascial defect.
- Fold the fascia lata onto itself to create a three-ply graft. Wrap the fascia over the articular condyles of the distal humerus, and secure it with #1 braided nonabsorbable sutures.
- Reduce the elbow and repair the lateral ligaments through drill holes in the lateral epicondyle. Close the fascia between the anconeus and extensor carpi ulnaris to augment lateral elbow stability.

Consider an articulated external fixator to maintain motion while protecting the interposed graft tissue during healing. Options include the Dynamic Joint Distractor (Howmedica, Rutherford, NJ) developed by Morrey (Fig. 102.2) or the Compass Universal Hinge (Smith & Nephew Richards, Memphis, TN) developed by Hotchkiss (Fig. 102.3).

**Figure 102.2. Dynamic Joint Distractor.**

**Figure 102.3. Compass Universal Elbow Hinge.**

The Dynamic Joint Distractor uses a large threaded pin, which is placed through the axis of rotation of the distal humerus as well as two pins for fixation in the ulna. Adjustable distraction of the joint is permitted. This device maintains stability of the elbow while allowing early active and passive mobilization. It is easy to apply; however, because the intrarticular axis pin is left in the distal humerus, it may have a higher incidence of postoperative joint sepsis.

The Compass Universal Elbow Hinge places two to three pins in the humerus and two pins in the ulna. All pins are placed remote from the axis of the joint, which reduces the possibility of postoperative infection. Distraction of the joint is permitted, and a worm gear mechanism allows the patient controlled passive postoperative mobilization of the elbow. This hinge is bulkier and somewhat more difficult than the Dynamic Joint Distractor to apply.

The technique for using an articulated external fixator is as follows:

- Identify the axis of motion of the elbow, passing from the center of the radius of curvature of the capitellum laterally to just anterior and distal to the medial epicondyle, and place a guide pin. Take care to identify and protect the ulnar nerve (Fig. 102.4).

**Figure 102.4. Elbow flexion axis.**

- Reduce the elbow joint and repair the soft tissues as previously described.
- Mount the fixator on the central axis pin and apply the remainder of the pins for the articulated external fixator. Distract the joint 2 to 3 mm to prevent dislodgement of the graft during early active and passive mobilization.

**Rehabilitation**

Administer a continuous axillary block either preoperatively or in the recovery room to facilitate postoperative pain control. With an axillary catheter in place, the patient and therapist can initiate immediate postoperative passive range of motion. Alternatively, employ a continuous passive motion machine. Use ice packs to control edema. Commence active assisted motion after removal of the axillary block. Throughout the postoperative period, maintain elbow and forearm motion, along with meticulous pin site care. Remove the elbow distraction device 6 weeks after surgery. Begin passive stretching at 6 weeks and strengthening at 12 weeks. Provide resting extension and static progressive flexion splints after fixator removal to help regain motion under the supervision of a physical therapist.

**Results**

Morrey et al. (55) have reported good results with distraction interposition arthroplasty. Pain was reduced, although at least half the patients had some residual discomfort. Motion increased from an average arc of 27° preoperatively to 107° postoperatively (Fig. 102.5). Unlike earlier reports of interposition arthroplasty without distraction, the stability achieved with this approach has been good. Others (5, 6, 33, 41, 60, 78) have reported good results from interposition arthroplasty without distraction (Table 102.1).

---

Minimize the incidence of these complications by careful patient selection and meticulous operative technique. Avoid bone resorption by preservation of the

Subchondral collapse of the radial head is a common feature of primary osteoarthritis, up to 40% in one series (86). At present, the primary indication for debridement arthroplasty is the younger patient with evidence of loose bodies or impinging osteophytes and a preserved joint space. Older patients with advanced arthritis may be better candidates for a total elbow arthroplasty. Patients who have impingement pain—that is, pain at the extremes of motion with minimal pain in the central arc—are considered ideal. Patients with pain throughout motion generally have more articular destruction and may require an alternative procedure such as an interposition or prosthetic arthroplasty. Patients with

Debridement arthroplasty has long been performed for patients with osteoarthritis. Even though there is increasing experience with arthroscopic debridement, there are

limited clinical reports available documenting the medium- and long-term results of this procedure (see Chapter 82). As a consequence, open debridement is preferred for selected patients with primary or secondary osteoarthritis.

**Indications**

The most common indication for debridement arthroplasty is primary osteoarthritis of the elbow. In one series (83), the prevalence of osteoarthritis was reported at 2%

of 1,000 patients attending a fracture clinic. This disorder is most commonly found in men, particularly those involved in heavy manual labor. Osteoarthritis occurs

secondary to trauma and other disorders such as Panner’s disease, osteochondritis dessicans, and synovial osteochondromatosis. Cubital tunnel syndrome is commonly associated with elbow osteoarthritis, up to 40% in one series (86). At present, the primary indication for debridement arthroplasty is the younger patient with evidence of loose bodies or impinging osteophytes and a preserved joint space. Older patients with advanced arthritis may be better candidates for a total elbow arthroplasty. Patients who have impingement pain—that is, pain at the extremes of motion with minimal pain in the central arc—are considered ideal. Patients with pain throughout motion generally have more articular destruction and may require an alternative procedure such as an interposition or prosthetic arthroplasty. Patients with

a well-preserved ulnohumeral joint but advanced involvement of the radial capitellar joint can be considered for a radial head excision in combination with a

debridement arthroplasty. Patients must be able to understand and cooperate in the postoperative rehabilitation program if a successful result is to be obtained from a

debridement arthroplasty.

**Contraindications**

Consider patients with advanced joint space loss for alternate procedures such as interposition arthroplasty as described above or total elbow replacement. Consider patients with a poor soft-tissue envelope for flap coverage, either concomitant with debridement or before it.

**Operative Technique**

Various procedures have been described for debridement arthroplasty of the elbow. All involve resection of impinging osteophytes and removal of loose bodies. Excise

the radial head only if it is involved by advanced disease.

Several surgical approaches have been described, including posterior, medial, and lateral approaches. The use of a posterior midline incision provides the most

flexibility while performing the surgical procedure. Regardless of the surgical approach, remove all osteophytes, particularly on the olecranon and coronoid process,

which typically impinge as the elbow is extended and flexed, respectively.

**Medial Approach**

If the patient has ulnar nerve symptoms preoperatively, routinely perform an anterior ulnar nerve transposition as part of the operative procedure. Particularly in patients who lack elbow flexion preoperatively, increased motion of the elbow after surgery may stretch the ulnar nerve and exacerbate these symptoms.

- Make a midline posterior elbow incision centered just medial to the tip of the olecranon. Develop a full-thickness medial skin flap and perform an anterior ulnar nerve transposition.
- Expose the anterior aspect of the elbow by developing the interval between the pronator teres and flexor carpiradialis, as described by Hotchkiss (Fig. 102.6) (32).
  - Excise the tip of the coronoid process if it is redundant and remove any loose bodies. Excise the anterior capsule. Clear the coronoid and radial fossi of any
  - impinging osteophytes so that near-full elbow range of motion is achieved at the completion of the debridement.
Debridement arthroplasty—medial approach: After isolation and transposition of the ulnar nerve, the interval between the pronator teres and flexor carpi radialis is developed to expose the anterior aspect of the elbow. The anterior capsule is excised, as well as any loose bodies or impinging osteophytes. The triceps is elevated posteriorly to expose the posterior capsule, which is excised.

Elevate the triceps off the posterior aspect of the humerus. Excise the tip of the olecranon and remove any osteophytes or loose bodies from the olecranon fossa. Resect the posterior capsule to optimize the postoperative range of motion.

Lateral Approach Patients who do not have ulnar nerve symptoms can be approached using lateral muscular intervals. Preserve the lateral ulnar collateral ligament. Visualization of the coronoid process is more difficult than with a medial approach.

Make a midline posterior elbow incision centered just lateral to the tip of the olecranon. Develop a full-thickness lateral skin flap and identify the interval between the extensor carpi radialis longus and extensor digitorum communis. This interval provides adequate access to the anterior aspect of the elbow while avoiding damage to the lateral ulnar collateral ligament.

Excise the anterior capsule and any osteophytes, as described for the medial approach.

Expose the olecranon and olecranon fossa by elevating the triceps off the posterior aspect of the humerus and excise the posterior capsule and any osteophytes.

Transhumeral Approach Outerbridge and Kashiwagi have described a procedure whereby the distal humerus is fenestrated through the olecranon and coronoid fossae. Humeral fenestration is particularly useful when the olecranon and coronoid fossae are obliterated by hypertrophic osteophytes.

Make a midline posterior elbow incision centered just medial to the tip of the olecranon. Perform a midline split in the triceps tendon to visualize the posterior aspect of the distal humerus. If there is a pre-existent ulnar neuropathy, transpose the ulnar nerve anteriorly during the same procedure. Alternative exposure can be obtained by elevating the triceps from medial to lateral off the tip of the olecranon.

Fenestrate the distal humerus using a Cloward drill. Ensure central placement of the drill on the olecranon fossa such that the medial and lateral columns of the distal humerus are not violated. Direct the drill 40° cephalad to correlate with the shaft-capitellar angle of the distal humerus. The drill should exit the anterior aspect of the elbow in the region of the coronoid fossa.

Working through the fenestration in the distal humerus, remove any coronoid osteophytes with an osteotome and excise the anterior capsule.

Debridement arthroplasty: Anteroposterior radiograph of a 52-year-old laborer with persistent stiffness and pain at the extremes of motion. Note preservation of the ulnohumeral and radiocapitellar joint spaces with obliteration of the normal radiolucency seen in the region of the olecranon fossa. Lateral radiograph showing osteophytes on the coronoid as well as the olecranon. Postoperative anteroposterior radiograph showing fenestration of the central portion of the distal humerus. Lateral radiograph showing adequate excision of the olecranon and coronoid osteophytes.
Rehabilitation

Administer a continuous axillary block either preoperatively or in the recovery room to facilitate postoperative pain control. Begin elbow motion immediately after surgery with a continuous passive motion machine for 48 hours. Following the discontinuation of the axillary block, commence active motion. Use extension splinting at night to minimize postoperative flexion contractures. A static progressive flexion splint may be used intermittently during the day to optimize postoperative elbow flexion.

Results

Debridement arthroplasty improves pain in more than 80% of patients in most reported series (Table 102.2) (31,53,56,66,86). Although preoperative pain is generally markedly reduced, many patients have mild residual pain, particularly with heavier activities. Gains in motion have been modest, on the order of 20° to 25°. The procedure provides durable pain relief in spite of the tendency to redevelop osteophytes at long-term follow-up (68).

Complications

Elbow instability, stiffness, heterotopic bone formation, infection, ulnar neuropathy, and incomplete pain relief have been reported following debridement arthroplasty. The most common cause of persistent pain is incomplete osteophyte excision and advanced articular degenerative changes. With careful patient selection and meticulous operative technique, patient satisfaction has been high with this procedure.

UNLINKED TOTAL ELBOW ARTHROPLASTY

Constrained, semiconstrained, unconstrained, and resurfacing are all terms that have been used to describe categories of elbow arthroplasties. These terms are somewhat misleading because even “unconstrained” implants have some intrinsic constraint by virtue of the interlocking shape of their articular surfaces (39). A more simplified classification designates implants as linked or unlinked.

Unlinked replacements rely on the capsuloligamentous tissues as well as the intrinsic constraint of the implant to maintain joint stability (40). The decision to use an unlinked or a linked arthroplasty depends on the amount of bone destruction, the status of the capsuloligamentous tissues of the elbow joint, and the surgeon’s experience with these devices. Numerous unlinked implants have been developed. The most popular designs in current use are the Capitellocondylar (Johnson & Johnson) (10,16,17,74,76,87), Kudo (44,45 and 46), Pritchard ERS (Depuy), Sorbie (Wright Medical) (79), and Souter (Howmedica) (48,54,69,75,80).

Many of the early unlinked elbow replacements were designed without stems on either the humeral or ulnar components. A high incidence of mechanical loosening was reported with these early designs (44,46,47,75); however, improved results have been reported with newer stemmed devices. At present, there is no consensus as to whether a radial head replacement should be used in conjunction with the humeral and ulnar components. Although there is a theoretical basis for a radial head component from the perspective of load transfer, this has not been confirmed by clinical experience (89).

All unlinked designs replicate the axis of motion of the elbow to optimize ligamentous balance and maintain joint stability. Differences between implants include the type and length of intramedullary fixation and the shape of the articular surfaces. For example, the depth of the trochlear groove is much greater in the Souter implant than the capitellocondylar design (Fig. 102.10). The intrinsic constraint of these two devices is clearly different, which may have implications with regard to the incidence of dislocation and loosening. The more constrained the implant, the greater the transfer of loads to the bone–cement interface and, hence, the greater potential for loosening. Conversely, less constrained devices may have a higher tendency to postoperative instability or dislocation.

Figure 102.10. A: The humeral component of the Souter total elbow arthroplasty has a deep trochlear groove. B: The capitellocondylar design has a shallower trochlear groove with much less intrinsic constraint.

Indications

Pain, stiffness, and loss of elbow function due to rheumatoid arthritis comprise the most common indication for total elbow replacement. Joint space loss, with relatively well-preserved bone stock and adequate capsuloligamentous tissues, is the main indication for an unlinked design. Patients with advanced bone destruction and joint instability are best treated with a linked device, as is discussed later in this chapter. Patients with rheumatoid arthritis who have less joint destruction may be candidates for synovectomy (either open or arthroscopically), with or without radial head excision as a means to defer arthroplasty. Other forms of inflammatory arthritis, such as hemophilia, are also indications for total elbow arthroplasty. Posttraumatic arthritis is an increasingly common indication for replacement arthroplasty; however, careful consideration should be given to patient age and functional demands because failure rates have been higher in these patients. Patients with periarticular nonunions and acute fractures generally require a linked implant due to bone loss.

Contraindications

Inadequate bone stock and incompetent collateral ligaments are the most frequent contraindications to unlinked arthroplasty. Previous infection has been considered an absolute contraindication to elbow arthroplasty. However, in selected patients, replacement arthroplasty can be considered despite remote sepsis. A staged debridement of the elbow that yields negative cultures should be performed before proceeding with an elbow arthroplasty in the face of previous infection. Elbow arthrodeseis is considered a relative contraindication for replacement arthroplasty. The conversion of an elbow fusion to an arthroplasty is challenging, and the outcome
is unpredictable. A linked arthroplasty will usually be required due to bone loss and ligamentous insufficiency. Paralysis of muscles about the joint or inadequate soft tissues would be considered relative contraindications if they can not be improved preoperatively.

Operative Technique

The preferred surgical technique will be specific to the implant used. The Sorbie device (79) is the author’s preferred unlinked total elbow arthroplasty (Fig. 102.11). One of the principles of treatment for most unlinked implants is to preserve the medial collateral ligament. Accordingly, most surgical approaches are through an extended Kocher approach (Fig. 102.12). Sublux the elbow on the intact medial collateral ligament to achieve adequate exposure for placement of the components. Management of the ulnar nerve is controversial, but most surgeons recommend identification and protection of the nerve with or without formal transposition.

**Figure 102.11.** Humeral, ulnar, and radial components of the Sorbie-Questor total elbow arthroplasty.

![Image](https://example.com/image2)

**Figure 102.12.** Sorbie total elbow arthroplasty: A: Through an extended Kocher approach, the lateral collateral ligament complex is identified and detached from the lateral epicondyle. B: The triceps is elevated off the olecranon from lateral to medial and the elbow is subluxated on the intact medial collateral ligament to achieve adequate exposure for placement of the components. C, D, E: After identification of the axis of rotation of the distal humerus appropriate bone cuts are made and the distal humerus is prepared. CAFE, central axis of rotation. F, G: By using a specialized ulnar cutting jig, the greater sigmoid notch of the ulna is prepared. (Redrawn from “The Sorbie-Questor Total Elbow System” brochure, with permission from Wright Medical Technology.)

- Make a midline posterior elbow incision just medial to the tip of the olecranon to avoid damage to cutaneous nerves (15). Identify and transpose the ulnar nerve into a subcutaneous pocket through a medial flap.
- Expose the elbow with a lateral flap and an extended Kocher approach. Elevate the triceps off the olecranon from lateral to medial and hinge the elbow open on the intact medial collateral ligament.
- Make bone cuts and open medullary canals by using instruments specific for the implant to be done.
- Before cementing the definitive components, perform a trial reduction and ensure congruent tracking of the arthroplasty. Flex and extend the elbow with the forearm held in pronation to tension the medial collateral ligament and close the lateral side of the elbow that has been destabilized by the surgical exposure. If there is maltracking, reposition one or both of the components.
- Perform a linked arthroplasty if there is instability due to an incompetent medial collateral ligament or persistent incongruity in spite of component repositioning. An unlinked elbow arthroplasty that is unstable or maltracks intraoperatively usually continues to function poorly postoperatively.
- Prepare the medullary canals with pulse lavage, dry thoroughly, and insert antibiotic-laden cement retrograde by using a cement gun. Pressurize the cement if the medullary canal is adequately occluded with cement restrictors (18).
- Insert the components and reduce the elbow. Hold the elbow at 90° flexion and full forearm pronation while the cement sets. Elbow reduction allows the components to align with one another and enhances implant tracking.
- Place drill holes through the lateral epicondyle to accommodate sutures that reattach the lateral collateral ligament complex. Close the fascia of the Kocher interval to augment lateral elbow stability, as has been described by Cohen et al. (8). Reattach the triceps tendon to the olecranon using nonabsorbable sutures. Close the skin over suction drains.
- Evaluate elbow stability throughout motion. Splint the elbow in a position of stability, generally 60° of flexion, taking care to avoid any pressure over the posterior incision (Fig. 102.13).

![Image](https://example.com/image3)

**Figure 102.13.** A: AP radiograph of a 44-year-old man with polyarticular rheumatoid arthritis of 20 years’ duration. Note complete loss of joint space with relative preservation of bone architecture. B: Lateral radiograph. C: Postoperative anteroposterior radiograph following Sorbie total elbow arthroplasty. The patient had complete relief of pain and restoration of a functional arc of elbow motion. D: Lateral postoperative radiograph.

Rehabilitation

Begin motion within 48 hours alternating with a resting splint at 90°. Have the patient perform elbow flexion and extension with the forearm fully pronated for 6 weeks to protect the lateral ligament repair. Active assisted flexion and passive gravity-assisted extension protect the triceps tendon repair. Have the patient avoid extension past 30° for the first 3 to 4 weeks to guard against posterior subluxation or, worse, dislocation of the elbow. Permit forearm pronation and supination only with the elbow at 90° of flexion. Apply a resting extension splint 4 to 6 weeks after surgery if the patient is having difficulty achieving extension. Continue this treatment for 12 weeks. Counsel patients not to lift more than 5 kg and not to participate in any upper extremity impact sports (e.g., golf, tennis) after total elbow arthroplasty.

Results
There are numerous published results of unlinked elbow arthroplasty (Table 102.3) (17,44,45,46,47 and 48,69,72,73,74 and 75,80,87). The greatest reported experience in North America is with the capitellocondylar total elbow prosthesis (18). The inventor of this implant has had excellent results, with only a 1.5% incidence of postoperative dislocation. However, other surgeons have reported instability in up to 20% of patients (87). The mechanical loosening rate of this implant has been low in patients with rheumatoid arthritis.

Table 102.3. Unlinked Arthroplasty Results

Similar results with other unlinked arthroplasties have been reported from Europe, Great Britain, and Japan. Souter et al. (80) reported good functional results with the Souter total elbow arthroplasty as well as a low incidence of loosening and instability.

Complications

The most devastating complications of unlinked total elbow arthroplasty are infection and instability. Infection is difficult to eliminate. Immediate surgical debridement is essential if the implant is to be retained. Intravenous antibiotics followed by suppressive antibiotics may allow retention of the implant. If the infection is acute, either in the postoperative period or from a hematogenous source, then consider debridement. Manage late, indolent infections, or persistent sepsis in spite of debridement, by removal of the implant and all cement. Reimplantation of an infected elbow arthroplasty remains controversial; however, a staged revision arthroplasty may be successful.

Postoperative subluxation or dislocation of an unlinked arthroplasty often requires revision to a linked design. Carefully evaluate the radiographic position of the components before revision. If one or both components are malpositioned, then consider repositioning. If the component position is adequate, perform closed reduction and casting to allow capsule and ligament healing. If the elbow remains unstable after a period of immobilization and the component position is acceptable, repair or reconstruction of one or both of the collateral ligaments may stabilize the arthroplasty. If stability cannot be achieved by component repositioning or ligament reconstruction, consider revision to a linked arthroplasty.

Damage to the ulnar nerve can occur at any time during surgery. If the ulnar nerve is not protected and transposed, it may be compressed while the elbow is subluxed to place the components. The nerve may be damaged by power instruments or cement leakage due to its proximity to the olecranon.

Intraoperative fractures of one or both humeral columns may preclude the successful placement of an unlinked design. Consider intraoperative conversion to a linked arthroplasty. Open reduction and internal fixation of the columns can be performed in patients with good bone quality and reconstructible fractures. Cortical perforation or fracture of the humerus or ulna can occur due to the small diameter of the medullary canals. Extravasation of cement with damage to neural structures may occur. Careful repair of the triceps tendon to the olecranon is required to prevent triceps disruption and postoperative extension weakness.

The elbow may become stiff due to inadequate capsular release during surgery or a delay in postoperative rehabilitation. Heterotopic ossification can occur, particularly in patients with hypertrophic osteoarthritis. Wound healing problems are uncommon with postoperative extension splinting and suction drains. Delayed wound healing is occasionally seen in patients with rheumatoid arthritis, particularly those on steroids. Treat minor areas of superficial dermal necrosis by delayed mobilization and extension splinting. Consider surgical debridement, with or without flap coverage, in patients with full-thickness skin loss to avoid secondary infection.

LINKED TOTAL ELBOW ARTHROPLASTY

The initial experience with fully constrained hinged arthroplasty of the elbow had a high mechanical loosening rate (13,26,59,64). The advent of improved loose-hinge linked designs has improved survivorship equaling that of unlinked elbow arthroplasties at medium-term follow-up. Biomechanical data suggest that muscle activation about the elbow may allow semiconstrained linked arthroplasties to function within the laxity of their loose hinge (65). This limits loading of the bone–cement interface and may explain the lower mechanical loosening rates relative to a fixed hinge. Linked devices have a significant advantage over unlinked designs because instability is uncommon. Commonly used linked devices include the Morrey-Coonrad (Zimmer) (7,9,27,58,76), GSB (Gschwend-Scheier-Bahler) (Allopro) (28,29,30), and the Osteonics (43) prostheses.

Indications

Linked devices allow broader indications for total elbow arthroplasty from rheumatoid arthritis to posttraumatic arthritis, bone loss due to tumors, nonunions, and fractures. Be careful when considering total elbow arthroplasty in patients who do not have rheumatoid arthritis. Those with high functional demands and single joint disease will have a higher mechanical failure rate due to the excessive loading they place on their implants. In addition, consider age, vocation, and avocations of the patient. Some linked designs can be employed with loss of the distal humerus up to the level of the proximal aspect of the olecranon fossa and loss of the proximal ulna to the level of the coronoid (59). Most linked designs do not incorporate a radial head component, and therefore, the presence of the proximal radius is not required.

Contraindications

Patients with a recent or remote history of an infection have a higher risk of postoperative infection for any total elbow arthroplasty, including linked designs. Do not consider total elbow arthroplasty for patients who cannot be expected to comply with the postoperative restrictions. Such surgery requires a satisfactory soft-tissue envelope, adequate muscle power, and a functional hand.

Operative Technique

The chosen surgical technique is specific for each implant design. The author’s current preferred linked implant is the Morrey-Coonrad design (Coonrad III) (Zimmer, Warsaw IN) (Fig. 102.14).

Figure 102.14. Morrey-Coonrad linked total elbow arthroplasty: A: Humeral component with beaded flange, ulnar component with polymethylmethacrylate (PMMA)
Position the patient supine with a sterile tourniquet in place. Make a midline posterior elbow incision centered just medial to the tip of the olecranon. Elevate a full-thickness fasciocutaneous flap and transpose the ulnar nerve into an anterior subcutaneous pocket.

Use a Bryan-Morrey approach (Fig. 102.15) for patients without significant distal humeral bone loss. Elevate the triceps off the olecranon from medial to lateral in continuity with the anconeus to expose the distal humerus. This creates a continuous sling of the extensor mechanism.

**Figure 102.15.** Triceps-reflecting Bryan-Morrey approach: A: A midline posterior elbow incision is used. B: After identification and anterior transposition of the ulnar nerve, the triceps is elevated off the olecranon from medial to lateral in continuity with the anconeus to expose the distal humerus.

Use a triceps-sparing approach (58,68) in elbows with deficient distal humeral columns (Fig. 102.16). Work through either side of the triceps while preserving its attachment to the olecranon. Take care to identify and protect the ulnar nerve.

**Figure 102.16.** Triceps-sparing approach: A: The medial collateral ligament is divided. B: The lateral collateral ligament and lateral common extensor origins are released from the lateral epicondyle. C: The distal humerus and ulna are delivered through the lateral muscular interval.

Divide the humeral origins of the collateral ligaments to dislocate the elbow and facilitate exposure of the proximal ulna and distal humerus (Fig. 102.17). Excise the tip of the olecranon and coronoid to avoid restricting postoperative elbow motion by abutting the humeral component.

**Figure 102.17.** Morrey-Coonrad total elbow arthroplasty surgical technique: A: After obtaining exposure of the distal humerus, the intercondylar area is opened and an alignment stem is placed into the humeral canal. A humeral cutting block sits on the capitellum, and appropriate saw cuts are made. B: The ulnar canal is opened with a burr, and the tip of the olecranon is excised. Ulnar rasps are used, and a trial placement of the components and reduction of the joint is performed. C: Cement is injected, and the components are inserted. A bone graft is placed behind the humeral flange. D: The components are connected with an axis pin and locking clip. E: The triceps is reattached to the olecranon with nonabsorbable sutures through drill holes. (Modified from “Coonrad/Morrey Total Elbow: Surgical Technique” brochure, with permission from Zimmer Corp.)

Open the humeral canal in the midline at the level of the olecranon fossa and place the humeral cutting block over the intramedullary guide. Excise the intercondylar portion of the distal humerus using a microsagittal saw. Prepare the humeral canal with appropriate-sized rasps and place a trial humeral component. Use a humeral component with a 100 cm stem for most patients; however, a 150 cm component can be used for those with deficient distal humeral bone stock or severe osteopenia. Use a 100 cm stem if there is shoulder disease that may necessitate the need for a shoulder arthroplasty in the future.

Excise the radial head if it is diseased. Open the medullary canal of the ulna with a power burr and widen with ulnar rasps. Insert trial components and articulate the implant. Ensure that an adequate range of motion is achieved without impingement of the olecranon, coronoid, or radial head on the implant.

Plug the humeral and ulnar canals with cement restrictors. Lavage and dry the canals and inject antibiotic-laden cement retrograde using a cement gun. Cement the ulnar component first and allow the cement to cure. Inject the humeral canal and insert the component. Place an autogenous local cancellous bone graft beneath the anterior flange of the humeral component. Articulate the components using an axis pin before fully seating the humeral component.

Hold the elbow in extension until the cement sets. Reattach the triceps to the olecranon with sutures through drill holes. Ensure that the ulnar nerve is secured anteriorly in a subcutaneous pocket. Close the wound over suction drains and splint the elbow in extension with anterior plaster slabs (Fig. 102.18).

**Figure 102.18.** A: AP radiograph of a 68-year-old woman with a 30-year history of polyarticular rheumatoid arthritis. Note the advanced bone loss and articular destruction. The patient presented with a painful unstable elbow. B: Lateral radiograph. C: Postoperative AP radiograph following a Morrey-Coonrad arthroplasty through a triceps-sparing approach. D: Lateral radiograph.
Rehabilitation

Begin active assisted flexion and forearm rotation 24 to 48 hours postoperatively. Have the patient perform gravity-assisted extension exercises to protect the triceps repair for a 6-week period. If a triceps-sparing approach was used, active assisted extension exercises can be initiated immediately. Have the patient use a night extension splint for 12 weeks to optimize elbow extension and a 90° daytime resting splint for 6 weeks. Long-term restrictions are identical to those recommended for an unlinked arthroplasty.

Results

Numerous reports document the improvements in function following linked total elbow arthroplasty (Table 102.4) (7,9,12,21,22,23,24,25,26,27,28,29 and 30,34,36,43,51,56,57,58,59 and 60,64,77,84). The loosening rate of the Morrey-Coonrad device has been low at medium-term follow-up in patients with rheumatoid arthritis (27). Unfortunately, in patients with posttraumatic arthritis, the mechanical loosening rate has been considerably higher (77). The clinical experience with the Pritchard Mark II hinge device has been less successful (51).

Table 102.4. Linked Arthroplasty Results

The GSB implant was originally designed as a fully constrained hinge and had a high loosening rate (28,30). A semiconstrained metallic polyethylene bushing was added, and excellent clinical results have been reported with this modified implant (30). Although the loosening rate of this implant has been low, disassembly of the linkage mechanism has occasionally occurred.

Complications

The complications of linked total elbow arthroplasty are similar to those previously discussed for unlinked designs (61). The major difference has been that elbow instability is uncommon, given appropriate intraoperative coupling of the implant. Failure of the linkage mechanism requiring revision has been reported with a number of available linked devices. This has been a particular problem for the Triaxial device (52), but failure of the linkage bearings has also been reported in patients with Morrey-Coonrad prostheses (77). The mechanical loosening rate of these devices in younger patients with posttraumatic arthritis is of concern at short- to medium-term follow-up (77). Osteolysis has been seen in some patients. Fracture of the ulnar component has occurred with the Morrey-Coonrad device in patients after falls or heavy lifting (27).

REVISION TOTAL ELBOW ARTHROPLASTY

In spite of the advances in total elbow arthroplasty design and implantation, the increasing numbers of implants being performed, as well as the tendency to extend the indications to younger, more active patients have resulted in failures requiring revision.

Indications

The most common indication for revision elbow arthroplasty is mechanical loosening. This may be asymptomatic or present with an insidious onset of pain. Occasionally, loosening presents as an acute fracture due to cortical thinning from osteolysis (Fig. 102.19). Patients with progressive osteolysis, even in the absence of significant symptoms, should be considered for revision before the development of extensive bone loss (Fig. 102.20).

Figure 102.19. A: AP radiograph of a well-functioning Morrey-Coonrad total elbow arthroplasty 4 years following the index procedure for posttraumatic arthritis. B: Note the osteolysis evident at the tip of the ulnar component. C: AP radiograph following a pathologic fracture of the ulna at the site of the aforementioned osteolysis 1 year later. D: Lateral radiograph. E: AP radiograph following a revision of the ulnar component. Note the cement leakage evident at the tip of the ulnar component through a cortical perforation. F: Lateral radiograph.

Figure 102.20. A: AP radiograph of a 67-year-old woman 10 years after revision total elbow arthroplasty for posttraumatic arthritis. The patient has mild aching pain in the elbow that is worse following activities. Cement leakage is evident at the tip of the humeral component. B: Lateral radiograph. Note the radiolucency around the ulnar component and the osteolysis evident at the tip. C: Intraoperative photograph of titanium synovitis from a loose total elbow arthroplasty. D: AP radiograph following revision to a long-stem cemented Morrey-Coonrad total elbow arthroplasty. This gave the patient complete pain relief and return of function. E: Lateral radiograph demonstrating autogenous bone graft behind the flange of the humeral component.
Patients with instability of an unlinked total elbow arthroplasty are particularly challenging to treat (Fig. 102.21). Removal of well-fixed, cemented implants often results in bone loss, which complicates the revision. Component failures from polyethylene wear of the coupling mechanisms may occur, particularly in younger, more active patients. Component fracture is occasionally seen and requires revision of the fractured component (Fig. 102.22). An infected total elbow arthroplasty that has not responded to debridement requires removal and conversion to an excisional arthroplasty (38,62). Delayed reimplantation has been reported and may be an option for selected patients (68).

B: Lateral radiograph showing persistent joint subluxation. C: Postoperative AP radiograph following revision to a linked arthroplasty. D: Lateral radiograph with pain-free elbow at 4-year follow-up.

![Figure 102.22](image2.png)

**Figure 102.22.** A: AP radiograph of a 32-year-old man 3 years after total elbow arthroplasty for posttraumatic arthritis. The patient developed pain and a sense of instability of the elbow following lifting a heavy object. B: Note the fracture that has occurred through the beaded portion of the ulnar component. In newer versions of this implant, these beads have been removed to avoid the stress riser effect of their application. C: AP radiograph following revision of the ulnar component with impaction grafting of the proximal ulna using autogenous iliac crest bone graft. D: Lateral radiograph demonstrating some cement leakage from a cortical perforation in the ulna.

**Contraindications**

Undertake with caution revision arthroplasty in patients with recent or remote history of infection, as outlined earlier. Consider coverage procedures before proceeding with revision arthroplasty for patients with a poor soft-tissue envelope. Consider excisional arthroplasty (13) or allograft or total elbow arthroplasty (TEA) composite reconstruction (11,23) for patients with inadequate bone stock.

**Operative Technique**

A linked prosthesis is indicated for most revision procedures due to bone loss, which occurs frequently with implant loosening and extraction (38). Exceptions to this would be a stable, unlinked design with aseptic loosening of one or both components, which can be successfully revised while preserving the soft tissues and bone (27).

Before proceeding with revision surgery, be sure that there is an adequate inventory of both standard and long stemmed implants. Standard linked designs can typically be used with or without composite allograft reconstruction, even in the most difficult revision cases (38). Other surgeons have reported using custom designed revision implants with good results at short-term follow-up (20,21,24). Ultrasonic cement removal devices have simplified the removal of cement from the small medullary canals. Use a sterile tourniquet to facilitate extended surgical exposure as needed.

- Use previous skin incisions, if possible, to avoid flap necrosis. Identify and protect the ulnar nerve, even if it has previously been transposed.
- Use a triceps-sparing approach, if possible, to avoid detachment of the triceps from the olecranon, which is often atrophic from previous surgery. Use a Bryan-Morrey or extended Kocher approach with elevation of the triceps from the olecranon if the patient has preserved distal humeral bone.
- Extract loose implants and remove all loose cement from the canals by using standard instruments or an ultrasound device, as indicated. Consider using a cortical window for retrograde removal of well-fixed implants. Leave well-fixed cement that does not interfere with component placement rather than risk cortical perforations and fractures. Remove all cement in cases of infection by using a cortical window in the humerus or ulna, or both.
- Expose the radial nerve in patients undergoing cement removal from the humerus because damage has been reported from power instruments and cement leakage through a cortical perforation at the time of component reinsertion (38).
- Consider the ulnar bow toward the radius, which predisposes the ulna to cortical perforation at the time of cement removal with straight-stemmed revision instruments. Expose the subcutaneous border of the ulna to guide cement removal.
- Place the trial implant and assess the need for cancellous or structural allograft bone. Use antibiotic-impregnated cement, taking care to avoid cement leakage from cortical perforations and consequent damage to nerve structures. Perform a meticulous soft-tissue closure over suction drains and splint the elbow in full extension.

**Rehabilitation**

Depending on the soft-tissue status, early or delayed motion may be indicated. Immobilize patients with tenuous soft coverage in an anterior splint with the arm in the extended position for as long a period as necessary to ensure adequate soft-tissue healing. Immobilization of up to 3 weeks allows restoration of a functional arc of motion while avoiding problems from wound slough. The therapy program generally follows that of a primary elbow arthroplasty but may need to be adjusted in patients with significant bone loss who have had structural allografts. If the triceps tendon is left in continuity, both active assisted flexion and extension can begin in the early postoperative period.

**Results**

Recent reports of revision elbow arthroplasty demonstrate functional results and survivorship rates approaching those of primary elbow replacement at short- to medium-term follow-up (Table 102.5) (14,19,21,24,38,63). Patients with posttraumatic arthritis have had a higher failure rate than those with rheumatoid arthritis, similar to those undergoing primary elbow replacement (38). The complication rate has been higher with revision total elbow arthroplasty, even in experienced hands, indicating that revision total elbow arthroplasty should be performed only by those with extensive experience with primary elbow arthroplasty.
Table 102.5. Revision Arthroplasty Results

**Complications**

Infection may be more common with revision arthroplasty due to the prolonged operative times and the extent of surgical exposures. Intraoperative fractures frequently occur with component or cement removal. Cortical perforation of the humerus has resulted in injury to the radial nerve from cement removal devices and from cement leakage at the time of arthroplasty replacement. Nonunion of allografts has been a problem, particularly when they are placed in a subcutaneous location. Further experience with these grafts is required. Aseptic loosening and failure of the articulating bearings have been reported at longer term follow-up.

**ELBOW ARTHRODESION**

Arthrodesis of the elbow is a salvage procedure indicated to relieve pain and restore stability in situations for which other reconstructive techniques are contraindicated. A successful fusion generally provides good pain relief; however, the loss of motion significantly impairs the patient's functional abilities and therefore even a successful arthrodesis renders only a fair outcome.

In the past, surgeons have recommended that the elbow be fused at 90° of flexion; however, because there is no truly good position for a stiff elbow, a trial of immobilization in different positions is recommended to allow the patient to participate in the decision. Generally, an arthrodesis at approximately 45° of flexion provides the best appearance and function for activities such as writing and bimanual tasks. This however, compromises the patient's potential for self-care. A 90° or 110° position allows the use of the arm for eating, but prevents many extrapersonal activities and care of the perineum.

**INDICATIONS**

The best indication for elbow arthrodesis is posttraumatic unilateral arthritis of the elbow in a young, healthy, active patient. These are patients who are not candidates for or who will not tolerate the limitations imposed by an interposition or replacement arthroplasty. Patients with postinfectious arthritis, tuberculous arthritis, or chronic osteomyelitis may also be candidates for elbow arthrodesis. Arthrodesis is occasionally used as an option for patients with juvenile rheumatoid arthritis; however, interposition arthroplasty or total joint replacements are preferred because of the already impaired function of their adjacent joints. Elbow arthrodeses have been attempted following failed total elbow arthroplasty, but fusions in these circumstances are very difficult to achieve and fraught with complications.

**CONTRAINDICATIONS**

Patients with limited motion in adjacent joints, such as the spine, shoulder, wrist, or hand, are poor candidates for elbow arthrodesis because they cannot compensate for the loss of elbow motion. Bilateral elbow disease is a relative contraindication.

**OPERATIVE TECHNIQUE**

Numerous techniques have been described for elbow fusions including no internal fixation, limited internal fixation, plate fixation, external fixation, and combined internal and external fixation. Plate fixation is preferred in patients undergoing arthrodesis without active sepsis.

- Use a triceps-sparing posterior approach. Transfer of the ulnar nerve is usually required.
- Apply a 10- to 12-hole dynamic compression plate with eight cortices of fixation above and below the elbow that is contoured to the posterior aspect of the distal humerus and proximal ulna. A tensioning device facilitates compression of the arthrodesis.
- Fashion the bone ends to maximize bone apposition and to fit the needs of the position selected for fusion. Use an autogenous iliac crest bone graft to promote fusion (Fig. 102.23).

- When there is evidence of ongoing or recent infection, perform a staged radical debridement with the removal of all internal fixation from the elbow. Treat patients with active sepsis initially with an external fixator using a triangulated lateral half-frame to achieve stabilization of the elbow while allowing adequate debridement and soft-tissue coverage (Fig. 102.24). Following debridement, perform delayed cancellous bone grafting to assist in achieving union. External fixation can be used as a definitive technique to achieve arthrodesis or subsequently changed to internal fixation by means of a plate.

*Figure 102.24. Elbow arthrodesis–external fixation.*
REHABILITATION

Immobilize the elbow postoperatively until fusion occurs. Take care to ensure hand, wrist, and shoulder motion are preserved. It is important to maintain rotation of the forearm because the radius is not usually involved in the fusion except under exceptional circumstances.

RESULTS

Good results have been reported by a number of surgeons, with the goal being successful fusion of the elbow (Table 102.6). Functional outcome studies have yet to be reported on patients with elbow arthrodesis due to the current infrequency of this procedure. In the series by McAuliff et al. (49), successful fusion was achieved in all but one patient despite a lack of postoperative immobilization.

COMPLICATIONS

Symptomatic nonunion has been reported in up to 50% of patients undergoing elbow arthrodesis. The current use of more reliable methods of internal fixation and autogenous cancellous bone has improved the frequency of fusion. Nonunions still occur. Careful debridement of dead and devitalized tissue, as well as control of infection, are critical to achieve union of an elbow fusion. Soft-tissue coverage is a concern with placement of posterior bulky hardware. Late fractures have been reported through a solid arthrodesis as well as adjacent to internal fixation from a stress riser effect. Avoid removal of internal fixation from an elbow fusion. However, if symptoms from hardware persist, waiting at least 18 months postoperatively will allow cortical remodeling and may decrease the likelihood of a fracture. Give appropriate protection to support the arm following hardware removal in these patients.

A. Revision Shoulder Arthroplasty

**GOALS OF TREATMENT**

When a patient presents with continuing symptoms after a shoulder replacement, carefully evaluate the potential factors that may be contributing to the failure, keeping in mind that the rotator cuff, capsule, and ligaments, although invisible on radiographs, are often more important than the position of the components. When contemplating revision surgery, you must have a reasonable idea of what you expect to accomplish at reoperation; exploratory procedures are less likely to succeed than is the correction of an identifiable problem.

**EVALUATION**

When a patient presents with a prosthetic failure, a careful and methodical evaluation is essential to planning appropriate treatment. Review all previous records, including the original preoperative radiographs, prior operative reports (including information about the make and size of the previous implants), and follow-up treatment and therapy records. Ask the patient specifically about recent dental work as well as about any episodes of fever, chills, redness, or drainage that might indicate infection. The therapy history is important both to assess whether the exercise regimen was appropriate and to gain a sense of the patient's reliability and compliance with aftercare: a revision to release scar will be of little help if the patient will not perform the postoperative range-of-motion exercises. Review all available postoperative radiographs, not just the most recent ones. Although different beam angles and technique can make comparison difficult, it is often possible to see increasing periprosthetic lucent lines or frank component migration, indicative of loosening.

On physical examination, assess the active and passive range of motion. Loss of passive motion may be an indication either that contractures were not adequately released at the first operation or that the postoperative exercise regimen failed to maintain motion. Increased external rotation combined with an active internal rotation lag (loss of terminal active internal rotation) suggests a loss of the subscapularis insertion. Loss of terminal active internal rotation is revealed by the lift-off test or the...
stomach press sign. In the lift-off test (Fig. 103.1), the patient puts the hand of her affected arm on her lower lumbar spine and is asked to lift the dorsum of her hand off her spine. The test is positive if she is unable to lift her hand off her back, indicating compromise of the subscapularis tendon. Weakness of elevation and external rotation may suggest loss of the rotator cuff, but always consider a nerve or brachial plexus injury. Assessing elbow and hand motor function can be helpful in this differential. Investigate other sources of pain that may be referred to the shoulder, such as a cervical radiculopathy.

Figure 103.1. The lift-off test can be used to evaluate the integrity of the subscapularis. From Gerber C, Farron A, Hersche O. Isolated Ruptures of the Subscapularis. J Bone Joint Surg Am 1997;78:1015, with permission.

Obtain carefully positioned radiographs, including an anteroposterior (AP) view in the plane of the scapula (ideally, both the glenoid and the humeral components should be shown in profile), an outlet lateral view, and an axillary view. Fluoroscopically positioned films can be used to achieve precise orientation (39). The humerus is seen in profile when the arm is externally rotated by an amount equal to the retroversion in which the humeral component was originally placed. The glenoid is generally best seen when a true AP of the scapula is taken: This gives the best imaging of the cement mantle and of lucent lines.

We generally obtain an erythrocyte sedimentation rate and a complete blood count with differential on all cases of failed arthroplasties. If these are normal, and there is no other indication of infection, then we do no further evaluation. If there is some suspicion, then joint aspiration followed by a bone and indium-labeled white blood count scans are performed. In some situations, a biopsy for culture and pathologic examination may be performed.

While early magnetic resonance imaging (MRI) and computed tomographic (CT) scans were unable to provide adequate images in the presence of a large metal implant, current techniques allow some information to be obtained. MRI scans with special sequences can show subscapularis avulsions and can demonstrate massive cuff deficiency and cuff muscle atrophy. Small tears at the supraspinatus insertion, however, are often obscured by implant artifact. CT arthrography with the use of digital subtraction software can provide useful information in cases of suspected glenoid loosening, and it allows an accurate evaluation of glenoid bone stock, especially in patients who have had a hemiarthroplasty.

Triple-phase bone scan, while not specific, is highly sensitive for loosening or infection and may be a useful adjunct test (13). An electromyogram may be helpful in ruling out nerve and plexus injuries and cervical radiculopathy.

INDICATIONS AND TREATMENT

The source of problems may have been in the planning of the original replacement (improper indications for surgery or poor patient education), or they may have occurred during the surgery (technical errors), immediately after (e.g., improper aftercare), or years after (e.g., trauma or late loosening). Nevertheless, it is most useful to classify prosthetic failure by the mode of failure at the time the patient presents for treatment. The most common types of failure after shoulder arthroplasty are listed in Table 103.2.

### INSTABILITY

Successful prosthetic reconstruction of the shoulder joint requires accurate alignment of the prosthetic joint surfaces and careful balancing of the surrounding soft tissues. Instability following arthroplasty can result from failure to achieve one or both of these objectives and is best considered according to the direction of instability (Table 103.3).

Rates of postoperative subluxation or dislocation following total shoulder replacement have been reported to be as high as 18.2% (18). There are some conflicting reports about the most common instability pattern seen after arthroplasty (5,18,72,73). A collective review of clinical series published before 1988 found that anterior instability occurred most frequently, followed by posterior and inferior instability (18). In contrast, Boyd et al. (5) reported a series of 127 shoulders and found that 23% of shoulders demonstrated superior migration. When approaching prosthetic instability, categorization according to the direction of subluxation is useful for developing
261 total shoulders. Two patients underwent surgical repair, two had no pain but were unable to raise their arms, and one patient had intermittent pain but refused.

Rotator cuff rupture occurs in 2% of patients who have undergone total shoulder arthroplasty (ROTATOR CUFF TEAR). If no component malposition is present, a posterior approach may be used for the capsulorrhaphy. If component revision is also being performed, suture anchors may be placed in the posterior glenoid and the sutures placed through the posterior capsule before implanting the new component. If glenoid retroversion, or if the soft tissues are also imbalanced, posterior capsulorrhaphy can be performed to eliminate redundancy. This may be performed from an anterior approach if component revision is also being performed.

Subscapularis deficiency after total shoulder replacement is more common than was previously recognized. Etiologies include inadequate surgical repair, use of a sharp-edged or an oversized humeral head, and an overly aggressive physical therapy program. Frank dislocations do not always result, but there is usually some element of static anterior subluxation, best appreciated on the axillary view.

Integrity of the subscapularis can be evaluated clinically using the lift-off test or the modified lift-off test (26,27). Careful evaluation of passive range of motion can reveal increased external rotation compared to that of the contralateral extremity. Take scapular AP and axillary radiographic views to assess prosthetic stability and version. In the case of chronic subscapularis rupture, static anterior subluxation may be observed on the axillary view. An MRI with digital subtraction software, or an arthrogram, is useful for assessing the integrity of the subscapularis. A CT arthrogram with digital subtraction can determine component version and stability.

Moedkel et al. (49) reported seven cases of subscapularis rupture following arthroplasty. All patients underwent repair, with rupture occurring in three cases. These patients underwent reoperation using an Achilles tendon allograft as a static anterior restraint. Wirth and Rockwood (73) described pectoralis major transfer for subscapularis deficiency. This technique transfers the pectoralis major tendon over the conjoint tendon to the greater tuberosity. Recently, transfer of the pectoralis under the conjoint tendon has been described as a salvage procedure for chronic loss of the subscapularis (H. Resch, personal communication, 1998).

Glencore anteversion or inadequate humeral retroversion may lead to increased anterior humeral head translation but rarely causes frank dislocation unless the mal-alignment is severe. However, if inadequate retroversion in combination with soft-tissue deficiencies is found, revision of the humeral component, and reconstruction of the anterior soft-tissue deficiencies must be considered (18,72,73). Wirth and Rockwood reported on 18 anterior instabilities in 1994 (72). Four shoulders were treated with closed reduction and immobilization and 14 underwent operative treatment. Clinical results were guarded regardless of treatment (72).

Superior Instability

Superior humeral migration following total shoulder arthroplasty is often seen in association with an attenuated or dysfunctional rotator cuff. When the dynamic stabilizing effect of the rotator cuff is lost, the humeral head migrates superiorly because of the unopposed pull of the deltoid. Component malposition, including humeral lengthening and an inferiorly placed glenoid component, is a less common cause of superior instability. Subtle superior subluxation of the humeral component is not always painful (4,73). However, eccentric superior loading of the glenoid component has been linked to glenoid loosening (26).

Symptomatic anterosuperior humeral migration is of greater concern. This can be especially severe if both cuff deficiency and loss of the passive stabilizing effect of the coracoacromial arch (resulting from surgical decompensation) are present. Options for this difficult problem include attempts to reconstruct the cuff with direct repair or tendon transfers; revision of the humeral component to place it in increased retroversion, and/or to replace it with a wider head that is less able to escape between the remaining acromion and the coracoid; and coracoacro- mial arch reconstruction with fascia or bone grafts. However, little information exists to support the efficacy of any of these approaches, and early results have been disappointing (71).

Inferior Instability

Inferior instability following total shoulder arthroplasty is an infrequent complication and is most commonly seen in patients undergoing arthroplasty for acute fracture of the proximal humerus. In fracture cases, normal bony landmarks have been obliterated, making intraoperative determination of appropriate humeral length extremely difficult. Neer (53) emphasized the importance of maintaining proper tension on the myofascial sleeve of the shoulder. Preoperative templating using the contralateral extremity can be a useful method to determine prosthetic height. Intraoperatively, prosthetic height should allow for 50% inferior translation. If greater translation occurs, more humeral length is required. This may require the addition of bone graft to augment humeral shaft length. Inferior subluxation may also result from nerve injury with deltoid paralysis.

When recognized early, treat inferior subluxation by sling support to prevent permanent capsular stretching. When an axillary nerve injury is present, electrical stimulation may help to prevent atrophy of the deltoid. Inferior subluxation resulting from insufficient component height is difficult to correct with revision surgery, but it may be improved if the myofascial sleeve can be properly repositioned.

Posterior Instability

Posterior instability following total shoulder replacement usually presents as intermittent subluxation rather than as recurrent or chronic dislocation, and it is often related to technical problems at the initial procedure. Component malposition most commonly occurs on the glenoid side because erosion of the posterior glenoid is a common occurrence in osteoarthritis of the shoulder. When not recognized and corrected at the time of surgery, increased glenoid retroversion can result. Furthermore, this can be compounded by posterior capsular redundancy secondary to longstanding posterior humeral subluxation and inadequate release of anterior contractures, which then force the head posteriorly.

Early recognition of posterior subluxation before soft-tissue healing is complete may allow nonoperative treatment to be effective, especially when component malposition is not severe. Exercises can be modified to avoid flexion and internal rotation, and in severe cases a brace may be worn temporarily to keep the arm in slight extension and slight external rotation between exercise sessions. The patient may be told to perform activities with the palm up.

When malposition is severe, or if the posterior subluxation is longstanding, you may need to consider revision surgery. A malpositioned glenoid may require revision into a more appropriate angle. Revision of a modular humeral stem is not usually required unless it is also malpositioned. When there is no apparent glenoid retroversion, or if the soft tissues are also imbalanced, posterior capsulorraphy can be performed to eliminate redundancy. This may be performed from an anterior approach if component revision is also being performed. Place imbricating sutures in the posterior capsule. The imbrication may be side to side, or, if glenoid revision is being performed, suture anchors may be placed in the posterior glenoid and the sutures placed through the posterior capsule before implanting the new component. If no component malposition is present, a posterior approach may be used for the capsulorraphy.

ROTATOR CUFF TEAR

Rotator cuff rupture occurs in 2% of patients who have undergone total shoulder arthroplasty (18). Neer et al. (56) reported five rotator cuff tears in their 1982 review of 261 total shoulders. Two patients underwent surgical repair, two had no pain but were unable to raise their arms, and one patient had intermittent pain but refused.
further surgical intervention. Cofield (14) reported five rotator cuff ruptures in his review of 77 unconstrained Neer prostheses. One patient suffered severe pain, had limited range of motion, and was considering further surgery. The remaining four patients had no pain but had functional weakness.

Rotator cuff tears that occur after total shoulder replacement for osteoarthritis with an initially intact cuff may present with pain and increasing weakness. Base the decision to repair the cuff on the degree of symptoms and functional compromise. If the humeral component was placed too proud, revise the humerus at the time of cuff repair, lest the compression against the acromion and the increased stress in the cuff tendon as it winds around the overly superior head lead to a retear. In such a situation, the cuff is most easily repaired while the prosthetic head is out.

**Repair of Rotator Cuff Tear**

- In the absence of humeral malposition, you may approach tears involving the supraspinatus and/or infraspinatus tendons from a standard superior deltoid-splitting approach.
- Preserve the coracoacromial arch for stability, but shell out and remove any large acromial spurs.
- If the coracoacromial ligament must be detached to remove a spur, then reattach it with transosseous sutures to the acromion.
- Identify and mobilize the torn rotator cuff. Fixation to the tuberosity presents a unique challenge. Bone tunnels can sometimes be created for fixation despite the presence of a cemented humeral component. When severe osteopenia is present, you may achieve bone augmentation with commercially available plastic reinforcement devices (Cuff Link, Innovative, Marlborough, MA) or with the use of small plates. Suture anchors can also facilitate repair.
- Repair the rotator cuff tissue with modified Mason-Allen stitches (26).
- Miticulous repair of the deltoid incision is essential.

Have the patient perform passive range-of-motion exercises postoperatively for 6 weeks, staying within the limits determined at surgery. Follow with a graduated stretching program. Delay resistive exercises until 3 months postoperatively (63).

**INFECTION**

Infection complicates shoulder arthroplasty in less than 0.5% of cases (18). This rate is lower than those seen in replacement of the hip and knee, which range from 0% to 3%. This may be in part a result of the excellent soft-tissue coverage and abundant vascularity present in the shoulder. The hip and knee literature have identified rheumatoid arthritis, male sex, skin ulcers, diabetes, postoperative urinary tract infections, trauma, and revision arthroplasty as potential risk factors for the development of sepsis (23,69). Prosthetic replacement for shoulder trauma has higher rates of infection than that for arthritis, with rates ranging from 3.1% to 4.8% (13, 18,72). This increase is likely because of the additional soft-tissue trauma, bone damage, and hematoma.

The presentations of aseptic loosening and late infection after total shoulder arthroplasty can be similar. Codd et al. (13) found no preoperative investigation to be a reliable indicator for active sepsis in an arthroplasty. They found a 20% false-negative rate for joint aspiration, a 40% false-negative rate for triple-phase bone scans, and a 13% false-negative rate for intraoperative cultures. Analysis of preoperative blood work showed that white blood cell counts were usually within normal limits, and in 13% the sedimentation rate was normal. (These problems occur in the hip and knee as well.) When infection is suspected in a patient with shoulder arthroplasty, a thorough evaluation is required. When in doubt, an open biopsy sent for pathologic evaluation and culture is the most reliable assessment tool.

Early reports recommended resection arthroplasty for infected shoulder replacements (15,53). In contrast, treatment options for infected total hips and knees include irrigation and debridement, immediate exchange arthroplasty or staged reimplantation, and resection arthroplasty. The application of these principles to infected shoulder arthroplasties has been reported recently (13).

Because shoulder arthroplasty infection is uncommon, a treatment algorithm has yet to be defined. Given the poor functional results for activities performed at or above shoulder level with resection arthroplasty (15,52), reimplantation is the preferred treatment (Fig. 103.3).

Codd et al. (13), in a series of 16 patients with septic shoulder arthroplasties, showed that reimplantation of another prosthesis after treatment of the deep infection is a reasonable option. These patients had no recurrence of infection at an average follow-up of 47 months. Base decisions about timing and whether to do another arthroplasty on the relative virulence of the organism, the chronicity of the infection, and the overall health of the patient. In rare cases of early infection (less than 6 weeks after surgery) by antibiotic-susceptible organisms, irrigation and debridement without component removal may be considered by inference from the hip literature; however, data for the shoulder are limited.

**Technique for Infected Total Shoulder Replacement**

In preoperative planning, determine the make and size of the implant that is in place. Have the appropriate instrumentation for prosthetic extraction available, as well as flexible osteotomes, ultrasonic cement removal systems, and specialized cement removal instrumentation.

- Use an extended deltopectoral incision. Excise sinus tracts as part of the skin incision.
- Tissue planes are often obliterated by the infection. Employ caution throughout the procedure to protect the neurovascular structures.
- Release the upper 1 cm of the pectoralis major tendon if necessary to facilitate exposure.
- Identify the subscapularis, and localize the axillary nerve along the inferior margin of the muscle.
- Gently free the anterior surface of the subscapularis tendon from the posterior surface of the conjoined tendon. Take care to protect the musculocutaneous nerve.
- It lies an average of 66 mm from the tip of the coracoid, with a range of 31 to 82 mm (24).
- Release the subscapularis tendon from the proximal humerus. Identify and remove sutures used previously for subscapularis closure, because they may act as a nidus of infection.

**Removal of Infected Shoulder Arthroplasty**

When a cemented arthroplasty is infected, both the prosthesis and cement mantle need to be removed entirely. Take great care in these cases, as the risk for humeral fracture is high. The loose, infected humeral stem and cement mantle can often be removed as one piece.

- If the cement mantle is well fixed, break it with thin, flexible osteotomes and extract the prosthesis.
- An ultrasonic cement removal system may be helpful to free the humeral stem and assist in clearing the canal of remaining cement. The use of intraoperative fluoroscopy and x-rays is of great assistance.
- Take multiple cultures from the prosthesis and canal, and send the interface tissue for pathologic analysis.
- Remove glenoid components: Cut the face of the glenoid components from the underlying pegs or keel with an osteotome. Then remove the peg or keel from the glenoid with curets and osteotomes. In the presence of an osteolytic glenoid, removal of the implant is best performed with the use of a high-speed burr to minimize the risk of fracture.
- Place an antibiotic-impregnated polymethylmethacrylate cement hemiarthroplasty spacer in the humeral canal (Fig. 103.4). Palacos (Smith & Nephew Richards,
Intraoperative cultures have been obtained. If the stem is well fixed but the modular head needs to be resized. Careful preparation will give you greater flexibility during the operation. Hold preoperative antibiotics around the glenoid.

Figure 103.5. Anteroposterior (A) and lateral (B) radiographs of an antibiotic spacer placed after removal of an infected prosthesis.

- Repair the subscapularis with nonabsorbable monofilament sutures, and close the deltopectoral interval over the suction drains. Leave drains in place for 48 hours.

**HINTS AND TRICKS**

- When extracting a humeral stem, it is useful to attach the humeral stem inserter to the fixed prosthesis. The use of a slap-hammer attachment allows the extraction force to be transmitted along the long axis of the humeral stem. This substantially decreases the force required to remove the prosthesis.
- Place the patient on appropriate intravenous antibiotics.

Undertake revision arthroplasty after an appropriate course of antibiotics, usually at least 6 weeks. When the patient’s functional demands are modest, when the organism is virulent or resistant to antibiotics, or when immunologic compromise is present, consider simple removal of the cement spacer and a resection arthroplasty.

**LOOSENING**

The increased frequency of arthroplasty in the treatment of arthritic shoulder conditions, and the increased functional demands of patients with shoulder implants have led to concern over implant loosening. Aseptic loosening in hip and knee prostheses is well documented and is thought to be induced by wear particles that stimulate giant cell–mediated bone resorption (31,35,36,38,57,67). A recent study characterized the particulate debris generated in the total shoulder arthroplasty when radiographic evidence of osteolysis was present. The particles were larger and more varied in shape than those in total hip arthroplasties that required revision (70). No information is currently available regarding the immune response generated by particles of this size.

Clinical series of shoulder implants have demonstrated few revisions for symptomatic component loosening, particularly on the humeral side. Indeed, aseptic loosening of cemented humeral components is extremely rare. In their 1982 series, Neer et al. (59) reported only two patients with such loosening among 94 total shoulders with radiographic evidence of humeral loosening. Although both were symptomatic, neither underwent revision arthroplasty. Information regarding press-fit humeral stems is more varied, but the rate of loosening would appear to be, if anything, higher than that of cemented stems. Cofield (16) reported that less than 1% of cemented humeral stems demonstrated radiographic evidence of loosening, compared to 12% of uncemented stems. Several stems with textured surfaces have been introduced to facilitate bone adherence to the prosthesis, but long-term follow-up is lacking (16,22,27). A new problem introduced by these designs is the difficulty of removing a malaligned or infected ingrowth stem that is not loose.

Most concerns for long-term loosening have centered on the glenoid component. Lucency lines about the glenoid component have been reported in 30% to 83% of cases (18,53), with progression occurring in 12% to 16% of cases. The clinical significance of these radiolucent zones is unclear. Several authors have attributed glenoid lucencies to technical errors occurring at the time of glenoid placement (7,12,63,64). Neer (53) believed that radiolucencies about a glenoid component could be caused by a number of factors, including inconsistent radiographic technique, variable density and strength of glenoid bone stock, stress shielding caused by the glenoid component, and disuse osteoporosis. Both Neer (53) and Brems (7) reported higher incidences of radiolucent lines in cases performed earlier in their series, and that it might be related to inexperience with the technique in earlier cases. Clear radiographic evidence of humeral loosening is present when a completely circumferential radiolucent line of greater than 1 mm width is seen to progress at the bone–cement/prosthesis interface, or when the prosthesis changes position on serial plain radiographs.

Revision for symptomatic glenoid loosening (Eq. 103.5) remains uncommon (2.8%) (7). In a series of 70 total shoulder replacements followed for 5–11 years, complete lucent lines of 1.5 mm or more were found in one third of the glenoid components, but only three components required revision (52). However, unlike the situation with a lower extremity, the use of one arm may be decreased by compensating with the other arm; thus, the rate of revision may underestimate the true rate of component loosening.

**Figure 103.5.** A: One-year follow-up radiograph of a total shoulder replacement performed for osteoarthritis. B: At the 15-year follow-up, progressive lucency is seen around the glenoid.

**Surgical Revision for Loose Implants**

Surgical revision for loose implants requires careful preoperative planning. Special instrumentation is often required, including high-speed motorized burrs, thin flexible osteotomes, and ultrasonic cement removal systems. Have a full complement of prostheses available, including long and short stems. Use prior operative notes to identify the size and make of the failed implant. Have full instrumentation for both insertion and removal available for the system, as well as multiple humeral head sizes. Even if you prefer a different system (which may be employed if all prior components are removed), situations may arise in which the prior system is useful (e.g., if the stem is well fixed but the modular head needs to be resized). Careful preparation will give you greater flexibility during the operation. Hold preoperative antibiotics until intraoperative cultures have been obtained.

- In making a long deltopectoral approach, incorporate the prior incision when possible. The coracoid serves as an important landmark.
- Open the deltopectoral interval, and release the upper 1 cm of the pectoralis tendon to facilitate exposure.
- Identify the underlying subscapularis tendon, and localize the axillary nerve along its inferior margin.
- Release the subscapularis from the proximal humerus, preserving as much tendon length as possible.
- Examine the humeral component for malposition.
- When the stem is loose, it can be removed from the shaft with little damage to the humerus. Removal of a porous-coated stem can be extremely difficult, especially if the textured coating extends to the distal stem. Begin removal with bone and/or cement removal at the stem. This can be done with small curved...
cures and thin osteotomes.

- Place an extraction device, and pull it in line with the stem. Use instruments specifically designed for this, to minimize the force required for extraction.
- If attempts at removal fail, it may be necessary to cut a longitudinal slot anteriorly in the humeral shaft, one third of its circumference in width and three quarters of the stem's length long, giving it a laterally based soft-tissue hinge, to extract the stem (Fig. 103.6). In a standard-length prosthesis, this lies well above the spiral groove, minimizing risk to the radial nerve.

**Figure 103.6.** Osteotomy used to extract a well-fixed prosthesis.

- With the stem removed, take cultures and frozen sections from the bone–implant interface. If more than 10 polymorphonuclear cells are seen per high-power field, place an antibiotic spacer until final cultures and pathology are obtained. If there is no evidence of infection, remove the antibiotic spacer and implant final components in a second operation. If a modular humeral component does not need to be revised but glenoid work is indicated, remove the head and leave the stem in place. Protect it from damage.
- Retract the humerus posteriorly to visualize the glenoid.
- If a humeral head component is being converted to a total shoulder replacement because of glenoid wear and pain, perform a glenoid resurfacing at this time.
- If revision of a glenoid component is required, clear the soft tissue from the rim of the component. If the component is loose, it can be removed easily. If the face of the glenoid component is well fixed but worn or malpositioned, it can be cut from the underlying pegs or keel with a sharp, curved osteotome. The keel or pegs can be extracted from the glenoid with a high-speed burr or curved osteotomes.
- Remove the cement, and obtain cultures and frozen section.

Consider glenoid reimplantation when the remaining glenoid bone stock is sufficient for implant support and the cuff muscles are intact or repairable (53,54 and 55). Otherwise, removal of the glenoid component with conversion to a hemiarthroplasty is preferred. Both approaches may yield good results. Although glenoid bone deficiency can be bone grafted (55), this is rarely performed. Central defects can be treated with impacted particulate graft with cement fixation of the glenoid component, or as a staged grafting procedure. In staged grafting, the defect is packed with cancellous allograft and a hemiarthroplasty is performed. When graft consolidation occurs, a glenoid is implanted at a later date, usually 6 weeks to 3 months. Rim defects can be treated with corticocancellous bone graft fixed with screws. When screw fixation is not feasible, secure the graft with heavy absorbable sutures.

- Place a humeral trial component to determine implant stability and motion. Take care to properly size the components; this is critical for implant stability and postoperative motion.
- Place heavy nonabsorbable sutures around the lesser tuberosity and humeral neck for repair of the subscapularis, then implant the humeral stem with antibiotic-impregnated cement.
- In cases where humeral slotting was necessary to remove the implant, close the osteotomy and secure it with cerclage wires or cables. Maintain complete visualization of the osteotomy during cementation, as extravasation of cement can occur, which may lead to thermal injury of the radial nerve.

**RESULTS**

The results of revision shoulder arthroplasty depend on the preoperative condition of the surrounding soft tissues. Neer and Kirby (54) found that, although pain relief is often possible when specific causes are found, functional recovery is limited. Results of published series are listed in Table 103.4.

**Table 103.4. Results of Revision of Failed Shoulder Arthroplasty**

**PITFALLS AND COMPLICATIONS**

**NEUROLOGIC INJURY**

Neurologic injury after total shoulder replacement is, fortunately, a rare occurrence. The rates of injury are much lower than the 0% to 3% reported for total hips and knees. The cause of neurologic injury is most often traction or compression, but accidental transection is possible. Injuries to the axillary, musculocutaneous, ulnar, or radial nerves have been reported (18,42,72,73). Most injuries are neuropraxias that resolved with time. Lynch et al. (42) reviewed 417 patients undergoing total shoulder arthroplasty and found that 18% of shoulders had a neu- rologic deficit after surgery. Most of these deficits involved the upper and middle trunks of the brachial plexus. Of the 18 shoulders affected, four had lesions that interfered with their rehabilitation. This series identified the long deltopectoral approach, use of methylmethacrylate, and shorter operative times as risk factors for injury.

Patients undergoing total shoulder arthroplasty should have a careful neurologic evaluation postoperatively. If a deficit is identified, institute physical and occupational therapy to maintain joint mobility. When indicated, provide support with splints. If there is no clinical evidence of neurologic recovery in 4–6 weeks, obtain electromyography and nerve conduction studies to document the extent and type of injury and to provide a baseline for monitoring improvement in nerve function. If no improvement is seen in 3 months, consider exploration of the nerve for neurolysis or nerve grafting.

**FRACTURE**

Fracture following prosthetic shoulder replacement is rare, occurring in 1.6% to 1.8% of patients (6,74). Boyd et al. reported seven patients with humeral shaft fracture following shoulder arthroplasty. Two were treated nonoperatively: One developed a painful nonunion but refused surgical intervention, and the other attained union but required revision for a loose glenoid component. Five patients underwent operative intervention when conservative treatment failed after an average of 8 weeks of treatment. Two of those patients developed radial nerve palsies following the fracture, which prompted early surgical exploration. All fractures united.

Wright and Cofield (74) classified periprosthetic fractures according to their morphology:

- Type A: The fracture is centered at the tip of the prosthesis and extends proximally for one third the length of the stem.
• Type B: The fracture is centered at the tip of the prosthesis with slight proximal extension.
• Type C: The fracture is distal to the tip of the stem.

Fractures that fell into category C behaved like closed humerus fractures, and those in categories A and B had a greater risk of nonunion. The authors recommended surgical treatment for type A fractures, operative treatment for type B fractures when satisfactory alignment could not be achieved with closed means or if no evidence of union was present by 3 months, and nonoperative management for type C fractures. Groh et al. (30) reported on four postoperative fractures that occurred an average of 14 months after arthroplasty. They were treated with a fracture brace and early range-of-motion exercises. At an average of 9 weeks, all fractures had united.

Given the paucity of data, it is difficult to establish reliable rules for the treatment of these fractures. We prefer conservative treatment with immobilization in a functional brace if the fracture is well aligned and has a long oblique pattern with a stable stem. However, if the fracture is unstable or the humeral stem loose, we recommend open reduction and internal fixation.

Fixation of a Periprosthetic Fracture

- Use Henry's extensile anterolateral exposure (see Chapter 1). Make a longitudinal incision along the lateral aspect of the arm to expose the biceps tendon.
- Retract the biceps medially to reveal the brachialis muscle. Avoid injury to the musculocutaneous nerve. Identify and protect the radial nerve if it is in the region of the fracture.
- Split the brachialis fibers longitudinally to expose the humeral shaft. Visualize the entire fracture.
- You must evaluate the humeral stem intraoperatively, either with imaging or by direct examination. If the stem is stable and well fixed, reduce the fracture and stabilize it with a large plate, using screws and cables to fix it to the bone depending on its location and configuration.
- Autologous bone graft is recommended to increase the chances for union (4).
- When the humeral stem is loose, perform revision shoulder arthroplasty with a long-stem humeral component.
- Reduce the fracture, and fix it with cerclage cables or wires before the final implantation of the prosthesis stem.

B. SHOULDER ARTHRODESIS

In an age of progressive improvements in shoulder arthroplasty and other reconstructive procedures, the indications for shoulder arthrodesis have become limited. However, glenohumeral arthrodesis remains an important and valuable treatment option for restoring useful function in situations where arthroplasty either has failed or is not indicated. Whereas the optimal results seen with glenohumeral arthrodesis do not compare with those seen with conventional arthroplasty, it should be noted that when arthrodesis is indicated, significant and meaningful improvement in quality of life can be obtained. Although arthrodesis is performed uncommonly, numerous reports show that a functional fusion can be obtained reliably with an acceptable complication rate (17, 33, 40, 51, 59, 60, 61 and 62, 65).

GOALS OF TREATMENT

The specific goal of glenohumeral arthrodesis is to obtain a solid bony fusion between the proximal humerus and the scapula that alleviates pain and allows function through scapulothoracic motion (Fig. 103.7).

![Image](Fig. 103.7). Algorithm for indications and type of shoulder arthrodesis for failed shoulder arthroplasty.

INDICATIONS

The indications for glenohumeral arthrodesis are listed in Table 103.5. Glenohumeral arthrodesis is a reliable means of obtaining shoulder stability and function sufficient for most activities of daily living in patients in whom this would not otherwise be attainable (33, 59). Shoulder stability may come with significant loss of motion because all glenohumeral rotation is lost. In some patients who do not have much glenohumeral motion, the additional loss of motion is negligible. Shoulder arthroplasty is preferred when the final outcome provides stability and good pain control.

![Image](Table 103.5. Indications for Shoulder Arthrodesis)

Surprising function can be obtained after a glenohumeral arthrodesis because of scapulothoracic motion. The procedure reliably controls pain originating in the glenohumeral joint. Counsel patients carefully about the advantages and disadvantages of glenohumeral arthrodesis. Either arthrodesis or arthroplasty is generally hard to reverse. Glenohumeral fusion after a failed arthroplasty, and arthroplasty after takedown of an established glenohumeral fusion are both technically challenging surgical procedures with compromised results.

A general minimum requirement for the performance of a glenohumeral arthrodesis is sufficient strength of the axial and scapular musculature to maintain stability of the scapula. This includes adequate trapezial function. The patient should be in sufficiently good health to withstand major surgery. Additionally, because postoperative recovery (including strengthening of periscapular musculature) can be prolonged, glenohumeral arthrodesis requires a mature patient with long-term goals. This is particularly relevant in patients needing reconstruction after tumor resection.

PARALYSIS

Arthrodesis is generally the treatment of choice for a flail shoulder. Paralytic shoulder secondary to anterior poliomyelitis, upper-trunk brachial plexus lesions, and axillary nerve palsy in the presence of a nonfunctional rotator cuff are indications for arthrodesis. The flail shoulder is a particularly strong indication for an arthrodesis when good elbow and hand function and strong periscapular musculature are present (44, 45, 59, 61, 65). In addition to limited function, patients with flail shoulders may...
The operative technique we prefer for glenohumeral arthrodesis with internal fixation is that of Richards et al. (decreased length of time in plaster or orthotic immobilization. The postoperative care is easier. Internal fixation is the preferred method for achieving glenohumeral arthrodesis. Its advantages are rigid fixation, better maintenance of arthrodesis position, and is indicated in patients with an active infection of the shoulder. Fixation can be achieved by using half-pins in the clavicle, acromion, scapular spine, and glenoid neck.

Intra-articular arthrodesis can be achieved with external and/or internal fixation. External fixation is now rarely indicated because of the superiority of internal fixation. It is contraindicated in patients in whom a glenohumeral arthrodesis is likely to be performed, do not use the trapezius for a muscle transfer, because this is an extremely important muscle. Vascularized bone graft or allograft reconstruction may be necessary to achieve an arthrodesis (the rotator cuff and the deltoid are often removed as part of the resection, stability is difficult to achieve without arthrodesis. After aggressive bone resection, vascularized bone graft or allograft reconstruction may be necessary to achieve an arthrodesis (11,41,43).

**HINTS AND TRICKS**

In patients in whom a glenohumeral arthrodesis is likely to be performed, do not use the trapezius for a muscle transfer, because this is an extremely important muscle for function and pain relief following arthrodesis.

**CONTRAINDICATIONS**

Do not do a glenohumeral arthrodesis if a reasonable method of shoulder reconstruction is available. In general, if the rotator cuff or deltoid still functions, then a total shoulder or hemiarthroplasty can be performed. Additionally, do not do a glenohumeral arthrodesis in the presence of a failed arthroplasty. In patients who have partial periscapular function, lost trapezius function is a contraindication to arthrodesis.

Because glenohumeral arthrodesis requires a prolonged recovery to achieve bone healing as well as periscapular strengthening, it is relatively contraindicated for patients who cannot tolerate prolonged rehabilitation, those who have limited life spans, and those in whom bone healing would be a problem. For this reason, shoulder arthrodesis is generally contraindicated in patients who are physiologically over the age of 70 years.

**TREATMENT ALTERNATIVES**

Glenohumeral arthrodesis can be performed either extra-articularly or intra-articularly, or with both methods, using external or internal fixation. Extra-articular arthrodesis is used often now and was primarily indicated in patients with tuberculous arthritis in whom there were concerns about disseminating an intra-articular infection (29,58,68). Intra-articular arthrodesis can be achieved with external and/or internal fixation. External fixation is now rarely indicated because of the superiority of internal fixation. It is indicated in patients with an active infection of the shoulder. Fixation can be achieved by using half-pins in the clavicle, acromion, scapular spine, and glenoid neck (37,40,51).

Internal fixation is the preferred method for achieving glenohumeral arthrodesis. Its advantages are rigid fixation, better maintenance of arthrodesis position, and decreased length of time in plaster or orthotic immobilization. The postoperative care is easier.

**SURGICAL TECHNIQUE**

The operative technique we prefer for glenohumeral arthrodesis with internal fixation is that of Richards et al. (59,60 and 61).

- Place the patient in an upright beach-chair position with the entire arm, including the scapula, draped free. Place a bump along the medial border of the scapula to position the scapula laterally.
- Make an extensile deltoperioral incision that extends vertically from the spine of the scapula 2–3 cm medial to the acromioclavicular joint and then down a line from the coracoid process toward the deltoid insertion (Fig. 103.84) (see Chapter 1). This avoids placing the incision directly over the plate. In patients with paralytic shoulders and complete atrophy of the deltoid, soft-tissue coverage of the plate is a concern.
Figure 103.8. A: Incision for an extended deltopectoral approach for the shoulder arthrodesis. B: Reflect the deltoid off the lateral clavicle and acromion as needed for exposure. Release of a portion of the insertion into the humerus is helpful. C: Ten-hole 4.5 mm AO reconstruction plate contoured along the spine of the scapula over the acromion and onto the humerus, and fixed with multiple lag screws.

- Develop a subcutaneous lateral flap at the level of the deep fascia.
- Identify the deltopectoral interval, and remove the deltoïd from the anterolateral clavicle as well as the anterior and lateral acromion. If distal extension is necessary, also release the anterior two thirds of the deltoid insertion. In comparison to a muscle-splitting approach, releasing the deltoïd from the anterior and posterior maintains it for coverage of the plate and spares the axillary nerve, avoiding a possible neuroma (Fig. 103.8B).
- Release the anterior and superior rotator cuff cuff directly off its humeral attachment, and retract it medially. Do not excise it. Maintaining the rotator cuff musculature for later repair can help contain bone graft.
- Dislocate the humeral head anterolaterally to expose the glenoid.
- Place a posterior glenoid retractor, and decorticate the glenoid. A standard glenoid reamer from a total shoulder set is helpful for concentric decortication of the glenoid.
- Decorate the humeral head using large curets and a rasp. Maintain the semicircular contour of the proximal humerus to provide a congruent surface area for fixation against the glenoid.
- For fixation, we do not generally recommend superior translation of the humeral head against the undersurface of the acromion. Rather, center the humeral head on the glenoid. This provides a large concentric area of contact, and the glenoid vault is an important area for obtaining screw purchase for fixation and compression of the humeral head against the scapula.
- Apply iliac crest bone graft to bridge the gap between the humeral head and the acromion.
- Alternatively, Richards et al. (61) reported a technique in which the humeral head is translated superiorly for bony abutment against both the undersurface of the acromion and the glenoid. Using this method, bone grafting was not necessary to achieve fusion in most cases. This technique is preferred by many.
- Position the arm for fusion, using an arm holder. Our preferred position is at 20° of abduction, 20° to 30° of forward flexion, and 40° of internal rotation (Fig. 103.9).

The position for arthrodesis has been controversial. Early recommendations from the American Orthopaedic Association established criteria of 45° to 50° of abduction, 15° to 25° of forward flexion, and 25° to 30° of internal rotation (1). Additionally, the method for measuring the position of fixation has varied. Early recommendations used the medial border of the scapula in reference to the long axis of the humerus. Now most surgeons use the side of the body as the reference point and place the arm at 20° to 30° abduction from the side of the patient.

Early recommendations for arthrodesis positioning have been modified. Rowe (66) observed that the previous recommendation of 45° to 50° for abduction was excessive. This position could result in uncomfortable scapular winging when the arm was resting at the side. He noted that shoulder flexion and internal rotation were important for activities of daily living, and some abduction was required to provide clearance for axillary hygiene. Richards et al. (61) noted that the optimum position of glenohumeral arthrodesis is one that allows the hand to be raised in the midline with elbow flexion so that the mouth can be reached. Abduction should not exceed that which allows the arm to rest comfortably at the side. To make it easy, Richards recommends placing the hand on the face and setting the shoulder at 30° of abduction, 30° of forward flexion, and 40° of internal rotation.

HINTS AND TRICKS
- It is important to note that regardless of the position of fusion, the arm will rest at the side a significant amount of the time. Thus, a significant amount of scapular winging would occur if the arm were fused in too much abduction, causing chronic pain due to excessive tension on the trapezius (Fig. 103.10).

The shoulder is fused in excessive abduction. The arm rests at the side, excessive tension occurs in the upper trapezius which can cause chronic pain.

- Once the position of fusion is established, fix the proximal humerus to the glenoid with two 6.5 mm, partially threaded cancellous screws with washers, either independently or through a precontoured plate.
- Next, contour a 10-to 14-hole, 4.5 mm pelvic reconstruction plate to fit over the spine of the scapula across the acromion and down the lateral side of the proximal humeral shaft. The length of the plate is dictated by what is necessary to obtain three bicortical screws distal to the surgical neck of the humerus as well as three cortical screws into the spine of the scapula. Often, a screw can be placed through the acromion into the proximal humerus in a superior-to-inferior direction (Fig. 103.8C). Use either 4.5 mm cortical or 6.5 mm cancellous screws depending on the quality of the bone. Securely compress the head of the humerus to the glenoid using lag techniques.
- Test the entire construct for stability. If there are concerns about the strength of fixation, a spica cast or a rigid orthosis may be necessary.
In many circumstances in which an arthrodesis is necessary, significant scapular and proximal humeral osteopenia has occurred (Fig. 103.11). Screw purchase in the scapular spine can be poor. The strength of the fixation can be improved by placing cerclage wires around the pelvic reconstruction plate and the base of the acromion (Fig. 103.11B).

**Figure 103.11.** A: Radiographs of a patient who had a previously failed hemiarthroplasty and hypoplastic glenoid. Because there was bone loss on the humerus and a hypoplastic glenoid, she went on to nonunion after an unsuccessful attempt at arthrodesis. B: Revision glenohumeral arthrodesis was performed using plate fixation and local vascularized bone graft. Note that plate fixation to the spine of the scapula was augmented with three cerclage wires.

**POSTOPERATIVE CARE**

Unless a rigid external orthosis is necessary because of inadequate internal fixation, use a soft, removable abduction pillow. It will unload the weight of the arm and is easily removed for hygiene; thus it is better tolerated than the orthosis for the 8- to 12-week period that is often necessary to obtain a solid fusion. Once clinical or radiographic fusion has been obtained, place the patient on a rehabilitation program for periscapular strengthening. Give particular attention to strengthening the trapezius, rhomboids, and serratus anterior. Throughout the postoperative period, employ elbow range-of-motion and hand exercises in conjunction with shoulder rehabilitation.

**GLENOHUMERAL ARTHRODESIS IN THE PRESENCE OF BONE LOSS**

Achieving glenohumeral fusion in the presence of proximal humeral or glenoid bone loss such as after failed total shoulder arthroplasty is challenging. Autogenous bone grafting is always indicated in these situations. Additionally, vascularized local bone graft transfers can be effective. The axillary border of the scapula provides a convenient and excellent source for local vascularized bone graft (Fig. 103.12). The axillary border of the scapula is well vascularized by the circumflex scapular artery and muscular attachments of both the teres minor and teres major. To utilize this transfer, extend the vertical saber incision posteriorly approximately 7 cm.

**Figure 103.12.** Schematic of the technique for local vascularized bone grafting. A: Muscle pedicle bone graft developed from the lateral border of the scapula. B: Graft transferred to bridge the glenohumeral joint posteriorly.

- Take the subcutaneous dissection to the superficial deltoid fascia, and release the deltoid off the posterior spine, exposing the infraspinatus and teres minor.
- Split the infraspinatus–teres minor interval up to the glenoid neck, and place multiple drill holes in the scapula along the line between the infraspinatus and teres minor.
- Sharply free the axillary border away from the scapular body by using an osteotome to connect the drill holes. Leave the glenoid intact. Superiorly, the transverse cut is inferior to the glenoid neck and inferiorly the cut is proximal to the inferior angle of the scapula, which leaves the important attachment site of the serratus anterior. Protect the origin of the teres minor from the scapula, as it maintains the vascularity.
- Rotate the axillary border bone graft horizontally, and fix it to the scapular body just inferior to the scapular spine, as well as the proximal humerus laterally (Fig. 103.12).
- Intercalary allograft or a free microvascularized fibular graft might be helpful in very difficult fusions with loss of bone

**RESULTS**

Union following shoulder arthrodesis that employs internal fixation and supplemental external support is generally over 90%. Earlier series, which relied primarily on external support, achieved union but required immobilization for at least 6 months. Pain relief after shoulder arthrodesis is less predictable, with many patients reporting some postoperative discomfort (33,59). Overall patient satisfaction after arthrodesis has not been universally established. A recently published functional outcome analysis of 33 patients found that the single best predictor of the ability to perform activities of daily living was preoperative diagnosis. Satisfaction rates were highest in osteoarthritis, brachial plexus injuries, and failed total shoulders (59). Published results of shoulder arthrodesis are listed in Table 103.6.

| Table 103.6. Results of Shoulder Arthrodesis |

**PITFALLS AND COMPLICATIONS**
HUMERUS FRACTURE

Glenohumeral fusions are often performed in osteopenic bone, where a stress riser distal to the plate is dangerous. It is not surprising that a high fracture rate can occur in this area. Cofield and Briggs (17) reported a fracture rate of 15%. Because this complication often occurs with only minor trauma, closed treatment is often successful. If a glenohumeral arthrodesis is established and internal fixation of a distal humerus fracture becomes necessary, then removal of the proximal plate is recommended for the future to prevent a stress riser.

INFECTION

Infection has been a relatively rare complication. Treat it as you would infected fractures or implants elsewhere (see Chapter 132 and Chapter 135). In general, avoid removal of internal fixation devices until you achieve an arthrodesis. Following this, remove all internal fixation and perform repeat irrigation and debridements and treat with intravenous antibiotics as necessary to eradicate the infection. If the internal fixation has loosened in the presence of infection, remove it and convert to external fixation augmented by an external orthosis.

NONUNION

Clinical union of the arthrodesis site has been a reliable measure of outcome for glenohumeral arthrodesis. Nonunion is rare. In Cofield's (17) series of 71 shoulders, only 4% went to nonunion. Richards et al. (59) reported similarly high fusion rates.

MALPOSITION

In general, patients with arthrodesis can tolerate a large range of flexion and rotation positions. Glenohumeral abduction, in contrast, is poorly tolerated in adults at angles greater than 40°. This is because of the significant scapular winging and trapezial tension that occur when the arm is resting at the side. When malposition causes significant pain or dysfunction, an osteotomy may be required. It is generally performed in the humerus distal to the glenohumeral fusion.

AUTHORS' PERSPECTIVE

Revision shoulder arthroplasty and shoulder arthrodesis can improve functional activities and relieve pain. Careful preoperative evaluation is critical to the planning and success of these procedures: Preoperative counseling is important to provide the patient with realistic postoperative expectations. With realistic expectations and a clear preoperative plan, good clinical results can be expected in these challenging clinical situations.

With the advent of total hip arthroplasty three decades ago, the number of osteotomies about the hip for the treatment of adult hip disease has understandably decreased. However, despite the advancements in joint replacement technology, the challenges remain much as they were in the early 1970s. Even an optimal hip replacement is not expected to survive for a lifetime in a healthy patient younger than 50 years, especially given today’s longer life expectancy. Survivorship of joint replacements in younger adults is possibly less than 10 years.61,62,67,85,102,126,143,153.

Polyethylene wear, aseptic loosening, bone loss, and a host of other potential problems are encountered in young adult patients (defined as being 20–50 years old) who undergo total joint replacement. Complications such as these call for alternative treatments for the patient with a life expectancy exceeding 20 to 25 years. What is to be done for these patients? Many are told that they must modify their activities and palliate their pain until they reach an appropriate age, while their hip continues to deteriorate. A significant portion of these patients, particularly if identified before they develop advanced arthritis, can be successfully treated with an osteotomy of the pelvis or proximal femur (or both).

There is mounting evidence that anatomically abnormal hips do not last a lifetime. In addition, studies have suggested that many hips—actually a majority—that develop osteoarthritis have preexisting pathology.1,7,15,16,169,170 and 171. Such secondary arthritis is generally the result of a biomechanical abnormality affecting the joint. The major predisposing diseases include developmental dysplasia of the hip (DDH), Legg-Calvé-Perthes (or Perthes) disease, slipped capital femoral epiphysis (SCFE), osteonecrosis, and trauma, of which the most common is DDH. Reports vary, but taken together the prevalence of significant osteoarthritis with these diseases by 50 years of age is between 20% and 50%. For dysplasia, the risk is probably 25% to 50%, depending on the severity of involvement, in spite of current treatment methods.83,109,176. For Perthes disease, the chance for painful arthritis by 50 years of age is around 50%.7,91,147,149,173. In the case of SCFE, it is only about 20%, but it certainly varies with the severity of the slip.22,53,118. Often in these patients the childhood hip disease was subclinical and went undiagnosed until the onset of adult hip pain. Nevertheless, many of these patients required hip replacement surgery before 50 years of age.

The morphologic anomalies following these diseases can result in excessive shear and compressive stresses on the hyaline cartilage and subchondral bone. When the biomechanical tolerance and potential for repair of the joint are exceeded, progressive secondary degenerative occurs. Additionally, as the life expectancy of our population increases, so does the opportunity for an underlying hip condition to express itself as symptomatic secondary degenerative arthritis.

The treatment of dysplasia has been greatly improved by the development and success of the Bernese periacetabular osteotomy.49,51,75,83,93. Prior to the development of this operation, diagnosing dysplasia in painful adult hips did not seem as important. Most of the surgical procedures were of a salvage nature for relatively more advanced arthritis such as valgus–extension intertrochanteric or Chiar osteotomies, and these did not correct the primary abnormality. Partly because of this “salvage” mindset, physicians have not been taught a sense of urgency about making the diagnosis or referring patients for early surgical consultation. Indeed, the presence of moderately severe acetabular dysplasia is frequently overlooked by nonpediatric radiologists, primary care physicians, and even orthopaedists. Increased education and discussion about dysplasia and the other causes of secondary hip arthritis can facilitate earlier treatment in younger adults with painful hips.

As our knowledge in this area has increased, so has the importance of early diagnosis for these at-risk hips. When an anatomic abnormality exists that exposes the joint cartilage to high stresses, and this situation is correctable by osteotomy, the potential long-term benefits of reorienting or realigning the joint must be considered. Salvage of a young patient’s joint cartilage holds more promise for a good life-long result than does an early implant arthroplasty. In other cases, an osteotomy may serve as a bridge to carry the patient safely into the age range appropriate for total joint replacement. In this chapter, we do not support the indiscriminate selection of osteotomy for any adult hip disease, as the majority of patients with established hip arthritis are best managed by total hip replacement (THR) surgery. In this chapter, we define the indications for, and appropriate selection of, osteotomies of the pelvis and femur for specific problems in the adult hip.

PATIENT EVALUATION

HISTORY

Many patients who present with a hip problem amenable to treatment with an osteotomy do not give a history of a childhood hip disorder. They may have vague anterior groin or greater trochanteric pain, which has been treated for years as a “groin pull” or “trochanteric bursitis.” They complain of difficulties with athletics and endurance. Some may come with radiographs that have been interpreted as normal despite the presence of significant dysplasia.

EXAMINATION

Assess the patient’s general health, noting the degree of fitness or presence of obesity. Observe gait and check for Trendelenburg’s sign. Check the range of motion in all planes. Carefully document the actual and apparent leg lengths as well as strength and neurologic status of the lower extremities. Examine other joints as they may
RELATIONSHIP BETWEEN AGE AND HIP OSTEOTOMY

Age is one of the key issues when a patient is considered for an osteotomy around the hip joint. In patients older than 60 years, there must be a compelling reason to choose a hip osteotomy over implant arthroplasty. Being over 60, however, is not by itself an absolute contraindication to a hip osteotomy. A patient's physiologic age and life expectancy are more relevant than chronologic age. The actual status of the joint cartilage and lifestyle of the patient are more important than any assumptions.

PATIENT SELECTION AND TIMING

Age is one of the key issues when a patient is considered for an osteotomy around the hip joint. In patients older than 60 years, there must be a compelling reason to choose a hip osteotomy over implant arthroplasty. Being over 60, however, is not by itself an absolute contraindication to a hip osteotomy. A patient's physiologic age and life expectancy are more relevant than chronologic age. The actual status of the joint cartilage and lifestyle of the patient are more important than any assumptions.
about arthritis or activity based solely on a patient's age.

In general, all the osteotomies described in this chapter have the best results when performed for clearly correctable biomechanical abnormalities in joints with at most mild arthritis. Good range of motion also correlates with a better long-term outcome for hip osteotomies. Deviation from these principles may still yield good results, but at an increased risk of failure. One of the most difficult decisions frequently encountered is determining just how much arthritis is too much. The risks of increased stiffness, pain, or other modes of clinical failure increase with the degree of preoperative degenerative changes. The amount of risk that the surgeon and patient are willing to assume may be tempered by other factors such as the patient's age and surgical options. Figure 104.2 shows a patient with a dysplastic hip whose arthritis progressed rapidly, leading to cancellation of a planned periacetabular osteotomy. Figure 104.3 by comparison shows a patient with moderate preoperative arthrosis who has done well after a periacetabular osteotomy.

The ideal candidate for an osteotomy is highly motivated and has a realistic understanding of the potential risks and benefits of the procedure, including the possible need for an extended period of rehabilitation. Moderate obesity should be considered a relative contraindication and morbid obesity a nearly absolute contraindication. Absolute contraindications to osteotomy include neuropathic arthropathy, severe osteopenia, inflammatory arthritis, and active infection. Relative contraindications include a stiff joint, advanced age or arthritis, and smoking.

PREOPERATIVE PLANNING

Detailed preoperative planning helps reduce complications and provide for reproducible results. An AP radiograph with a magnification marker in the plane of the bone allows scaled digitization of the image for computer planning (76,108,130) (see Chapter 26). The computer facilitates the exploration of many possible surgical plans with accuracy and speed. Sound planning, and successful surgery, does not require computer-based planning. In fact, the majority of the world's leading osteotomy surgeons have never used, or relied on, computer planning. The principle is that careful planning of the goals of the surgery and the specific surgical techniques must be considered prior to surgery. Issues that can be planned preoperatively include osteotomy level, angulation, wedge resection, leg length, displacement, effect on mechanical axis alignment, fixation choice(s), bone grafting, and compatibility with future THR. Bring all the relevant preoperative planning drawings or computer printouts to the operating room and post these for easy reference during the procedure. Attention to detail and technique during the surgery follows from attention to the procedural details before the surgery.

PELVIC OSTEOTOMIES AND THE ACETABULUM

CHIARI PELVIC OSTEOTOMY

Rationale

The Chiari pelvic osteotomy in adults is a salvage procedure for patients with arthritis caused by acetabular dysplasia. In general, young patients with fixed subluxations and/or femoral head deformities are well suited for this procedure. It is a capsular interposition arthroplasty and an extra-articular acetabular augmentation utilizing a slightly inclined (distal–lateral to proximal–medial) supra-acetabular iliac osteotomy. Chiari initially described this procedure in 1955, and he later reported the results of more than 600 cases in 1974 (76). His original methods included a relatively minimal exposure through an anterolateral approach. He made a slightly upslipping, inferiorty concave osteotomy just above the joint capsule. He rarely used internal fixation and patients were immobilized in a hip spica cast. Most of Chiari’s patients were children, although adults were included in his study, and 104 had coexisting arthritis. Subsequent reports by Chiari and others on the results in adults have better defined the indications and outcomes (28,76,128,136,177). Many of Chiari’s large group of patients would now be treated with a rotational pelvic osteotomy.

The Chiari procedure accomplishes two goals. First, the displaced superior fragment forms a lateral shelf over the pathologically lateralized and uncovered femoral head. The proximal fragment can be manipulated anteriorly as well as laterally. Through metaplastic transformation, this new buttress and the interposed capsule produce a fibrocartilaginous articular surface. This broadens the surface area available for weight bearing. The coverage also prevents progression of the subluxation and is not dependent on joint congruity.

The second goal is the medialization of the hip joint, usually around 1.5 cm, which reduces the resulting joint reaction forces. The inferior fragment is hinged on the symphysis pubis, and displacement actually slightly increases the already abnormal inclination of the acetabulum. This is more than compensated for by the medialization and improved coverage (162,178). Additionally, the osteotomy increases hip abduction, an essential goal for many patients. Although the Chiari procedure is conceptually one of the easier pelvic osteotomies to visualize, its results are very dependent on precise surgical technique (46).

Most patients who are candidates for a Chiari osteotomy have a limp and a Trendelenburg gait preoperatively. Usually only the antaligic portion of a limp will be improved by the procedure. Some authors (see later) have reported an improvement in the Trendelenburg lurch in a majority of patients, attributing the improvement to the medialized hip center and to advancement of the greater trochanter in some patients. In general, advise patients that their Trendelenburg lurch may not improve and can worsen postoperatively. This is, in part, because the traditional surgical approach involves stripping of the tensor and much of the abductor musculature from the lateral iliac wall.
Operative Technique for Chiari Osteotomy in Adults

Position the patient supine on a radiolucent table, with the pelvis and leg draped free, or on a fracture/traction table with the leg slightly abducted and externally rotated. Utilize routine antibiotic and thromboembolic prophylaxis throughout the procedure.

Make a 10-cm-long anterolateral ilioinguinal incision beginning at the iliac crest and extending medially. The less cosmetic iliofemoral (Smith-Peterson) approach may be preferred for more exposure or in larger patients, or for combined pelvic and femoral osteotomies through one incision.

Expose the iliac wing by subperiosteal dissection medially and laterally. Minimize lateral stripping to minimize injury of the hip abductor muscles.

Use curved osteotomes to complete the semicylindrical osteotomy, inclining 15° superiority from inferolateral to superomedial. A less steep inclination may be necessary in the case of proximal head migration. In such a case, the osteotomy could exit into the sacroiliac joint, which would block the desired displacement.

Expose the iliac wing by subperiosteal dissection medially and laterally. Minimize lateral stripping to minimize injury of the hip abductor muscles.

Release the tensor, sartorius, and direct head of the rectus femoris from their origins off the ilium.

Expose the anterior and lateral iliac fragment. Do not incise or damage the capsule, especially superiorly.

Separate the tendon of the rectus femoris from the capsule and divide the reflected head. The curved insertion of the rectus serves as a marker for the level of the osteotomy.

Dissect subperiosteally from the capsule to the sciatic notch posteriorly and place a blunt retractor, such as a relatively radiolucent flexible metal ribbon. Similarly, place a retractor medially after careful dissection to the greater sciatic notch.

Radiographically confirm the starting point and direction of the osteotomy with a pin drilled into the pelvis just superior to the capsule.

Use curved osteotomes to complete the semicylindrical osteotomy, inclining 15° superiority from inferolateral to superomedial. A less steep inclination may be necessary in the case of proximal head migration. In such a case, the osteotomy could exit into the sacroiliac joint, which would block the desired displacement.

A Gigli saw can be used to cut the most posterior portion from the sciatic notch anteriorly about 1 cm. This reduces the danger of injuring the neurovascular structures in the sciatic notch from an osteodome or bone splinters or spikes. Alternatively, a Gigli saw or power saw can be used for the entire cut. The senior author (RS) prefers the Gigli technique for safety and simplicity.

After carefully completing the osteotomy of the medial cortex, displace the osteotomy. Release any traction on the leg and abduct the hip. Displace the inferior fragment medially 1–1.5 cm but at times up to 2.5 cm (76) as needed to provide 80% to 100% lateral coverage of the femoral head. Because the sacroiliac joint allows some lateral motion of the proximal fragment, not all of the osteotomy displacement results in hip center medialization. Confirm that the displacement has occurred both posteriorly and anteriorly, because a posterior hinge may remain (13).

Evaluate any remaining deficiency in coverage, which is common anteriorly. Harvest a supplemental corticocancellous shelf graft from the iliac wing as needed. Wedge this into the osteotomy, or otherwise secure the graft.

Place internal fixation from the iliac wing across the osteotomy to eliminate the need for a spica cast in adults. We use long 4.5 mm AO (Synthes, Paoli, PA) cortical screws. Figure 104.5 shows a patient with a Chiari osteotomy in which a supplemental graft was used. After more than 4 years, she remains asymptomatically using no walking aids.
Where more than 75% displacement of the osteotomy is required, consider placement of a bone graft medially to assist with healing.

- Confirm the radiographic appearance of the osteotomy and check hip range of motion, to be certain that there is no block to flexion anteriorly.
- Irrigate the wound and close it in layers over a suction drain.
- Take care to repair all muscles, suturing the tendons back to bone through drill holes where initial release was from bone. Avoid injury to the lateral femoral cutaneous nerve.

Postoperative Care
Postoperatively, begin protected ambulation as soon as tolerated. Do not allow active flexion or abduction exercises initially, to allow repaired muscles to heal. Weight bearing is partial for 6 weeks. Most patients can bear full weight by 3 months if healed, with longer healing times expected for osteotomies with greater displacements.

Results
Pain relief is significant in 80% to 90% of patients in the first few years and remains reduced in 50% to 60% at 15–20 years follow-up. Because pain relief is a primary goal of this surgery in adults, the reported rates of good and excellent results in the literature are similar. Lack et al. (28) reported 75% good results at 15 years in 100 hips in patients older than 30 years at the time of operation. During these 15 years, 20% of patients required THR at an average time of 11.5 years after osteotomy. Windhager et al. (177) also summarized the results of many patients who had undergone Chiari osteotomy at a mean follow-up of 25 years, showing 51% continued good results out of 236 patients. In patients who had developed pain, the period of significant pain relief was an average of 17 years. Zlatic et al. (175) reported 87% complete or nearly complete pain relief in adults at the 9-year follow-up. De Waal Malefijt et al. (36) described 61% good results in their adult patients at 5 years, with the poor results mostly attributable to technical errors. Betz et al. (14) reported 88% good or excellent results in 24 patients with follow-up ranging from 3 to 20 years. When performed as a time-buying salvage operation for the hip, it seems reasonable to expect 10–15 years of good service from the Chiari osteotomy.

Gait improvement is less dramatic than pain relief because a positive Trendelenburg limp may persist in some and normalize in others. Graham et al. (55) found no change in the Trendelenburg test after 58 osteotomies were followed for 3.5 years. Other authors have reported that the Trendelenburg gait was the same or slightly worse at short- and long-term follow-up (28,36,175). By contrast, another group of authors reported improved Trendelenberg gait without osteotomy of the greater trochanter (63,85,128). Osteotomy of the greater trochanter with advancement shows more significant improvement in the Trendelenburg test. For example, Matsuno et al. (63) described a lateral approach with greater trochanteric advancement. They reported only 2 of 66 patients with a Trendelenberg test postoperatively.

Although abduction may improve, overall range of motion does not. Severe limitation of motion has been reported, but its incidence may be reduced by the use of internal fixation and early physical therapy. In general, there is not a strong relationship between preoperative radiographic findings and clinical results following Chiari osteotomy (28,63).

Nishina et al. (117) reported on the importance of an intact labrum, as determined by preoperative hip arthrography, for good results following Chiari osteotomy in adults. In their series, all 23 hips with normal labra had good or excellent results at 4 years, whereas 1 of 21 with torn labra and 10 of 20 with detached labra had fair or poor results. The authors felt that a detached labrum was a contraindication to the procedure. Gadolinium-enhanced MRI is now our preferred method for evaluating the labrum, if the capsule is opened at the time of surgery, either for inspection or resection of a labral tear, secure repair is essential, as an intact capsule is a prerequisite for a successful Chiari result.

Several authors have investigated the effects of age and arthritis on the outcome after Chiari osteotomy. As may be expected, in adults the results are best and most durable in patients who are younger and have no signs of arthritis at the time of surgery. Reynolds (128) found that without severe dysplasia or arthritis, patients achieved significant and lasting improvement in 29 of 32 cases (90%) at a 5-year follow-up. However, those with more severe dysplasia and/or arthritis failed in 9 of 12 cases. Calvert et al. (28) found significant correlation between either younger age at operation or absence of arthritic changes on preoperative radiographs and Harris hip scores of 49 hips at a 14-year follow-up. Windhager's (177) review of patients most of whom had undergone Chiari osteotomy, found that the oldest third of the patients developed the worst arthritis at a 25-year follow-up and that subjectively poor results were seen in patients with preoperative signs of arthritis. In a report of subsequent Chiari patients, Lack et al. (70) more clearly defined the effects of age in an adult-only population. They showed 80% good results for patients younger than 45 years of age at operation (age range, 30–44 years) and only 50% good results for patients older than 44 years of age.

Conversion of a Chiari to a THR is difficult. (The intuitive concept that a prior Chiari facilitates cup insertion techniques is not valid.) Such an arthroplasty should be viewed as a revision acetabulum with the presence of scar, bone defects, and anatomic distortions anticipated. Especially important is the recognition that the anteroposterior host bone diameter is much less than the perceived superoinferior or mediolateral dimension. It is necessary to avoid excessive reaming of the anterior and posterior walls. Furthermore, the projecting shelf of bone anteriorly and laterally may be a source of impingement that predisposes to dislocation of the hip replacement if not dealt with at the time of arthroplasty by resection of bone.

Complications
Complications specific to the Chiari osteotomy are summarized in Table 104.2. Complications and how to avoid them are discussed in detail by Benson and Evans (13), Fixsen (48), and Hoffman et al. (62).

Summary
In adult patients with painful hip dysplasia who are not candidates for redirection of acetabular osteotomy, the Chiari procedure offers a good choice when surgery is required (139). The more ideal patients do not have advanced arthritic deterioration and are much too young to be reasonable candidates for THR. In these properly selected patients, 10–20 years of significant pain relief may be expected, making the Chiari osteotomy a durable salvage option.

### SHELF PROCEDURES AND SLOTTED ACETABULAR AUGMENTATION

A variety of extra-articular acetabular augmentation osteotomies can be classified as shelf procedures. These bone-grafting surgeries are cousins of the Chiari type of osteotomy in that they are capsular interposition arthroplasties. They rely on capsular metaplasia into fibrocartilage as well as bony remodeling to provide coverage over an otherwise deficiently contained femoral head. In these procedures, an iliac bone graft is created or inserted immediately superior to the hip capsule. A variety of techniques, shapes, and fixation methods have been described. A common feature among these methods is the importance of graft placement in direct apposition to...
the superior capsule and the prevention of graft displacement. Because of these considerations, most authors have recommended postoperative spica casting (129,145,146,153,167). The use of casts and the dependence on bony remodeling are part of the reason that this type of procedure, when done alone, is probably best reserved for pediatric patients. In addition, the need for certain pediatric procedures, such as open reduction of hip dislocations, provides access to the hip joint and an opportunity for supplemental shelf grafting. The use of simple shelf augmentations in adults has diminished markedly since the development of redirectional acetabular osteotomies.

Today, the most common use for a shelf procedure in adults is as an adjunct to another coverage osteotomy, particularly that of Chiari. As discussed in the preceding section on the Chiari osteotomy, a shelf graft is a useful supplement to extend the capsular arthroplasty surface, usually anteriorly but also laterally (75). Conceptually, the combination of these procedures is logical because they both are designed to rely on metaplasia of the joint capsule to fibrocartilage and can be applied to the same patients. The shelf procedures have the benefit of being able to be tailored to adjust coverage in an anterior or posterior direction more than is possible with a Chiari osteotomy.

The buttress provided by a shelf graft is less stable than with other pelvic osteotomies, even when using a slotted technique. Hardware breakage, recurrent subluxation, or graft failure due to displacement can occur. Many authors recommend spica casting; however, complications from the cast itself can be significant (175), especially in large adolescents or adults. When combined with another primary procedure, almost any of the described shelf augmentations can be performed with little increase in surgical risk or technical difficulty. Our experience supports the use of a shelf procedure in combination with a Chiari osteotomy, but we do not any longer perform shelf grafting alone or in combination with periacetabular osteotomy.

PERIACETABULAR OSTEOTOMIES

Developmental dysplasia of the hip is associated with a high incidence of premature arthritis of the hip (7,107,150,159,171). In the award-winning, retrospective review of 130 hips with so-called idiopathic or primary osteoarthritis, Sullivan and Harris (151) discovered a 48% incidence of dysplasia of the hip as the etiologic factor. Additionally, Cooperman et al., in a minimum 22-year follow-up study of 32 hips in 20 patients with acetabular dysplasia (center–edge angle < 20°), found a 100% incidence of roentgenographic evidence of degenerative joint disease (53). Symptoms and radiographic changes present early in adult life. Once established, degenerative changes progress rapidly (169).

Ganz et al. (51) have described three variations of clinical presentation. In an early one, there may be muscle-related trochanteric or anterolateral discomfort only. In another subgroup, there is sudden onset of pain, giving way, and clicking. These patients have the so-called acetabular rim syndrome, often associated with a tear of the acetabular labrum. Finally, there are those who present with already-established arthritis, secondary to the underlying dysplasia.

Rotational pelvic osteotomies have emerged over the past 15 years as the most effective procedures for adults with prearthritic or early arthritic symptoms due to the adult sequelae of childhood dysplasia of the hip (6,10,44,49,51,59,61,64,66,72,76,79,97,99,101,105,113,114,115 and 116,140,147,148,155,156,158,165,168,173) (Figs. 104.5, 104.6). Congruency of the hip is a near absolute requirement. Dislocation and fixed subluxation are contraindications, as is the presence of significant arthritis. The periacetabular (Bernese or Ganz) osteotomy offers the most theoretical and practical advantages, and it has largely supplanted the role formerly played by varus–extension ITO of the femur for adult dysplasia.

Figure 104.6. Classic periacetabular osteotomy (PAO). A: AP radiographic view of the pelvis in a 20-year-old woman with bilateral hip pain for over a year. B: AP view of the pelvis 1 week after a right PAO and 7 months after a left PAO. By 3 months after the second PAO, the patient had no pain or limp bilaterally. C: False-profile view of the left hip preoperatively. D: False-profile view postoperatively. E: False-profile view of the right hip preoperatively. F: False-profile view postoperatively.

Just prior to his retirement, Heinz Wagner of Germany stated that rotational osteotomies of the pelvis were the most worthwhile operations he had performed in his illustrious career as both a children's and an adult reconstructive hip and knee surgeon. It was not uncommon in his experience to have an enduring good result 30 years after the osteotomy (personal communication, 1989).

There have been many successful types of rotational pelvic osteotomies introduced and used over the last 40 years, including the spherical dome or dial (Wagner, Ninomiya and Taqawa, Epipratt), single innominate (Salter), double innominate (Sutherland), triple innominate (LeCoeur, Hopf, and Steele), and the ilio-ischial-articular triple (Tonnis), among others. All share the same main principle of redirecting the position of the acetabulum to reduce sheer forces and decrease compressive forces on the articular cartilage. Rotational osteotomies do not result in an increase of the amount, size, or volume of articular cartilage or supporting bone. The quantity of cartilage that already exists is rotated into a more favorable position to achieve one or more objectives. These objectives include achievement of a more horizontal position of the acetabular sourcil in the frontal plane as visualized on AP radiograph, enhanced appearance of femoral head coverage on the frontal radiograph, and enhanced anterior coverage.

A number of myths exist regarding the capabilities of these procedures. One is the erroneous concept that rotational pelvic osteotomies increase articular cartilage volume or amount. The apparent increase seen on AP radiographs after successful redirections is accomplished at the expense of loss of coverage or contact elsewhere (usually medial and posterior). The losses elsewhere may have implications for future THR as well as for instability of the hip in cases of extreme correction. Another myth is the concept that the hip will be totally normal after the osteotomy. Many hips manifest radiographic evidence of joint space narrowing, early osteophytes, and subchondral sclerosis that reflect some element of permanent and irreversible damage to articular cartilage and the joint environment. Although regression of some of these elements (sclerosis and cysts) may occur after favorable architectural changes, the joint is never as normal as a joint unaffected by dysplasia.

The role of Chiari osteotomy in adult hip surgery has changed, commensurate with the improvement in the reliability of pelvic rotational osteotomies. Whenever a rotational osteotomy can be performed, it is preferable to a Chiari. However, in cases of fixed subluxation in young patients, impressive results lasting many years are possible, frequently aided by concomitant valgus ITO, as previously described.

UNIQUE FEATURES OF THE PERIACETABULAR OSTEOTOMY

A fundamental difference between the periacetabular osteotomy (PAO) as developed by Ganz et al. (51) in the mid 1980s, and the other rotational osteotomies, is the ability of this technique to achieve three-dimensional freedom of the acetabulum without transection of the posterior column of the ilium. In Figure 104.7, note the superior appearance of the acetabulum on the right side in this 33-year-old woman who had a triple innominate osteotomy of the left hip followed by a PAO several years later on the right. The right side has no residual dysplasia and is 100% free of all symptoms. Three or four 4.5 mm screws achieve secure fixation of the acetabular segment to the ilium above. Full-weight-bearing gait without limp is sometimes possible within 8 weeks of surgery. Further, the segment can be rotated anteriorly as well as laterally to customize the coverage and alignment based on variations of pathology. Importantly, these changes are accomplished without lateralization of the center of rotation of the femoral head. In rare cases, deliberate medial or posterior rotation can be done to correct less common types of dysplasias.
Figure 104.7. Triple (Steele) osteotomy on the left hip and PAO on the right hip in the same patient and by the same surgeon. A: AP view of the pelvis in a 33-year-old woman with bilateral hip dysplasia and pain in the left hip. B: AP view of the pelvis following left triple (Steele) pelvic osteotomy. C: AP view of the pelvis 4 years later following the onset of right-sided hip pain and performance of a right PAO. Patient was working full time without restrictions before 6 months after PAO. Recovery from the triple osteotomy was more prolonged. D: AP view of the pelvis 1½ years after the PAO. The patient had occasional symptoms on the left secondary to some restriction of motion, but no pain.

OPERATIVE TECHNIQUE

The PAO was conceived by Reinhold Ganz et al. (51) at the Kantonspital in Bern, Switzerland, and was based on their experience in surgery for pelvic fractures. Understandably, the surgical approach was borrowed from that used successfully for complex double-column fractures with mobilization of the femoral neurovascular bundle and the development of distinct surgical “windows” requiring complete reflection of the tensor fascia and gluteal muscles off the lateral wall of the ilium. Although this exposure afforded good access, problems were encountered, including femoral vein thrombosis, a high incidence of heterotopic ossification and long-lasting or permanent limp due to abductor muscle insufficiency, among others.

Murphy and Millis of Boston (110) modified their approach to expose the medial side of the ilium only, avoiding stripping the lateral wall of the tensor fascia and gluteal muscles. Matta (personal communication, 1992) devised a double oblique fluoroscopic intraoperative view to permit radiographic visualization of the difficult osteotomy of the ischium without direct surgical exposure through a medial window. Santore and Stevens (personal communication, 1993) perfected the use of grooved subperiosteal retractors to cut the pubic bone with a Gigli saw from the direct anterior approach without access through a medial window. An expanded discussion of the technique for this osteotomy is warranted because of its emergence as the procedure of choice for symptomatic DDH.

- Position the patient supine on a fully radiolucent operating table. Be certain that fluoroscopic visualization of the operated hip is excellent on all views. Do a wide preparation and drape the involved hip to well above the iliac crest. Drape the extremity free (Fig. 104.8).

Figure 104.8. Drape the iliac crest free (right shown here). The planned incision along the anterior iliac crest is outlined.

- Make a longitudinal Smith-Peterson type of incision over the iliac crest and extending several inches distal and lateral to the anterior superior iliac spine (ASIS).
- Make an oblique osteotomy of the medial half of the ASIS and reflect the sartorius and iliacus muscles medially in continuity with this bone and each other (Fig. 104.9).

Figure 104.9. Do a splitting osteotomy of the anterior superior iliac spine (ASIS) with the attached origin of the sartorius muscle. The rake to the right is retracting the sartorius medially.

- Incise and detach the indirect and the direct heads of the origin of the rectus femoris and reflect them medially.
- Do not strip any of the muscles from the lateral aspect of the ilium, including the tensor.
- Address the superior pubic ramus first. Expose it with careful subperiosteal dissection, first superiorly, then inferiorly. Protect the obturator nerve and vessels, which lie directly beneath the pubic arch using subperiosteal retractors. Transect the superior pubic ramus with a Gigli saw (Fig. 104.10).

Figure 104.10. Perform an osteotomy of the superior pubic ramus by exposing it through the incision (Fig. 104.8, Fig. 104.9) and placing dual retractors around the pubic bone. A Gigli saw has been passed around the pubic bone and will be used to cut it safely from posterior to anterior.

- Next, address the ischium near its attachment to the body of the ilium 1 cm below the joint. Approach the ischium underneath the iliopectineus tendon and place the cutting edge of a specially designed 40° angled osteotome (Synthes, Paoli, PA) in the proper position under fluoroscopic control using the previously described double oblique view to ensure that the ischial cut does not violate the joint space and is oriented in the correct trajectory. This trajectory is from inferolateral to
superomedial. The ischium is not transected.

**Figure 104.11.** For the osteotomy of the ischium, an angled AO (Synthes) osteotome is positioned under fluoroscopic control to cut it partially through from inferolateral to superomedial.

- Cut the ilium using an oscillating saw from the ASIS toward the sciatic notch, stopping 10–15 mm short of the pelvic brim (iliopectinate line) (Fig. 104.12). Then use a curved standard ½-inch osteotome to cut across the pelvic brim as originally described by Ganz et al. (61). Next, use the angled Synthes osteotome to cut parallel to the posterior column intersecting with the previous cut made in the ischium.

**Figure 104.12.** Cut the ilium with a power saw from just inferior to the ASIS toward the sciatic notch, stopping approximately 15 mm above the pelvic brim, which is marked by the iliopectinate line (refer to Fig. 104.17).

- The final cut frees the acetabulum from its continuity with the ilium. Insert the angled osteotome into the medial osteotomy of the quadrilateral surface and transect the ilium from medial to lateral, carefully avoiding the hip joint.
- Mobilize the free acetabular segment with an osteotome inserted as a lever into the osteotomy and/or with the aid of a Schanz screw inserted into the fragment (Fig. 104.13, Fig. 104.14). Ensure that the fragment is completely mobile and then reduce it back to its original position.

**Figure 104.13.** After cutting the lamina quadrilatera with an angled Synthes osteotome (not shown), mobilize the acetabular fragment with the same osteotome. The osteotome is shown in the iliac osteotomy with the ASIS just above the osteotome.

**Figure 104.14.** More extensive anterior mobilization is shown here.

- Arthrotomy of the hip joint may now be performed with optimum timing since recovery of clear fluid suggests that the hip joint has not been penetrated. Inspect the labrum of the hip and resect any tears or detachments (Fig. 104.15). The capsule may be left open to allow assessment of possible impingement of the femoral neck caused by anterior reorientation of the acetabulum.

**Figure 104.15.** Now re-reduce the acetabulum and perform an anterior arthrotomy to inspect the labrum, which was normal in this hip.

- Reorient the acetabulum fragment to improve both lateral and anterior coverage of the femoral head. This can be continuously monitored under fluoroscopic control using the AP and double oblique views. In the frontal plane, achieve a horizontal sourcil without under- or overcorrection. Anterior coverage enhancement is just as important as the lateral coverage. Multiple attempts are often necessary until optimal radiographic appearance is achieved. Confirm the final position with an AP radiograph before placing definitive fixation.
Now fix the osteotomy by inserting three or four AO 4.5 or 3.5 mm pelvic screws from the superior iliac crest in an inferomedial direction into the acetabular segment (Fig. 104.16, Fig. 104.17). Whenever possible, direct a screw approximately 145 mm in length into the tear-drop area of the acetabulum at the far medial aspect of the acetabular segment. Be certain that the osteotomy is stable.

Figure 104.16. Internally fix the osteotomy in the corrected position with four 4.5 mm cortical AO (Synthes) screws. This provides very rigid fixation.

Figure 104.17. Periacetabular osteotomy. Cuts drawn on an AP view of the pelvis for the left hip (A). Cuts seen on the inner wall of the pelvis (B). Cuts seen on the outer wall of the pelvis (C). Osteotomy with screw fixation seen from the front (D), inside (E), and outside (F). The method of screw fixation varies. The senior author (RS) prefers three or four screws from the top of the iliac crest into the acetabular fragment. (From Trousdale RT, Ganz RG. Periacetabular Osteotomy. In: Callaghan JJ, Rosenberg AG, Rubash HE, eds. The Adult Hip, Vol. 1. New York: Lippincott-Raven, 1998:792, with permission.)

Ensure hemostasis, place two drains deep in the wound, and perform a layered closure. Reattach the ASIS osteotomy, which contains the origins of the sartorius and rectus femoris tendons with strong (#5) nonabsorbable suture (Fig. 104.18). Take care to avoid injury to the lateral femoral cutaneous nerve during the fascial layer closure (Fig. 104.19).

Figure 104.18. Appearance of the ilium after repair of the ASIS osteotomy.

Figure 104.19. Final appearance of the repair of the abdominal wall and fascia before skin closure.

Figure 104.20 shows a patient with a history of bilateral Perthes who had already had a contralateral joint replacement. He underwent a combined PAO and trochanteric advancement and by 1 year was working without restrictions and had rare need of a cane.

Figure 104.7 shows a comparison between a triple pelvic (Steele) osteotomy on the left and a PAO on the right by the same surgeon. Note the better correction obtained after the PAO. Recovery after the “triple” was more prolonged than after the later PAO.

POSTOPERATIVE CARE

Use continuous catheter epidural analgesia for 3 days. Mobilize patients from bed to chair the day following surgery if they can tolerate it. Start the patient walking with physical therapy as soon as tolerable, utilizing a walker or two crutches to bear the weight of the limb. Physical therapy is not prescribed after discharge from the hospital. Weight bearing as tolerated with crutches is permitted after 6 weeks. Full weight bearing without support is usually achieved at 10–12 weeks after surgery.

We recommend removal of all screws once the osteotomy is fully healed, as they can be a source of discomfort. Very long screws deep within the ilium can eventually fail due to micromotion within the pelvis. Removing these prior to breakage avoids complications that might lead to a later total hip arthroplasty.

Many patients have bilateral dysplasia and require bilateral osteotomies. We suggest spacing these 6–12 months apart so that the initially operated hip is rehabilitated before operating on the second hip.

Figure 104.6 shows a patient with bilateral DDH and classic indications for PAO. She underwent osteotomies 7 months apart and had no pain or limp by 3 months after the procedure.
The Bernese osteotomy can be used to salvage a hip after prior surgeries in specific cases: Figure 104.21 shows a patient who was referred for a revision PAO after failure of an attempted periacetabular procedure 1 year earlier. Figure 104.22 shows an attempted periacetabular procedure done elsewhere (B), AP views of the hip (C) and pelvis (D) over a year later show subluxation of the hip with poor coverage and the patient had increasing pain. A revision PAO was done. At 3 months after surgery, the patient was already walking without aids and limping only late in the day. At 8 months after surgery, it is healed (E,F). False profile view of the left hip preoperative before revision (G) and postoperative when healed (H).

Figure 104.21. Revision of a previous, inadequate PAO. AP view of the left hip in a 31-year-old woman with dysplasia and pain (A). This AP view of the left hip shows an attempted periacetabular procedure done elsewhere (B). AP views of the hip (C) and pelvis (D) over a year later show subluxation of the hip with poor coverage and the patient had increasing pain. A revision PAO was done. At 3 months after surgery, the patient was already walking without aids and limping only late in the day. At 8 months after surgery, it is healed (E,F). False profile view of the left hip preoperative before revision (G) and postoperative when healed (H).

Figure 104.22. PAO salvage of a failed Chiari osteotomy. A: AP radiograph of the pelvis in a 37-year-old woman prior to Chiari osteotomy for the right hip done elsewhere. B: Postoperative radiograph after the Chiari procedure. C: This radiograph of the pelvis is 4 years after a salvage PAO on the right. Patient had no pain and no limp on left but did have a Trendelenberg limp on right. D: This false-profile view of the right hip is just prior to salvage PAO. E: A postoperative radiograph.

COMPLICATIONS

Complications are significant in both frequency and severity. The learning curve is steep. Davey and Santore (35) have shown that the incidence of significant complications decreases impressively with increasing experience. A 2.9% incidence of serious complications persists after gaining considerable experience. Life-threatening hemorrhage; intra-articular penetration or fracture; posterior-column fracture; malunion; nonunion; malposition of the socket; hardware breakage; paralysis in the distribution of the sciatic, obturator, or femoral nerves; thrombosis; phlebitis; pulmonary embolization; heterotopic ossification; hardware-related bursitis; numbness in the distribution of the lateral femoral cutaneous nerve; herniation of bowel into the operative field; and vascular injury can occur. Blood loss can be substantial and intraoperative use of the cell saver and postoperative use of reinfusion drains are recommended.

The breadth and seriousness of the potential complications deserve added emphasis, since the operation is ideally suited to young adults with early, often minimal, symptoms. Figure 104.21 shows a 31-year-old woman who was seen after a failed attempt at a dome-type osteotomy. A PAO was done proximal to the previous cuts with an excellent radiographic and clinical result.

The upper age limit for the operation has not been established. The senior author (RS) has performed the operation on patients up to the age of 60. Patients above the age of 50 must be screened very carefully. They should be excellent candidates in terms of all physiologic and radiographic criteria.

CONVERSION OF FAILED PERIACETABULAR OSTEOTOMY TO TOTAL HIP REPLACEMENT

Unlike the situation with post-Chiari hips, the conversion of a failed PAO to a THR because of progression of arthritis is virtually indistinguishable from a routine primary THR, especially for surgeons who use the posterior approach for THR. One area for particular attention is the anterior impingement in the case of excessive anterior displacement of the osteotomy segment at the time of the index osteotomy. Additionally, after complications such as gross medial or proximal displacement or malposition, major intra-articular fracture or heterotopic ossification, the conversion can be quite difficult (Fig. 104.23).

COMBINED PERIACETABULAR AND INTERTROCHANTERIC OSTEOTOMIES

A small minority, 10% or less, of cases of adult PAO are significantly aided by adjunctive ITO. However, even in cases of moderate concomitant valgus of the upper femur, PAO alone is usually sufficient and is associated with a much-enhanced speed of recovery. In cases of high valgus neck–shaft angle (greater than 145°), varus with extension helps to restore more physiologic biomechanical parameters, including offset, greater trochanter-tip-to-center-of-femoral-head parallelism and to correct anterior extrusion of the femoral head by virtue of the extension component in the sagittal plane (90). The senior author (RS) prefers to perform a precisely planned ITO first, through a separate straight lateral incision in the supine position, followed by the PAO under the same anesthetic. Figure 104.28A. Figure 104.28B illustrates a 29-year-old woman from Japan who underwent varus–extension ITO to normalize adductor mechanics, followed by PAO under the same anesthetic. She is asymptomatic, now 6 years after surgery.

Figure 104.28. Combined varus ITO and PAO. A: AP view of the right hip of a 29-year-old woman with several years of right hip pain. B: Abduction–internal rotation AP view of the right hip prior to surgery. C: AP view of the right hip following PAO and simultaneous varus–extension ITO. The patient required 4 months of rehabilitation to achieve a normal unassisted gait. D: AP view of her right hip 2 years later, when she had no limp and was playing tennis.
Currently, we would do the PAO alone and have a very low incidence of combined ITO/PAO. Up to 6 months or more is required before normal walking resumes, and limp may persist for up to a year after the surgery. Circumstances that add to the appeal of the ITO include a significant, ipsilateral leg-length inequality and/or limb malrotation. The varus osteotomy can be planned to equalize the leg lengths. A transverse, non-wedge-rectifying technique allows full correction of any malrotation. When the leg lengths are equal preoperatively, an open hinge technique for the varus should be utilized, which minimizes the shortening inherent in varus osteotomies. An intraoperative adjunctive ITO is rarely, if ever, indicated. A better strategy would be to realign the position of the PAO to maximize coverage.

PERACETABULAR OSTEOTOMY FOR LEGG-CALVÉ-PERTHES DISEASE

The combination of moderate acetabular dysplasia and high-riding greater trochanter is seen in adults as a sequel to childhood Perthes disease ([1]). Options for treatment include lateral-distal advancement of the greater trochanter alone, ITO of the upper femur alone, PAO alone, or a combination of PAO of the acetabulum and distal-lateral advancement of the greater trochanter. The preference of the senior author (RS) has been the latter option, which addresses the two principal features responsible for disability: the acetabular dysplasia and the dysfunction of the abductors related to the high-riding trochanter. A unique technical consideration in this subset of patients is the close anatomic relationship of the lesser trochanter to the ischium. This requires that the ischial osteotomy be done on the medial surface of the iliosposa tendon. Great care must be taken to avoid injury to the neurovascular structures in this region. The trochanteric osteotomy must be done prior to the repositioning of the acetabular segment into its new position. Otherwise, the position of the trochanter limits your ability to laterally rotate the acetabular segment fully. Once the periacetabular segment has been rotated and fixed, the trochanter is advanced and fixed.

Acceptance criteria include minimal central head fragmentation, good mobility of the hip, and good joint congruence. Blood loss is greater and postoperative rehabilitation more difficult after this combined procedure than after isolated PAO alone. Although trochanteric advancement alone would address the abductor insufficiency and augment endurance for walking and standing, the opportunity to combine definitive correction of the dysplasia with the biomechanical enhancement of the abductors in one surgery and one rehabilitation period is a significant advantage of this strategy.

Figure 104.20 shows a 52-year-old man with disabling pain and abductor weakness. PAO and trochanteric lateralization were combined under one anesthetic. He returned to full-time work 6 months after surgery.

RESULTS

The results of PAO for arthritis secondary to dysplasia at 4 years after surgery (range, 2–8 years) are excellent if minimal (Tonnis grade I) arthritis was present at the time of surgery ([159]). In this subgroup, Harris hip score improved from 58 to 94. No patient required conversion to a total hip arthroplasty. Conversely, in the nine hips with Tonnis grade III changes preoperatively, the average Harris score improved only modestly, from 59 to 67. Fifty (56%) were converted to THR and 8 of 9 (89%) had a Harris score below 70 by the time of final follow-up. Therefore, patients with evidence of grade III (severe) arthritis are not suitable candidates, based on an 88% failure rate within 5 years of the osteotomy.

In the moderate arthritis subgroup (grade II Tonnis), the average Harris score went from 67 to 89 and one of the 18 was converted to a THR. Overall, there were 31 secondary operations in this series of 42 patients (42 hips), for a total of 73 operations in the 4-year (average) period including the index osteotomy, indicative of the nontrivial nature of the decision to perform major pelvic osteotomy in adults.

A more recent 11-year (average) follow-up of the first cohort of 75 periacetabular osteotomies by the group in Bern, Switzerland, revealed a 73% incidence of good or excellent results ([141]). The average age of the patients was 29 (range, 13–56) and 18% had been converted to THR, with 49 subsequent operations in the 71 hips available for follow-up. Unfavorable outcomes were associated with older chronologic age at time of surgery, presence of significant arthritis, and insufficient anterior coverage at the time of surgery.

Matta et al. ([50]) reported on a U.S. series of 78 hips in 70 patients, with a minimum follow-up of 2 years on 66 (85%) of the 78 hips ([90]). The average age was 33.6 (range, 19–51) with 17% excellent, 59% good, 12% fair, and 12% poor at the follow-up (averaging 4 years after surgery). There were 17 subsequent procedures (26% incidence of any revision) in 14 hips in 13 patients. No complications were reported due to the iliopsoas tendon. Great care must be taken to avoid injury to the neurovascular structures in this region. The trochanteric osteotomy must be done prior to the repositioning of the acetabular segment into its new position. Otherwise, the position of the trochanter limits your ability to laterally rotate the acetabular segment fully. Once the periacetabular segment has been rotated and fixed, the trochanter is advanced and fixed.

Figure 104.20 shows a 52-year-old man with disabling pain and abductor weakness. PAO and trochanteric lateralization were combined under one anesthetic. He returned to full-time work 6 months after surgery.

Jeffrey Mast, one of the developers of the procedure, reported on the minimum 2-year follow-up of 123 procedures in 115 patients ([161]). Overall, 83% of the hips were rated as good or excellent at final follow-up. The average preoperative Harris score of 65 increased to 89 at final follow-up. As in other series, there were a high number of subsequent surgeries, that is, 70 in 44 patients, including seven THRs at an average of 41 months after the PAO (5.6%). The frontal plane center–edge angle of Wiberg increased from 6° (range, –20° to +20°) to 29° (range, –10° to +60°). The anterior center–edge angle of Lequesne ([80]) increased from an average of 3° to an average of 23°. This series, PAO alone or in combination with ITO or trochanteric advancement was utilized successfully in multiple underlying conditions, including Legg-Calvé-Perthes disease (10 hips), Charcot Marie Tooth disease (four hips), epiphyseal dysplasia (three hips), SCFE (one hip), posttraumatic dysplasias (seven hips), and other causes of heterotopic ossification. At the time of submission for publication, there were three more pending conversions to THR, for a total conversion rate of 8 of 68 (12%).

A Boston series of 130 patients (135 hips) with minimum follow-up of 2 years (range, 2–7) demonstrated a rate of conversion to THR of 4%. The average age of patients in the series was 29 (range, 10–59) ([111]).

Tonnis reported intermediate-term follow-up data on 216 of 1,400 juxta-articular pelvic osteotomies, 138 in adults, at an average 7.3 years after surgery ([157]). Although pain relief was seen in 82%, Trendelenburg gait was common and 81% of adults had no change or worsening of limp compared with preoperative status. Best results were seen in patients with concentric, nonarthritic hips preoperatively.

Although effective at short and medium follow-up, PAO is technically demanding, associated with a relatively high incidence of perioperative complications and reoperations, and should be utilized with caution in patients with advanced arthrosis on screening radiographs.

SLIPPED CAPITAL FEMORAL EPIPHYSIS

The treatment of SCFE is discussed in Chapter 172. Several authors have reported on the acute treatment of SCFE with immediate corrective ITO accompanying the pinning of the slipped epiphysis ([114]). This approach has been abandoned because of excessive occurrence of AVN and chondrolysis ([67,163]). Most patients with SCFE are now treated with pinning in situ ([29]), and any resulting deformity is addressed later, depending on its severity and the symptoms ([144]). Because of the high risk of early-onset degenerative arthritis, treatment of a symptomatic moderate to severe SCFE is better performed early, once the child has matured and reached the age of initial treatment is evident. This allows for maximal remodeling and preempts years of abnormal biomechanics that can cause significant cartilage damage ([154]). Occasionally, the deformity of relative greater trochanteric overgrowth can occur because of proximal femoral physeal arrest following an SCFE ([71]). This may be amenable to a simpler trochanteric osteotomy, as in the patient in Figure 104.24, with advancement of the greater trochanter.

Figure 104.24. Isolated advancement of the trochanter for SCFE. A: AP view of the right hip in a 36-year-old woman with a history of a SCFE treated in adolescence. Patient had lateral hip pain and a Trendelenberg limp that was worse when she was fatigued. B: AP view of the right hip 1 month after isolated trochanteric advancement. By 9 months after surgery, the Trendelenberg limp was gone, although the patient had some end-of-day fatigue.
INDICATIONS

The typical deformity seen following an SCFE is a posterior and varus (medial) displacement of the epiphysis relative to the rest of the femur, with the posterior displacement usually being the most significant. Additionally, the femoral shaft is relatively externally rotated as part of the deformity. The external rotation is directly related to the posterior slip of the epiphysis. When the slip angle is 30° to 60°, correction of all three components of the deformity is essential, utilizing an ITO. The angulation of the ITO is flexion and valgus with internal rotation of the distal fragment as needed. The so-called triplane ITO was proposed by Imhauser and introduced to the English literature by Southwick. It is, in fact, a biaxial ITO with additional rotational correction included when necessary.

PLANNING AND OPERATIVE TECHNIQUE FOR THE IMHAUSER OSTEOTOMY

Planning for the operation includes careful documentation of the slip angle on biplane radiographs. On physical examination, document the range-of-motion deficits, leg lengths, and positions of comfort. On radiographs, confirm the mobility and congruency of the hip in adduction and extension (the relative direction that the femoral head will need to move after a valgus-flexion ITO). These measurements determine the degree of correction that will need to be made in each plane.

The procedure is similar to a valgus ITO for arthritis, which is described in detail in the next section of this chapter. The following details require attention:

- The flexion component of the osteotomy corrects for the posterior slip of the epiphysis. This requires insertion of the blade plate so that the chisel is angled with the aspect rotated anteriorly as it is inserted into the proximal fragment. Correction of this posterior displacement with an anterior repositioning of the proximal segment will result in the plate sitting flush on the lateral surface of the femoral shaft.
- In this same osteotomy, orient the cuts to produce a closing wedge laterally to correct the varus deformity. A full lateral wedge resection, equal to the magnitude of the plane correction, is necessary to avoid lengthening of the limb.
- To me the rotational correction, insert parallel Kirschner wires (K-wires) above and below the osteotomy for referencing. Even more important, though, is to monitor the patella for anterior position prior to fixation.
- Check the range of motion of the hip after fixation is in place to identify any bony blocks to motion, especially in flexion or adduction. If present, this may require excision of impinging bone or repositioning of the fragments. With detailed preoperative planning and technique, surgical complications such as limb-length inequality, rotational or angular malposition, and nonunion can be minimized.

RESULTS

Imhauser (68) reported in 1977 the results of 68 hips in 55 patients with 11- to 22-year follow-up. Of these, only 27% showed early degenerative changes and one had osteoarthritis and complained of pain. Five hips had significant limitation of motion, with one patient dissatisfied by this. Imhauser felt that these results represented a large improvement over historical controls.

In 1967, Southwick (144) reported on a series of 55 patients, with 28 hips having greater than a 5-year follow-up. He did not perform any in situ pinning of the epiphysis in the osteotomy group but used spica casting postoperatively for all acute slips. There were no cases of AVN in the 55 patients. Three hips required a second operation, all for bony impingement blocking either adduction or flexion; all of these had subsequent excellent results. All hips experienced 5° to 1° of shortening. Southwick stated that slips greater than 60° could not be fully corrected because of excessive shortening of the femur. In those patients with more than a 5-year follow-up, he reported 21 excellent, five good, and two fair results.

In 1996, Schai et al. (134) reported on 51 patients with unilateral chronic slips with angles of 30° to 60° who were treated by early corrective ITO. The average patient age was 12.6 (girls) to 14.6 years (boys), and mean follow-up was 24 years, with the surgery done an average of 6 months after the first symptoms. At the latest exam, 55% of the patients had no symptoms or radiographic deterioration, 28% had moderate osteoarthritis, and 17% had severe osteoarthritis. The authors stated that this 17% represents a significant improvement over what they believe to be a 28% to 40% chance of developing early onset degenerative arthritis if these severe slips are left uncorrected.

Several studies have helped to define the natural history of SCFE and serve as the control for most of the series in the literature. Goodman et al. (53) in 1997 studied more than 200 skeletally mature patients found that the major risk factor for the development of high-grade osteoarthrosis. In a Swedish study (118) of 30 untreated grade 3 slips (see Chapter 17) with at least a 20-year follow-up, 57% had pain and 43% had limitations in walking activity, despite an average age of less than 40 years. In a distillation of these studies, Aronson et al. (9) concluded that by the fourth decade, severe SCFE increases the risk of hip osteoarthritis by a factor of 20 over the normal population. Aronson et al. (6) reported on a series of Bombelli’s patients, which included 24 grade 2 slips corrected by primary triplane ITO. The group with more than a 2-year follow-up had a 39% gain in total arc of motion after having had a preoperative mean slip angle of 58°. Less aggressive bony wedge removal than that described by Southwick (144) resulted in fewer problems with limb shortening. All were pain free at 2–10 years follow-up, with no cases of AVN, chondrolysis, infection, or nonunion.

INTERTROCHANTERIC OSTEOTOMY FOR OSTEOARTHRITIS

Total hip replacement is the standard surgical treatment for osteoarthritis of the hip against which other surgical options must be weighed. Even with modern advances, however, hip replacement cannot yet be offered to younger adults routinely. Early failures, primarily due to rapid wear and loosening, have been well documented in patients younger than 50 years (30,40,41,156). Proximal femoral osteotomy therefore remains an important and effective treatment option for the painful osteoarthritic hip in adults.

The techniques for ITO have descended from Pauwels in Germany (119) and have been followed or modified by Müller (105), Bombelli (16,17,18, and 19.132), Wagner and Holder (165), and others in Europe and many countries around the world (1,6,7,8,15,23,32,38,52,64,65,68,80,76,77,82,84,94,95,103,104,106,121,123,124,127,133,135,137,138,163,172,174). ITO has a record of success in the treatment of osteoarthritis of the hip, whether primary or secondary. Most authors have reported better results from ITO in patients with secondary hip arthritis, such as from dysplasia, Legg–Perthes disease (130,132), and dysplasia (144). These patients have a definable biomechanical predisposition to develop degenerative arthritis. Because the predisposing deformity can often be improved or even completely normalized by ITO, it is understandable that results have been superior in this group. Surgical intervention may both relieve pain and decelerate further deterioration of the hip.

Historically, groups of patients who underwent varus ITO have had better long-term results than those who had valgus ITO. The selection criteria for those receiving a varus osteotomy, however, often resulted in these patients being younger, with less radiographic arthrosis and better joint congruity. Therefore, patient selection has been biased, making comparisons between these procedures in the literature difficult. In fact, with the advent of modern periacetabular rotational osteotomies, the indications for isolated ITO in the adult have narrowed considerably, particularly for varus ITO. Currently, the most common osteotomy of the proximal femur indicated for significant adult arthritis is a valgus–extension ITO. Valgus and extension refer to the position of the distal fragment at the osteotomy site. Therefore, a valgus–extension ITO moves the proximal fragment and the hip joint itself toward adduction and flexion. For this reason, therefore, passive positioning of leg in adduction, externally rotated, and to some degree the status of the hip after a valgus–extension osteotomy.

PATIENT EVALUATION AND PLANNING

Several aspects of the patient workup merit special attention when considering a varus or valgus ITO. In addition to performing a routine evaluation, determine the position of comfort by history and exam. Relief of pain in adduction suggests improvement from a valgus osteotomy. Perform functional radiographs in abduction and adduction, and obtain fluoroscopy of the patient under fluoroscopy. With the hip positioned to replicate the planned effect of an ITO, joint congruity and the remaining joint space should be improved, or at least similar. A false-negative view will reveal any deficiency in anterior coverage, which may favor the addition of an extension component to the osteotomy.

Carefully document the actual and apparent limb-length inequality because there is a profound potential effect of ITO. Given equal leg lengths preoperatively, routinely remove wedges from the osteotomy site with varus osteotomies, or preserve maximal length in varus ITO, using no wedges at all. Preserving or improving limb length almost always takes precedence over the goal of obtaining total apposition of the raw cut surfaces at the osteotomy site.

A full-length standing radiograph can be helpful to document overall limb alignment preoperatively by displaying the mechanical axis (see Chapter 26 and Chapter 32). All things being equal, lateral shaft displacement will accompany a varus ITO, and relative medial displacement of the distal fragment occurs with a varus ITO. This is necessary to accommodate future total hip stem insertions and minimize any frontal plane medullary axis total hip hingement, which may predispose to later knee (or ankle) problems. Nevertheless, planning for the placement of a future total hip stem generally takes priority over shaft displacement when considering final position of the fragments after osteotomy. The patient in Figure 104.25(A), Figure 104.25(C), Figure 104.25(E) demonstrates the importance of limb-length planning. Her leg was 1%
inches short before, but equal in length and pain free after a valgus ITO with no wedge and lateral shaft displacement.

**Figure 104.25.** Leg-length discrepancy and arthritis treated with valgus ITO. This 32-year-old woman with a history of hip dysplasia, childhood hip surgeries, and treatment-related osteonecrosis. A: AP view of the right hip. B: False-profile view. The right lower extremity was 1½ inches (3.75 cm) short. C: AP view of the right 6 months after a valgus ITO. D: AP view of the right hip 15 months postoperative. After hardware removal, the patient had no pain, a 95° flexion arc, and equal leg lengths.

**VALGUS–EXTENSION INTERTROCHANTERIC OSTEOTOMY**

The most common indication for ITO is for the adult sequelae of DDH. Bombelli (16, 17, 18 and 19) has studied and categorized the morphologic features of osteoarthritis of the dysplastic hip, including a nomenclature for the osteophytes that develop. The vast majority of patients (95% of Bombelli’s valgus–extension series) have superolateral rather than medial degenerative changes. The superolateral group also had the best results in Bombelli’s series as well as those of others (54, 77).

The rationale of the valgus–extension osteotomy is to utilize the noninnervated medial “capital drop” osteophytes as a new fulcrum along with the “floor” osteophytes of the acetabulum. This more medial fulcrum acts as a new center of rotation for the hip joint. Lateral impingement is reduced, and weight-bearing forces are moved away from the painful superolateral femoral head and toward the medial osteophytes, and the lever arm of the body weight is reduced. “Roof” osteophytes also play a role. The additional extension component to the osteotomy allows improved anterior coverage of the femoral head and elimination of any fixed flexion contracture. Extension, which refers to the relative position of the distal fragment at the osteotomy site, is therefore “apex-anterior.” Ideally, these features improve joint congruity and the radiographic joint space, as well as increasing the weight-bearing surface area. In patients with some flexion (with or without adduction) contracture, a valgus–extension ITO moves the restricted anatomic range of motion closer to the functional range of motion needed for daily activities. This reduces a major source of pain and impingement. The extension component also relaxes stresses of hyperlordosis on the lumbar spine and often permits patients to rest without pain in the supine position for the first time in years.

**Indications and Contraindications**

Indications and contraindications for valgus–extension ITO are listed in **Table 104.3.** Figure 104.26 shows a patient who had a valgus ITO on the left with later recurrence of some pain at 7 years. He had a mild valgus ITO on the right for protrusio-pattern arthritis.

**Table 104.3. Indications and Contraindications for Valgus (and Varus) Extension Intertrochanteric Osteotomies**

**Figure 104.26.** Arthritis with bilateral protrusio acetabulae treated with a valgus ITO. A: AP view of the pelvis in a 28-year-old with a history of a left ITO done elsewhere 4 years earlier with initial pain relief. B: AP view of the right hip early following a mild valgus–derotation right ITO. C: AP view of the pelvis 1 year after surgery. By 2½ years, the patient rated the right hip as “excellent,” while symptoms had recurred on the left.

**Operative Technique**

- Position the patient supine with the operative hip at the edge of a radiolucent operating table. Place a bump under the sacrum and prepare and drape the hip and leg free.
- Perform a lateral approach to the proximal femur through a straight lateral incision, or one that curves anteriorly in the proximal limb if access to the hip joint is needed.
- Reflect the vastus lateralis muscle anteriorly from the posterolateral aspect of the femoral shaft, and release the origin from the vastus tubercle. The femoral neck need not be routinely exposed if good fluoroscopic images are obtained.
- Slide a K-wire along the anterior surface of the femoral neck to mark the anteverision of the femoral neck.
- Mark the site of the chisel insertion by drilling a transverse 7/64-inch K-wire at the level of the vastus tubercle, (usually) parallel to the first K-wire and at an angle in the frontal plane that corresponds to the preoperative plan. Confirm by fluoroscopy.
- Generally, we use a 120° or 130° plate for a valgus ITO. For a 30° valgus correction with a 130° plate, insert the wire at 80° from the lateral cortex of the shaft and parallel to the femoral neck pin on the lateral view (Fig. 104.27). Make fine adjustments to the start point and lateral position based on AP and lateral imaging. The wire should be in the center or slightly inferior portion of the neck on the AP view, and in the center of the neck on the lateral view. The greater trochanter is posterior, so the blade should enter anterior to the midtrochanteric line to avoid exiting the posterior femoral neck.
Operative Technique

The indications and contraindications for varus–extension ITO are listed in Table 104.3.

Operative Technique

The surgical technique for varus–extension ITO is similar to that for valgus–extension ITO, but there are some significant differences.

- Position the patient, expose the hip, and insert guide wires in a fashion similar to that described previously for the extension–valgus ITO.

- Generally, a 90° blade plate is utilized for a varus ITO. For a 15° varus correction with this plate, insert the guide wire at 75° from the lateral cortex of the shaft and parallel to the femoral neck pin on the lateral view. Make fine adjustments based on AP and lateral imaging. The wire should be in the center or slightly inferior portion of the neck on the AP, and down the center of the neck on the lateral view. The greater trochanter is a posterior structure, so the blade should enter anterior to the midtrochanteric line to avoid exiting the posterior femoral neck.

- Drill in a final reference K-wire perfectly parallel to the wire marking the course of the blade, but 1–2 cm superior to it in the greater trochanter. This will help guide placement of the seating chisel or wire loosers or needs to be bent or removed. Remove the initial extraneous femoral neck wire.

- Clean the blade insertion site of any remaining soft tissue.

- Prepare the lateral cortex for the seating chisel using the AO (Synthes) 4.5 mm triple drill guide in the site of the second K-wire and rotated posterior to the femoral shaft for the desired amount of extension. Confirm that the passage for the chisel through the neck will be safe by checking a lateral radiographic view with drill bits in the outer holes of the triple guide. Use the router as needed to further develop this opening in the outer cortex to prevent bone splitting or incarceration of the seating chisel.

- Now slowly impact the seating chisel, parallel in both planes to the reference K-wire and rotated posteriorly for the desired extension component. Preset the attached adjustable angle guide on the chisel to be parallel to the femoral shaft to monitor the frontal plane insertion angle, that is, 80° to the shaft. Check multiple AP and lateral images during insertion.

- Back the chisel out several times as it gets deeper, to prevent incarceration.

- Prior to doing the femoral osteotomy, score the anterior cortex longitudinally as a reference for rotation, or insert reference K-wires above and below the osteotomy.

- Leaving the chisel in place, perform the osteotomy 1.5 cm below the chisel, 90° to the shaft. The preoperative plan should place the osteotomy at the upper border of the lesser trochanter. Cut slowly with an oscillating saw using retractors to protect the posterior soft tissues. Use copious irrigation to prevent overheating. Adduct and externally rotate the leg vigorously after the osteotomy. This permits access to the iliopsoas tendon insertion into the lesser trochanter.

- This is released from the lesser trochanter with the electrocautery device.

- Next, correct the rotation prior to removing any bone wedges.

- Then use the oscillating saw to remove a biplanar wedge of appropriate size from the proximal end of the distal fragment. For example, if 30° of additional valgus and 10° of extension of the proximal fragment were desired, a wedge that combined these two amounts would be removed. The cuts can be made sequentially rather than as a single cut; it is technically easier to do two separate cuts but more bone is usually sacrificed. The location of the apex of the wedge removed relative to the medial-lateral width of the femur determines the degree of apposition of the surfaces of the osteotomy and the gain in length. Placing the apex at the medial cortex maximizes the contact area in the osteotomy and minimizes the gain in length.

- Remove the seating chisel and carefully insert the blade plate by hand along the same path. Impact to final depth while checking images in two planes.

- Lateralization of the shaft is built into the selected blade plate according to preoperative planning, but it can be fine-tuned at this stage by the final depth of blade insertion. For instance, if the plan calls for 15 mm of lateral shaft displacement, and the seating chisel depth of insertion was 70 mm, use an 85 mm 130° plate to achieve full insertion and 15 mm of lateral shaft displacement.

- Without using excessive force on the implant, manipulate the fragments and dissec soft tissues as needed to allow easy apposition of the bone ends. Before osteosynthesis, resct any planned wedges from the proximal surface of the distal fragment.

- Apply a transport clamp (Synthes, Paoli, PA) and approximate the plate to the lateral cortex of the shaft. With the osteotomy reduced, tighten the clamp. Pay attention to the displacement in the sagittal plane to avoid creating difficulties with future femoral stem placement.

- The calibrated compression device is now used. Avoid aggressive compression, which may place the lateral bone bridge at risk. Make sure that the patella is in an anterior position to control leg rotation.

- Gently flex the hip and knee to confirm normal rotational alignment.

- Insert one or two screws in the side plate. Check images in two planes for implant position and fragment alignment. If satisfactory, then complete screw insertion.

- Use any removed bone as graft around the osteotomy after thorough irrigation.

- Insert a 4.5 mm cortical screw into the head fragment through the most proximal hole in the plate before use of the compression device.

- Insert one or two screws in the side plate. Check images in two planes for implant position and fragment alignment. If satisfactory, then complete screw insertion.

- Use any removed bone as graft around the osteotomy after thorough irrigation.

- Insert a drain and close the wound in layers.

Postoperative Care

Postoperatively, initiate physical therapy with toe-touch weight-bearing the day after surgery. Do not allow straight leg raises or active abduction exercises during the initial 6 weeks. Begin weight bearing with two crutches at 6 weeks after surgery and keep the patient bearing only partial weight until bony healing and strength allows transition to one crutch or cane, usually between 12 and 14 weeks. We remove the implants at 12–24 months postoperatively.

VARUS–EXTENSION INTERTROCHANTERIC OSTEOTOMY

Isolated varus ITO is rarely performed now because most patients previously selected for varus osteotomy are usually candidates for a PAO. Some patients with acetabular and femoral deformities may require both procedures. Indications for an isolated varus ITO include minimal femoral head deformity and little or no acetabular dysplasia, a valgus neck–shaft angle, signs of early lateral joint arthritis, and improved joint congruency on abduction radiographs (95). Experience over the past 20 years, however, has shown that good results do not depend on medial displacement, and that problems with healing as well as with future femoral stem placement increase with the degree of displacement. In fact, deliberate medial displacement of the distal fragment is strongly contraindicated for this reason.

Varus ITO has several drawbacks. Significant shortening of the leg is guaranteed if wedges are resected. An opening wedge technique can preserve some length but is associated with a longer time to complete bony union. A Trendelenberg gait is common and may persist permanently. Simultaneous or staged osteotomy and distal displacement. In fact, deliberate medial displacement of the distal fragment is strongly contraindicated for this reason.

Biomechanical Classification of Osteoarthrits of the Hip. In: Schatzker J, ed. The Intertrochanteric Osteotomy. New York: Springer-Verlag, 1984:115, with permission.)
thromboembolic prophylaxis, and use of an arthroplasty-style operating theater. As osteotomy patients are, by selection, physiologically younger than total joint replacement protocols are generally applicable and may include autologous blood donation, cell-saver for certain cases, perioperative antibiotic and anticoagulation therapy.

In patients with bilateral disease, the avoidance of THR in the contralateral hip is important for the survivorship of the surgery. In cases of bilateral osteotomies, the contralateral side is treated after a minimum of 3 years. In cases where the contralateral side is treated in the same year as the initial surgery, the risk of failure is increased. Therefore, it is prudent to remove implants that might interfere with subsequent surgery.

Landais et al. (77) reported the results of 150 valgus–extension ITOs in patients with severe arthritis. Mean follow-up was 6 years, and 45% were older than 65 years. In patients under 50 years at the time of surgery, with secondary arthritis, 85% were pain free at the 10-year follow-up, with 77% good or excellent results. Overall, results were 77% good or excellent at 3-year follow-up. Results for patients with concentric hips and primary osteoarthritis were only half to two-thirds as good as for posttraumatic or other secondary arthritides. Radiographic improvement of the joint space was seen in 60% of all patients.

Maistrelli et al. (87) published the results of 277 valgus–extension osteotomies in patients with a mean age of 52 years. At 11–15 years of follow-up, they reported 67% good or excellent results. Results were better in those under 40 years old (76% good or excellent). Patients with unilateral disease had better results (77% good or excellent) than those with bilateral disease (40% good or excellent). Good results were obtained in 68% if preoperative flexion was 60° or more compared to only 31% if flexion was less than 60°. With the preceding study, a mechanical etiology for arthritis predicted results almost twice as good (71% good or excellent) as for patients with primary arthritis (42% good or excellent). Maistrelli et al. (87), Bombelli et al. (18,19), and others (23) have recommended a minimum biaxial correction of 20° to obtain their expected results. Santore and Bombelli (132) reported the results of 45 patients with a mean age of 50 years. At the 11-year (average) follow-up they had 33% good or excellent results, which included 35 valgus and 10 varus ITOs. The average Harris hip score increased from 44 to 84. Unlike in previous reports, older patients or those with preoperative hip stiffness did not have worse outcomes.

There have been no recent large series reporting on varus ITO, in part because of the success of rotational pelvic osteotomies. Most reports include a combination of pelvic and femoral varus and valgus osteotomies, although when done for arthritis, an extension component has usually been combined with both types. Morscher’s (103) summary of the large Swiss series reported the varus ITO results separately, with nearly 90% good to excellent long-term outcomes. Deltenbeck et al. (38) reported a series of 59 ITOs according to the method of Pauwels in patients with a mean age of 57 years. Results at 2½ years were satisfactory in 80% (32 excellent, 15 good). The majority of patients had a varus procedure, and these results (89% satisfactory) were superior to the results in valgus osteotomy (65% satisfactory). These results cannot be directly compared because of the different selection criteria for each group. In a more recent report, Iwase et al. (70) followed 110 hips with dysplasia more than 20 years after ITO, with nearly equal numbers of varus and valgus osteotomies. Again, varus osteotomy was selected for early coxa varum (mean age, 25 years) and valgus for end-stage disease (mean age, 37 years). Using the endpoint of a Harris hip score of less than 70 or a salvage surgery, the 10- and 15-year survival rates for varus osteotomies were 87% and 87% and for valgus ITO were 66% and 38%, respectively. The younger age range in this series was almost certainly a factor in the excellent long-term outcomes, which also included 82% good to excellent 20-year results for their varus osteotomies.

Recent publications have documented a favorable experience with ITO. Gotto et al. (55) reported on 31 valgus–extension ITOs in patients with a mean age of 43 years, including four that had a concomitant Charn osteotomy. The good results in these osteotomies had a survivorship of 85% at 5 years, 67% at 10 years, and 51% at 15 years. Good radiographic results correlated with the size of the preoperative osteophytes, particularly the width of the capital drop and length of the roof osteophytes. D’Souza et al. (43) published a series of 25 hips (6 varus–extension and 19 valgus–extension osteotomies) with a mean age of 38 years and average follow-up of 7 years. Four hips (16%) were converted to total hip arthroplasty at an average of 8 years after ITO, with a survival rate at 12 years of 87%. Schneider (137), in a report with 12–16 years of follow-up, also found that the median time to conversion to total hip arthroplasty was 8 years. Despite the fact that many of the studies in the literature have included inhomogeneous groups and less than ideally selected patients, similar selection criteria and results in properly selected patients have emerged over the years. There is a growing consensus that at 10 years or more after surgery, 70% to 80% of patients continue to have satisfactory results following an appropriate angulation ITO (77, 87, 103, 129, 132, 135, 137).

REMOVAL OF FIXATION IMPLANTS AFTER OSTEOTOMIES

We routinely remove implants after osteotomies of the pelvis and proximal femur for several reasons. Some patients have pain related to the implants. Even patients who do not have tenderness to palpation over the hardware can experience pain relief after removal. With pelvic osteotomies, long cortical fixation screws are used, often more than 10 screws. These can be some of the biggest sources of pain and the reason for failure due to screw loosening in the pelvis. Removal of these screws from the iliac crest is a simple outpatient procedure if performed before screw breakage, but is otherwise much more complicated. Patients who have an osteotomy of the pelvis or proximal femur are at increased risk for requiring a subsequent THR; therefore, we feel that it is prudent to remove implants that might interfere with subsequent surgery.

PITFALLS AND COMPLICATIONS

Many of the complications of osteotomy of the pelvis or proximal femur are not specific for osteotomy surgery and will not be discussed in detail here. These include anesthesia-related events, such as strokes and transient ischemic attacks, acute compartment syndrome, deep venous thrombosis, and perforating arteries, particularly the obturator, which can result in arterial injury. Infection is also a major concern and can lead to failure due to infection. Other complications include implant loosening, which can lead to failure due to pain, and dislocation or avascular necrosis, which can lead to failure due to pain.

Infection: Infection is the most common complication of osteotomy surgery, and it can occur at any stage of the procedure. The risk of infection is influenced by several factors, including the type of procedure, patient factors, and surgical technique. The risk of infection is higher in patients with diabetes, obesity, or immunosuppression. The most common type of infection is pelvic osteomyelitis, which can occur after the procedure, and it can be difficult to treat.

Dislocation: Dislocation is a common complication of osteotomy surgery, and it can occur at any stage of the procedure. The risk of dislocation is influenced by several factors, including the type of procedure, patient factors, and surgical technique. The risk of dislocation is higher in patients with a history of dislocation, and it can be difficult to treat if it occurs after the procedure.

Avascular Necrosis: Avascular necrosis is a common complication of osteotomy surgery, and it can occur at any stage of the procedure. The risk of avascular necrosis is influenced by several factors, including the type of procedure, patient factors, and surgical technique. The risk of avascular necrosis is higher in patients with a history of avascular necrosis, and it can be difficult to treat if it occurs after the procedure.

Other Complications: Other complications of osteotomy surgery include wound healing problems, nerve injury, and neurovascular injury. These complications can be managed with appropriate postoperative care, and they can be minimized with proper surgical technique.
patients, surgery is better tolerated, and nonspecific complications such as those listed previously are unusual.

Other complications are more specific for osteotomy surgery and deserve special consideration:

- Trochanteric bursitis or painful bursae over implants (24,112)
- Malunion, that is, undercorrection, overcorrection, malrotation, retroversion (PAO only)
- Delayed union and nonunion
- Joint preparation
- Penetration of the hip joint
- Loss of fixation
- Changes in leg length
- Abductor weakness and limp
- Difficulty with subsequent THR (134)
- Pain associated with the lateral femoral cutaneous nerve (PAO)
- Intraoperative fracture of the femoral neck, acetabulum, or the lateral bone bridge below the blade of the blade plate
- Clinical failure in spite of a well-performed procedure, including increased hip joint stiffness, and persistent or increased pain. Figure 104.23 shows a 47-year-old woman who, after a technically successful PAO, maintained a pain-free status for 6 months, followed by failure requiring THR. The degree of difficulty of the THR was no different from that of a standard primary THR.

The first six complications are familiar to surgeons who routinely care for fractures around the hip joint. The most common complication seen with osteotomy of the pelvis or proximal femur is bursitis. The nearly subcutaneous position of the greater trochanter and iliac crest makes prominent hardware nearly unavoidable. This is commonly seen over large fragment screw heads at the iliac crest following pelvic osteotomy, and laterally over a blade plate in the proximal femur. Routine removal of the implants usually eliminates this problem. When varus of the proximal femur is present or when the greater trochanter has been lateralized, trochanteric bursitis can persist despite hardware removal, because of the prominence of the greater trochanter (2).

Probably the most common serious complication from an ITO around the hip is overcorrection when performing a varus proximal femoral osteotomy. This may lead to abductor weakness, an unsolvable Trendelenburg limp, marked leg-length inequality, and patient dissatisfaction. Overcorrection, undercorrection, and rotational malalignment can all lead to a problematic malunion. Malunion after osteotomy can result from several potential sources, including malpositioning following a poor or inadequate preoperative plan; error in technical execution of a good plan; or postoperative loss of a good position obtained in the operating room secondary to other problems such as delayed union, poor internal fixation, or patient noncompliance.

A reliable technical plan can be made only with an adequate radiographic workup and skillful preoperative tracing or computer templating. For many osteotomies, a computerized osteotomy planning system is now standard. The converse is true for varus ITO who also has milder knee arthritis, some lateral mechanical osteotomy plan is perhaps the most common complication described in the literature, and it is also the complication most within the surgeon's control. Sufficient experience with these osteotomies is required to avoid these errors.

In the operating room, critical factors include adequate surgical exposure, good radiographic control with both the image intensifier and confirmatory plain films, and the skill and patience for precision. With rigid internal fixation and good immediate alignment and position, a position is unlikely. However, premature weight bearing or delayed union can predispose to such a shift. Helping to prevent delayed union and fostering bony healing is somewhat within the surgeon's immediate control, as discussed next.

Delayed union and nonunion are not preventable but can be minimized by following a few principles. Rigid internal fixation is critically important. If there is any question of stability at the time of surgery, ensure stability by reengineering the osteosynthesis. As long as fixation and other factors are appropriate, however, even point-contact apposition (as in a varus ITO) can be expected to heal, although restricted weight bearing may be required for a longer period of time.

In general, bone grafts are not needed, even with large gaps in the pelvis or upper femur. Exceptions include significantly displaced Chiari osteotomies, markedly displaced periacetabular pubic, ischiial, or iliac cuts, and nonunions of the proximal femur or pelvis.

Breakage of implants, loss of fixation, hardware penetration, and cutout are all directly related to the problem of achieving stability and union of the osteotomy and/or fracture site. Documented recent breakage of fixation implants generally indicates that the osteotomy has not healed. Whether implant breakage is a significant clinical problem depends on the stability remaining in the construct and the stage of healing. If the osteotomy or proximal femoral fracture is unstable, then broken implants make revision surgery more difficult and more urgent. Hardware penetration into the hip joint following cutout of an implant from the femoral head also calls for an expedited revision to prevent additional damage to the articular cartilage of the hip.

One of the characteristics of osteotomy around the hip joint that can be either an asset or a liability is the potential for affecting leg length. This is most prominent with proximal femoral osteotomy but can be seen with pelvic osteotomies as well. The Chiari procedure tends to cause shortening, which can be significant depending on the slope of the osteotomy and the degree of displacement. A PAO can result in a slight lengthening, although this is typically minimal (less than 1 cm). A valgus ITO has the potential for lengthening of several centimeters. If the operative leg is short, this can be a principal benefit and can contribute to the indications for the surgery. This is especially true for valgus varus with malunions, femoral valgus, or severe deformity of the femur, such as those seen in adolescence, congenital varus deformity, and SCFE. However, if leg lengths are equal or the operative leg is long, then full-wedge resection combined with removal of an additional segment of bone from the distal fragment may be necessary because of the inherent lengthening effect of a varus ITO.

The greatest difficulty with leg length after osteotomy around the hip accompanies varus ITO. For major angular corrections (> 15° of varus), resection of any bone wedges essentially guarantees a noticeable amount of limb shortening. The patient needs to understand this aspect of the surgery before the fact. With minimal or no wedge resection and rigid fixation, maximum length can be preserved during a varus ITO. Accuracy in preoperative planning combined with careful intraoperative verification can help to ensure that the expected leg lengths are obtained following any hip osteotomy.

A postoperative limp is a complication that can be long lasting and the source of patient dissatisfaction following surgery. A chronic limp not caused by pain is usually secondary to abductor dysfunction. Procedures that damage or shorten the abductors or place them at a mechanical disadvantage are most likely to cause a limp or a Trendelenburg gait. These include pelvic osteotomies that involve release of the abductor origin laterally for exposure, Chiari osteotomies, and varus osteotomies of the proximal femur. This type of limp can take a year or more to improve or can be permanent. The patient should, of course, be educated about this before surgery. In some cases, a preoperative Trendelenburg limp can be improved after osteotomy. This is usually seen when greater trochanter advancement is performed or when a valgus ITO improves subobturator abductor mechanics.

Changes in alignment of the proximal femur influence the biomechanical axis through the knee. This can lead to secondary knee pain and arthritis after a hip procedure. In frontal plane angular osteotomies, a valgus ITO places a valgus stress on the knee, whereas a varus ITO generates varus forces and increases medial joint loadings. Lateral displacement of the shaft (distal) fragment at the time of a valgus ITO can correct the mechanical axis and eliminate abnormal forces at the knee secondary to the correction. The converse is true for a varus ITO. The converse is also true for varus ITO who also has milder knee arthritis, some lateral mechanical axis shift may be desirable, and therefore less lateral displacement of the osteotomy is indicated. In addition to frontal plane displacement, anterior shaft displacement generally accompanies a flexion ITO, and posterior displacement accompanies an extension ITO. The significance of this displacement that is not seen on the AP radiograph should not be underestimated when planning for a subsequent THR. Despite the importance of displacement, as discussed, if a choice must be made between obtaining the full displacement desired and obtaining a proximal femur compatible with future total hip stem placement, the displacement that is compatible with the future THR is preferred.

Osteotomy can make subsequent THR surgery more difficult on both the pelvic and femoral sides (20,65). Of the pelvic osteotomies discussed, the Chiari procedure creates the most difficulty for acetabular component placement, which is more fully discussed in the Chiari osteotomy section of this chapter. The periacetabular rotator cuff osteotomies generally do not alter the difficulty of cup placement. While better superior and lateral coverage is obtained in an otherwise dysplastic hip, this is at the expense of posterior and inferior coverage, leaving a partially deficient bed of host bone for acetabular fixation. The most significant postosteotomy arthroplasty challenges come on the femoral side when a previous ITO with excessive displacement or subtrochanteric osteotomy has been done. Intraoperative perforation of the femoral shaft, varus fracturing of the femoral neck, and compromised fixation, whether cemented or uncemented, may potentially lead to early failure of the femoral component (12,142).

In some cases, a revision osteotomy of the femur is necessary prior to proceeding with a THR, although this is usually done at the time of the hip replacement. The presence of an implant such as a blade plate from a previous osteotomy can be a source of problems for a subsequent THR. Simultaneous implant removal and THR surgery results in slightly increased operative time and possibly an increased infection rate for the THR. The presence of open screw holes can diminish the effectiveness of cement pressurization when a cemented femoral component is used. For these reasons, we prefer early hardware removal of fixation devices years
Nerve injury after proximal femoral osteotomy is rare. The femoral, obturator, and sciatic nerves are generally well protected, and no major cutaneous nerves are at risk with the straight lateral incision. Nerve injury is more common after pelvic osteotomy. The lateral femoral cutaneous nerve is at risk with any anterior exposure of the pelvis. Despite every attempt to preserve this nerve, anterolateral thigh numbness and paresthesias are quite common. The typical injury to the nerve is a traction neurapraxia. The majority of these palsies completely resolve with time, but some patients do have a permanent sensory deficit. The major nerves that pass the hip joint are all at risk with a pelvic osteotomy, particularly in a rotational periacetabular procedure. The femoral nerve is close to the anterior and medial retractor. The obturator nerve is at risk during the pubic osteotomy. Use of a Gigli saw for the pubic cut may reduce the chance of damage to the obturator neurovascular bundle. The sciatic nerve is in jeopardy at the sciatic notch, whether from laceration from an osteotomy or bone spike, or from traction. With complete pelvic osteotomies into the sciatic notch area, such as a ChiarI, use of a Gigli saw for this cut, as well as specialized or maleable retractors, may minimize the risk of sciatic injury. Avoid paralytic anesthetic agents, as they preclude recognition of any inadvertent stimulation of a motor nerve.

One of the more dreaded complications is AVN. This may apply to the femoral head or to the acetabulum, depending on the location of the osteotomy. Osteotomies closer to the joint surface are more likely to disrupt the critical blood supply to the mobilized joint fragment. Therefore, as a general rule, the smaller and more isolated the fragment, the greater the risk of AVN. This is one of several reasons that we (and others) prefer the Bernese PAO over the spherical rotational or dial acetabular osteotomies. It also supports our preference for intertrochanteric over femoral neck or cuneiform proximal femoral osteotomies. Minimize the soft-tissue stripping during surgery to reduce the chances of AVN. The remaining blood supply of either a rotated acetabular fragment or femoral head is via the ligamentum teres capitis and the capsule, especially its posterior anastomoses. When an incision into the capsule is necessary, use a minimum of dissection to respect the importance of this circulation. In some cases, such as in a SCFE (with or without reduction) or a femoral neck fracture nonunion, the risk of AVN is significant. In patients who have surgery within a year of injury, it may be difficult to determine the potential role that an osteotomy plays in increasing this risk.

In addition to AVN, other complications potentially related to creation of a thin or short fragment are fracture and intra-articular hardware. The dial osteotomy is performed closer to the articular surface than a triple pelvic or Bernese periacetabular procedure. Difficulties in stabilizing the fragment or in avoiding intra-articular penetration are more challenging with the dial osteotomy or similar procedures. On the femoral side, cuneiform and femoral neck osteotomies and cases of femoral neck nonunion provide less proximal bone for safe placement of fixation hardware. Quality fluoroscopic images in multiple planes with some use of light fluoroscopic visualization may be necessary to document safe screw placement. Trauma surgeons have described the use of a sterile esophageal stethoscope along the quadrilateral plate (or, in fact, against any nearby bone) as a method of audibly detecting the unmistakable scraping sound of an intra-articular screw in radiographically uncertain cases. We have not found this to be necessary. Radiographically uncertain screws generally do not have to be tolerated in osteotomy surgery, for which screw placement options are usually more varied than they are in complex pelvic fracture osteosynthesis.

Another site for potential intraoperative or postoperative fracture is the lateral bone bridge of the proximal fragment of an ITO. A 15–20 mm bridge of intact bone is needed between the seating chisel entry site and the osteotomy for safety. The integrity of this bone must be assessed during surgery, especially in revision or femoral nonunion cases. Change from a higher-angle blade plate to a lower-angle blade plate may be required to ensure stable osteosynthesis. This should be ascertained in preoperative planning, rarely during surgery itself.

A discouraging problem is persistent or increased pain or increased stiffness following osteotomy. Heterotopic ossification may appear after an otherwise uncomplicated osteotomy, more commonly on the pelvic side. It is usually an incidental finding but can cause symptomatic stiffness. Increased stiffness independent of pain in the hip is more common after surgery in patients with more advanced arthritis. Persistent or increased pain is also more common in patients with worse preoperative degenerative changes. Strict adherence to described surgical indications will minimize the number of such clinical failures. The guidelines to patient selection previously discussed are not rigid but serve as guides by which the patient and surgeon can come to understand the potential risks and benefits of a given procedure. Once the surgeon understands the patient and the patient is educated about the treatment options, together they can decide whether an osteotomy will best serve the patient’s needs.

## AUTHORS’ PERSPECTIVE

The most significant development in the last decade in this field has been the adoption of the Bernese PAO as the procedure of choice for the painful hip with prearthritic or early arthritic changes secondary to underlying dysplasia in adults.

The philosophy of true adult reconstructive surgery of the hip as an interest area within the field of orthopaedic surgery should include osteotomies of the pelvis and upper femur as well as arthrodesis when indicated, in addition to primary and revision arthroplasty.

On the femoral side, ITO has an enduring role in posttraumatic conditions (femoral neck nonunions, malunion), osteonecrosis (131), SCFE and superolateral arthritis secondary to dysplasia, among others.

I (RS) cannot emphasize too strongly the importance of careful preparation and detailed, virtually step-by-step planning prior to any osteotomy surgery. Particularly with regard to the PAO, when the best results are achieved is irreversible radiographic deterioration, complications could leave a patient much worse off than before the surgery, and at a young age. Careful study, multiple cadaveric dissections, and visits to centers with extensive experience are valuable building blocks. This surgery should not be undertaken casually or infrequently.

The bones of the pelvis and upper femur are remarkable organs, capable of extensive remodeling, filling-in of gaps and defects, and healing of arthritis. The art of patient selection is as important as the ability to perform the surgery. Obesity, lack of motivation, and unrealistic expectations are as important contraindications to surgery as any adverse radiographic union space remodeling, relief of pain, and restoration of function after a successful osteotomy is one of the most rewarding aspects of reconstructive surgery in adults.

## CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; I, basic research article; and +, clinical results/outcome study.

Total hip arthroplasty (THA) is a remarkably successful and predictable procedure that provides pain relief, functional improvement, and improved quality of life for several hundred thousand patients each year worldwide. The success of hip arthroplasty is predicated on proper patient selection, use of well-designed implants, and skilled technical execution of the procedure. Long-term results demonstrate that THA is durable in many patient populations, although they also demonstrate durability problems in specific patient groups. Durability also depends on implant type, method of fixation, and technique of insertion. The excellent results of hip arthroplasty are due in part to the fact that patients with higher functional demands and more difficult anatomical problems, with a consequent increase in the mechanical demands on implant fixation and prosthetic-bearing surfaces.

THA has been used for more than three decades. During this time, operative techniques and implant technology have matured. Many principles that have contributed to the success of the procedure are now widely accepted. At the same time, implants and surgical techniques continue to evolve. Today, surgeons are confronted with many choices of implant design, fixation type, and bearing surface. This chapter reviews the indications, results, and techniques of primary THA. Where possible, the focus is on broadly applicable principles. Unresolved issues and unsolved problems are also addressed.

PRINCIPLES OF TREATMENT

Treatment of the damaged hip joint is determined by the diagnosis, symptom severity, the degree of hip joint damage, and the patient’s functional demands. Nonoperative management is appropriate for patients with milder hip symptoms and less damage to the hip joint, and for those who by virtue of age, activity level, or medical problems are not candidates for operative treatment. The mainstays of nonoperative treatment include nonsteroidal anti-inflammatory medications, activity modification, use of a cane, and, when appropriate, weight loss.

Some patients with hip problems are candidates for operations that preserve the hip joint (see Chapter 102). Arthroscopy has a limited role: it is particularly useful to manage symptomatic labral tears and intra-articular loose bodies. Pelvic and femoral osteotomies have a limited but important role, particularly in the treatment of younger patients with mild to moderate joint damage and anatomy that are amenable to correction with joint surface redirection. Many young patients with developmental hip dysplasia and minimal arthritis are candidates for redirection pelvic osteotomies. Some younger adults with proximal femoral abnormalities due to childhood hip problems such as Perthe’s disease or slipped capital femoral epiphysis are candidates for intertrochanteric femoral osteotomy. Selected patients with osteonecrosis of the femoral head may benefit from femoral osteotomy or other procedures designed to preserve the femoral head. Finally, arthrodesis is an option for some young patients with a single destroyed hip joint and high activity demands, but the operation is less well accepted by patients than it once was (see Chapter 106).

Many alternatives to hip arthroplasty are technically more difficult to perform or less predictable with respect to outcome than THA. With the exception of arthrodesis, alternatives to THA are most successful when advanced hip arthritis is not present. For most patients of middle age or older with severely damaged hip joints and marked hip pain, THA offers the most reliable pain relief and restoration of function.

PREOPERATIVE EVALUATION

A systematic approach to the preoperative evaluation of patients considered for THA is essential. It ensures proper patient selection and exclusion for the procedure, collection of critical physical findings, and proper radiographic evaluation. Because most candidates are older, many have significant comorbidities involving cardiac, pulmonary, renal, hepatic, neurologic, or hematologic systems. The patients should be evaluated, when appropriate, by an internist.

Take the patient’s history with three major goals in mind:

- Determine the source of symptoms.
- Determine whether the symptoms are severe enough to warrant consideration of THA.
- Determine whether the patient has contraindications to THA.

Establish the pain location and chronology. Most pain caused by intra-articular hip pathology is felt in the groin, buttock, lateral hip, “deep hip area,” thigh, knee, or a combination of several of these anatomic areas. Pain is typically increased with weight bearing and often is worse after the patient has been on his or her feet for a period of time. Exclude spinal, neurologic, vascular, and tumor problems as sources of the pain. Establish the symptom severity by learning the pain intensity and frequency, the degree to which pain limits ambulation, and the amount the pain limits use of stairs and other activities, such as putting on shoes and socks, getting in and out of vehicles, and sexual function. Ask what limitations the hip problem places on the patient’s life, and consider whether the limitations that bother the patient can realistically be improved with arthroplasty. Search for contraindications for which THA should be considered only cautiously (Table 105.1). Perform a preoperative medical evaluation.
Implants are all available. Implant materials vary, the most common being cobalt-chromium and titanium. Different surface finishes, including porous-coated surfaces, are chosen, the surgeon must decide whether to use an implant with a collar as well as whether to use an implant with a polished or a rougher surface finish. If acetabular implants are chosen, the surgeon must decide whether to augment the press-fit of the socket with further fixation such as screws. If cemented femoral components are to be used, the surgeon must decide whether to use bone cement to achieve a secure fixation of the femoral component to bone.

Many implant designs and types of fixation are available. A surgeon must choose between cemented and uncemented acetabular and femoral implants. If uncemented implants are used, the surgeon must consider the potential for early loosening due to bone resorption and the need for a secure initial fixation.

INDICATIONS

Necessary prerequisites for consideration of elective hip replacement include significant hip pain or dysfunction, or both, caused by intra-articular hip problems. This finding must be confirmed by radiographic evidence that the hip joint is damaged sufficiently to explain the symptoms. The symptom severity necessary to justify hip arthroplasty requires judgment about the potential operative risks and benefits in a given patient. The more severe a patient’s pain and the more profound the disability, the stronger the indication for hip arthroplasty. In distinction, the milder the symptoms and the fewer the limitations, the more cautiously surgery should be recommended. Most patients with pain that markedly limits ambulation, interferes with sleep, or requires narcotic pain medication are strong candidates for surgery. Patients with moderate to severe pain that occurs with moderate activity also deserve strong consideration for surgery. Although severe hip pain is the strongest indication for surgery, marked functional loss associated with less pain is a relative indication in some patients. Severe loss of function due to hip stiffness, particularly if it is associated with a marked flexion contracture, is a relative indication in a few patients. For less debilitating symptoms, the surgeon and patient must assess the degree to which the patient’s symptoms restrict activities that the patient expects to resume after THA, and then they must balance the risks and benefits of the potential benefits of the surgery.

By far the most common diagnosis leading to hip arthroplasty is osteoarthritis. Other diagnoses include inflammatory arthritis, osteonecrosis of the femoral head, developmental dysplasia of the hip, other developmental or congenital hip abnormalities, traumatic conditions leading to secondary degenerative arthritis of the hip, some proximal femoral fracture nonunions, occasional acute displaced proximal femur fractures that are not ideal for internal fixation or hemiarthroplasty, and some tumors around the hip.

Active infection is a contraindication to total hip replacement. In most circumstances anatomically distant bacterial infection should be treated before THA. Hip area pain in the absence of demonstrable hip pathology is a contraindication to surgery. Age, medical illness, or orthopaedic comorbidities that make it unlikely that the patient would obtain substantial functional benefit from THA are relative contraindications to surgery. Cognitive, behavioral, and substance abuse problems that may preclude compliance with critical portions of the postoperative regimen, such as hip dislocation precautions, are also relative contraindications.

Patient populations who have increased short-term and long-term risk for complications should be considered more cautiously. The threshold for surgery should be higher in patients with medical comorbidities that put them at markedly elevated operative risk (34). Young and very active patients who are at higher risk for mechanical arthroplasty failure and subsequent multiple revision procedures should consider arthroplasty cautiously. Finally, unrealistic expectations should prompt a review of the goals of the procedure with the patient and re-evaluation of the indications for elective surgery.

IMPLANT CHOICE

Many implant designs and types of fixation are available. A surgeon must choose between cemented and uncemented acetabular and femoral implants. If uncemented acetabular implants are chosen, the surgeon must decide whether to augment the press-fit of the socket with further fixation such as screws. If cemented femoral implants are chosen, the surgeon must decide whether to use an implant with a collar as well as whether to use an implant with a polished or a rougher surface finish. If an uncemented femoral implant is chosen, wedge-shaped metaphyseal filling proximally porous-coated implants, tapered implants, and extensively porous-coated implants are all available. Implant materials vary, the most common being cobalt-chromium and titanium. Different surface finishes, including porous-coated surfaces,
Surgical prostheses need to be stable initially as well as in the long term. The most popular materials for biologic fixation have been cobalt-chromium and titanium. Biologically active osteoconductive ceramics have gained popularity, although they have not enjoyed reliable long-term fixation in patients with THA (32,61). Grit-blasted titanium or a ceramic such as hydroxyapatite (32,61) smooth press-fit implants that lack coatings or texturing to provide for bone ongrowth or ingrowth have not enjoyed reliable long-term fixation in patients with THA (39,76). For porous ingrowth to occur reliably, the optimal pore size appears to be 100 to 400 µm (20). The most popular materials for biologic fixation have been cobalt-chromium and titanium. Biologically active osteoconductive ceramics have gained popularity, although it is unproven whether they have advantages over porous metal surfaces. Regardless of the surface material, a key prerequisite for bony fixation of uncemented implants is stable initial fixation of the implant against bone. Micromotion of less than 50 µm favors bone ingrowth, whereas larger amounts of micromotion tend to allow only fibrous fixation (20). For stable long-term biologic fixation to occur, the implantation must be securely fit against bone of sufficient strength to resist forces that could lead to micromotion before bone ingrowth occurs.

For the acetabulum, I prefer uncemented porous-coated hemispherical sockets fixed with screws for most primary THAs (Fig. 105.2, Fig. 105.3 and Fig. 105.4). The indications for an uncemented socket are especially strong in young patients, for whom cemented sockets have a higher loosening rate. I reserve cemented sockets for patients with previous therapeutic pelvic radiation and for elderly patients with very poor bone quality. Good cases can be made for both cemented and uncemented femoral stems. Regardless of the fixation method, femoral results depend on technique, so choose a method or methods that you can perform well. I tend to use smooth press-fit implants that lack coatings or texturing to provide for bone ongrowth or ingrowth for young active patients with good bone quality and cemented fixation for older patients or those with poor bone quality. Femoral canal morphology influences decisions about femoral fixation (Fig. 105.5). Patients with a very small canal diameter and thick cortices (Dorr type A bone) (38) are good candidates for uncemented implants. Patients with a typical canal geometry (Dorr type B bone) are good candidates for either a cemented or uncemented implant. Patients with a very large canal diameter and thin cortices (Dorr type C bone) are often good candidates for cemented fixation. Patients with large diameter femoral canals appear to be at greater risk for thigh pain and stress shielding if uncemented implants are used. I tend to use uncemented, fully porous-coated femoral implants for patients with Dorr type A bone (Fig. 105.2), uncemented proximally coated metaphyseal filling implants for young patients with Dorr type B bone (Fig. 105.3), and cemented femoral implants for older patients with Dorr type B bone and for patients with Dorr type C bone (Fig. 105.4).

Figure 105.3. AP radiograph of an uncemented total hip arthroplasty using an extensively porous-coated femoral component.

Figure 105.3. AP radiograph of an uncemented total hip arthroplasty using a proximally hydroxyapatite-coated uncemented stem.

Figure 105.4. AP radiograph of a hybrid total hip arthroplasty using an uncemented socket and a cemented stem.
may further enhance durability of cemented implant fixation, but this remains unproven. Innovations, such as pulsatile lavage of the femoral canal, cement pressurization, cement porosity reduction, and centralization of the implant in the cement mantle, prosthesis design (72,73). Several cemented femoral component designs have demonstrated excellent survivorship at 20 and more years after THA (56). Cemented acetabular components provide excellent early results, but loosening increases with time and is much more common after the first decade compared with other components. Loosenings (80, 116, 119) is more common in younger patients (4,21). Acetabular loosening often causes fewer symptoms in the elderly. Loosening of cemented sockets correlates with the quality of the bone-cement interface achieved at surgery: better interfaces correspond to better implant survivorship. Cemented acetabular loosening is due in part to linear osteolysis along the bone-cement interface caused by particulate debris from the joint implant surface (114). Factors such as younger age, and higher activity and large femoral head size, which increase polyethylene wear, correlate with higher acetabular component loosening rates.

UNCEMENTED ACETABULAR COMPONENTS

Uncemented porous-coated sockets were developed to increase durability over cemented sockets. Midterm results demonstrate that porous-coated uncemented sockets can become osteointegrated and perform well clinically (25,59,72,76,84,102,112,132) (Table 105.2). Uncemented porous-coated sockets now have been implanted for more than a decade, so relevant comparison to cemented sockets is becoming possible. Results demonstrate that some uncemented sockets can perform at least as well as cemented sockets 10 years after surgery, even in demanding patient populations (6). However, some first-generation uncemented sockets experienced a high failure rate related to a 32-mm head size, thin polyethylene, poor polyethylene-socket congruity, and poor liner–shell locking mechanisms (6,136). Many of these problems have been eliminated or reduced with newer designs.

Table 105.2. Uncemented Sockets

Most porous-coated uncemented sockets have demonstrated a low loosening rate, and implant fixation to bone appears to be more favorable for uncemented sockets than for cemented sockets at a similar time interval. Exceptions to these data results have been threaded, nonporous-coated sockets and sockets with hydroxyapatite over a smooth substrate surface, both of which have had higher loosening rates. For uncemented designs with a good fixation record, the two main modes of failure have been osteolysis, and catastrophic failure of the polyethylene liner. Catastrophic failures are typically due to wearing through of very thin polyethylene, polyethylene fracture, or failure of the liner—shell locking mechanism (12). Catastrophic failures have diminished markedly with improved locking mechanisms and recognition that very thin polyethylene shells are undesirable. Osteolysis remains the single biggest problem associated with uncemented cups (Table 105.2). The three main strategies used to reduce osteolysis are

- Reduce wear debris from the bearing surface.
- Reduce wear debris from nonbearing surfaces.
- Reduce access of the wear debris to bone.

Polyethylene wear debris from the bearing surface can be minimized by

- Using smaller femoral head sizes
- Avoiding titanium femoral heads
- Avoiding oxidized polyethylene sterilized in air by gamma irradiation (see Chapter 100)

Polyethylene debris from nonbearing surface sources can be reduced by

- Improved liner-shell locking mechanisms
- Avoiding impingement between the prosthetic neck and polyethylene liner

To date, it is uncertain whether wear debris can be restricted absolutely from reaching the pelvic bone. Cups without holes are used with the rationale that eliminating holes from the cup may reduce debris access to bone. However, some cups without screw holes have demonstrated high rates of pelvic osteolysis (the particulate debris gains access to bone peripherally around the cup), so it is unclear that this strategy reduces lysis rates (111). The majority of uncemented sockets with midterm results demonstrating good fixation had screws, pegs, or spikes to augment initial socket fixation, and it is yet to be proven that uncemented cups placed without fixation augmentation will perform as well.

CEMENTED FEMORAL COMPONENTS

Several cemented femoral component designs have demonstrated excellent survivorship at 20 and more years after THA (Table 105.3). However, some early and some more modern designs have demonstrated high failure rates. Modern cementing techniques demonstrate good long-term results when coupled with successful prosthesis design (16,56,77,91,119) (Table 105.4). These techniques include use of a medullary canal plug and retrograde filling of the canal with cement. Other innovations, such as pulsatile lavage of the femoral canal, cement pressurization, cement porosity reduction, and centralization of the implant in the cement mantle, may further enhance durability of cemented implant fixation, but this remains unproven.
Durability of cemented femoral components depends critically on implant design. Implants with a broad medial border that reduces medial cement stresses perform better than implants with a sharp medial border (123). The implant needs to remain mechanically stable in the cement mantle. There appear to be several strategies that can successfully achieve this goal. The first is use of smooth tapered stems that remain stable within the cement even if the stem is not bonded to the cement (i.e., a taper within taper arrangement). The second is use of rougher stems that remain bonded to the cement by virtue of geometry and surface finish. The surface finish of cemented implants has recently attracted much attention, based on the finding that if rough surface implants debond from the cement, osteolysis ensues (121). The process is caused by the debonded rough stem abrading the surrounding cement and creating a large amount of particulate debris. This problem increases with adverse combinations of surface finish and stem geometry. At present, there is no consensus that a single ideal surface finish exists for all stems. Rather, it appears that there are certain combinations of stem geometries and surface finish that function well together and others that do not.

**UNCEMENTED FEMORAL IMPLANTS**

Many early uncemented femoral component designs had problems with loosening and thigh pain (15,53,55,88). The problem of thigh pain often resulted from loose implants but also occurred in some patients with well-fixed stems, probably secondary to micromotion between the distal tip and femoral endosteum or stress concentration at the stem tip (22,127). Uncemented femoral designs have improved, and now the best clinical results reported with uncemented implants match those of cemented implants (18,33,43,69,100,103,106,107) (Table 105.5).

To be successful, the uncemented implant must initially achieve axial and rotational stability in the femur. Implants fixed in the metaphysis, at the metaphyseal–diaphyseal junction, or in the diaphysis appear to work in some design iterations. A surface coating that provides for long-term biologic fixation is necessary. Porous coating with cobalt-chromium (43,55,100) or titanium beads, titanium fiber metal (64) or plasma spray (66,90), roughened titanium surfaces (106), and hydroxyapatite coatings (48,108) have been successful. The main goal of uncemented implants is to improve long-term durability over cemented implants. Studies of selected uncemented implants at 10 and more years are encouraging, but longer follow-up is needed before definitive comparison to cement fixation can be made.

**HYBRID HIP REPLACEMENT**

The combination of an uncemented socket and a cemented stem is commonly called hybrid hip replacement. The goal of this combination of implants is to take advantage of the clinical reliability, durability, and ease of use of uncemented sockets and cemented femurs. The method has produced excellent midterm results and is presently popular in North America (Table 105.6).
PREOPERATIVE PLANNING

Planning implant size, position, and availability before surgery reduces operative time and complications. In planning, also address leg length and hip stability. Preoperative planning requires information obtained from the patient's history, physical examination, and radiographs.

Plan surgery with templates on radiographs with a known magnification. Simulate optimum socket size, location, and position (Fig. 105.6A). Both the AP and true lateral films of the hip and pelvis help determine implant size. The goal is to optimize socket orientation and contact with native bone and to restore the normal hip center of rotation when possible. The optimal socket position is 40° to 45° of abduction on the AP radiograph and 10° to 25° of anteversion on the true lateral radiograph. Most surgeons prefer to target the lower range of anteversion when an anterolateral approach to the hip is used, and the higher range when a postero lateral approach is used. Anticipate areas where bone removal or graft reconstruction will be required. In most cases of degenerative disease, plan to remove a small amount of med ial bone to place the acetabular prosthesis in an appropriate position, that is, touching the lateral aspect of the foveal bone (radiographically, the teardrop). On the AP radiograph, note the amount of socket left uncovered laterally. On the true lateral radiograph, note the position of the socket relative to the ischium and anterior wall of the acetabulum (Fig. 105.6B). Knowing the expected relationship of the socket to the pelvic landmarks improves socket positioning during surgery. Finally, mark the socket center of rotation on preoperative radiographs (Fig. 105.6A).

Figure 105.6. A: AP hip radiograph with acetabular component template in place. The cup is oriented in approximately 40° of abduction. The cup is positioned properly, with the medial socket against the lateral aspect of the radiographic teardrop. From the templating, the surgeon can anticipate the need to deepen the socket slightly by reaming away osteophytes medially so as to position the socket properly. The planned center of hip rotation is marked with a dot. B: True lateral hip radiograph with acetabular component template in place. The cup is oriented in about 20° of anteversion. From templating, the surgeon should expect that the rim of the acetabular component will be inset slightly with respect to the anatomic acetabular rim.

Use femoral component templates to determine femoral implant geometry, size, position, and neck length. Patient factors and surgeon preference guide the choice of implant design and fixation. Preoperative templating also plays a role in choosing the implant design: certain femoral canal geometries are more favorable for cemented implants, whereas others are better for uncemented implants. Very poor bone quality, very large canal diameters, and marked canal deformities are indications to consider cement fixation. In contrast, excellent bone quality with thick cortices and a small canal diameter are indications to consider uncemented implants more strongly. The Dorr classification of canal morphologies (36) is helpful in organizing this decision-making process (Fig. 105.5).

Overlay templates of the chosen femoral design on the radiograph. Properly sized cemented implants leave room for a cement mantle of appropriate size and also leave adequate cancellous bone after broaching for cement interdigitation (Fig. 105.6A). Most templates show the outline of the broach corresponding to each implant size, making it possible to visualize the amount of intramedullary cancellous bone left after broaching. Choose uncemented implants to fit and fill the part of the femur in which that particular implant obtains fixation (Fig. 105.8A and Fig. 105.8B). Different implants variously obtain fixation in the metaphysis, at the diaphysis, or in a combination of metaphyseal-diaphyseal junction, and in the diaphysis. Identify the femoral neck osteotomy level necessary to provide restoration of leg length. When possible, choose a neck resection level that avoids long modular femoral necks with a "skirt" because such devices allow less motion before impingement between the prosthetic femoral neck and the acetabular polyethylene (128). Choose a prosthesis that restores femoral offset (Fig. 105.9). If an implant of proper size cannot restore offset, then consider a stem design with a higher femoral offset. Many implant companies now provide implants with high and standard offset options. High offset stems commonly provide better restoration of femoral offset without excessive leg lengthening in patients with varus femoral necks. Restoring femoral offset allows the abductors to function more efficiently (thereby reducing limp) and also helps restore soft-tissue tension (thus improving hip stability).

Figure 105.7. AP radiograph of the hip with template for a cemented femoral component. The template shows the broach envelope (a dotted outline, which simulates the minimum cement mantle), as well as the femoral component (solid line). Note that the implant size chosen should leave some cancellous bone behind after broaching to provide for cement interdigitation.

Figure 105.8. A: AP hip radiograph template for a proximally coated uncemented stem. Note that with this type of implant, priority is given to obtaining a good fit in the metaphyseal and metaphyseal-diaphyseal junction areas. B: AP hip radiograph with a template for an extensively porous-coated uncemented stem. Note that with this type of implant, priority is given to getting a good fit in the diaphysis.
Templating predicts the effects of implant location, design, and size on leg length and femoral offset. Once the center of hip rotation is determined by acetabular templating, the difference between the femoral head center and the acetabular center on templating predicts change in leg length. If the templated center of the femoral head is superior to the templated acetabular center, the leg will be lengthened by that amount, and if the templated center of the femoral head is inferior to the templated acetabular center, the leg will be shortened by that amount (Fig. 105.10). The position of the templated femoral head center to the templated acetabular center from medial to lateral corresponds roughly to femoral offset restoration (Fig. 105.10).

Figure 105.10. AP hip radiograph with acetabular and femoral templates demonstrating the position of possible modular femoral neck lengths relative to the planned center of hip rotation (The inferior dot marks the center of the acetabular component.) Femoral head centers inferior to the planned center of the acetabulum shorten the leg relative to the preoperative condition, whereas femoral head centers superior to the planned center of the acetabulum lengthen the leg relative to the preoperative condition. Likewise, femoral head centers lateral to the planned center of the acetabulum reduce femoral offset relative to the preoperative status, whereas femoral head centers medial to the planned center of the acetabulum increase femoral offset relative to the preoperative status. The term femoral offset in this context is used as an approximation because true femoral offset refers only to the femur and is not dependent on the center of the acetabulum. The patient’s symptomatic leg was 4 mm shorter than the opposite side preoperatively so the femoral component position is chosen to provide proper leg length reconstitution with a +5 mm modular neck length. To obtain proper femoral offset, and thus to help restore soft tissue tension and abductor lever arm, a high-offset femoral component is chosen.

Mark the chosen femoral neck osteotomy, the femoral head center of rotation for each available neck length, and (for collared implants) the relationship of the collar to the medial femoral neck.

**Surgical Technique**

- Position the patient in either the lateral or supine position. Advantages of the lateral position are that soft tissues fall away from the wound, the assistant has better visualization of the procedure, and both anterior or posterior approaches to the hip joint are possible. The main disadvantage is the possibility the pelvis may tilt during surgery, making acetabular orientation difficult (Fig. 105.11). This problem can be reduced by making sure the pelvis is held securely with a positioning device. Advantages of the supine position include more certain pelvis position and easier direct comparison of leg lengths intraoperatively. The supine position restricts the surgical approach, however: Only anterior hip dislocation is possible. Pad the opposite leg and arms for all positions to prevent skin and nerve problems.

Figure 105.11. The pelvis can roll when the patient is in the lateral decubitus position. This is particularly common with the posterior approach, in which femoral retraction tends to cause the pelvis to roll forward. When the pelvis is rolled forward, the acetabular component anteversion falsely appears to be greater than it is in reality. Failure to recognize this problem can lead to insufficient acetabular component anteversion and posterior hip instability.

- Give the first dose of antibiotics within an hour before the skin incision is made. Perioperative antibiotics are one of the most effective means of preventing infection. For most patients, use a broad-spectrum, first-generation cephalosporin. For patients with an allergy that precludes using cephalosporin, use another intravenous antibiotic with a gram-positive bacterial spectrum. Continue the prophylactic antibiotic for 24 to 48 hours after surgery.

- A variety of exposures are available for THA. Most can be categorized as variations of anterolateral, posterolateral, or transtrochanteric approaches (see Chapter 3). The main advantage of anterolateral approaches is the low dislocation rate; the main disadvantage is the potential for abductor muscle dysfunction to cause a limp after surgery (owing to poor abductor healing or abductor denervation). The posterior approach spares the abductors, and postoperative limp is uncommon; the main disadvantage of the posterior approach is a higher reported rate of hip dislocation. Both anterior and posterior approaches have strong followings, and the choice of approach is best left to the surgeon. Consider patients at very high risk for posterior dislocation good candidates for an anterolateral approach. I use both approaches selectively; I use the anterior approach for patients at higher dislocation risk and the posterior approach for patients judged at lower dislocation risk. The transtrochanteric approach provides excellent hip exposure but is associated with more blood loss and a risk of trochanteric nonunion or migration. Reserve the transtrochanteric approach for unusual cases with special anatomic considerations, such as marked proximal femoral deformities or revision surgery.

- In the anterolateral exposure, make an incision directly over the proximal lateral femur centered on the greater trochanter. Curve the incision slightly posteriorly at the proximal third of the incision. Divide the iliotibial band in the direction of its fibers, and split the interval between the tensor fascia lata and gluteus maximus. Reflect the anterior third of the glutus medius and the glutaeus minimus in continuity with the anterior third of the vastus lateralis from the proximal femur. To avoid injury to the superior gluteal nerve, take care not to extend the incision in the glutaeus medius more than 5 cm from the trochanter (Fig. 105.10). Note that the glutaeus minimus fibers run at 90° to those of the glutaeus medius. The anterior, superior, and inferior hip capsule can be excised to gain exposure or can be preserved if exposure is satisfactory. Place a retractor in the ilium to hold the soft tissues out of the field. See Chapter 3 for more details.

- In the posterior exposure, make a Kocher-style incision centered over the greater trochanter. The distal limb is parallel to the femur and the proximal limb is
parallel to the gluteus maximus muscle fibers. Split the iliotibial band in the direction of its fibers and then divide the fascia of the gluteus maximus in the direction of its fibers in line with the skin incision. Split the gluteus maximus using a muscle-splitting technique. Identify the sciatic nerve by visualization or palpation. Split the iliotibial band in the direction of its fibers and then divide the fascia of the gluteus maximus in the direction of its fibers in line with the skin incision. Split the gluteus maximus using a muscle-splitting technique. Identify the sciatic nerve by visualization or palpation.

****

If posterior stability is unsatisfactory, determine the cause. Is there insufficient acetabular or femoral anteversion? Is there soft-tissue or bony impingement and center of rotation of the hip.

- Some surgeons take an AP radiograph of the pelvis with the trial implants in place to check position and radiographically verify restoration of leg length prematurely and leads to implant undersizing.

- Be sure to prepare the femoral canal in the proper orientation. Avoid varus malalignment, which gives the tactile impression that canal preparation is complete preparation or poor instruments provides unsatisfactory initial implant stability. Too small a cavity can lead to femoral fracture when the implant is inserted. Be

- The methods of implanting an

- For a cemented acetabulum, remove remaining soft tissues from the fovea. Good visualization of the floor of the fovea provides a guide to determine the depth of reaming. Remove large osteophytes around the inferior, posterior, and anterior rim of the acetabulum with an osteotome or rongeur. Superior osteophytes can usually be left in place. Preserve the transverse ligament because this will help restrict inferior cement extrusion. Remove remaining acetabular cartilage with a large curette or osteotome. Proper acetabular preparation is not possible without satisfactory acetabular exposure. Proper exposure increases the likelihood of acetabular implant malposition and hip instability. Place retractors carefully around the acetabulum to avoid injury to neurovascular structures. If a posterior retractor is placed, make sure it is against bone and that the sciatic nerve is protected.

- If none are used, it is imperative to make certain that the press-fit of the socket is very rigid. Avoid placing screws anterior to a line drawn from the anterosuperior spine and the transacetabular fixation of screws in total hip arthroplasty.

- The methods of implanting an unementeed acetabulum, unementeed socket, unementeed implant, and the transacetalum fixation of screws in total hip arthroplasty. (Bone Joint Surg 1990;72A:501, with permission.) In the anterior two quadrants, the risk of neurovascular injury if a drill or screw extends beyond the far cortex is high. In the posterior two quadrants, there is less risk but the sciatic nerve still needs to be respected.

- Dislocate the hip and identify the lesser trochanter. Use cutting guides or implant trials to mark the level and orientation of the femoral neck osteotomy. Base the trochanter medially and retract until it reaches a bony stop. Open the femoral canal with a T-handled broach or awl. The proper starting point is usually the piriformis fossa, which is located directly over the medullary canal. Avoid an excessively medial starting point, which can lead to varus alignment. There is a tendency with a high neck cut to introduce instruments into the canal in flexion due to femoral neck anteverision; avoid this problem by starting more posteriorly in the femoral neck.

- Figure 105.12. The “safe zone” for acetabular screw placement (Redrawn from Wawlewski RC, Cooperstein LA, Kruger MP, Rubash HE. Acetabular anatomy and the transacetalum fixation of screws in total hip arthroplasty. J Bone Joint Surg 1990;72A:501, with permission.) Figure 105.12. The “safe zone” for acetabular screw placement (Redrawn from Wawlewski RC, Cooperstein LA, Kruger MP, Rubash HE. Acetabular anatomy and the transacetalum fixation of screws in total hip arthroplasty. J Bone Joint Surg 1990;72A:501, with permission.) (a) In the anterior two quadrants, the risk of neurovascular injury if a drill or screw extends beyond the far cortex is high. In the posterior two quadrants, there is less risk but the sciatic nerve still needs to be respected.

- Before preparing the femur, remove soft tissues just medial to the greater trochanter to allow access to the piriformis fossa. If these soft tissues are not removed, instruments and the implant tend to be pushed into a varus position. Open the femoral canal with a T-handled broach or awl. The proper starting point is usually the piriformis fossa, which is located directly over the medullary canal. Avoid an excessively medial starting point, which can lead to varus alignment. There is a tendency with a high neck cut to introduce instruments into the canal in flexion due to femoral neck anteverision; avoid this problem by starting more posteriorly in the femoral neck.

- For a cemented femur, prepare the femur with broaches alone or reamers and broaches. Use reamers only to start the canal preparation, and avoid excessive reaming. Good remaining cancellous bone is required for cement interdigitation. As the canal is prepared, avoid varus or valgus orientation of the instruments. Broach the canal in proper anteverision, usually about 15°. After the final broach is in place, use a calcar planer to smooth the femoral neck. Perform a trial reduction and check anterior and posterior hip stability, leg length, and soft-tissue tension. Remove any loose, unsupported, cancellous bone from the canal with a uleterine curet or canal brush. Place a cement restrictor at an appropriate depth in the femoral canal to provide about 2 cm of cement distal to the tip of the stem. Impacting the cement (povely) is not necessary in a cemented femur because cement can be conveniently inserted pressurized, or pressurized with a cement gun or special acetabular pressurizers. A sponge inside a rubber glove works well for this purpose but tends to exterad cement around the rim of the acetabulum. If you prefer to pressurize the cement into the acetabulum, each part of the acetabular surface with my thumb.

- Insert the socket into the acetabulum with a positioning device and hold it securely in proper position until all cement is hardened. The ideal socket position is 40° to 45° of abduction and 10° to 25° degrees of anteverision. Many surgeons err on the lower side of anteverision for the anterior approach and the higher side for a posterior approach. Remove any cement around the periphery of the socket before it hardens. Ensure that no large pieces of cement remain after all the cement has hard.

- For an unementeed socket, remove soft tissue from the fovea and large inferior, anterior and posterior osteophytes. Excise the transverse ligament. Use a small reamer to reach the lateral aspect of the fovea and then ream with sequentially larger reamers to expose a bleeding hemisphere of subchondral bone. Keep the reamer centered in the acetabulum by judging the reamer position relative to the peripheral rim of the socket. There is a tendency for power reamers to migrate finger pressurized, or pressurized with a cement gun or special acetabular pressurizers. A sponge inside a rubber glove works well for this purpose but tends to exterad cement around the rim of the acetabulum. If you prefer to pressurize the cement into the acetabulum, each part of the acetabular surface with my thumb.

- Preserve the transverse ligament because this will help restrict inferior cement extrusion. Remove remaining acetabular cartilage with a large curette or osteotome. Proper acetabular preparation is not possible without satisfactory acetabular exposure. Proper exposure increases the likelihood of acetabular implant malposition and hip instability. Place retractors carefully around the acetabulum to avoid injury to neurovascular structures. If a posterior retractor is placed, make sure it is against bone and that the sciatic nerve is protected.

- The steps of implanting an unementeed femur component are specific to the implant design. Techniques associated with each implant differ because of different instrumentation and because different parts of the femur are used to gain fixation. Nevertheless, several important points are common to insertion of most unementeed femoral components. Obtain rigid fixation of the implant against strong, hard bone. Recent understanding of unementeed implant fixation has emphasized the importance of gaining rigid fixation of the implant and of the proper and precise positioning of the implant to avoid complications associated with inferior implant fixation. Two key principles to obtain initial rigid fixation and subsequent biologic fixation. Prepare the femur with reamers or broaches until contact is made in the appropriate area of the canal with the femoral neck. Use a calcar planer to smooth the femoral neck. Perform a trial reduction and check anterior and posterior hip stability, leg length, and soft-tissue tension. Remove any loose, unsupported, cancellous bone from the canal with a uleterine curet or canal brush. Place a cement restrictor at an appropriate depth in the femoral canal to provide about 2 cm of cement distal to the tip of the stem. Impacting the cement (povely) is not necessary in a cemented femur because cement can be conveniently inserted pressurized, or pressurized with a cement gun or special acetabular pressurizers. A sponge inside a rubber glove works well for this purpose but tends to exterad cement around the rim of the acetabulum. If you prefer to pressurize the cement into the acetabulum, each part of the acetabular surface with my thumb.

- Before preparing the femur, remove soft tissues just medial to the greater trochanter to allow access to the piriformis fossa. If these soft tissues are not removed, instruments and the implant tend to be pushed into a varus position. Open the femoral canal with a T-handled broach or awl. The proper starting point is usually the piriformis fossa, which is located directly over the medullary canal. Avoid an excessively medial starting point, which can lead to varus alignment. There is a tendency with a high neck cut to introduce instruments into the canal in flexion due to femoral neck anteverision; avoid this problem by starting more posteriorly in the femoral neck.

- For a cemented femur, prepare the femur with broaches alone or reamers and broaches. Use reamers only to start the canal preparation, and avoid excessive reaming. Good remaining cancellous bone is required for cement interdigitation. As the canal is prepared, avoid varus or valgus orientation of the instruments. Broach the canal in proper anteverision, usually about 15°. After the final broach is in place, use a calcar planer to smooth the femoral neck. Perform a trial reduction and check anterior and posterior hip stability, leg length, and soft-tissue tension. Remove any loose, unsupported, cancellous bone from the canal with a uleterine curet or canal brush. Place a cement restrictor at an appropriate depth in the femoral canal to provide about 2 cm of cement distal to the tip of the stem. Impacting the cement (povely) is not necessary in a cemented femur because cement can be conveniently inserted pressurized, or pressurized with a cement gun or special acetabular pressurizers. A sponge inside a rubber glove works well for this purpose but tends to exterad cement around the rim of the acetabulum. If you prefer to pressurize the cement into the acetabulum, each part of the acetabular surface with my thumb.

- Make the capsular flap the
between the femur and pelvis? Is soft-tissue tension insufficient? If implants are not ideally positioned, reposition the appropriate component. Small adjustments in acetalubar component position can be made using elevated lip liners if modular uncemented sockets are used. Elevated lip liners increase hip stability in one direction at the expense of hip stability or range of motion in the opposite direction (69). If impingement is present, try to remove the source. Commonly, some remaining an-tero-superior hip capsule, part of the head of the rectus femoris tendon, or the anterior aspect of the greater trochanter are sources of impingement with the hip flexed and internally rotated. Redundant posterior inferior capsule can cause impingement between the femur and ischium with the hip in extension and external rotation.

Test the soft-tissue tension. If it is lax, a longer neck length may be needed. Soft-tissue tension is often less in small women or in patients with profound muscle relaxation. Relying solely on soft-tissue tension to choose neck length can lead to inadvertent overlengthening of the limb. Sometimes soft-tissue tension can be improved without increasing leg length by increasing the femoral offset. Increase offset by using a high-offset femoral implant or by placing the same implant deeper in the femur and using a longer neck length. Make sure the prosthetic femoral neck does not impinge on the acetabular polyethylene. If it does, consider repositioning the acetabular component. Prosthetic impingement can lead to hip instability or polyethylene wear.

Judge whether leg length has been restored according to the preoperative plan (133). If a pin was placed in the pelvis intraoperatively, compare the distance from the pin to the fixed point marked on the femur (compared with the same measurement performed before femoral neck osteotomy). Use bony landmarks, including the position of the femoral head relative to the greater trochanter and position of the femoral collar relative to the lesser trochanter, to help estimate the leg length based on preoperative templating. Compare the position of the patient’s knees and heels to one another compared with their relative position before femoral neck osteotomy. The legs must be in the same relative positions for this to be a valuable test. An intraoperative radiograph of the pelvis and both hips can provide information on leg lengths. None of these tests of leg length are perfect, but all provide some information concerning relative leg length in surgery.

- Irrigate the wound and make sure fragments of cement or bone are removed. Obtain good hemostasis.
- To close the anterolateral approach, reattach the gluteus minimus, medius, and vastus lateralis muscles to their beds using strong absorbable or nonabsorbable sutures passed through bone. Metliculous repair is necessary because failure of the abductors to heal can cause limp and hip instability.
- To close the posterolateral approach, reapproximate the capsule and short external rotators to the posterior aspect of the abductors and the greater trochanter. If possible, ensure that these soft-tissue repairs are not too tight. If the leg length cannot be equalized to the other side or if the femoral offset is marked, avoid over-tensioning the piriformis tendon, which passes over the sciatic nerve. A good repair of the capsule and short external rotators may reduce the risk of early hip dislocation after a posterior approach (Fig. 105.13) (101). Close the remaining tissues in layers. I prefer, as do others, to use closed suction drains; some surgeons do not. Treat the patient with intravenous antibiotics for 24 or 48 hours after surgery. There is no evidence that longer treatment has any advantage.

**Figure 105.13.** Diagram showing formal soft tissue repair of the posterior capsule and short external rotators after posterior approach to the hip.

---

**POSTOPERATIVE CARE**

Patients treated with THA are at risk for venous thromboembolic disease. Most North American surgeons use some prophylaxis for this potentially life-threatening complication (75,92). Available measures include warfarin (28,74), low-molecular-weight heparin (28,98,105), unfractionated heparin, aspirin, dextran, and mechanical foot or leg compression devices (128,131). Warfarin or low-molecular weight heparin is widely used in North America (18,29,45). If warfarin is used, the target international normalized ratio (INR) is usually 1.5 to 2.2. The ideal treatment duration is not defined and varies from 1 to 6 weeks. I prefer 2 to 3 weeks of treatment under routine conditions, and 6 weeks for patients with a history of venous thromboembolic disease or strong risk factors for thromboembolic disease, such as obesity, malignancy, or a history of previous deep venous thrombosis. Warfarin or low-molecular weight heparin should be used according to the manufacturer’s recommendations concerning timing of administering the first dose. If the drug is given too early, bleeding complications are more common. See Chapter 5 for additional details.

Mobilize the patient, if possible, the day after surgery. Individualize the weight-bearing regimen according to the type of implant fixation. Most surgeons allow cemented and hybrid hip replacements to begin partial weight bearing immediately. The duration of arm support varies, but by 6 weeks most patients can begin to make the transition to a cane. The postoperative regimen after uncemented THA is more controversial. Some allow immediate weight bearing, whereas others restrict weight bearing for 8 to 12 weeks. Those who advocate immediate weight bearing believe that it stimulates bone healing; those who advocate protected weight bearing believe it provides time for tissue ingrowth before maximally loading the femoral implant.

Discuss hip dislocation precautions with the patient. Show the patient hip positions that can lead to dislocation and demonstrate how to avoid them. Show the patient how to rise from a chair and get in and out of bed safely.

**TREATMENT RESULTS**

Total hip arthroplasties of many different designs can provide excellent pain relief and a very good level of function for moderate activities. Studies have demonstrated a high level of patient satisfaction after THA (58,71,83). For patients with well-fixed implants, most decrements in function in large series are due to increasing disability with age (62). When implants fail for mechanical reasons, many patients develop pain and poorer function (65) and require revision surgery. Thus function free of mechanical failure is considered a key parameter of arthroplasty success. Mechanical failure rates depend on fixation method, implant design, and demographic factors (Table 105.2, Table 105.3, Table 105.4, Table 105.5 and Table 105.6).

**PITFALLS AND COMPLICATIONS**

**INFECTION**

Infection after THA is uncommon; it presently occurs in about 0.5% of primary hip arthroplasties (47). The single most important factor in preventing early infection is use of perioperative antibiotics (65). Careful surgical technique, low traffic in the operating theater, body exhaust suits, and laminar flow may also reduce the risk of early infection (47). Late prosthetic infection can occur from bacteriaemia. Recent guidelines developed by the American Academy of Orthopaedic Surgeons suggest that for 2 years after hip arthroplasty, prophylactic antibiotics be given to all patients for dental and other procedures that might cause bacteremia. The recommendations for prophylaxis for dental or oral procedures for patients with no pericillium allergy are for amoxicillin 2.0 g orally 1 hour before a dental procedure and for amoxicillin 2.0 g orally before a gastrointestinal or genitourinary procedure. Alternative antibiotics for dental or oral procedures are cephalexin 2.0 g orally or clindamycin 600 mg orally 1 hour before the procedure, and for genitourinary or gastrointestinal procedures, ciprofloxacin 750 mg orally 1 hour before the procedure. For immunocompromised patients, other patients at high risk for infection, and for certain high-risk procedures, lifetime prophylaxis for dental or other invasive procedures is recommended.

Infection of a hip prosthesis is a serious complication that requires prompt treatment. If the problem is identified early, infection may be treated successfully with prompt surgical treatment and proper antibiotics. More typically, however, treatment of the infection requires implant removal. In North America, most surgeons prefer a two-stage approach to treat most patients with infected implants, but under specific circumstances, one-stage reimplantation may also be considered (47) (see Chapter 133).

**DISLOCATION**

The frequency of hip dislocation varies dramatically in different series, from 0.3% to greater than 10%. In most large series, the rate is around 2% to 3%. The rate of highest risk for dislocation is the first 3 months after surgery, but there is always some risk of dislocation, and first-time dislocations can occur even years after a THA. Certain patient populations are at risk for dislocation: females have a higher risk than males (130), and patients treated with a posterolateral approach are at higher risk than those treated with an anterolateral approach (130). The risk of dislocation can be minimized by preoperative, intraoperative, and postoperative measures. Preoperative measures include appropriate patient selection, careful templating, and consideration of an anterolateral approach for patients at high risk for...
Most dislocations are treated by closed reduction. Before reduction, make a true lateral radiograph of the hip (in addition to a standard AP radiograph) to confirm the direction of dislocation. Most first and second dislocations are treated nonoperatively with patient education and with an abduction bracing program; however, re-current dislocations usually require reoperation. When reoperation is considered, determine the etiology of dislocation. Component malposition, impingement, or inadequate soft-tissue tension are the most frequent categories. Once the specific problem has been identified, institute specific measures to address that problem. Conversion to constrained sockets (49) or bipolar implants are also effective means of managing dislocation, but these measures are usually reserved for problem patients who have failed previous operative attempts to gain hip stability or who have markedly deficient abductor mechanisms. See Chapter 106 for additional details.

NERVE INJURY

Injury to the sciatic, femoral, obturator, or superior gluteal nerves can occur during THA (104). Injury to the sciatic nerve, particularly the peroneal division of that nerve, is probably the most common injury. Women, patients with peripheral neuropathy, and patients with lumbar disc disease are at increased risk (115). Marked lengthening of the leg is associated with a higher risk of palsy, but a specific cut-off for the maximum amount of shortening that can be performed safely has not been identified. The etiology of nerve injury is unknown in many cases (108,115). Reoperation is indicated if hematomas is thought to contribute to the palsy. Many patients recover significant function over time; some early recovery of function and initial incomplete dysfunction correlate with better likelihood of eventual complete recovery. Treatment during the recovery period involves bracing with an ankle-foot orthosis, skin care, and pain management for dysesthetic pain.

VASCULAR INJURY

Injury of major vascular structures during THA is rare. The main vessels at risk are the femoral artery anteriorly, the obturator artery inferiorly, and the iliac vessels medial to the pelvis. Avoid socket screw placement anterior to a line between the anterior superior iliac spine and ischium to minimize the risk of iliac vessel injury (63,129).

HETEROPTIC OSSIFICATION

Minimal heterotopic bone formation after THA is frequent, but severe heterotopic bone that markedly limits hip range of motion is uncommon (Fig. 105.14). Patients at risk include those who have previously formed heterotopic bone after another hip operation, patients with diffuse idiopathic skeletal hyperostosis (DISH), patients with pelvic Paget's disease, and probably patients with active ankylosing spondylitis. Men are at higher risk than women. Heterotopic bone formation can cause pain while the process is active early after THA. The process may not be visible on radiographs for 6 to 8 weeks after the operation. Mature ectopic bone typically does not cause pain.

Figure 105.14. AP hip radiograph demonstrating heterotopic bone formation. The patient had marked limitation of motion.

Effective measures to prevent heterotrophic ossification are available but must be instituted early (preferably within 3 days postoperatively) to be effective (30,68). Nonsteroidal anti-inflammatory medicines given for a duration of 2 to 6 weeks after surgery reduce the risk of heterotrophic ossification (69). Low-dose radiation therapy (600 to 800 cGy) given in a single or divided dose to the field at risk either immediately before or within the first 3 days after surgery has also proven effective (54,95). Radiation shielding is useful to avoid irradiation of bone around uncemented implants and to avoid irradiation of trochanteric osteotomies or abductor muscles. Patients that develop heterotrophic bone with marked limitation of range of motion can be treated effectively with surgical excision of heterotopic bone. Most surgeons prefer to wait 1 year after THA to excise the bone. If heterotopic bone is excised, treat the patient with an effective method to prevent recurrence. See Chapter 124 for additional information.

INTRAOPERATIVE FRACTURE

Intraoperative fractures of both the acetabulum and the femur can occur during hip arthroplasty and are much more common during insertion of press-fit uncemented implants (8). Acetabular fractures are less common than femur fractures. Minimize acetabular fractures by avoiding an excessive discrepancy between the diameter of the final reamer and the outside diameter of the socket and by testing with trial components before impaction of the final implant (64). Most intraoperative acetabular fractures are minor cracks of the posterior wall of the acetabulum that do not compromise acetabular implant stability or pelvic integrity. More extensive fractures occur rarely and may require stabilization of the pelvis with plates. When an acetabular fracture is recognized intraoperatively, consider augmenting fixation of the socket with screws (118). Intraoperative femur fractures can be minimized by careful attention to preoperative planning, proper implant sizing, and surgical technique. Fractures occur most often during broaching and during implant insertion. Patients with unusual femoral geometries and poorer bone quality are at higher risk. A prophylactic cerclage wire around the proximal femur may prevent fracture during canal preparation or implant seating in patients at high risk for fracture. The pattern of intraoperative fractures varies according to implant design. Metaphyseal fractures of the femoral neck are most common with proximally coated metaphyseal filling implants, whereas extensively coated diaphyseal filling implants more often cause diaphyseal cracks (117). Most small cracks that do not compromise implant fixation or femoral integrity can be treated with cerclage fixation without changing femoral component design. If the fracture compromises implant fixation, a different implant is required; the type chosen depends on fracture location and severity.

LATE COMPLICATIONS OF TOTAL HIP ARTHROPLASTY

Implant Loosening

Improvements in cemented and uncemented techniques have reduced the problem of implant loosening, but it still is a major long-term problem. Choosing well-designed implants and using meticulous surgical techniques are the most effective means to reduce loosening. For cemented components, make sure implant alignment is optimum, obtain good cement interdigitation with bone, and obtain an adequately thick, circumferential cement mantle. For uncemented implants, size the implant optimally and obtain secure fixation to good-quality bone. Most patients with implant loosening develop pain; acetabular loosening is most commonly felt in the buttock or groin, femoral loosening most commonly in the thigh. Weight-bearing pain associated with loose implants is often triphasic: patients experience pain with initiation of weight bearing, feel better after a short distance of ambulation, then develop more pain as they walk farther. The treatment of most symptomatic loose implants for medically fit patients is revision surgery (see Chapter 105).

Polyethylene Wear and Osteolysis

As the durability of implant fixation has improved, wear of the polyethylene bearing surface and associated osteolysis have become limiting factors in the durability of many arthroplasties, particularly in young active patients (Fig. 105.15). Some wear of the polyethylene bearing surface of THA occurs in all patients. Marked polyethylene wear leads to billions of submicron-sized polyethylene debris particles in the periprosthetic space (67,110). This debris causes osteolysis (81) by a pathway, the details of which are still being worked out, that involves mediators of inflammation and a cellular response. Factors known to correlate with increased volumetric polyethylene wear (and hence more polyethylene debris) include large femoral head size (32 mm or greater), thin polyethylene (less than 6 mm), titanium femoral heads, and polyethylene oxidized by gamma irradiation in air (11,124). There is some evidence that ceramic femoral heads against polyethylene-bearing surfaces may produce less polyethylene wear. However, to produce a dramatic reduction in the problem of polyethylene wear and associated osteolysis, major efforts
are being directed toward the development of new bearing surfaces. These include ceramic-on-ceramic surfaces, metal-on-metal bearing surfaces, and a new class of highly cross-linked polyethylenes. Further clinical experience is needed to determine whether these new bearing surfaces will dramatically reduce the problem of bearing surface wear and osteolysis without causing new unanticipated problems (135).

Figure 105.15. Marked polyethylene wear (note femoral head eccentricity in the socket) and associated extensive periprosthetic acetabular and femoral osteolysis.

Osteolysis associated with particulate debris occurs in patterns based on access of the debris to the periprosthetic pelvic and femoral bone (6, 14, 80, 113, 125). When marked particulate debris-induced periprosthetic osteolysis occurs, intervention should be considered. The specific type of treatment is contingent on the status of implant fixation, the pattern of osteolysis, and specific features of the acetabular and femoral implants (see Chapter 106) (8, 79).

Stress Shielding

Implantation of an intramedullary femoral component changes the stress distribution in the proximal femur and leads to bone remodeling (26, 59). Bone loss around femoral implants by this mechanism is called stress shielding. The amount of bone loss that occurs, regardless of implant design fixation type, correlates with the quality of bone prior to hip implantation (82). Bone that is more osteopenic preoperatively leads to a higher percent of postoperative bone loss. Larger, stiffer, un cemented implants, and particularly coated implants in which distal bone ingrowth is possible, appear to be at higher risk for marked stress shielding (43, 64). If stress shielding occurs, in most cases, only observation is recommended. To date, the primary problem caused by stress shielding has been poor bone quality if a further operation is required. As long as the stem continues to function well, stress shielding appears to remain a clinically silent problem.

Postoperative Periprosthetic Femur Fracture

Postoperative periprosthetic femur fractures are treated according to their location and the fixation status of the femoral component. An excellent classification system that helps guide treatment is available (38). Treat fractures involving the trochanter operatively if the displacement is unacceptable or if the etiology is progressive osteolysis. Fractures around the femoral stem or stem tip almost always need to be treated surgically. Nonoperative treatment is associated with a high rate of nonunions and malunions, and requires prolonged immobilization. Most fractures around well-fixed stems can be treated with open reduction and internal fixation using strut allografts and plates that allow fixation with combinations of cerclage, wires, or cables, and screws. See Chapter 20 for more details. Fractures around loose implants are treated with revision surgery, usually to longer stemmed implants in association with fracture stabilization with cerclage fixation, strut allografts, or plates (72).

Arthrodesis of the Hip

REVISION HIP ARTHROPLASTY

Hip arthroplasty is one of the most successful surgical procedures yet developed. It provides millions of people with freedom of mobility and preserves their independence. Originally intended for the elderly, low-demand user with significant arthritis, hip arthroplasty has been so successful that it is now used in increasingly younger, more active patients. In the appropriate patient, total hip arthroplasty can now be considered at any time after skeletal maturity and has largely supplanted other options, such as hip fusion, as a form of treatment acceptable to the majority of patients. With older patients living longer and arthroplasty being performed in younger patients, the need for revision arthroplasty has dramatically increased.

Revision surgery is more complicated than primary arthroplasty and has become a focus for arthroplasty surgeons (Fig. 106.1) (44). Revision arthroplasty ranges from simply exchanging the polyethylene liner of a cup to major pelvic reconstruction. It demands more of the surgeon and of the hospital. The key to successful revision surgery is preparation for multiple possibilities and clear plans as to what to do for each possible eventuality.

Figure 106.1. A: Periprosthetic fracture treated with plates and strut grafts. B: Refractures with weight bearing. C: Revised with a fully coated component acting as intramedullary fixation reinforced with strut grafts.
ETIOLOGY AND MECHANISMS OF FAILURE

Hip prostheses have a finite life span. In older patients, this factor may not present a problem, because they will not outlive their prosthesis. It is, however, a problem in younger patients. Of the many causes of failure, including aseptic loosening, component failure, infection, and femoral fracture, the most common is aseptic loosening, which accounts for more than 80% of all failures (73).

ASEPTIC LOOSENING

The principal cause of aseptic loosening is the generation of particle debris, to which the body responds with an inflammatory reaction resulting in focal or linear osteolysis (Fig. 106.2). Particles may originate from several sites, principally at the articulation of the head with the liner, with backside wear of the liner on the shell, at any modular junction or at the prosthesis cement interface (Fig. 106.3).

![Figure 106.2: A: Focal osteolysis in the supracetabular region. Cup remains stable. B: Linear osteolysis leading to an unstable cup.](image)

![Figure 106.3: Multiple interfaces acting as potential particle generators in total hip replacement. UHMWPE, ultra high molecular weight polyethylene.](image)

The main source of particles is the polyethylene liner, which is the limiting factor in implant longevity. The presence of microscopic polyethylene particles in the joint fluid initiates a macrophage response that leads to the release of lytic enzymes that can cause bone destruction and loosening of the prosthesis (64,89). The joint fluid may conduct particles to bone where they incite lysis. All periprosthetic areas accessible to joint fluid are vulnerable, and this area is defined as the “effective joint space” (88).

The effective joint space can be decreased, thus protecting portions of the arthroplasty, by prosthetic design and surgical technique. An example of this is the use of porous coating. Some of the early uncemented, proximally porous-coated components had noncircularferential coating. This allowed joint fluid access to the distal portion of the stem, causing osteolysis (7). Modern components have circumferential porous coatings proximally to promote bone ingrowth that acts as a relative seal against the passage of joint fluid distally and thus decreases the effective joint space. Acetabular components are similarly designed with fewer screw holes to diminish access to the supra-acetabular region. This design may decrease the size and number of osteolytic lesions. Decreasing the effective joint space is more difficult with cemented designs.

COMPONENT DESIGN

It is clear that small changes in component design can have major effects on the longevity of the implant. In one prosthesis, laser etching was used to write on the stem, and this led to stem fractures in the area of the etching (106). Review of previous failures has built consensus in the design of modern prostheses as compared with those available 20 years ago. Catastrophic failures are rare.

Most femoral components are made of either cobalt chrome alloys or titanium, and acetabular components are made principally of titanium. Titanium heads, which were widely used until they were shown to be a poor bearing material, have been supplanted by cobalt chrome or ceramic. A major goal in hip prosthesis design is better durability of polyethylene. Previous attempts at improving the durability of polyethylene have included carbon fiber reinforcement and higher crystallinity forms of polyethylene such as Hylamer (DePuy, Dupont), both of which have met with little success (34). Alternative bearing surfaces of ceramic and metal on metal are under investigation.

INFECTION

Infection following joint replacement has decreased with the use of preoperative antibiotic prophylaxis. The use of laminar air flow and body exhaust suits may reduce the risk of infection but has not been proven (29,57,93). The current rate of infection is 0.5% to 2% in primaries and 2% to 4% in revisions (2,29,32,87).

CLINICAL RESULTS

Femoral components cemented with hand mixing and finger packing (first-generation techniques) have demonstrated failure rates as high as 40% at 10 years and as low as 7% at 20 years (91,101). Second-generation techniques, with a medullary plug, lavage of the intramedullary canal, and retrograde cement delivery, have demonstrated failure rates as low as 7% at 15 years (73). Third-generation techniques with porosity reduction of the cement and pressurization may provide further improvement. Cemented acetabular fixation has not been improved comparably. First-generation techniques for cemented cups have had failure rates up to 30% at 10 years, and second-generation techniques have had failure rates of 44% at 14 years (43,72).

Uncemented components have shown good results on femoral and acetabular sides, although the length of follow-up is generally less than that of cemented components. The Anatomic Medullary Locking (AML, DePuy, Warsaw, Indiana) stem has the longest follow-up, with a 1.5% loosening at 11 years (66). Uncemented acetabuli have shown some excellent intermediate results, with revision rates as low as 1.4% at 10 years; however, long-term results remain to be seen (51).

INDICATIONS

Aseptic Loosening

Aseptic loosening is a radiographic diagnosis that does not constitute an indication for surgery by itself. Loose, symptomatic components should be revised if the
patient can tolerate the surgery medically. Asymptomatic patients may require surgery if osteolysis is progressive. Because osteolysis is usually asymptomatic until component stability is compromised, routine follow-up evaluation is appropriate. Osteolytic lesions can be bone grafted with an exchange of the acetabular liner and femoral head at an early stage (65) (Fig. 106.4). Limited surgery becomes less feasible as the lesion enlarges.

**Figure 106.4.** A: Polyethylene wear leading to large supra-acetabular lesion. Note asymmetric position of the head in the cup. B: Cup is stable; therefore, retained and osteolytic lesion grafted with good results.

### Septic Loosening

Established sepsis, with or without loosening, requires surgical treatment, usually to remove components. In North America, most infected arthroplasties are treated by a staged exchange (29,58). The first stage involves removal of the components with or without placement of an antibiotic spacer, accompanied by intravenous and oral antibiotic therapy. Depending on the microorganism and the patient's response to the treatment, reimplantation can be performed 6 to 12 weeks later (58). Some infections, such as those caused by virulent gram-negative bacteria, cannot be treated by this protocol, and the patient may require a Girdlestone excisional arthroplasty (29). Some patients may not be fit enough to tolerate two operative procedures, and single-stage revision with antibiotic impregnated cement should be considered.

### Recurrent Dislocation

Revision of recurrent hip dislocation is perhaps the most difficult type of revision surgery. The many causes of dislocation include component malposition, neuromuscular problems, and lack of patient compliance. Malposition of the acetabular or femoral components is the most common cause (47,69). The offending malposition may be apparent only at surgical revision. A malpositioned component may require revision despite being well fixed. If the acetabulum is the culprit, then alternatives to removal include liners with peripheral buildups. These buildups, or lips, come in varying thicknesses and can be rotated in the area of instability. If the femoral component is malpositioned, there are fewer options. One solution is a constrained acetabular liner. A constrained liner has polyethylene that extends past the midpoint, or maximal circumference of the femoral head (Fig. 106.5). The femoral head must be forced into the polyethylene to reduce the hip and then a locking ring locks the head in place. This design decreases hip motion and increases the stress necessary to dislocate the hip. However, the strain that occurs when this device prevents dislocation is transferred to the component bone interface and may lead to early loosening. Another concern is a higher rate of wear. The use of these devices should be limited to situations without other good alternatives (35).

**Figure 106.5.** A: Bipolar constrained liner, which is inserted into a metal-backed shell. B: Motion is decreased with a constrained design, and stress at interfaces is increased. (Reprinted from Cameron HH. Modified Cups. The Orthopedic Clinics of North America 1998;28:277, with permission.)

In some patients, recurrent dislocation may be solved by changing femoral heads to increase the neck length. There is a limit to the leg lengthening that the patient will accept, especially when the problem is an inadequate offset of the stem.

Less commonly, the problem is neurologic or related to the abductors. A trochanteric nonunion can be treated with reattachment and fixation. If the problem is a short abductor lever arm, a trochanteric advancement can increase the muscle tension. If the problem is purely neurologic, there are few solutions and a constrained cup may be needed.

### Femoral Fracture

The treatment of periprosthetic fractures is dictated by the location of the fracture and the bone quality, and how these factors affect component stability. Fractures distal to the prosthesis may not affect fixation and can be treated with conventional open reduction and internal fixation (ORIF). Fractures that affect component fixation can sometimes be treated with ORIF or may require revision of the component. This procedure is covered in Chapter 20 and elsewhere (111).

**EVALUATION OF THE PATIENT: HISTORY AND PHYSICAL EXAMINATION**

Surgical planning begins with the patient's history and physical examination (25). Details of the history can vary, and not all patients have pain. Osteolysis of periprosthetic bone before mechanical loosening of a component can be completely asymptomatic.

Pain, when present, should be localized anatomically, and the temporal quality should be determined. Thigh or knee pain is most commonly associated with the femoral component, and pain in the groin or the buttock with the acetabular component. Pain that shoots down into the calf is rarely associated with the hip, and spinal or other pathology may be the cause. Simple muscle strains or bursitis can cause thigh pain. Groin pain may be secondary to muscle strain or possibly to hernias.

The temporal nature of the pain is important. When did the pain start? Is the pain present all the time? If not, when does it occur? Patients in whom the pain never improved following primary arthroplasty should be suspected of being infected. This is also true for patients who have pain at rest and at night. Mechanical loosening commonly presents with start-up pain or pain on activity. For example, pain in the thigh when rising from a chair is often due to a loose femoral component.

Infection must always be considered before revision surgery. Question patients about their postoperative course following the primary arthroplasty. Was there drainage? Did it require debridement? Did they receive antibiotics for extended periods of time postoperatively? Question patients for possible recent infections that may have seeded the prosthesis, such as recent hospital admissions, surgical procedures, dental procedures, or infection requiring antibiotics.

Evaluate the patient's functional status to assess the impact that the hip problem is having on daily and social activities. There are several functional scales such as the Harris Hip Score or the Hospital for Special Surgery Hip rating system that help to determine the level of the patient's disability (40,107). These can be useful in
A medical history and review of systems should note conditions that increase the risk of surgery, such as a history of previous thromboembolic disease. Factors that increase the risk of infection include obesity, smoking, diabetes, steroid use, suppressed immune status, and malnutrition, which is quite common in the elderly (29,35).

It is important to review the operative record from the primary surgery. This provides insight into technical difficulties that were encountered and also describes the type of components implanted and their sizes. This is especially important to ensure compatibility when only one component will be revised.

**PHYSICAL EXAMINATION**

Two priorities in the physical exam are to establish limb-length discrepancy (LLD), if present, and to evaluate abductor strength. Note the use of walking aids and presence of a limp. Is the limp antalgic or Trendelenburg (194), or is it the result of a short limb or another problem? LLDs should be quantified because they are a frequent cause of patient complaints. True limb length measured from the anterior superior iliac spine to the medial malleolus can be compared with the apparent limb length measured from the umbilicus to the medial malleolus. Any discrepancy between the two measurements may indicate an oblique pelvis or a fixed flexion contracture of the hip. Another test for LLD that incorporates the patient’s perception of his or her limb-length discrepancy is to use foot blocks of variable sizes. Place the blocks incrementally under the shorter limb until the patient “feels balanced.” Posteriorly, the S-2 dimples can be examined to verify that the pelvis is level. This can be confirmed radiographically with a standing anteroposterior (AP) view of the pelvis. This test may give the most accurate idea of what the patient would like in terms of leg lengths. However, it is important to explain to the patient that hip stability is the priority during surgery and that leg lengths may not be equalized.

Evaluate abductor strength by using the Trendelenburg test and having the patient abduct the leg against gravity while in the lateral supine position. Examine the existing incision for signs of infection and evaluate its usefulness in a revision. Perform a thorough neurovascular examination, paying careful attention to the peroneal nerve distribution because it is the most commonly injured in primary arthroplasty.

**INVESTIGATION**

The principal laboratory studies are those necessary to rule out infection. Infection can present a diagnostic challenge, and the workup for infection involves both preoperative and intraoperative studies.

**Preoperative Investigations**

Preoperative studies include a peripheral white blood cell count (WBC), erythrocyte sedimentation rate (ESR), and a C-reactive protein (CRP). The WBC is rarely useful, and in one study, only 8 of 52 patients with an infected arthroplasty had an elevated WBC (12). Neither the ESR nor the CRP is specific to infection, and either can be elevated by inflammatory and neoplastic conditions (15). However, if patients with inflammatory conditions such as rheumatoid arthritis or recent operations are excluded, the ESR and CRP become useful tools, as has been shown in a recent prospective study. This study demonstrated a sensitivity and specificity of .82 and .85 for the ESR and .92 and .96 for the CRP (109). However, if both tests were negative, the probability of infection was found to be zero, and if both tests were positive, then the probability of infection was .83. An ESR greater than 30 mm/hr and a CRP greater than 10 mg/L are considered positive (69).

Aspiration of the hip was previously recommended for all failed arthroplasties (73). However, more recently, many authors have favored a more limited role for aspiration owing to varying reports of the sensitivity of this test (4,37). Aspiration is not indicated when there is no clinical evidence of infection and when the ESR and CRP are negative. Aspiration should be used when an infection is suspected because it can provide confirmation of clinical suspicions and can identify the infecting organism. Aspiration is also indicated when the inflammatory markers ESR and CRP give mixed results, with one being positive and the other being negative, or when an inflammatory condition such as rheumatoid arthritis is present (103).

**Intraoperative**

Hold preoperative antibiotics on patients undergoing revision surgery. Once the pseudocapsule is exposed, aspirate the joint for fluid. This fluid can be sent for cell count, Gram’s stain, and both aerobic and anaerobic cultures. Give antibiotics once the joint has been aspirated.

Synovial fluid with a white blood cell count of more than 50,000 and a neutrophil count of greater than 80% is suggestive of a bacterial infection (49,52). However, this test has a poor sensitivity, with a recent study demonstrating 18 negative results in 28 periprosthetic infections (106). Similarly, the Gram stain has been shown to be unreliable, with one study demonstrating a sensitivity of 0 out of 32 infected hips (14). Intraoperative cultures of tissue and fluid are very accurate, and some would consider them to be the gold standard for the diagnosis of infection (77). Postoperative antibiotic treatment is also dependent on the culture results; therefore, several samples should be sent to ensure adequate results. The last of the intraoperative tests is the histologic sample sent for frozen section (27). This has been shown to be a reliable test to differentiate septic from aseptic failure of the hip (28,60,67). Studies with large numbers of infections have shown sensitivity from .80 to .91 and specificity from .94 to .95 (28,60). The histologic sample that is sent should be from an area of the hip that shows inflammation. The sample is then examined for the number of polymorphonuclear neutrophils (PMNs) per high-power field (HPF). More than 5 PMNs/HPF suggest infection, and more than 10 PMNs/HPF indicate a probable active infection (28,60,67). The frozen section and cultures are the best of the intraoperative tests to rule out infection.

**RADIOGRAPHIC EVALUATION**

Take three views initially: AP pelvis, AP hip, and a lateral view of the hip. After the initial evaluation, it may be necessary to obtain full-length femur x-ray studies or 45° oblique (Judet) views of the pelvis, which are useful for evaluating the integrity of the bony columns above the acetabulum. The iliac oblique view shows the posterior column and the anterior wall, and the obturator oblique shows the anterior column and posterior wall. These views are not routinely required but are necessary when there is evidence of column destruction on the plain films. Radiographic evaluation of loosening is improved by having previous films for comparison. Radiographic evidence that differentiates aseptic from septic loosening is rare; however, some believe that periprosthetic new bone formation is pathognomonic of deep infection (28). Endosteal scalloping and rapid progression of lysis can also be suggestive of infection (82).

**CEMENTED COMPONENTS**

The radiographic interpretation of loosening can be categorized according to O’Neill and Harris (76) (Fig. 106.6):

- **Definite Loosening**: Migration of the component or cement column, fracture or fragmentation of the cement, fracture or deformation of the component, radiolucency at the cement-bone interface (Fig. 106.7).

**Figure 106.6.** Radiographic evaluation of the cemented femoral component. (A) Definitely loosening; (B) probable loosening; (C) possible loosening. See text for details.
Probable Loosening: Presence of a radiolucent zone at the cement–bone interface around the periphery of the entire component on at least one radiograph, extending for more than 50% of the stem circumference.

Possible Loosening: Presence of a radiolucent zone at the cement–bone interface extending for more than 50% but less than 100% of the periphery of the component, and less than 50% of the stem circumference.

These guidelines need to be correlated with clinical findings. Several studies have concluded that subsidence of the femoral component of less than 2 mm does not affect the long-term result and is not a sign of loosening.

Radiographic evaluation of the cemented acetabulum differs slightly because loosening occurs more often at the cement–bone interface rather than component–cement interface, as with femoral components. Signs of a loose cemented acetabular component include:

- Radiolucent zone more than 2 mm wide surrounding the entire component.
- Migration of the cup, which is seen as changes in the horizontal inclination and the version.

**UNCEMENTED COMPONENTS**

Engh et al. (24) outlined several radiographic signs that indicate bone ingrowth (Fig. 106.8):

- Spot welds that occur at the distal limit of the porous coating
- Stress shielding of the proximal femur
- Lack of a distal pedestal
- Lack of reactive lines around the porous-coated portion of the stem

All of the above-mentioned signs indicate bone ingrowth, and their absence suggests that the stem has either stable or unstable fibrous fixation (Table 106.1).

**COMPARISON OF RESULTS**

**FEMORAL REVISION**

The major problem in revision hip arthroplasty surgery is loss of bone due to osteolysis and mechanical destruction by loose components. The remaining bone is sclerotic and fragile in comparison to when a primary arthroplasty is performed.

Sclerotic bone compromises the bond that can be formed between cement and bone due to the lack of interdigitation that is normally available with a fresh cancellous bed. Bench testing has shown that the shear strength of the bone cement interface is reduced by 79% in the revision setting (19). The revision femur frequently has metaphyseal and diaphyseal bone defects that preclude producing a solid cement mantle.

As with primary arthroplasty, there are two principal methods of fixation of components: cemented and uncemented. The majority of early revisions were performed with cement, using first-generation techniques, but these revisions have demonstrated failure rates of 12% to 44% (9,44,81,82) (Table 106.2). More recent studies using second and third-generation cementing techniques have shown better results, but failure rates still remain high at 10% to 23% (42,72,88,106) (Table 106.3; Fig. 106.9).
The use of uncemented stems in revision arthroplasty has become more common because of the poor results with cemented fixation. Uncemented components can be proximally or fully porous coated. Uncemented components require adequate living bone stock to be in intimate contact with the prosthesis in a mechanically stable setting so that bone ingrowth can occur. The implant must be rotationally and axially stable at the time of implantation to maximize the opportunity for biologic ingrowth.

Proximally porous-coated components aim for fixation in the metaphysis of the femur; this is the area of the femur that is most commonly damaged by the primary arthroplasty. The metaphysis of the femur also shows the greatest amount of anatomic variability among patients, making it more difficult to achieve stable fixation with intimate bone contact. Proximally coated revision devices have demonstrated failure rates from 20% to 50% (5,63,108) (Table 106.4; Fig. 106.10). Failure rates of proximally fixed modular devices that can more clearly fit the metaphysis, such as the S-Rom (J & J, Stanford CT), have been slightly better but remain high at 10% (19).

The term “bypass fixation” is sometimes used to describe fully porous-coated femoral components because they obtain their fixation in the diaphysis of the femur. The femoral diaphysis is able to support a prosthesis in the majority of cases because it is usually less affected by bone defects than the metaphysis. The cylindrical
diaphysis is easier to fill with a component, and revisions with this technique have results that approach those of primary hip arthroplasty, with failure rates from 3% to 7% (50,55,68) (Table 106.5).

### Table 106.5. Uncemented Femoral Revision with Fully Porous-Coated Components

| Failure Conditions | Failures with bypass fixation occur (1) when the canal fill is less than 90% and (2) when less than 4 to 6 cm of diaphysis supports the prosthesis (50). If these two conditions are satisfactory, the success rate compares with that of primary arthroplasty (Fig. 106.11). There are two principal disadvantages with this technique: stress shielding and the difficulty of removing an ingrown, fully coated stem. Stress shielding is more pronounced in stems greater than 13.5 mm in diameter and in cobalt chrome stems as compared with titanium (24). Revision stems are larger than primary stems due to loss of bone and are frequently greater than 13.5 mm in diameter. Therefore, patients who have undergone this type of revision surgery are at increased risk of stress shielding. Although stress shielding associated with the use of large cobalt chrome stems is present on radiographs, it has not presented clinical problems to date. Patients with significant stress shielding secondary to a large revision components may require repeat revision in the future, and management of proximal bone atrophy may become an issue. Removal of an ingrown fully coated femoral stem is difficult; however, it is rarely necessary.

**Figure 106.11.** A: Failed primary cemented component with extensive proximal femoral destruction. B: Bypass fixation using a long-stemmed fully porous-coated device obtaining fixation in healthy supportive diaphyseal bone.

More recently, cemented revisions have been performed with “impaction grafting.” This technique claims to restore femoral bone stock and can be used despite large femoral defects (Fig. 106.12). The major potential advantage of this technique is the restoration of femoral bone, which is particularly important in the young patient who may require future re-revision. Bypass fixation can induce proximal femoral remodeling and restoration of bone stock, with the advantage of avoiding bone grafting, which is expensive and includes the risk of infection. Early results with impaction grafting have been promising, with good functional and radiographic results. There is some histologic evidence of bone reconstitution. The current indication for impaction grafting is a femoral isthmus incapable of providing rotational stability to a fully porous-coated stem (22,97).

**Figure 106.12.** Successful reconstruction using impaction grafting. (Reprinted from Duncan CP, Masterson EL. Impaction Allografting with Cement for the Management of Femoral Bone Loss. The Orthopedic Clinics of North America 1998;28:297, with permission.)

### ACETABULAR REVISION

Acetabular reconstruction is less controversial. Cemented acetabular revision has been more disappointing than cemented femoral revision. Several studies have shown a 10% to 20% repeat revision rate from as early as 3.6 to 7.4 years (44,46,85) (Table 106.6). As with cemented femoral revisions, this high failure rate is secondary to sclerotic and compromised bone that prevent the formation of a good cement mantle (19). Modern cementing techniques in acetabular revision have not improved the results. Based on these results, there is no place for cemented cups in revision surgery except in conjunction with a cage or allograft.

### Table 106.6. Cemented Acetabular Revision

| Failure Conditions | Cemented acetabular revision has been more disappointing than cemented femoral revision. Several studies have shown a 10% to 20% repeat revision rate from as early as 3.6 to 7.4 years (44,46,85) (Table 106.6). As with cemented femoral revisions, this high failure rate is secondary to sclerotic and compromised bone that prevent the formation of a good cement mantle (19). Modern cementing techniques in acetabular revision have not improved the results. Based on these results, there is no place for cemented cups in revision surgery except in conjunction with a cage or allograft.
By contrast, uncemented acetabular revision has been very successful (Table 106.7). Silverton et al. (96) showed a repeat revision rate of 0% at 8.3 years, and other studies show comparable results (23,96,102). The advent of “jumbo” cups available in sizes up to 80 mm in diameter has enabled the reconstruction of large defects and reduced the need for structural grafts (Fig. 106.13). Success with uncemented cups depends on achieving more than 50% host bone contact with stable initial fixation. When these criteria cannot be met, alternatives such as a high hip center, oblong cup, or cages and allograft must be considered.

Figure 106.13. Revision of a large acetabular defect with a “jumbo” cup. Peripheral screws are used to enhance initial fixation.

Uncemented cups implanted in the ilium with a high hip center have been controversial. They can be used in the presence of bone loss in the superior acetabulum, where a cup cannot be placed in the normal position owing to anatomic constraints such as a mismatch between the acetabular AP and the superoinferior diameters. Host bone is still available superiorly where the ilium becomes thinner. However, nonanatomic placement of the cup changes the biomechanics of the hip significantly and subjects the cup to higher mechanical loads. Several studies (18,53,84) of this technique have demonstrated failure rates that range from 42% to 72% (Fig. 106.14). Accordingly, the hip center should be as close to anatomic as possible.

Figure 106.14. High hip center was used in the primary arthroplasty for developmental dysplasia of the hip. This failed, was revised, and more normal biomechanics were restored. Offset is not optimal, and the greater trochanter has fractured.

The oblong cup is a device that fills the superior defect and does not depend on bone graft reconstruction yet preserves the anatomic center of rotation. Implants are available “off the shelf,” or they can be custom ordered. These prostheses have shown good initial results in small groups of patients with short-term follow-up. One multicenter trial reported 64 cases, with an average follow-up of 44 months with 97% cup retention (11,75). The chances of long-term fixation should theoretically be good because there is a large surface available for biologic fixation (Fig. 106.15). This is in contrast to cages and rings that have no or limited potential for biologic fixation.

Figure 106.15. A: Oblong cup showing large surface area for potential ingrowth. B: Cup filling large segmental superior defect. Reprinted from Cameron HH. Modified Cups. The Orthopedic Clinics of North America 1998;28:277, with permission.)

Cages and rings have been used to handle the most difficult acetabular reconstructions. These devices have been studied at short to intermediate duration follow-up, and the patients are few. The initial results have been encouraging, with failure rates between 0.5% and 12% at 5 years (6,70,82). These devices are used principally to bridge bone defects, as in the case of acetabular discontinuities, and they must be secured to both the ilium and the ischium. Cages require solid contact with host bone or they will fail due to cyclic loading. The long-term results are unknown, and at present, their use should be restricted to situations in which an uncemented cup
cannot be used (Fig. 106.16).

Figure 106.16. A: Paprosky Type 3B defect with extensive loss of host bone and high hip center. B: Reconstruction using a cage and allograft with restoration of anatomic center of rotation. C: Burch–Schneider cage. D: Cage bridging the defect with secure fixation in the ischium and to the ilium.

Figure 106.17. Paprosky Femoral Defect Classification. A: Type 1 defect minimal damage able to support any type of prosthesis. Type 2 defect metaphyseal damage unable to support a proximal porous-coated device. Treat with bypass fixation or possible cemented revision in the elderly. B: Type 3A defect extensive proximal femoral damage diaphyseal fixation is available proximal to the isthmus. Type 3B defect has damage that extends even further and diaphyseal fixation is available only past the isthmus. What appears to be a radiographic type 3B may not be able to support a prosthesis intraoperatively and must then be treated as a type 4. C: Type 4 defect has extensive diaphyseal involvement. It is unable to provide rotational and axial stability to a fully porous-coated device and is treated with impaction grafting or an allograft prosthetic composite.

Good initial results of impaction grafting of the acetabulum have been described. However, the number of patients and duration of follow-up are small. The technique is not yet widely used.

CLASSIFICATION OF DEFECTS AND TREATMENT PLAN

A classification system should provide a standardized description and a guide to treatment. Numerous systems assess bone loss, but none has found widespread acceptance or been validated independently.

FEMORAL DEFECTS

The American Academy of Orthopaedic Surgeons (AAOS) has adopted a classification system that divides femoral bone loss into segmental and cavitary defects (16).

Segmental femoral defects involve loss of bone in the cortical shell of the femur and are divided into partial and complete. Cavitary defects may be cancellous or cortical, with cancellous defects being less severe. Erosion of the cortex is by definition a cavitary cavitary defect. Combined defects have both segmental and cavitary bone loss.

This system also describes femoral alignment, stenosis, and the level of bone loss. Level 1 is proximal to the bottom of the lesser trochanter. Level 2 is 10 cm distal to level 1, and level 3 is everything distal to this. This system provides a fairly accurate description of the femoral defect but does not incorporate a treatment plan.

PAPROSKY FEMORAL DEFECT CLASSIFICATION

The Paprosky classification system evaluates the ability of the femoral diaphysis to support an uncemented, fully porous-coated prosthesis (3) (Fig. 106.17). This system is less detailed in its description of the bony defect present than the AAOS system, yet it is more useful in decision making for an uncemented femoral revision. By using this classification system, the appropriate method of treatment can be chosen preoperatively (Table 106.8).

Table 106.8. Paprosky Femoral Defect Classification System and Treatment Plan

A fully coated long stem will work in all types 1 through 3A; in types 1 or 2, other options can be used. Type 3B is the most difficult to evaluate and will require intraoperative evaluation of the ability of the isthmus to support a fully coated long stem. Without 4 to 6 cm of intimate bone contact, impaction grafting or an allograft prosthetic composite (APC) will be required, as in the type 4 femur. If, during preoperative templating, it appears questionable that the femoral isthmus can support a long fully porous-coated stem, then you must treat it as a type 3B or type 4 femur and be prepared for impaction grafting or the use of an APC.

ACETABULAR DEFECTS

The AAOS acetabular defect classification system has some radiographic validity, but it is based principally on the intraoperative assessment of bone loss (17). This system divides bone loss into two major types: segmental (type 1) or cavitary (type 2). A segmental deficiency is loss of bone in the supporting hemisphere of the acetabulum. These defects involve the rim of the acetabulum or the medial wall and may compromise the ability of the acetabulum to provide rigid fixation to an
acetabular component. Cavitary defects involve volumetric loss of bone but are contained within a shell of bone. These defects rarely affect the ability of the acetabulum to support a cup. Type 3 defects refer to combined segmental and cavitary bone loss and are the most common type found in revision hip surgery. Type 4 defects refer to a pelvic discontinuity and Type 5 to a hip arthrodesis (Fig. 106.18).

Figure 106.18. Classification of acetabular defects according to the American Academy of Orthopaedic Surgeons Committee on the Hip: type 1, segmental; type 2, cavitary; type 3, combined segmental and cavitary; type 4, pelvic discontinuity; and type 5, hip fusion. (Reprinted from the Journal of the American Academy of Orthopaedic Surgeons 7:1, with permission.)

The Paprosky classification system for acetabular defects is based on preoperative AP radiographs and uses four landmarks to evaluate bone destruction (Table 106.9). These landmarks allow for preoperative quantification of the defect and treatment planning (79). Two of the four are measurements from a horizontal line tangent to the tops of the obturator foramina (Hilgenreiner’s line) (Fig. 106.19). The other two radiographic landmarks are柯勒’s线 and the tear drop. Remember to allow for magnification when making measurements.

Table 106.9. Paprosky Radiographic Landmarks to Evaluate Bone Destruction

Figure 106.19. (A) Kohler’s line, (B) tear drop, (C) superior obturator line (Hilgenreiner’s line), used as a reference to measure superior displacement of the femoral head center and to measure inferiorly the amount of ischial lysis.

Acetabular defects can be classified into one of three major types with five subtypes by evaluation of these four radiographic landmarks (Table 106.10; Fig. 106.20).

Table 106.10. Paprosky Acetabular Defect Classification System and Treatment

Figure 106.20. Paprosky classification of acetabular defects: (A) type 1, minimal damage; (B) type 2A–C, increased destruction but greater than 50% host bone
The Paprosky classification guides treatment. Types 1 and 2 may have large cavity defects but can be treated with an uncemented cup because the defects are contained and the supporting rim of the acetabulum is largely intact. The type 3 defects include large cavity and segmental defects, effectively becoming partially uncontained cavity defects. In this situation, an uncemented cup depends on sufficient host bone for stability. This is not always available, necessitating the use of cages and allografts. In the type 3B acetabulum, the host bone cannot be relied on and must be supplemented with either cancellous or structural grafts.

**PREOPERATIVE PLANNING**

The goal of revision surgery is to re-establish the normal biomechanics of the hip as well as possible and to maximize the patient's function. The need for preoperative planning must be emphasized because revision hip surgery is demanding of the surgeon, the equipment, and the institution. Preparation begins with a clear understanding of why the hip is being revised and how it will be done. Often only one component will be revised; therefore, multiple implant systems are required. The surgeon must be familiar with them. Previous operative reports are essential to establish the type of component in place and their sizes. Many older systems were nonmodular, or replacements are now unavailable. Therefore, the surgeon must be prepared to remove a well-fixed component or perhaps cement a polyethylene liner into a metal-backed cup. These decisions should be considered preoperatively to avoid unfortunate surprises in the operating room.

**TEMPLATING**

Begin the templating by determining the LLD (Fig. 106.21A).

- **Acetabulum**
  - Use the lesser trochanters, the ischial tuberosities, and greater trochanter as landmarks.
  - Correlate the measured limb length discrepancy (LLD) with the clinically noted LLD.
  - Mark the preoperative center of rotation (COR). Measure the displacement of this COR from Hilgenreiner's line. Using known radiologic landmarks, determine the degree of acetabular destruction.
  - Evaluate the integrity of the columns.

  Use the Paprosky classification system to determine the degree of destruction and plan the reconstruction. Any system can be used, as long as the acetabulum can be visualized in three dimensions.

  - Decide whether an uncemented acetabular component can be placed using component templates and mark the new COR on the AP hip radiograph. Look for superior rim support of the acetabular prosthesis and the integrity of Kohler's line (Fig. 106.21B).
  - Template for alternatives if fixation with a standard cup is questionable. Decide whether bone graft or cages may be required. Prepare for pelvic plating in the presence of pelvic discontinuity.
  - Note the COR of the new cup in comparison to the old COR. This will be the change in leg length contributed by the acetabular component. If the new COR is higher, the limb will be shortened and vice versa. Mark the position of the new COR on the AP hip x-ray film.

- **Femur**
  - As previously discussed, the location and severity of femoral bone defects will determine the type of component. Fixation must be stable to both rotational and axial forces. Fully porous-coated devices must meet two criteria: (1) templates should show greater than 90% canal fill and (2) 4 cm of undisrupted diaphysis at or before the femoral isthmus (50) (Fig. 106.21C).

  - On the AP radiograph, select a component to satisfy the two requisites noted earlier.
  - Assess and plan to restore offset because this is an important contributor to hip stability.
  - Position the selected femoral component to make up any LLD that remains after templating the new acetabular component. If the leg needs to be lengthened further, template the femur so that the center of the femoral head sits above the planned acetabular center by the amount of the LLD remaining so when the hip is reduced, the LLD is eliminated. Likewise, position the femoral component lower if you want to avoid lengthening the leg.
  - Look for potential conflicts of the prosthesis with the proximal femur and on the lateral radiograph. If a stem longer than 175 mm (7 inches) is to be used, a conflict with the anterior cortex may exist in the lateral plane and a curved stem will be needed.

**EXTENDED TROCHANTERIC OSTEOTOMY**

An extended trochanteric osteotomy should be templated because its location affects the choice of implant. The location of the osteotomy is a compromise between enhancing exposure and maintaining component fixation.

- Plan the distal extent of the osteotomy at the most advantageous location to accomplish the necessary task. To remove cement, this would be at the most distal extent of the cement mantle. To remove a porous-coated component, this would ideally be at the junction of the metaphyseal and diaphyseal portion of the stem. An osteotomy is also indicated when there has been varus remodeling of the femur caused by a loose femoral component. Varus remodeling prevents appropriate reaming and placement of the new component. With varus remodeling present, the osteotomy should ideally end at the apex of the varus deformity (Fig. 106.22A).
ACETABULAR EXPOSURE

Exposure is the key to acetabular reconstruction. This often seems daunting in the face of extensive scar and difficult visualization. However, with patient removal of scar and gradual retraction of the femur anteriorly, a femoral osteotomy is usually unnecessary with a posterior approach.

- Incise the capsule superiorly at the 12 o’clock position. Then dissect subperiosteally along the superior and anterior edges of the acetabulum.
- Place a Hohmann retractor at the 2 o’clock position at the junction of the superior and the anterior acetabular rims. Do not place the retractor on the thin portion of the anterior wall or you risk creating a segmental defect. Alternately, a Taylor retractor may be placed on the anterior ilium, which is useful when the anterior wall and column appear fragile.
- Gently lever the retractor anteriorly and release the capsular tissue bluntly or sharply until the superior and anterior portions of the acetabulum are exposed.
- Release a tight inferior capsule with electrocautery because there are vessels in this area. This will facilitate anterior translation of the femur.
- Place a second retractor into the obturator fossa after the inferior capsule is released. This retractor can be used to translate the femur distally and anteriorly.
- Debride the scar.
- Dislocate the hip and remove a modular head, if present. Dislocation, if impossible owing to protrusion, can be achieved with a standard trochanteric osteotomy, a vastus slide, or an extended trochanteric osteotomy.

EXTENDED TROCHANTERIC OSTEOTOMY

Some revisions require greater exposure than that achievable by soft-tissue dissection alone. There are bony procedures that expose the acetabulum and femur. The most useful is the extended trochanteric osteotomy.

Indications for an extended trochanteric osteotomy include

1. Acetabular exposure
2. Removal of femoral components or cement
3. Neutral reaming of varus and valgus femoral remodeling
4. Adjustment of abductor tension
5. Promotion of femoral remodeling

The extended trochanteric osteotomy is versatile and reduces operative time, blood loss, and complications. The extended trochanteric osteotomy may be regarded as a conservative approach to revision hip surgery. It allows direct visualization during cement removal and reduces the incidence of cortical perforation. It allows controlled access to the femoral canal and facilitates removal of well-fixed cemented and uncemented stems. It allows reaming of the femur parallel to the canal, which is important when using long-stemmed components or when there has been varus remodeling of the femur secondary to aseptic loosening. The osteotomy is useful in the presence of malunions of the greater trochanter or femur that prevent reaming parallel to the axis of the medullary canal.

The extended trochanteric osteotomy is easier to perform once the femoral component has been removed. This is not always possible, and the technique is modified slightly with the femoral stem in place.
Position the hip in 0° of flexion with internal rotation of approximately 20°.

Create a long bony segment comprising the lateral third of the femur with minimal stripping of the musculotendinous sleeve composed of the gluteus medius and minimus proximally and the vastus lateralis distally (Fig. 106.24A).

- The longitudinal limbs of the osteotomy are on the anterolateral and posterolateral cortex of the femur, parallel to the long axis of the femur. The transverse limb of the osteotomy joins the two longitudinal limbs and is transverse to the length of the femur. The goal is to create a coffin lid composed of the lateral third of the femur. The length of the osteotomy is based on preoperative templating and is covered in that section of this chapter.
- Expose the femur from the proximal neck cut to the templated distal extension of the osteotomy, along the junction of the posterior and lateral femur. Do not elevate the vastus lateralis for the length of the incision because this approach will devascularize the planned osteotomy segment. Do not expose the anterior cortex.
- Reflect the vastus lateralis anteriorly for 2 cm of its length at the distal extent of the osteotomy and retract it.
- Mark out the planned osteotomy using a narrow diameter pencil burr. Mark out the longitudinal portion along the posterolateral femur, then curve it gently onto the lateral cortex to mark the distal extent of the osteotomy. Curving the transition from a longitudinal to a distal cut reduces stress risers that could lead to fracture. Avoid 90° transitions (Fig. 106.23B).
- The anterior cortex does not need to be exposed except for a small 1 to 2 cm area that can be accessed where the retractor is retracting the vastus lateralis. In this area, extend the distal osteotomy from the lateral cortex to the anterolateral cortex from distal to proximal, marking the anterolateral cortex for 1 to 2 cm. The distal portion of the osteotomy can be completed with the burr (Fig. 106.23C).
- Complete the posterior longitudinal portion with an oscillating saw along the lines marked with the burr. Once the posterior cortical cut is complete, cut the anterior cortex from inside the femur using the posterior cortical cut as guide going from back to front. The anterior cortex should be cut at the same depth as the posterior cortex so that the osteotomy segment has a uniform depth.
- When the femoral component is still in place, the anterior femoral cortex cannot be cut directly. Cutting the anterior cortex for short distances both proximally and distally creates a controlled fracture and prevents stripping of the vastus lateralis that would otherwise be necessary to expose this area. Distally, the cut is marked as previously described, going from lateral cortex to the anterolateral, using the narrow diameter burr and cutting the anterior cortex for 1 to 2 cm from distal to proximal. The proximal femur should be cleared of anterior capsule for 1 to 2 cm distal to the neck cut. This should be proximal and anterior to the vastus lateralis origin. Using the pencil burr, the anterior cortex is cut for 1 to 2 cm. Exposure of the proximal anterior femur can be improved by flexing the femur 30°, and this area can usually be reached with the stem in place.
- Open the osteotomy slowly with two wide osteotomes. Pay careful attention to the distal aspect for fracture extension (Fig. 106.23D).
- With the osteotomized segment gently retracted anteriorly, release the scar along the anterior osteotomy plane from inside the femur. This scar tissue is most pronounced proximally. If this scar tissue is not released, the segment may fracture during retraction. This is a critical step in performing the osteotomy (Fig. 106.23E).
- A trial reduction of the hip allows for adjustments of abductor tension or repositioning of the femoral component. The osteotomy is not closed until the final reduction has been performed.
- It is often necessary to contour the inside of the greater trochanter with a barrel-shaped burr before closure so that it fits over the shoulder of the component.
- Close the osteotomy with two or more cables, depending on the length of the segment.
- Pass the cables around the femur, deep to the vastus lateralis, and tighten them partially with the hip reduced (Fig. 106.24).

Maintain tension on the cables as the hip is taken through a range of motion to check stability.

If the reduction is stable then crimp and cut the cable sleeves in final position.

Do not be alarmed if the osteotomy does not reduce with bone-to-bone contact. With greater deformities of the proximal femur or previous varus stems, anatomic reduction may be neither possible nor necessary.

The extended trochanteric osteotomy is stable because the vastus lateralis prevents proximal migration and the gluteus tendons remain attached, preserving abductor strength. An intact musculotendinous sleeve, consisting of the gluteus medius and vastus lateralis, are the keys to successful healing. We experienced no nonunions in 122 cases (3). The most common complication (10%) has been fracture of the segment, but this was not clinically significant, and the incidence of this complication decreases with increased experience. Proximal migration has been limited to less than 2 mm (3).

One drawback of the extended trochanteric osteotomy is that it cannot be used to provide exposure or adjust abductor tension in the presence of a well-fixed cemented component that is being removed temporarily, the so-called “tap-in, tap-out” procedure. Its use in cemented revisions is also limited, although it can function with impaction grafting.

**Trochanteric Osteotomy**

The traditional transtrochanteric approach popularized by Charnley is another method of exposure (13). This approach provides excellent exposure because the trochanter is detached from the femur and reflected superiorly with the gluteus muscles attached (Fig. 106.25A). In revision surgery the proximal femur is often damaged and the greater trochanter is compromised by osteolysis. This factor has significant drawbacks in the reattachment of the trochanter. Healing is usually fibrous, and fixation of the small proximal segment is difficult, even with the use of claws and grips.
Cement Removal

Cemented stem removal can be divided into three steps: (1) disruption of the cement prosthesis interface, (2) removal of the component, and (3) removal of the cement.

- Disrupt the interface proximally where any cement overhanging the shoulder is removed. The greater trochanter may fracture if this area is not cleared before removal of the component.
- After the proximal cement is fractured with a thin osteotome, disimpact the prosthesis with an extraction device.
- A component with a methylmethacrylate precoating to enhance the cement bond will not be extracted as easily. In this case, either continue to disrupt the cement mantle using flexible osteotomes or, more safely, with an extended trochanteric osteotomy.

Cemented Stem Removal

Cement removal can be divided into three steps: (1) disruption of the cement prosthesis interface, (2) removal of the component, and (3) removal of the cement.

- Clear the "shoulder" of the prosthesis of soft tissue or bone that may limit access to the lateral component, or that may impede removal of the implant.
- Clear the entire proximal femur of fibrous tissue to view the component–bone or cement–bone interface around the entire prosthesis.
- Removal is safer once the proximal component can be visualized.

Low-torque, high-speed burrs such as the Anspach (Lake Park, FL), Midas Rex (Fort Worth, TX), or the Ultra-Power (Warsaw, IN) should be available. They are versatile in revision surgery, and cutting heads with the ability to cut metal should be available in various shapes and sizes.

FEMORAL REVISION

Component Removal

Femoral components may be easily removed if loose, or their removal may require much equipment and time. Cemented components are easier to remove than cement, and the most difficult to remove is the fully porous-coated ingrown stem.

Numerous tools are used for the removal of specific components. Other instruments are used more generally for cement and component removal. The Moreland (DePuy, Warsaw, IN) hand tools are useful for the removal of cemented and uncemented components. Other similar systems (Osteonics, Allendale, New Jersey) provide extraction devices and multiple hand tools with specific functions such as splitting cement or drilling into a cement plug (Fig. 106.26).

Trochanteric Slide

As a modification of the lateral approach, the trochanteric slide involves an osteotomy of the anterior trochanteric bone, which is reflected anteriorly in continuity with the gluteus medius and vastus lateralis. Make the osteotomy just lateral to the gluteus minimus insertion, or alternatively, it can be made thicker to include the gluteus minimus with the fragment. Reattach the slice of trochanter with cerclage wire around the lesser trochanter and through the bony fragment. Stability is usually excellent following realignment owing to the opposing pulls of the gluteus medius and vastus lateralis (Fig. 106-25A). The trochanteric slide can improve visualization in the difficult primary arthroplasty as well as the revision. In addition, the dissection can be extended proximally for exposure of the ilium with less risk to superior gluteal neurovascular structures as can be encountered with the modified Hardinge approach (39). The mobility of the trochanteric fragment has the advantages of re-establishing abductor tension and facilitating fixation to a proximal femoral allograft.

FEMORAL REVISION

Component Removal

The mobility of the trochanteric fragment has the advantages of re-establishing abductor tension and facilitating fixation to a proximal femoral allograft.

Removal of the head facilitates acetabular exposure and should be done early in the exposure, even if the femoral component is to be retained. Protect the Morse taper on the femoral neck from scratches with a sponge from scratches during the surgery.

Once the hip has been exposed and dislocated, the modular femoral head must be disengaged from the Morse taper of the neck. This can usually be accomplished by placing a bone tamp at the undersurface of the femoral head and striking it sharply with a hammer. Dedicated instruments are also available from most manufacturers. Removal of the head facilitates acetabular exposure and should be done early in the exposure, even if the femoral component is to be retained. Protect the Morse taper on the femoral neck from scratches with a sponge from scratches during the surgery.

If the femoral component is to be revised, it can be removed immediately to improve acetabular exposure. An extended trochanteric osteotomy, if necessary for femoral component removal, improves acetabular exposure. If acetabular exposure does not seem to be a problem, there are advantages to leaving the femoral component in place until later. The femoral neck can be used as a fulcrum to transpose the femur anteriorly, although this should be done gently. Also, removal of the femoral component and cement leaves the femur as a fragile tube that is susceptible to fracture. Finally, removal of the component and or cement leads to increased bleeding from the canal. If the femoral component does not interfere with exposure, we leave it in place during the acetabular revision.

There are fewer options if the femoral component is to be retained. When exposure is a problem, the cemented femoral component may be tapped out of the cement mantle, with good results on replacement. If the femoral component removed, if there is a solid bond between the cement and bone, then either the same or a new femoral component can be remouted into place. If a new component is to be used, the cement mantle will require with a bone tamp at the undersurface of the femoral head and striking it sharply with a hammer. Dedicated instruments are also available from most manufacturers. Removal of the head facilitates acetabular exposure and should be done early in the exposure, even if the femoral component is to be retained. Protect the Morse taper on the femoral neck from scratches with a sponge from scratches during the surgery.

Femoral component removal begins with exposure of the proximal femur:

- Clear the "shoulder" of the prosthesis of soft tissue or bone that may limit access to the lateral component, or that may impede removal of the implant.
- Clear the entire proximal femur of fibrous tissue to view the component–bone or cement–bone interface around the entire prosthesis.
- Removal is safer once the proximal component can be visualized.

Cemented Stem Removal

Cemented stem removal can be divided into three steps: (1) disruption of the cement prosthesis interface, (2) removal of the component, and (3) removal of the cement.

- A component with a methylmethacrylate precoating to enhance the cement bond will not be extracted as easily. In this case, either continue to disrupt the cement mantle using flexible osteotomes or, more safely, with an extended trochanteric osteotomy.

Cement Removal

Numerous tools are used for the removal of specific components. Other instruments are used more generally for cement and component removal. The Moreland (DePuy, Warsaw, IN) hand tools are useful for the removal of cemented and uncemented components. Other similar systems (Osteonics, Allendale, New Jersey) provide extraction devices and multiple hand tools with specific functions such as splitting cement or drilling into a cement plug (Fig. 106.26).

Trochanteric Slide

As a modification of the lateral approach, the trochanteric slide involves an osteotomy of the anterior trochanteric bone, which is reflected anteriorly in continuity with the gluteus medius and vastus lateralis. Make the osteotomy just lateral to the gluteus minimus insertion, or alternatively, it can be made thicker to include the gluteus minimus with the fragment. Reattach the slice of trochanter with cerclage wire around the lesser trochanter and through the bony fragment. Stability is usually excellent following realignment owing to the opposing pulls of the gluteus medius and vastus lateralis (Fig. 106-25A). The trochanteric slide can improve visualization in the difficult primary arthroplasty as well as the revision. In addition, the dissection can be extended proximally for exposure of the ilium with less risk to superior gluteal neurovascular structures as can be encountered with the modified Hardinge approach (39). The mobility of the trochanteric fragment has the advantages of re-establishing abductor tension and facilitating fixation to a proximal femoral allograft.

Figure 106.25. A: Sagittal view of the trochanteric osteotomy. B: Sagittal view of the trochanteric slide.

Figure 106.26. Cement splitting tools.
Specialized hand tools are most useful for cement removal. Cement removal can be hazardous and commonly leads to cortical perforation. If the cement is grossly loose, it can often be removed as a unit by drilling a hole into the center of the distal cement, tapping threads into the cement, and screwing in an extraction device to remove the cement. Cement that is well bonded to the diaphysis is difficult to remove and will require high-speed burrs, a light to illuminate the canal, and possibly an image intensifier.

The extended trochanteric osteotomy is a safe and fast method to remove cement. Based on preoperative templating, the osteotomy should be extended as far distally as possible without compromising fixation of the revision stem.

- Split cement that is intact circumferentially into three or four segments with T- or V-shaped cement removal chisels. Do this before disrupting the bone–cement interface (Fig. 106.27). If the cement mantle is not disrupted, the chisels tend to lever against the bone and can lead to femur fracture.

![Figure 106.27. Proximal metaphyseal cement can be split with special T- or V-shaped cement removal chisels.](image)

- Patiently remove cement from proximal to distal in 1 to 2 cm segments. The well-bonded distal cement plug will be difficult to remove.
- If there is space between the plug and bone, a small hook can be passed beyond the plug to then remove it.
- If there is no space, drill into the distal plug with drill guides that fit tightly into the femoral canal and centralize the drill bit (Fig. 106.28). Tap the threads in the hole and screw in a threaded extractor. Try to remove the cement as a unit only if it does not extend past the isthmus or is not well bonded. If the unit is solidly bonded, split the cement through the drill hole and use hooks to remove it piece by piece.

![Figure 106.28. Drill guides allow a tap to be placed centrally in the distal cement. If the cement is not well bonded, it can then be disimpacted.](image)

We do not attempt to remove well-bonded cement or distal plugs without an extended trochanteric osteotomy. The osteotomy has decreased the frequency of perforations and expedited complete cement removal. Failure to remove small pieces of well-bonded cement can misdirect reamers and lead to component malposition and femoral fracture.

**Cementless Stem Removal**

The principles of interface disruption are the same as with cemented components but are more difficult. The techniques depend on the extent of the fixation surface; a proximally porous-coated component can be removed with or without an osteotomy using flexible osteotomes, whereas a fully porous-coated component will require an osteotomy or distal cortical windows.

The type of fixation—bone ingrown, fibrous stable, or fibrous unstable—will influence the ease of removal. A fibrous unstable component can be removed fairly easily, as shown here:

- Remove soft tissue and bone from around the shoulder of the prosthesis.
- Use an axial force to remove the component (Fig. 106.29).

![Figure 106.29. A universal extraction device can be used for modular femoral components. A: If they are not already present, special notches must be made on these femoral components by using a carbide bit, and B: attachment of the device to the femoral component can allow for extraction.](image)

- If the component shows no signs of moving after 5 to 10 heavy blows, reassess the situation. Is there a proximal obstruction? Is the component partially bone ingrown or fibrous stable?
- Do not force the component out because this can fracture the femur. For components that are proximally coated and “bone ingrown” or fully coated and “fibrous stable,” start by disrupting the bone prosthesis bond proximally.
- Establish access to the interface with a narrow-diameter burr or osteotomes. Establish “straight shot” access to the lateral aspect of the component by removing any overhanging greater trochanteric bone.
- Use flexible osteotomes to disrupt the bond around the prosthesis.
- Use an axial force to extract the component.

If removal is unsuccessful or the component is fully porous coated and bone ingrown, proceed with the extended trochanteric osteotomy or a cortical window. The extended trochanteric osteotomy provides better access to the proximal portion of the stem and more direct, straight access to the distal portion with the trephines.

The osteotomy would proceed as follows:

- Extend the trochanteric osteotomy distally to the junction of the metaphyseal and diaphyseal stem (Fig. 106.30).
Disrupt the proximal bone prosthesis interface extensively with flexible osteotomes before opening the osteotomy. This will decrease the chance that the segment will fracture. Medial access is difficult and can be achieved by cutting the collar of the prosthesis.

Open the osteotomy by hinging it anteriorly.

Cut the stem at the metaphyseal–diaphyseal junction using a metal-cutting, carbide-tip, high-speed, low-torque burr.

Disrupt the well-bonded proximal interface with use of a Gigli saw (Fig. 106.31).

Drill over the distal cylindrical portion of the stem with trephines.

The cortical window achieves results similar to the extended trochanter osteotomy.

Use a high-speed burr to create a window in the lateral femoral cortex at the junction of the metaphyseal and diaphyseal portions of the stem (Fig. 106.32).

Cut the femoral stem with a metal-cutting burr through this window.

Drill over the distal portion of the stem with trephines.

Evaluate the femur for defects after removing the pseudomembrane, exposing healthy bone. Classify the defect based on the intraoperative evaluation and the preoperative templating. This information is used to decide treatment.

**Bypass Fixation**

The goal with bypass fixation is to achieve axial and rotational stability in the diaphysis of the femur, bypassing the metaphyseal bone. This can be achieved if at least 4 cm of undisrupted diaphysis is available to support the prosthesis and if more than 90% of the canal can be filled.

- Remove all cement and neocortex from the canal.
- Remove any overhanging trochanter or proximal sources of impingement because reaming must be performed in neutral alignment. In femurs with varus remodeling, this may not be possible. Failure to ream neutrally will lead to component malposition or femoral fracture.
- Perform an extended trochanteric osteotomy if neutral reaming cannot be achieved.
- The length of reaming depends on the stem chosen for revision; therefore, at least 4 to 6 cm of undisrupted bone must be available distal to the osteotomy site.
- Ream no farther than the area required for fixation.
- Use straight reamers for straight stems and flexible reamers for curved stems.

The femur has an anterior bow with the apex anterior and approximately 175 mm (7 inches) distal to the lesser trochanter. Therefore, any straight stems longer than 175 mm (7 inches) may impinge or perforate the anterior cortex of the femur. Longer curved stems have a far lower incidence of anterior cortical perforation than long straight stems (Fig. 106.33).

**Figure 106.30.** Removal of a well-fixed fully porous-coated component through an extended trochanteric osteotomy, cutting the stem and using trephines.

**Figure 106.31.** Use of a Gigli saw to disrupt the medial interface, which is the most difficult to access.

**Figure 106.32.** Cortical window at the stem metaphyseal–diaphyseal junction used to cut the stem, which is then removed as in Figure 106.31.

**Figure 106.33. A:** A 200 mm (8-inch) straight-stem template shows conflict with the anterior cortex. A shorter stem was inserted, but the anterior cortex was still
Impaction grafting uses small pieces of cancellous bone graft to create a new medullary canal into which a component can be cemented. In creating a new canal, bone graft will be compacted into the femur forcefully. The integrity of the femur must be restored to sustain this.

**Impaction Grafting**

More thoroughly than in a primary, there will be healthy cancellous bed proximally and good diaphyseal bone distally. This will not be the case in the revision and the femur will have to be prepared far more thoroughly than in a primary.

The major difference between performing a cemented revision and a cemented primary arthroplasty is in the preparation of the femoral canal. In a primary arthroplasty, the metaphyseal portion of the implant will need to be larger than in a primary. The diaphysis, by contrast, may be undamaged (Fig. 106.35). The stem of the larger implant may be too large for the femoral diaphysis. Extensive medullary canal reaming may be necessary to accommodate the larger stem.

**Proximal Porous Coating**

Devices that rely on proximal fixation require good fit and fill in the metaphysis. In revision surgeries, this bone is often sclerotic, fragile, and expanded. A proximally porous-coated device can be used if the metaphysis has sufficient structural integrity to provide rotational and axial stability. With proximal bone destruction, the metaphyseal portion of the implant will need to be larger than in a primary. The diaphysis, by contrast, may be undamaged (Fig. 106.35). The stem of the larger implant may be too large for the femoral diaphysis. Extensive medullary canal reaming may be necessary to accommodate the larger stem.

**Cemented Revision**

The major difference between performing a cemented revision and a cemented primary arthroplasty is in the preparation of the femoral canal. In a primary arthroplasty, there will be healthy cancellous bed proximally and good diaphyseal bone distally. This will not be the case in the revision and the femur will have to be prepared far more thoroughly than in a primary.

**Impaction Grafting**

Impaction grafting uses small pieces of cancellous bone graft to create a new medullary canal into which a component can be cemented. In creating a new canal, bone graft will be compacted into the femur forcefully. The integrity of the femur must be restored to sustain this.

- Sequentially wider reamers are applied until the cortex is contacted. Keep in mind that the size templated is usually within one size of the actual component.
- Plan on reaming to 0.5 mm less than the implant diameter with the Solution (DePuy, Warsaw, IN). This applies to most fully coated nontapered stems, but this amount should be checked for each prosthesis.
- A good test of whether the right size has been chosen is to take a reamer on a T-handle and try to rotate it manually in the canal. The appropriate size provides rotational stability. For example, if you have reamed to 16.0 mm, with plans to implant a 16.5 mm component, use the 16.5 mm reamer on a T-handle to test for rotational stability.
- If rotational stability is not achieved, continue reaming to the next size.
- Perform trial implantation before reaming to the final size. In most systems, the trial broaches are smaller distally than the planned stem.
- If an osteotomy has been performed, tighten a cable around the femur, distal to the osteotomy, before impacting the stem, to decrease the chance of a fracture.
- Measure the prosthesis and femoral canal with calipers. Do the same for the final reamer so that the true size differential between reamer and component is known. Owing to manufacturing and sharpening of the reamers, they may differ from their stated size by as much as 0.5 mm each, leading to a potential 1 mm mismatch.
- Insert the component initially by hand, rotating it back and forth to advance. If more than 5 to 6 cm remains proud, it will be necessary to ream line to line (Fig. 106-34).

**Figure 106.34.** Stem is inserted by hand using an impaction device as a pusher and a reamer through the shoulder of the prosthesis to toggle the component back and forth to advance it.

- After the component has been advanced maximally by hand, begin hitting it with the mallet. At this point, it is crucial to maintain the anteversion as determined by the trial reduction because once the prosthesis engages in the underreamed distal zone, it will be very difficult to rotate.
- The prosthesis should advance with each hammer blow, and the distal femur should be watched for fracture.

**Proximal Porous Coating**

Devices that rely on proximal fixation require good fit and fill in the metaphysis. In revision surgeries, this bone is often sclerotic, fragile, and expanded. A proximally porous-coated device can be used if the metaphysis has sufficient structural integrity to provide rotational and axial stability. With proximal bone destruction, the metaphyseal portion of the implant will need to be larger than in a primary. The diaphysis, by contrast, may be undamaged (Fig. 106.35). The stem of the larger implant may be too large for the femoral diaphysis. Extensive medullary canal reaming may be necessary to accommodate the larger stem.

**Cemented Revision**

The major difference between performing a cemented revision and a cemented primary arthroplasty is in the preparation of the femoral canal. In a primary arthroplasty, there will be healthy cancellous bed proximally and good diaphyseal bone distally. This will not be the case in the revision and the femur will have to be prepared far more thoroughly than in a primary.

- Remove all previous cement and pseudomembrane.
- Burr sclerotic bone down to bleeding bone, being careful to avoid perforation.
- Revisions require more cement than a primary, and two vacuum mixers may be required.

**Impaction Grafting**

Impaction grafting uses small pieces of cancellous bone graft to create a new medullary canal into which a component can be cemented. In creating a new canal, bone graft will be compacted into the femur forcefully. The integrity of the femur must be restored to sustain this.

- Expose the proximal femur completely and clear it of pseudomembrane.
- Examine the femur for cavity and segmental defects.
- Repair segmental defects to convert them to contained defects using mesh or strut grafts, or both, that are held with cerclage wires.
- Cerclage the fragile femur prophylactically with multiple cables before impacting bone graft because graft impaction can generate significant hoop stresses.
- Pass a guidewire through the center of a thick distal intramedullary plug.
- Seat this plug 2 cm distal to any lytic lesion. It is imperative that the plug is solidly in place and that the guidewire be neutrally aligned. If necessary, obtain a radiograph at this point to ensure that the alignment is correct. Perform the bone packing and trial insertion with a cannulated system to guide the position of the
Passing a K-wire transversely through the femur just distal to the plug can prevent distal plug migration.

Prepare cancellous chips of 3 to 5 mm in diameter. Chips that are too small can compromise the fixation by providing insufficient structural support, allowing stem subsidence (33).

Place the graft into the canal and begin impacting it with the cannulated tamps (Fig. 106.36).

Figure 106.36. A: Stages of distal impaction of the graft. See text for description. B: Proximal impaction with cannulated tamps and then trials with vigorous impaction of graft proximally. See text for description.

Continue to pack more bone distally to proximally.

When most of the canal has been filled, use the cannulated tamps (one to two sizes smaller than the prosthesis to be used) to compact bone.

Pack the bone graft tightly—this is considered important to a success. When there is a uniform layer of 5 to 6 mm of bone around the new canal, remove the guidewire.

The graft is impacted with the cannulated tamps (Fig. 106.36). They should be impacted to the appropriate depth as determined by trial reduction. The bone packing should be tight enough to prevent removal of the trial by hand.

The stem used by the developers of this technique is of a highly polished, collarless, double-tapered design. It is intended to subside in the cement mantle with time, thus “engaging” the cement somewhat like a Morse taper (33).

Keep the patient on protected weight bearing for 8 to 12 weeks postoperatively.

Allograft Prosthetic Composite and Strut Grafts

The use of an allograft prosthetic composite (APC) is complex and required infrequently, even at institutions that perform many revisions. Structural allograft is necessary when the host femur is incapable of stable fixation of a revision component (Fig. 106.37). Strut grafts can be used when there are small, noncircumferential segmental defects. A structural allograft will be necessary for circumferential defects greater than 5 cm in length. Proximal circumferential segmental defects less than 5 cm long can be treated with calcar replacing or long-necked components.

Figure 106.37. A: Allograft prosthetic composite. APC performed using modular components with cement distally and uncemented proximally. Junction is reinforced with strut grafts. B: Four and a half years later, the construct is stable. Experience has shown that cementing the proximal portion and uncemented distal fixation gives the best long-term results.

Strut grafts are easily applied and held with cerclage wires and have shown very reliable rates of healing (38). They can be used in many situations to span defects or as you would use plates to support deficient areas.

Proximal femoral allografts are best used with long-stemmed components that are cemented into the proximal segment and press fit distally into the host. This may require custom components because the allograft is often quite narrow, yet the diaphyseal host femur has a large circumference with thin cortices. The junction between allograft and host is important (39) and may be constructed as a butte, step-cut, or side-sleeve junction, or with the allograft telescoped into the host distally (Fig. 106.38). There is no consensus as to which type of junction is the best, but the greater the stability, the greater the chance of graft survival. The type of junction selected depends principally on the rotational stability of the prosthesis in the distal femur. A butte joint may suffice if distal stability is adequate. A step-cut joint can improve rotational stability but is technically more difficult. The junction can also be supplemented with strut grafts and plates for additional stability. Avoid cement intrusion into all junctions.

Figure 106.38. Variety of joints used at the junction of host bone and proximal femoral allograft.

Split the remaining proximal femur in two in the mediolateral plane, extending this distally to good bone.

Preserve the soft tissue attached to the proximal femur. This bone can be wrapped around the allograft to preserve muscular attachments.

Prepare the allograft to accept the prosthesis that best fits the distal femur without overreaming the allograft. This may require custom components because the allograft is often quite narrow, yet the diaphyseal host femur has a large circumference with thin cortices. The junction between allograft and host is important (39) and may be constructed as a butte, step-cut, or side-sleeve junction, or with the allograft telescoped into the host distally (Fig. 106.38). There is no consensus as to which type of junction is the best, but the greater the stability, the greater the chance of graft survival. The type of junction selected depends principally on the rotational stability of the prosthesis in the distal femur. A butte joint may suffice if distal stability is adequate. A step-cut joint can improve rotational stability but is technically more difficult. The junction can also be supplemented with strut grafts and plates for additional stability. Avoid cement intrusion into all junctions.

The prosthesis must achieve stable fixation in the host distally. If the junction between graft and host is above the isthmus, reliable fixation can be achieved in the isthmus. If the junction is distal to the isthmus or the femur is a Paprosky type 4, isthmus fit will not be possible. In this case, the prosthesis will need to be cemented.
into the host or fixed with interlocking screws into a custom implant.

**ACETABULAR REVISION**

**Removal of Acetabular Components**

The goal of acetabular component removal is to minimize loss of acetabular bone. Well-fixed or even partially fixed components that are forced out can result in extensive bone loss and may convert a straightforward reconstruction into a very complex affair. For this reason, consider retaining a stable metal-backed acetabular component. Porous-coated acetabular components are associated with areas of focal osteolysis. This focal osteolysis occurs in noningrown areas where the joint fluid has access to the supra-acetabular region. If this area is limited and the osteolysis does not affect the stability of the cup, it is advisable to retain the cup, apply bone graft to the lesion, and exchange the polyethylene (Fig. 106.39). Six criteria should be satisfied to retain the cup:

1. Cup position must be satisfactory.
2. Socket must be modular.
3. Locking mechanism of the shell must be intact.
4. Metal shell must not be damaged by femoral head penetration.
5. New polyethylene must be at least 8 mm thick.
6. Socket design must have an acceptable track record.

Failure to meet these criteria does not necessitate cup removal. The patient's age, activity level, and the reason for revision also should be considered. However, if two or more criteria are not met, cup removal may be preferable.

Removal of a well-fixed cup can be time-consuming and destructive. The average revision cup is 10 mm larger than a primary cup, reflecting loss of bone secondary to loosening and loss of bone during removal (65). The possibility of cutting a cup into sections should be considered. Cobalt-chrome cups are more difficult to cut than titanium cups. Any cup that is sitting directly on or medial to the teardrop should be sectioned rather than removed with curved osteotomes (Fig. 106.40). Curved osteotomes in this situation can damage the anterior column and injure the intrapelvic structures. We have a low threshold for cutting the cup, which facilitates removal and minimizes bone loss. When cups are more lateral, curved osteotomes can safely be used.

**Removal of Uncemented Components**

Remove uncemented acetabular components as follows:

- Expose all edges of the component. Remove modular polyethylene liners and be prepared for locking mechanisms that may require specialized extraction tools.
- Removal of the polyethylene improves visualization and gives access to the medial aspect of the cup, where there may be screw or insertion handle holes. Check all screw holes for screws, because some shorter screws may not be visible on radiographs.
- Establish a plane at the bone–component interface with a high-speed pencil burr (Fig. 106.41). Develop this plane around the entire perimeter of the cup to a depth of approximately 1 cm. This is easiest superiorly and posteriorly, and becomes more difficult anteriorly and inferiorly. With this plane developed, there is now access to the posterior aspect of the cup.

**Figure 106.39.** Uncemented cup demonstrating the persistence of areas of bone ingrowth despite extensive osteolysis.

**Figure 106.40.** A: Radiograph showing a cup sitting just medial to the teardrop in an osteoporotic patient. B: The use of an osteotome to remove stable cups that sit on or medial to the teardrop results in potentially disastrous anterior column bone loss and risk to intrapelvic structures.

Removal of cemented and porous ingrowth components differs somewhat, but the basic principle is the same: disruption of the interface between the component and the bone. Cemented cups usually have linear rather than focal osteolysis and therefore cannot be bone grafted. They also have a high loosening rate after 10 years, and therefore, they should be retained only if the cup is solid and the patient has a modest life expectancy (43,72).

**Removal of Uncemented Components**

Remove uncemented acetabular components as follows:

- Expose all edges of the component. Remove modular polyethylene liners and be prepared for locking mechanisms that may require specialized extraction tools.
- Removal of the polyethylene improves visualization and gives access to the medial aspect of the cup, where there may be screw or insertion handle holes. Check all screw holes for screws, because some shorter screws may not be visible on radiographs.
- Establish a plane at the bone–component interface with a high-speed pencil burr (Fig. 106.41). Develop this plane around the entire perimeter of the cup to a depth of approximately 1 cm. This is easiest superiorly and posteriorly, and becomes more difficult anteriorly and inferiorly. With this plane developed, there is now access to the posterior aspect of the cup.

**Figure 106.41.** Use a pencil burr to develop the interface between prosthesis and bone, allowing access to curved osteotomes.
At this point, a decision must be made based on preoperative planning. If the cup is medial to or directly on the teardrop, it is advisable to cut the cup and remove it in pieces. Use of osteotomes in the presence of medial bone deficiency can lead to major anteromedial bone loss or injury to intrapelvic structures. Use osteotomes only if there is medial bone present.

- The interface can be disrupted further with curved Moreland instruments. Begin by using the short-curved, and progress to the long-curved, going around the entire perimeter of the cup (Fig. 106.42).

**Figure 106.42.** A: The acetabular gouge can be inserted between polyethylene and cement or between cement and bone. Gentle placement around the edges of the component and cement can loosen them from the underlying bone, allowing removal of the component, cement, or both. B: The cementless cup extractors and levers can lock into the metal portion of the cementless acetabular component. A gentle rocking motion allows extraction of the component. Before levering with these tools, it is important to loosen the bone–prosthesis interface with curved acetabular osteotomes.

- Using an acetabular grabber device, toggle the cup gently to establish areas that are still bonded and concentrate on disrupting them (Fig. 106.42). Neither rock the cup forcefully nor pound it out because this method will lead to bone loss.

Despite complete disruption of the interface, some cups will still need to be cut for safe removal. This is usually because of fibrous or bony ingrowth on the inferomedial aspect of the cup, which is least accessible to the pencil burr and the curved osteotomes.

- Sectioning a stable metal-backed cup is the safest approach to removing it. Section it into two or three pieces under constant irrigation and protect the soft tissues from metal debris. Section a metal-backed component as follows:
  - Having gone through the previous steps, place sponges around the perimeter of the cup to keep metal debris from contaminating surrounding tissues.
  - Use a metal cutting burr under constant irrigation to divide the cup into halves from anterior to posterior.
  - Try to remove the superior half with careful use of the short, curved osteotomes and an acetabular grabber.

The superior half is generally easier to remove than the inferior half, which frequently needs to be divided again. We now proceed directly to a three-limbed Mercedes-type cut, with the top of the star at the 12 o’clock position (Fig. 106.43).

**Figure 106.43.** Acetabular component cut in three to facilitate removal.

**Removal of Cemented Components**

Follow the steps initially outlined for uncemented cup removal, including the development of an interface with the pencil burr.

- Drill into the center of the polyethylene with a large drill (i.e., 6 to 8 mm) and then screw a tap into the hole. Once securely attached to the cup, apply a slotted hammer to the tap. If the cup appears solid, disrupt the cement bond and remove the polyethylene. Cement removal is then fairly easy. Pay attention to cement plugs. It is occasionally necessary to section the cup, which is best done with a saw.

**Assessment of Bone Stock**

Once the component and scar tissue have been removed, carefully assess bony defects. Complete removal of fibrous tissue is necessary. This is especially important inferiorly where the teardrop, or cotyloid fossa, should be identified to establish the appropriate center of rotation. Failure to identify this feature may lead to an inadvertent high hip center.

- Examine the peripheral rim for defects, which may affect cup fixation. The location and size of these defects affects the ability of the acetabulum to support the cup.
- Assess cavitary defects for size to determine bone graft requirements and to determine if they compromise stability.
- Pelvic discontinuity can easily be missed if medial fibrous tissue has not been removed. Most discontinuities have a deceptive fibrous union and should be tested by attempting to move the superior acetabulum and assessing whether the pelvis moves as a unit. The discontinuity usually extends transversely across the acetabulum from the 3 to 9 o’clock positions.

Treatment can proceed based on the preoperative plan and the intraoperative assessment of bone loss. The need for structural grafting can usually be predicted with preoperative templating. Have bone graft in the form of femoral heads, distal femurs, and a hemipelvis available, especially if there is no bone bank. Femoral heads are not very useful as structural grafts.

Structural grafts are required whenever the bone stock of the acetabulum is compromised and cannot provide rigid cup fixation. Allograft can be used to restore bone stock in young patients, who may not require graft for stability. Structural grafts are most commonly needed for segmental defects located superiorly and posteriorly.

- Assess the need for a graft by placing a trial acetabular component after the initial reaming. If the cup is covered by bone superiorly and posteriorly to its widest diameter, the cup will likely be stable. Structural grafts will then be needed for bone stock restoration and not for stability (Fig. 106.44). The planned cup must have greater than 50% host bone contact.
Figure 106.44. A trial component wedged into position can help assess the extent of defects and how these defects affect stability.

- If there is inadequate posterior or superior coverage, structural grafting will be needed.
- At least 50% of the cup must be in contact with host bone.

With these deformities, treat the segmental defect first with a structural graft and provisional fixation. A discontinuity should be plated, and the plate should buttress the structural graft. One can then implant a prosthetic cup if there is more than 50% contact with host bone. A cage or cemented cup and allograft will be required for less than 50% contact with host bone.

**STRUCTURAL GRAFTING**

Small segmental defects can be filled with allograft femoral heads, whereas larger defects will require distal femurs. Very large defects or those of the posterosuperior column will require hemipelvis allografts. As previously discussed, structural grafting can produce successful results if certain principles are followed (30, 31, 38, 78):

- Rigid fixation
- Buttressing of the graft against host bone
- Alignment of the graft trabeculae along the lines of stress transfer
- Placement of screws along the lines of stress transfer.

**"Number 7" Graft**

The "number 7" designation of this graft comes from a distal femoral allograft, where part of the supracondylar area of the allograft is preserved, forming the vertical stem of the seven. The flange that is created is critical to the successful healing of the allograft and is far more stable than femoral heads (Fig. 106.45).

Figure 106.45. Number 7, or hockey stick, graft is cut from the distal femur.

- Prepare the acetabulum to accept the graft by using a reamer to create a more hemispherical defect. This should not be done aggressively, in order to preserve residual bone.
- Use a concave reamer 2 mm larger than that used to shape the defect on the femoral head or distal femur to create a matching shape to the defect.
- Position the graft in the acetabular defect. The supracondylar extension of the "seven" should have intimate contact with the ilium.
- Secure the graft with screws. Plate a discontinuous posterior column, with the plate spanning the allograft.

**Acetabular Allograft**

Fortunately, full acetabular allografts are required only for Paprosky type 3B defects in which there is less than 50% host bone contact. Host coverage of the prosthesis can be assessed with trial components or reamers. Hemipelvic allografts are superior to acetabular allografts because they provide a larger superior flange to allow for fixation to the host pelvis. Male donors are also preferred because their acetabuli have larger inner diameters, which allow for the placement of a larger cage, more cement, and thicker polyethylene. Unlike the femoral heads and distal femurs, the hemipelvic graft must be matched to the side of the patient. The goal is to shape the graft so that it locks into the acetabular defect.

The technique for a full acetabular allograft is as follows:

- Cut the graft from the hemipelvis as shown in Figure 106.46. Leave sufficient bone superiorly to create a large flange that will secure the graft and lock it into place.

Figure 106.46. Allograft pelvic graft: Cut the graft from the pelvis as shown.

- Cut a trough on the medial aspect of the allograft corresponding to the superior and posterior rim of the defect. This locks the allograft into the defect.
- Do not thin the graft excessively while creating a trough or the allograft could be fractured. The trough should be 1 cm wide and approximately 1 cm deep, depending on the size of the allograft.
- The medial surface of the allograft must be shaped to fit the defect. Use the concave reamers on the medial aspect of the allograft. This reamer should be 2 mm larger than the reamer used to size and shape the defect. A barrel-shaped burr is useful to shape the allograft.
- Place the graft in the defect and rotate it until the best fit is achieved. Detailed shaping of the medial surface is usually necessary to achieve an ideal fit.
- Secure the graft to the host with screws through the allograft and into the ilium. A plate along the posterior column crosses the allograft and extends onto the ilium.
Figure 106.47. Graft is secured with screws directed along the lines of force transmission through the flange.

Figure 106.48. A discontinuity must be fixed internally. The most secure method is with use of a posterior plate.

PELVIC DISCONTINUITY

Pelvic discontinuity is rare but requires plate fixation. Discontinuity results from a transverse fracture that extends from the anterior column through the medial wall and out the posterior column (Fig. 106.49). It is often associated with segmental and cavitary bone loss, which may require structural or cancellous grafting. When required, a graft should be performed before the plating. This technique is covered elsewhere.

Figure 106.49. Pelvic discontinuity usually extends from 3 to 9 o'clock.

Despite the disruption of both columns, most cases require only posterior column fixation. Although isolated anterior column deficiencies do not require fixation, isolated posterior column disruption should be plated owing to the tremendous stress placed on the posterior column during weight bearing.

- Expose the ilium superior to the superior rim, and extend this exposure along the posterior rim onto the ischium. The exposure must be performed carefully because this is the most common site of sciatic nerve injury.
- Use the plate templates to obtain a mold of the area to be plated. Curved pelvic reconstruction plates work best and are generally eight holes or greater.
- Mold the plate with benders using the plate template as a guide. Once the plate matches the pelvic anatomy, secure it with screws (Fig. 106.48). Large fragment screws are more secure but can be placed with only limited angulation. Small fragment screws may be oriented with greater freedom, and in cases of severe deficiency, this will increase the chance of secure purchase.
- The fracture site must be compressed, as with all fracture fixation.

Once plated, the acetabulum can be reconstructed using a metal-backed cup or a cage.

With the advent of "jumbo" cups, the majority of acetabular revisions can be performed using a metal-backed cup supplemented with screw fixation. These cups can sometimes be used in the presence of a discontinuity, often with structural allograft in conjunction with posterior plating.

REVISION WITH A METAL-BACKED COMPONENT

Acetabular defects are usually greater in the superoinferior dimension than in the anteroposterior dimension. Placement of a hemispherical cup into an oblong defect dictates that the AP diameter will need to be increased without compromising the rim integrity. The superior portion of the cup may remain partially uncovered as a compromise. This is acceptable as long as the cup has at least 50% contact with host bone. It is important to remember that bone is sclerotic and more fragile in revision surgery.

The goal of reaming is to create a hemisphere. There are usually irregularities in the rim, with areas of protruding bone that may give a false idea of the cup size. This bone can misdirect the reaming if you attempt to remove it with progressively larger reamers. The reamer displaces and destroys good bone.

- Obtain a rough estimate of the acetabular size using either a reamer or a trial component.
- Use smaller reamers to ream irregularities selectively in the rim and in the depth of the cup so that it more closely matches a hemisphere (Fig. 106.50).
**Figure 106.50.** A: Initial reaming should be done with a reamer much smaller than the defect. This should be used to ream areas selectively that may misdirect a larger reamer. B: Using a reamer that more closely matches the final size will lead to good bone being lost as you ream away the minor irregularities.

- Once the periphery and depth of the cup are fairly regular, begin reaming with sequentially larger reamers to create a true hemisphere. Do not compromise the anterior and posterior columns in an effort to obtain superior coverage.
- Place a trial component one to two sizes greater than the last reamer in 40° of horizontal inclination and 20° of anteversion. This position is optimal but may be unobtainable due to compromised bone stock.
- Perform a trial reduction, and if satisfied with the stability, implant the actual component. Mark the anteversion of the trial acetabular component before removing it.
- Perform necessary cancellous bone grafting. Use the last reamer in reverse to compact the cancellous graft.
- Check the component size with calipers and underream by 1 mm. A 2 mm press fit in revisions is sometimes difficult to obtain owing to the sclerotic nature of the bone.
- Drill screw holes into areas most likely to provide fixation. The safe zones for screw placement are posterosuperior and posteroinferior (**Fig. 106.51**). The most dangerous quadrant is anterosuperior.

**Figure 106.51.** The quadrant system divides the acetabulum, with the safest zones for screw placement being posterosuperior and posteroinferior.

- Check the position of the cup and if satisfied proceed with screw fixation.
- Do not tighten any screw fully until all are in place or the cup position can be altered.

**POSTOPERATIVE MANAGEMENT**

Postoperative management should be individualized and include guidelines regarding restricted weight bearing and dislocation.

When a porous-coated component has been implanted, restrict weight bearing to less than 50% of body weight for a minimum of 6 weeks. Extend this period if there are concerns about the stability of the construct. If structural graft has been used on the acetabulum, then extend restricted weight bearing to 12 weeks. Depending on the type of graft, the type of fixation and the component used, weight bearing may be restricted up to 1 year although this is rarely required. Weight bearing is usually restricted for 6 weeks after cancellous grafting. The extended trochanteric osteotomy does not change postoperative management.

The second major concern in the postoperative period is dislocation. Patients are educated about hip precautions, and these warnings are reinforced at each follow-up period. Patients are also placed in a Newport (hip spica-type) brace whenever they are out of bed (**Fig. 106.52**). In patients who have demonstrated instability, the brace is kept on 24 hours a day for a minimum of 6 weeks. The restricted motion allows for soft-tissue healing and muscle strengthening, thus reducing the chance of dislocation. Postoperative management is otherwise comparable to primary arthroplasty.

**Figure 106.52.** Patient with Newport (hip spica-type) brace to limit range of motion and decrease chance of dislocation.

**INTRAOPERATIVE COMPLICATIONS**

**BLOOD LOSS**

Blood loss is far greater in revision surgery, with patients routinely losing 1 to 2 L. The use of nonautologous transfusion can be limited by several methods. Predeposit autologous blood involves the collection of 1 to 4 units of blood from the patient before surgery over a period of several weeks. This blood is then available for transfusion postoperatively. This technique has reduced the need for nonautologous blood significantly. One study demonstrated a need for nonautologous donation in 71% of patients who did not predonate and only 8% in those that did (110). Another preoperative method of reducing nonautologous transfusion is the use of erythropoietin. At present, this method is being used on a restricted basis for orthopedic procedures with several ongoing studies (28). Goldberg et al. found that in those patients that did not predonate the use of erythropoietin reduced the need for nonautologous transfusion from 54% to 17% (36).

Anesthetic techniques also affect blood loss. Epidural and spinal anesthesia have demonstrated lower rates of intraoperative blood loss than general anesthesia (45,92). These regional anesthetic techniques should be used whenever possible. Intraoperatively, blood can be salvaged by washing and anticoagulating aspirated blood, which can be given back to the patient, decreasing transfusion requirements. This procedure should be performed routinely on revision surgeries (195). Postoperative reinfusion of blood collected in drains also salvages lost blood; however, this blood is not washed. This blood can be given back to the patient, although some surgeons have reservations about this technique due to possible contaminants such as fat.
VASCULAR INJURY

Vascular injury occurs in 0.2% to 0.3% of primary total hip arthroplasties (45,74). In revision surgery, the incidence is somewhat higher, although the exact prevalence is difficult to establish (56,84). The most commonly injured vessels are the femoral and external iliac arteries (56). Injuries occur most commonly from placement of retractors over the anterior brim of the acetabulum, where the femoral artery is vulnerable. Injury can also occur during screw placement, with the greatest danger being anterosuperior, where the external iliac vessels are at risk, and anteroinferior, where the obturator vessels are at risk (Fig. 106.51) (48,74). Screws should ideally be placed in the posterior half of the acetabulum where there is less risk of vascular injury and the screw fixation is superior.

NEUROLOGIC INJURY

Neurologic injury occurs in 0.6% to 1.3% of primary total hip arthroplasties (20,41). In revisions, nerve injury is more common and several large series have reported injury rates from 1.4% to 7.5% (20,48). This higher rate of injury associated with revision procedures may be due to several reasons. Direct injury to the nerve is possible from the use of screws, cerclage cables, or the prolonged use of retractors. Also, there is more scar tissue, which may tether nerves, predisposing the nerve to traction. As limb lengthening of greater than 4 cm has been shown to cause neural injury (25,30,41), it is important to plan the revision so that the limb lengthening is limited to 4 cm or less. Limb lengthening can also cause nerve compression and delayed palsy, and if hematomata is suspected, it should be decompressed (48).

POSTOPERATIVE COMPLICATIONS

LIMB LENGTHENING

Limb lengthening is a frequent complication of revision hip surgery and is a common cause of litigation. Lengthening more than 25 mm (1 inch) beyond normal can lead to back or knee pain and increase the risk of neurologic injury. At times, lengthening is required to ensure hip stability. This should be discussed with the patient preoperatively to avoid dissatisfaction postoperatively. Careful preoperative planning and patient education can avoid this problem or diminish its effects.

THROMBOEMBOLIC DISEASE

Prevention of thromboembolic complications is controversial (51). There is little conformity in the prophylaxis of deep vein thrombosis (DVT), with some patients receiving aspirin prophylaxis only, and others receiving heparin or warfarin. A compression stocking combined with heparin, low-molecular-weight heparin, warfarin, or aspirin. Each seems to provide protection to the patient, but it is difficult to determine which is the most effective with the fewest side effects. The incidence of fatal pulmonary embolism after primary total hip arthroplasty is 0.35% (54,59). For large DVTs that form above the knee, treatment should consist of heparin bolus followed by heparin or low molecular weight heparin. For larger DVTs that form below the knee, treatment should consist of warfarin and low molecular weight heparin. Lastly, anticoagulation should be continued for 3 months postoperatively.

Arthrodesis of the hip remains an important tool in the armamentarium of the adult and pediatric reconstructive orthopaedic surgeon. This is because a total hip arthrodesis of the hip is performed more commonly because the sophisticated procedures discussed in the previous paragraph are not readily available and the causes of these disorders is now being prevented. Equally as important, treatment for these disorders has improved substantially, thus avoiding the worst long-term consequences. Other operations developed in the last 30 years of the twentieth century, such as intertrochanteric and periacetabular osteotomies, provide an excellent alternative for young persons with symptomatic arthritis of the hip (see Chapter 5 and Chapter 7).

DISLOCATION

Dislocation complicates 5% to 7% of revision surgery as compared with primary rates of dislocation as low as 2% to 3% (21,69). The higher rate of dislocation can be attributed to several factors, integrity of the soft-tissue envelope in the revision setting, altered abductor attachments, the extensive exposures that are required, and the occasional need for nonanatomic component positioning. Dislocation rates have been linked to gender, with women having almost twice as many dislocations as men. Age, gender, and surgical approach are significant risk factors that are not unique to the revision setting. The most common cause of dislocation in both the primary and revision setting is component malposition, most frequently the acetabular component. Kahn et al. (47) examined recurrent dislocation and found that in 50% of patients, it was due to inadequate anteverision of the acetabulum. The surgeon should also be aware of impingement of the femoral neck on scar tissue anteriorly or on the cup posteriorly. This should be evaluated carefully during surgery. The possibility of impingement is increased when a small diameter femoral head is used with a larger diameter prosthetic neck. Longer neck length femoral heads with a collar that fits over the Morse taper are often required in revisions to obtain stability. The collar may impinge on the femoral neck. Most dislocations occur in the immediate postoperative period. If early dislocation can be avoided, the hip muscles become stronger and a pseudocapsule forms, making dislocation more difficult. All of our patients who have undergone revision surgery are braced in a hip spica-type Newport brace that is worn whenever the patient is out of bed for the first 6 to 8 weeks. The most important factor in preventing hip dislocation is patient compliance. Patients must be educated as to safe and unsafe positions and be provided with any aids such as grabbers that may prevent an unsafe position.

HETEROTROPIC OSSIFICATION

The incidence of heterotopic ossification in revision surgery is somewhat higher than in primary arthroplasty owing to the increased exposure required, especially when the abductors are stripped from the ilium. Routine prophylaxis with radiotherapy is not required. Patients who have demonstrated previous heterotopic ossification are irradiated within 72 hours of surgery with 1 dose of 800 centigrays (80). Indomethacin has been shown to be effective in a once-daily dose for 2 weeks (80). However, nonsteroidal medications interfere with bone ingrowth, and therefore, many surgeons hesitate to use them in the presence of porous-coated components, bone grafts, or osteotomies, although a specific adverse effect on arthroplasties has not been documented (103).

ARTHRODESIIS OF THE HIP

At present, arthrodesis of the hip is rarely performed. Most orthopaedic surgeons specializing in either adult reconstructive surgery or pediatric orthopaedics, even after many years of practice, may have performed only one or two in their career. The vast majority of residents completing training have not performed a hip arthrodesis, let alone having seen one.

During the first half of the twentieth century, arthrodesis of the hip was fairly common because there were few other alternatives available for severe incapacitating arthritis of the hip. With the development of total hip arthroplasty in the 1960s, the indications for arthrodesis of the hip decreased dramatically. Equally as important, the prevention of severe long-term disabling disease of the hip has improved substantially because of increased awareness on the part of primary care physicians and orthopaedic surgeons of developmental dysplasia of the hip, slipped capital femoral epiphysis, and infections in the hip. In developed countries, the severe sequence of these disorders is now being prevented. Equally as important, treatment for these disorders has improved substantially, thus avoiding the worst long-term consequences. Arthrodesis operations developed in the last 30 years of the twentieth century, such as intertrochanteric and periacetabular osteotomies, provide an excellent alternative for young persons with symptomatic arthritis of the hip (see Chapter 104). The development of microvascular surgery and free bone transplant during this same period of time now provides an alternative for the treatment of avascular necrosis of the femoral head, as discussed in Chapter 126. In underdeveloped countries, arthrodesis of the hip is still a viable option and in many cases, a hip disarticulation is performed. In this situation, the surgeon must be aware of the presence of porous-coated components, bone grafts, or osteotomies, although a specific adverse effect on arthroplasties has not been documented (103).

Arthrodesis of the hip remains an important tool in the armamentarium of the adult and pediatric reconstructive orthopaedic surgeon. This is because a total hip arthroplasty has not yet proven to have a sufficient life span in young active people that the procedure is justified unless the patient is willing to face the uncertainties of early revision arthroplasty and eventually either a resection arthroplasty or arthrodesis (14). In spite of their uncertain future, many patients still elect to undergo total hip arthroplasty rather than arthrodesis because of their unwillingness to accept the functional limitations of a fused hip.

The first successful arthrodesis of the hip reported in the literature was that by Huesner of Germany in 1894 (26). Since then, over 20 different techniques to arthrodesis a hip have been described. (43) Hip arthrodeses can be classified into three main categories: intra-articular, extra-articular, or combined intra-articular and extra-articular. Critical distinguishing characteristics of hip fusion are whether or not postoperative immobilization in a spica cast is required or whether rigid internal fixation that eliminates the need for cast immobilization is used, whether subtrochanteric osteotomy is performed, and whether muscle pedicle bone grafts are used. Extra-articular arthrodesis using a 25-mm Norian rod combined with internal fixation has been shown to decrease the risk of subsequent infections such as subtrochanteric. This is because the extra-articular arthrodesis avoided invading the infected area and arthrodesis of the joint combined with other medical treatment often resulted in resolution of the infection. Albee (4,15) and Maragliano (33) described the earliest extra-articular arthrodeses in the 1920s, and Britain (12,13) introduced his ischial femoral arthrodesis in the 1940s. Because these early arthrodeses were performed without internal fixation and used spica cast immobilization, prolonged periods of immobilization were required and nonunion was common. Farkas (23) in 1939 introduced the concept of a subtrochanteric osteotomy below the hip fusion, which prevented direct transmission of forces to the hip fusion by movement of the extremity through the long lever arm of the femur and lower extremity. Abbott and associates (1,2,3,5) further refined this technique, introducing the concept of arthrodesis in wide abduction, followed by secondary subtrochanteric osteotomy to reposition the limb for difficult cases. Watson-Jones (49,50) introduced the use of internal fixation for arthrodesis of the hip as early as 1938. Charnley (17) attempted to improve the success rate by centrally displacing the femoral head into the medial pelvis, combining this procedure with compression screw fixation in an attempt to increase stability. To increase the success rate further, Davis (16,20) used a muscle pedicled bone graft harvested from the anterior ilium to bridge across the hip joint to facilitate early consolidation. This has been modified by...
Ranawat et al. (29) with a particular goal of avoiding injury to the hip abductor musculature in order to provide optimal circumstances for eventual conversion of the arthrodesis to total hip arthroplasty in later life. Truly rigid fixation was used by Müller (35,36). This procedure was refined by Schneider (42), who introduced the cobra-head plate and pelvic ostectomy. These items resulted in one of the most stable arthrodesis constructs available today, which generally does not require any external immobilization. Murrell and Fitch (37) have modified this fusion to preserve the abductors for later conversion to total hip arthroplasty. The original description by Schneider (42) essentially sacrificed the abductors, precluding successful conversion to a total hip prosthesis. Kostuk and Alexander (29,30) modified Schneider's arthrodesis for failed hip arthroplasty in cases in which there is substantial loss of bone stock by using the cobra-plate in combination with an anterior plate producing a double-plate reconstruction. Matta (34) has advocated an anterior approach using an anterior compression plate to optimize conditions for conversion to a total hip arthroplasty but mixed results (11) have not led to its wide adoption as a technique at this time. Other types of fixation have been advocated to improve the union rate or avoid injury to the abductors, including insertion of a compression hip screw across the hip joint into the pelvis (38), intramedullary nail fixation from the ilium to the femoral shaft (6), and augmentation of internal fixation with iliofemoral external fixation (49).

INDICATIONS AND CONTRAINDICATIONS

Hip arthrodesis is a major surgery, even more so than primary total hip arthroplasty, and it has a more difficult postoperative course of treatment because of the time required for consolidation of the arthrodesis. For that reason, arthrodesis is the procedure of last choice for disabling disease of the hip other than resection arthroplasty. Be certain that the patient has had a full and an adequate regimen of nonoperative treatment and that other procedures that would preserve better function such as osteotomies above or below the hip joint have been considered and rejected as feasible, or have failed.

The ideal candidate for hip arthrodesis is an active person younger than 40 years of age, usually a laborer or individual who places high demands on her hip, with severe disabling involvement of one hip, normal health, and no impairment of function in the thoracolumbar spinous process or ilipsoas muscle. The most common indication is posttraumatic degenerative arthritis, and in second is the sequelae of septic arthritis. Other indications are avascular necrosis or cartilage necrosis in the young adult and tuberculosis of the hip, which is rare in developed countries today. Women are less likely to accept arthrodesis, but arthrodeses are compatible with sexual function and vaginal childbirth. The pain pattern of patients with unilateral hip fusion is characterized by increased compensatory motion in the lumbar spine and in the ipsilateral knee, decreased gait velocity, decreased stride length, decreased cadence, and asymmetry of gait (9,24). Barnhardt and Stehl (7) followed six patients who had an arthrodesis at an average age of 30.8 years for an average follow-up of 11.7 years. All patients who were working at the time of arthrodesis returned to work, but all complained of low back pain, all had impaired ambulation due to ipsilateral knee pain; and five of the six believed that their sexual function was impaired. This points out the importance of a thorough workup of the spine and both lower extremities to be certain that the joints above and below the hip fusion are as close to normal as possible. Patients must be warned as they become older that some low back pain and ipsilateral knee pain is expected. Incapacitating back pain is the most common reason for subsequent conversion of an arthrodesis to a total hip arthroplasty.

Contraindications include significant disability or impaired function in the lumbar spinous process and ilipsoas muscle, systemic disease such as rheumatoid arthritis or lupus erythematosus, and active pyogenic infection in the hip. Relative contraindications are an occupation that requires prolonged sitting and extreme obesity. Contraindications are also a relative contraindication; however, total joint arthroplasty on one side and arthrodesis on the other is an acceptable combination for some patients. Poor bone quality because of osteoporosis or metabolic bone disease and major bone loss due to tumors, infection, or revision arthroplasty are associated with a much higher incidence of nonunion, failure, and disability due to shortening of the limb.

Patient selection is critical to success and patient satisfaction. Most young patients today who are candidates for unilateral hip arthrodesis are reluctant to accept the procedure because of the superb short-term results of total hip arthroplasty. It is important to have patients who have undergone a hip fusion available who are willing to talk to patients for fusion because this is the best way to demonstrate the capability of a hip fusion in activities of daily living and gain an understanding of its positive and negative aspects. Sometimes, placing the patient in a removable orthosis with a locked hip hinge or a pantalo-on-type hip spica cast will give him or her a better feeling for its limitations and whether or not they receive relief by immobilization.

PREOPERATIVE PLANNING

Perform a thorough physical examination and history to be certain that the patient meets the indications for the procedure and has no contraindications as described earlier. Radiographs of the ilipsoas muscle are unnecessary if the patient is asymptomatic and the examination is normal. Obtaining an AP and lateral radiograph of the lumbar spinous process is wise, even in asymptomatic patients with a normal examination to rule out occult spinal conditions that might be aggravated by a hip fusion. The focus of preoperative planning otherwise is on the exact technique of fusion to be used. This depends on the patient's bone quality, history of previous surgeries (which may affect the choice of surgical approach), and the condition of the hip as far as whether its configuration is fairly normal or there is pre-existing bone loss, shortening, but all complained of low back pain; all had impaired ambulation due to ipsilateral knee pain; and five of the six believed that their sexual function was impaired. This points out the importance of a thorough workup of the spine and both lower extremities to be certain that the joints above and below the hip fusion are as close to normal as possible. Patients must be warned as they become older that some low back pain and ipsilateral knee pain is expected. Incapacitating back pain is the most common reason for subsequent conversion of an arthrodesis to a total hip arthroplasty.

Contraindications include significant disability or impaired function in the lumbar spinous process and ilipsoas muscle, systemic disease such as rheumatoid arthritis or lupus erythematosus, and active pyogenic infection in the hip. Relative contraindications are an occupation that requires prolonged sitting and extreme obesity. Contraindications are also a relative contraindication; however, total joint arthroplasty on one side and arthrodesis on the other is an acceptable combination for some patients. Poor bone quality because of osteoporosis or metabolic bone disease and major bone loss due to tumors, infection, or revision arthroplasty are associated with a much higher incidence of nonunion, failure, and disability due to shortening of the limb.

Patient selection is critical to success and patient satisfaction. Most young patients today who are candidates for unilateral hip arthrodesis are reluctant to accept the procedure because of the superb short-term results of total hip arthroplasty. It is important to have patients who have undergone a hip fusion available who are willing to talk to patients for fusion because this is the best way to demonstrate the capability of a hip fusion in activities of daily living and gain an understanding of its positive and negative aspects. Sometimes, placing the patient in a removable orthosis with a locked hip hinge or a pantalo-on-type hip spica cast will give him or her a better feeling for its limitations and whether or not they receive relief by immobilization.

PREOPERATIVE PLANNING

Perform a thorough physical examination and history to be certain that the patient meets the indications for the procedure and has no contraindications as described earlier. Radiographs of the ilipsoas muscle are unnecessary if the patient is asymptomatic and the examination is normal. Obtaining an AP and lateral radiograph of the lumbar spinous process is wise, even in asymptomatic patients with a normal examination to rule out occult spinal conditions that might be aggravated by a hip fusion. The focus of preoperative planning otherwise is on the exact technique of fusion to be used. This depends on the patient's bone quality, history of previous surgeries (which may affect the choice of surgical approach), and the condition of the hip as far as whether its configuration is fairly normal or there is pre-existing bone loss, shortening, or other considerations that may require specialized techniques to ensure fusion or regain some leg length.

SURGICAL TECHNIQUE

The most important goal is to achieve appropriate position of the arthrodesis, which is important to optimize function and minimize and delay both the incidence and the severity of subsequent low back and ilipsoas muscle pain. Recommendations for positioning of the arthrodesis have varied from $20^\circ$ to $45^\circ$ of flexion, $10^\circ$ of adduction to $10^\circ$ of abduction, and neutral to $20^\circ$ of external rotation (14). Benaroch et al. (8) found in 13 adolescents, who were operated on at an average age of 15.8 years at an average of 6.6 years follow-up, some adduction drift in the fusion. The lowest incidence of low back pain occurred when their fusion was between $20^\circ$ to $25^\circ$ of flexion, less than $2$ cm short, and $0^\circ$ of abduction. Based on my personal experience and a consensus of the literature, I suggest placing the hip in $20^\circ$ of flexion and neutral abduction, and placing the foot in the plane of the progression of gait to match the opposite normal side, which is usually $0^\circ$ to $10^\circ$ of external rotation.

The next most important goal is to achieve fusion. A high union rate is achieved by resecting any necrotic bone and ensuring that well-vascularized bone of the femoral head and acetabulum are in apposition, maximizing the cancellous bone surfaces in contact, using rigid internal fixation, and when necessary, augmenting fusion with an iliac crest bone graft or a vascularized muscle pedicle graft, or both.

Because hip fusion today is most commonly performed in young adults and the incidence of subsequent low back pain seems to be significant, the need for conversion to total hip arthroplasty once the hip is older than 60 years of age is quite high. For that reason, use a technique that preserves the function of the hip abductor muscles as well as other important muscles about the hip.

Last, by using rigid internal fixation in the presence of good quality bone. It should be possible to avoid any external immobilization. It is wise to have patients use crutches until the fusion is solid but the lack of an orthosis or spica cast enables them to rehabilitate quickly and keep unaffected joints and muscles in good condition.

The following techniques and modifications meet these criteria.

CABANELA AND PAGNANO HIP ARTHRODESI

In the second edition of this book, Cabanela described a simple intra-articular fusion technique combined with internal fixation and postoperative external support with a single spica or mini-spica cast (14,38).

- Position the patient on a fracture table, placing the foot in the hip holder on the traction device for the table.
- Expose the hip joint through a standard Watson-Jones approach (see Chapter 3). Detach the anterior third of the gluteus medius insertion into the greater trochanter to facilitate exposure of the hip.
- Expose the hip and flex the joint and place the capsule on stretch and to relax the femoral nerve and vessels to keep them away from the operative field.
- Detach the reflected head of the rectus femoris from the femoral head and then perform a sufficiently large anterior capsulectomy that dislocation of the hip anteriorly is possible.
- Have a nonsterile assistant remove the foot from the foot holder and place the leg into a figure-of-four position, which facilitates dislocation of the hip. Complete capsulectomy is sometimes required to mobilize the femoral head and to obtain access to the acetabulum.
- Holding the femoral head out of the way, totally debride the acetabulum down to bleeding cancellous bone. Begin with sharp long curets to remove the cartilage and soft tissue and then ream the acetabulum with a debris retaining reamer (Fig. 106.53).
The Modified Ranawat Technique involves using a muscle pedicle bone graft to ensure healing of a hip fusion. If a muscle pedicle bone graft is needed, this is now my preferred technique.

To preserve the function of the abductors, Ranawat et al. in 1971 described harvesting the muscle pedicle bone graft with osteotomes, which I prefer because it minimizes the risk of fracture. Davis (19,20) described the use of the anterior ilium containing the origins of the sartorius and rectus femoris muscles as a muscle pedicle bone graft. If a muscle pedicle bone graft is needed to ensure healing of a hip fusion, this is now my preferred technique.

** figure 106.53.** Dislocate the hip and ream the acetabulum with debris-retaining reamers.

** figure 106.54.** Debride the femoral head down to bleeding cancellous bone using a surface replacement femoral reamer of a size similar to that of the acetabulum.

** Postoperative Care**

- When the patient is comfortable, which is usually by the second or third postoperative day, have physical therapy stand the patient at bedside and begin walking with assistive devices supporting the weight of the limb on the floor but allowing no weight bearing.
- Before hospital discharge, it is usually wise to change the spica cast because this gives surgeons the opportunity to check the wound, remove staples or sutures, apply adhesive wound closures if appropriate, and apply a much more snug, better fitting cast.
- The home environment requires an overhead frame with a trapeze attached to either a regular or a hospital bed for 3 months.
- Before tightening the screws to compress the femoral head into the acetabulum, perform a subtrochanteric osteotomy.
- Reduce the hip and place the extremity in appropriate position for the fusion. Internally fix the femoral head to the acetabulum by inserting two 6.5 mm cancellous bone screws around the hip screw. Insertion of two 6.5 mm cancellous bone screws around the hip screw supplements and improves the fixation.
- Ensure that the hip is in proper position and internally fix the proximal femur to the acetabulum with a compression hip screw, using a side plate of 135° to 140° with three to four screws in the side plate.
- The technique for inserting the hip screw is identical to that for standard hip fracture fixation except that the guide pin is inserted across the hip joint into the superior-medial bone of the acetabulum and the compression screw is placed into the solid bone in the acetabulum. Fix the side plate to the femur and then use the compression screw of the device to apply compression across the joint.
- Insertion of two 6.5 mm cancellous bone screws around the hip screw supplements and improves the fixation.
- Ensure hemostasis, place a drain at the level of bone, and close the wound in layers in the usual accepted fashion.
- Apply a sterile dressing and then place the hip into a single hip spica while on the fracture table.

Benaroch and associates (6) described a simple method of hip arthrodesis for use in adolescent patients.

**ARTHRODESIS WITH A MUSCLE PEDICLE BONE GRAFT**

Davis (19,20) first described in 1954 the use of a muscle pedicle bone graft in fusion of the hip. The difficulty with his technique is that it transfers the origins of the tensor fascia lata and the anterior fibers of the gluteus medius and minimus, which can significantly interfere with the function of the hip if later conversion to a total hip arthroplasty is required. To preserve the function of the abductors, Ranawat et al. in 1971 (39) described the use of the anterior ilium containing the origins of the sartorius and rectus femoris muscles as a muscle pedicle bone graft. If a muscle pedicle bone graft is needed to ensure healing of a hip fusion, this is now my preferred technique.

**Modified Ranawat Technique**

- Position the patient in the lateral decubitus position on a fracture table supporting the trunk, pelvis, and lower extremity in the appropriate position.
- Expose the hip, anterior pelvis, and proximal femoral shaft through a modified Smith-Petersen approach. Expose the inner table of the ilium, iliac crest, the anterosuperior and anteroinferior iliac spines, and the pubic portion of the acetabular rim. Leave the sartorius and rectus femoris origins intact.
- Next harvest the muscle pedicle bone graft from the anterior ilium, including the origins of the sartorius and rectus femoris muscles, as illustrated in Figure 106.55. Although Ranawat et al. described harvesting the pedicle bone graft with osteotomes, I prefer an oscillating saw because it minimizes the risk of fracture of either the graft or the ilium. With the oscillating saw, transect the ilium 4 cm medial to the anterosuperior iliac spine (ASIS) and cut inferiorly parallel to the anterior border of the ilium to enter the acetabulum and then exit anteriorly, including the anteroinferior iliac spine (AIIS). Reflect the graft inferiorly and away from the hip joint to avoid injury to the origins of the hip abductor muscles.
HIP ARTHRODESIS WITH COBRA-PLATE FIXATION

Although this arthrodesis provides excellent fixation, Schneider's (42) original technique required sacrifice of the abductor mechanism. Murrell and Fitch (37) have modified Schneider's technique to preserve the function of the hip abductors in the event later conversion to total hip arthroplasty becomes necessary. The primary disadvantage of this technique and any technique that uses a plate for fixation is that the end of the plate becomes a stress riser below the stiff hip and the potential site for fracture in the event of significant trauma.

Murrell and Fitch Technique

- Position the patient supine on a radiolucent operating table with a bump under the ipsilateral buttock. The authors prepare and drape both lower extremities, including the pelvis, because this method permits better assessment of leg lengths and allows a Thomas test to be performed to verify the amount of flexion in the arthrodesis after temporary fixation. Make a mid-lateral longitudinal incision beginning 3 to 4 cm distal to the iliac crest extending directly over the prominence of the greater trochanter to a point 8 cm distal to the tip of the greater trochanter.
- Incise the fascia lata in line with a skin incision and place a Charnley retractor. Identify the sciatic nerve and protect it throughout the procedure.
- Reflect the vastus lateralis off the lateral intermuscular septum and release its origin and elevate it medially to expose enough shaft of the femur for application of the cobra plate. Delineate the anterior and posterior margins of the gluteus medius and minimus insertions.
- With an oscillating saw, ostotomize the greater trochanter, as illustrated in Fig. 106.55. Reflect the trochanter and attached hip abductors superiorly off the joint capsule and hold them with two large Steinmann pins inserted into the iliac wing (Fig. 106.55A).}

Postoperative Care Ranawat et al. immobilized patients in a one and one-half hip spica cast for 6 weeks, and they modified the cast to allow knee motion at about 6 weeks depending on the stability of the fusion. In their 10 patients, they performed a subtrochanteric ostotomcy in five. All but one hip fused in a patient who did not have a subtrochanteric osteotomy, and one subtrochanteric osteotomy went on to nonunion. For a typical case see Figure 106.57.
**Figure 106.58.** Murrell and Fitch modification of the AO cobra-plate arthrodesis of the hip. A: After exposure of the hip and proximal femur, osteotomize the greater trochanter, preserving the attachments of the hip abductors to the trochanter. B: Reflect the greater trochanter and attached glutaeus medius and minimus superiorly, exposing the supra-acetabular area by super perioseal dissection. Maintain the retraction of the greater trochanter with two Steinmann pins inserted into the ilium. Expose the lateral acetabulum from the sciatic notch posteriorly to the iliopectineal eminence anteriorly and place two blunt Hohmann retractors to protect the soft tissues anteriorly and the sciatic nerve and gluteal vessels posteriorly. The line of the osteotomy through the ilium is illustrated. C: Displace the distal acetabular fragment and femoral head medially, approximately the width of the ilium at the site of the osteotomy, and temporally fix a nine-hole cobra plate to the lateral aspect of the ilium, just above the osteotomy, and to the shaft of the femur, using the AO tensioner. Apply compression after the desired position of the hip has been obtained. D: Complete the fixation by securing the cobra plate to the ilium with six screws. Reattach the greater trochanter in an anatomic position with a screw and washer. (Washer is not shown). E: Lateral view of the fixation. (From Murrell GA, Fitch RD. Hip Fusion in Young Adults, Using a Medial Displacement Osteotomy and Cobra Plate. Clin Orthop 1994;300:147, with permission.)

- Complete the exposure with a capsulotomy of the hip. The hip capsule can be excised as necessary to gain exposure. Elevate the peristemeum off the outer table of the iliac wing to the sciatic notch posteriorly and to the ASIS and AIIS anteriorly. Place blunt Hohmann retractors in the sciatic notch to protect the sciatic nerve and superior gluteal vessels and a second retractor anteriorly over the iliopectineal eminence.

- With an oscillating saw, make a transverse osteotomy of the ilium from lateral to medial, extending from the iliopectineal eminence to the sciatic notch at the superior edge of the acetabulum, taking an 0.5 cm wafer of bone from the superior pole of the femoral head. Do not cut completely through the ilium with the oscillating saw, but complete the osteotomy with an osteotome to avoid cutting intrapelvic neurovascular structures.

- Remove cartilage and sclerotic cortical bone down to bleeding cancellous bone from the acetabulum and the superior half of the femoral head using curets and osteotomes.

- Reduce the femoral head into the acetabulum, and displace the femur and the distal portion of the acetabulum medially for a distance equal to the full thickness of the ilium at the osteotomy. Facilitate this procedure by placing a curved blunt instrument such as Hohmann retractor into the osteotomy to level the distal pelvic distally.

- Temporarily secure the cobra-plate with one screw in the proximal fragment and the compression screw in the femur, as illustrated in Figure 106.58C.

- To confirm proper position of the hip fusion, remove the bump under the hip and insert Steinmann pins into the right and left ASIS. Or simply palpate the ASISs to be certain that the limb is positioned into neutral abduction or adduction. Determine the position of rotation, which should be 0° to 10° by noting the position of the patella and malleoli relative to the ASIS. With the patient lying flat on the table, the hip will normally be in approximately 20° flexion. This can be confirmed with radiographs. Before completing the fixation, take AP and lateral radiographs, including the entire pelvis on the AP view, to confirm position. Use a Thomas test to be certain that the position is good, compress the hip with the AO tensioner and secure the plate to the ilium above and femur below by filling the remaining screw holes with biocortical 4.5 mm cortical screws. Secure the greater trochanter in anatomic position, as seen in Figure 106.58D and Figure 106.58E by drilling a hole through the middle of the trochanteric fragment and fragmenting it back into position using a screw and washer inserted through the appropriate hole in the plate. Pack cortical cancellous bone obtained from the debridenment of the hip around the joint and take final radiographs to verify the position of the fusion and fixation.

- Thoroughly irrigate the wound, place drains, and perform a layered closure.

**Postoperative Care**

- Encourage patients to be out of bed and bear partial weight as soon as they are comfortable and no later than the second or third day after surgery.

- Continue partial weight bearing to the weight of the limb with two crutches for 6 weeks. Early motion and gentle muscle rehabilitation can begin for unaffected joints.

- Radiograph the hip at 6 weeks and then at 6-week intervals until solid union is evident, which is usually around 12 to 14 weeks postoperatively. At that time, progress the patient to full weight bearing as tolerated.

Murrell and Fitch reported on the results in eight patients operated on at an average of age 17 years with a follow-up interval from 1 to 4.5 years. All eight hips went on to union, with no significant complications. The mean preoperative Harris hip score was 45 points, and the average at follow-up was 84 points. The average shortening of the operated limb was 2.6 cm, with a range of 0 to 4.7 cm. A typical patient is seen in Figure 106.59.

**Figure 106.59.** A: Preoperative radiograph of a 13-year-old boy with a severely painful, stiff, adducted hip and leg length discrepancy of 4 cm, secondary to slipped capital femoral epiphysis (SCFE) with avascular necrosis of the femoral head. B: AP radiograph showing solid fusion of the hip. The patient had a 7 cm leg-length discrepancy, which was equalized with Ilizarov femoral lengthening. (From Murrell GA, Fitch RD. Hip Fusion in Young Adults, Using a Medial Displacement Osteotomy and Cobra Plate. Clin Orthop 1994;300:151, with permission.)

**ARTHRODESIS WITH AN ANTERIOR PLATE**

In spite of the modification of Murrell and Fitch of the cobra-plate arthrodesis of the hip, the pelvic osteotomy and extensive surgery in the abductor mechanism will no doubt compromise eventual function of the abductor mechanism if a total hip arthroplasty is performed. Matta described a technique using anterior plate fixation to avoid any interference with the hip abductors.

**Modified Matta Technique (34)**

- Position the patient supine on a radiolucent operating table.

- Through a Smith-Peterson approach (see Chapter 3) expose the hip joint, proximal femoral shaft, and the inner pelvic brim by taking down the sartorius origin position of the iliacus muscle to expose the iliofemoral line. Avoid dissection on the outer wall of the ilium in the region of the hip abductors.

- Dislocate the hip anteriorly and prepare it for intra-articular arthrodesis as described for the Cabanela fusion. Relocate the hip, and fix it in appropriate position using multiple 6.5 cancellous screws inserted from the prominence of the greater trochanter up the femoral neck across the joint into the acetabulum.

- With an osteotome or oscillating saw, make a slot on the iliopectineal eminence on the anterior border of the acetabulum and partially into the femoral head to accommodate an AO 4.5 mm broad plate. Use a template to delineate the configuration of the anterior aspect of the femur through the slot and up the inner wall.
The complications of major trauma, most of the arthrodeses I have performed have been in the presence of pre-existing deformity; loss of bone stock, particularly in the quoted earlier to refamiliarize themselves with the important technical details of this challenging operation. Because my practice is predominantly reconstruction after orthopaedic surgeons today perform hip arthrodesis infrequently. Only in the practices of adult reconstructive hip surgeons doing large numbers of revision arthroplasty are discussed in the first section of this chapter.

Brien et al. (11) performed anterior compression plate arthrodesis in 16 patients followed for an average of 4.5 years after surgery. Of 11 patients undergoing primary fusion, five (45%) did not heal. More important, five patients undergoing repeat fusion for a previously failed surgical arthrodesis did not heal. They concluded that anterior plate fixation alone was inadequate in patients with limited bone stock, and I would agree. The anterior plate must be combined with intra-articular arthrodesis and intra-articular compression fixation at right angles to the plate to obtain sufficient stability. It can be combined with cobra-plate fusion for arthrodeses in the absence of the femoral head, as described below.

**ARTHRODESIS OF THE HIP IN THE ABSENCE OF THE FEMORAL HEAD**

In the early part of the twentieth century, the most common cause of loss of the femoral head and bone stock around the hip was infection due to trauma. Neglected nonunion of the femoral neck in conjunction with osteonecrosis of the femoral head can also result in substantial bone loss. Today, the most common cause of loss of the femoral head and bone stock is fracture of total hip arthroplasty.

Abbott et al. (1,2,3) described arthrodesis of the hip in wide abduction, placing the proximal femur into the acetabulum to achieve arthrodesis. Patients were treated in a spica cast in wide abduction, and when the arthrodesis was solid, they performed a subtrochanteric osteotomy with bilateral spica cast immobilization to place the limb in functional position. Because of the staged surgery and prolonged immobilization in a spica cast, I am not aware that this procedure is being performed today.

Bosworth (10) described a method for arthrodesis of the proximal femur to the ischium when the femoral head was absent. Achieving fusion between the femoral shaft and the ischium was challenging owing to limited bone stock and the inability to fix this fusion internally.

Kostuik and Alexander (28,30) described a modification of the cobra-plate technique for arthrodesis after removal of a failed total hip arthroplasty.

**Kostuik and Alexander Technique**

- The technique is performed as described earlier for the Murrell and Fitch modification of the cobra-plate arthrodesis with the following modifications:
  - After removal of the hip prosthesis components from the acetabulum and femur insert the remaining proximal femoral shaft into the acetabulum and internally fix to the ilium with a high cobra plate. Kostuik and Fitch advocate placing the hip into 5° to 10° of abduction to compensate for the shortening, which in their group averaged 4.6 cm. The only disadvantage of this method is that it forces the patient to walk with a constant pelvic tilt. I believe that fusing the patient in a neutral position and then either using shoe lifts or equalizing the leg length with a lizarov lengthening or closed intramedullary shortening of the opposite femur, if the patient desires, to have leg lengths equalized, is a better choice.
  - Next, harvest an iliac crest bone graft and pack it around the arthrodesis site.
  - Reattach the greater trochanter. If needed, the trochanter can be fixed across the arthrodesis site to function as a muscle pedicle bone graft.
  - Finally, add an AO broad plate anteriorly, as described above for the Mita fusion.

**Postoperative Care**

Because the bone stock in these patients is deficient and the bone is often osteoporotic the authors recommend routine use of a hip spica cast postoperatively. They continued this for an average of 3.3 months, at which time it was discontinued and the patient was then gradually progressed to full weight-bearing using assistive devices. They reported their results in 14 patients. Of these 14 patients, the arthrodesis healed in 13. One nonunion occurred in a patient in whom only the cobra plate was used. With repeat grafting, this nonunion healed. All patients were ambulatory; three used a cane, and nine returned to sedentary work.

**FIT P A T T L E S AND COMPLICATIONS**

Proper patient selection, careful surgical technique using compression fixation across broad surfaces of bleeding cancellous bone, combined with adjunctive fixation and muscle pedicle bone graft in difficult cases, and protecting the fusion as necessary postoperatively will minimize the occurrence of complications (13). Use prophylactic antibiotics routinely. In most cases, previous surgery will have been performed, which increases the incidence of infection somewhat. In these cases, do not administer antibiotics until deep cultures of the bone and soft tissues in the hip are taken and then institute intraoperative antibiotics. If cultures are positive, treat the patient with the appropriate antibiotics for 6 weeks postoperatively. Prophylaxis against thromboembolic problems is indicated. Nonunion rates of 10% to 35% occur with traditional techniques (9,16,46). However, modern techniques of arthrodesis, even after failed arthroplasty, have reduced the nonunion rate to 0 to 7% (15,21,28,29,30,37,38,41,47). Malunion is rare today if internal fixation is used (22). The challenge is determining the position of the hip intraoperatively. I find that using a fully radiolucent operating table and positioning the patients supine enhances the changes of obtaining optimal position for the arthrodesis. The double bean bag technique of Blasier and Holmes (3) can be adopted for the supine position.

**RESULTS**

Long-term follow-up of patients with hip arthrodesis shows a high incidence of patient satisfaction of 70% after 30 years' follow-up (15,43). There is little question that the patient with severe disabling pain and instability of a hip has improved function after a hip arthrodesis. Murrell and Fitch (37) showed an improvement in the Harris hip score from 45 points to 84 points in their eight patients. Roberts and Fetko (41), with 8.5 years of average follow-up in 10 young patients, showed 70% with good or very good pain relief and 90% with good or excellent functional results. However, longer term follow-up shows that most patients develop symptomatic low back pain and ipsilateral knee pain, which can impair function. This problem can be minimized by achieving ideal position of the hip fusion. However, in our aging population, these problems will lead to an increasing incidence of conversion of hip arthrodesis to total hip arthroplasty. Therefore, techniques that preserve the anatomic relationships of the hip and protect the abductor mechanism are important (7,9).

**CONVERSION OF HIP ARTHRODESIS TO TOTAL HIP ARTHROPLASTY**

As mentioned earlier, conversion of a hip arthrodesis to total hip arthroplasty is usually indicated for disabling low back or ipsilateral knee pain that is not responsive to nonoperative treatment. Malposition of an arthrodesis is also an indication for THA if an osteotomy to correct the position is not appropriate. Kreder et al. (31) reported on 40 patients who had an arthrodesis converted to a hip replacement. These patients had a 10% rate of infection and 10% incidence of revision. Five percent had the prosthesis removed and went on to resection arthroplasty owing to infection within 4 years of the conversion. These results point out that there is a high rate of complications associated with conversion of a hip arthrodesis to arthroplasty. Patients must be made aware of these potential outcomes before undergoing conversion. Klugius et al. (27) described conversion of 41 fused hips in 38 patients to a total hip replacement, with an average follow-up of 7 years. The postoperative arc of flexion averaged 97° and LLD averaged 2.5 cm. They noted that hip abductor muscle strength improved for at least 2 years after arthroplasty. The majority of patients experienced complete or significant relief of pain, improved mobility of the hip, and decreased dependence on walking aids. In the 41 hips, there were nine failures—four because of sepsis, four because of loosening, and one because of malposition of the acetabular component. Survivorship analysis of the prosthesis predicted a probability of survival of the implant of 96% at 13 years postoperatively. Rittmeister et al. (45) addressed the issue of total knee replacement for a failed hip arthrodesis. They suggested that a knee replacement alone in a patient with a fused hip is not likely to provide a satisfactory outcome. They recommended conversion of the hip fusion to a total hip arthroplasty, followed by total knee replacement. The details of conversion of hip arthrodesis to a total arthroplasty are discussed in the first section of this chapter.

**AUTHOR'S PERSPECTIVE**

Orthopaedic surgeons today perform hip arthrodesis infrequently. Only in the practices of adult reconstructive hip surgeons doing large numbers of revision arthroplasties is hip fusion reasonably common. These procedures are large operations that require attention to technical details to ensure a high rate union with good functional position of the hip. I advise all surgeons who perform hip arthrodesis infrequently not to only read a chapter such as this but also return to the original articles quoted earlier to familiarize themselves with the important technical details of this challenging operation. Because my practice is predominantly reconstruction after the complications of major trauma, most of the arthrodeses I have performed have been in the presence of pre-existing deformity; loss of bone stock, particularly in the
femoral head and neck; and often after infection. In undertaking fusion under these circumstances, it is important to avoid the complication of infection by resolving any
infection preoperatively and avoiding arthrodesis until there has been an infection-free interval of at least 1 year. Second, take deep cultures of bone and soft tissues,
and treat the patient prophylactically with antibiotics until cultures return negative. If cultures are positive, treat the patient with 6 weeks of appropriate intravenous
antibiotics.

To obtain optimal position of the hip, I prefer to place the patient supine, modifying the double bean bag technique (3) to ensure perfect position of the hip arthrodesis in
neutral abduction, 20° of flexion, and slight external rotation before prepping the hip. I confirm this with radiographs before the skin incision. I find this much easier to do
before prepping and draping the patient, and the double bean bag ensures that the position is maintained at the time of internal fixation.

For the arthrodesis itself, I frequently combine techniques. When there is loss of bone substance, I perform an intra-articular fusion with compression screw fixation
across the hip joint combined with an anterior plate, or I will use the modified double plate–cobra plate method described by Kostuik and Alexander (39). To this I will
add the anterior iliac crest muscle pedicle bone graft (39). I have not used a postoperative spica cast in adults for 20 years because I can usually obtain sufficiently
stable fixation that external immobilization is not necessary.

INTRODUCTION

Osteotomy of the tibia or femur was originally used to address osteoarthritis of the knee. Surgery was performed to shift load bearing from one arthritic biobifemoral compartment to the other, less affected compartment. Success rates of 85% at 10 years (19) and 63% at 9 years (24) are reported after high tibial osteotomy (HTO) for medial compartment arthritis. Current prosthetic knee arthroplasty techniques have provided successful results in over 93% of patients at 10 years (12). The role of osteotomy has decreased in the face of these outstanding results from joint replacement (50). Prosthetic arthroplasty requires activity modification to protect the implant. The implant also has a finite life span and may require repeated surgery to replace failed devices. Realignment osteotomy is viewed as a way to allow unrestricted patient activity and to delay the time to joint replacement surgery (23, 46, 47).

HISTORY

Sir Robert Jones first reported on the use of tibial realignment osteotomy to correct severe genu varum from rickets (47). Jackson (25) was the first to report his experience with femoral and tibial osteotomies to treat osteoarthritis with associated valgus and varus knee alignment. Jackson and Waugh (28) published a more detailed follow-up report. Their greatest success was with tibial osteotomy to correct varus knees. Subsequent reports by Wardle (47), Garépy (15), and Coventry (5) more clearly defined the indications and techniques of the operation, specifically an osteotomy performed between the tibial tubercle and the joint line.

PATHOPHYSIOLOGY

Realignment osteotomies are based on the presumption that excessive force is carried across the joint from the abnormal alignment of the limb leads to degeneration within the affected joint compartment (5, 26). A cadaveric model has demonstrated that increased contact pressures in the knee accompany increasing varus or valgus alignment of the tibia (33). With time, the excessive pressure leads to breakdown of the cartilage matrix, with loss of the cartilage structural integrity (3). The altered stress may also cause architectural changes in the subchondral bone, further altering the joint geometry (4). In the medial compartment of the knee, for example, once arthritis is established, serial examination reveals clinical and radiographic progression in nearly all cases (39). The goal of realignment osteotomy has been traditionally to alter the vector of forces across the knee, to unload the affected compartment, and thereby to gain relief of pain.

HIGH TIBIAL OSTEOTOMY

The most commonly performed procedure for medial osteoarthritis is a lateral closing wedge, valgus-producing proximal osteotomy. Valgus malalignment is usually due to lateral femoral condylar undergrowth and is best addressed through distal femoral osteotomy (16).

INDICATIONS

The main indication for valgus (HTO) is knee pain with isolated medial compartment arthritis on radiographs (1, 16, 22, 24). Also, patients with anterior cruciate ligament insufficiency with medial joint space narrowing will benefit from osteotomy. Osteotomy alone or in conjunction with anterior cruciate ligament reconstruction will help remove the varus forces that are present. The patient will generally report morning stiffness and medial knee pain with weight bearing that is relieved with rest and anti-inflammatory medication. The patient's arthritis should be from a structural cause due to osteoarthritis or posttraumatic arthritis. Knee range of motion should approach 90° of flexion with full extension. Any laxity should be addressed before osteotomy, although a lateral closing wedge osteotomy performed above the tibial tubercle can tighten the medial collateral ligament (16) by creating a valgus force sufficient to cause an opening of the medial joint. Also, performing an open-wedge osteotomy on the medial side will tighten the medial collateral ligament.

The patient's age is a significant factor to consider. Osteotomy is traditionally reserved for patients younger than 65 years of age; however, older patients with high activity levels may be candidates for HTO, whereas younger patients with lower activity levels may be candidates for knee replacement. The decision to operate must be individualized to each patient's circumstance.

The most significant contraindication to valgus-producing osteotomy is symptomatic or radiographic arthritis in one or both of the other joint compartments. Other generally accepted contraindications are varus deformity greater than 15°; flexion contracture greater than 15°, or underlying inflammatory arthritis (1, 6, 37, 42). The procedure, by design, results in valgus alignment of the lower extremity, which may be unacceptable to some patients.

PREOPERATIVE PLANNING

The patient's history of symptoms should be typical for arthritis. Inspect the affected leg for alignment, fixed knee deformities, range of motion, stability, and the integrity of the skin on the knee. Radiographs of the knees during weight bearing demonstrate the extent of arthritis and loss of joint space. Single standing, full-length radiographs offer the best method to determine limb alignment and to plan the osteotomy (19).

We prefer the method developed at Nara University (34, 38) for determining the degree of resection performed with a lateral closing wedge (Fig. 107.1).
First, draw the predicted mechanical axis of the affected limb on the full-length radiograph by connecting a point from the center of the hip to a point on the lateral tibial plateau that is one third of the way from the center of the knee to the lateral margin of the lateral plateau (line A). Extend this line to the level of the ankle.

- Make a second line (line B) from the point on the proximal medial tibia that will be the pivot point of the osteotomy to a point in the center of the ankle.
- Draw a third line (line C) from the medial pivot point to a point on the predicted mechanical axis (line A) that is at the level of the ankle. The angle (X) between the second and third lines (lines A and B) is the angle of the wedge to be resected.

The method outlined earlier only addresses deformity in the medial or lateral plane. Paley et al. (40,41) have pointed out that the center of rotation of the deformity, while close to the knee joint, can vary in position from patient to patient. The apex of the osteotomy should fall very close to the point of maximal deformity to avoid the creation of a secondary deformity. The patient may also have an associated rotational or sagittal plane deformity. Procurvatum deformity was the most commonly encountered deformity associated with tibia vara. All of these variations must be recognized during preoperative planning so that they may be corrected at surgery.

**COMBINED PROCEDURES**

Coventry (8) suggested that diagnostic arthroscopy be performed in order to examine the lateral and patellofemoral joint spaces before osteotomy. However, Keene and Dyreby (27) demonstrated that lateral compartment involvement noted on arthroscopy does not predict failure of valgus osteotomy. Korn (28) made the same observation in a more recent study. The combination of a valgus-producing osteotomy and the Maquet tibial tubercle elevation procedure for patellofemoral and medial compartment arthritis gives only 50% good or excellent results in short-term follow-up (29,21,44). The role of prophylactic osteotomy in patients with excessive varus alignment has not been established.

**OPERATIVE PROCEDURE**

The technique for the osteotomy depends on the proposed method of fixation. We prefer internal fixation of the osteotomy with an L plate and screws, as described by Hofmann et al. (29). When combined with preservation of the medial tibial cortex, this construct provides rigid fixation of the osteotomy, which allows early range of motion of the knee and shorter rehabilitation time (18). There are two osteotomy systems available in North America that use this type of plate. Both also use angular cutting jigs to allow more precise bone cuts.

- Perform surgery under a spinal or epidural block. Position the patient supine and use a tourniquet. Give prophylactic antibiotics before inflation of the tourniquet. A straight anterior midline incision may be used but will need to be extended proximally and distally for adequate exposure of the lateral tibia.
- We prefer an L-shaped incision. Begin it laterally at the joint line and extend it parallel to the joint to the midline and then extend it distally along the anterior tibia as necessary. The vertical midline of this incision can be incorporated into an anterior midline approach for total knee arthroplasty.
- Dissect the cephalad anterior compartment muscles at a subperiosteal level off the tibial cortex. Carry the dissection distally only as far as needed to accommodate the plate.
- Once the lateral tibia is exposed, carry the dissection posteriorly to the proximal tibiofibular joint. The tibiofibular joint can be handled in three different ways. The fibular head may be resected and the lateral collateral ligament sutured to the iliotibial band (8). Alternatively, a segment of proximal fibula may be resected (34). Finally, the joint may be disrupted, allowing the fibular head to slide proximally when the osteotomy is closed (20). We prefer the fibular slide because we believe proximal resection compromises lateral stability of the knee and resection of a shaft segment puts the superficial peroneal nerve at risk of injury. To complete the exposure, incise the anterior joint capsule, and place a periosteal elevator into the joint. Use the elevator to disrupt the remaining joint capsule.
- After exposing the tibia, line up the transverse osteotomy jig provided with each system with the articular surface of tibial plateau under fluoroscopic guidance. Once this jig is satisfactorily positioned, place two Steinmann pins across the tibial metaphysis by using the holes in the proximal guide. The Steinmann pins parallel the articular surface and serve as a reference from which all cuts are made. Place a variable-angle drill guide over the proximal pins. The guide directs two distal pins in at the desired angle of the resection (Fig. 107.2). Exchange the variable-angle guide for proximal and distal cutting blocks (Fig. 107.3A), and perform cuts with an oscillating saw (Fig. 107.3B). The two arms of the osteotomy meet at a point just lateral to the medial cortex.

- Remove the wedge of bone from the tibia (Fig. 107.4A). Removing the resection wedge can be difficult if the posterior bone cuts are incomplete. Poor visualization and concern over the safety of posterior soft-tissue structures can result in undercutting this portion of the osteotomy. A hand osteotome can be used to complete the cut, but the osteotome must not plunge beyond the cortex. A curved curet is also useful in removing the bone.
Once the wedge is removed, close the ostectomy. Apply the L plate and hold it with two cancellous screws through the proximal, transverse arm of the plate. Each ostectomy system provides a special ratched clamp that attaches to the distal arm of the plate through an empty screw hole, and to the tibial cortex by an additional drill hole or separate pin (Fig. 107.44). Slowly compress the clamp and close the ostectomy. The distal fragment should deform rather than fracture. Integrity of the medial cortex is imperative to maintain stability of the ostectomy. Once the ostectomy is closed, lock the clamp to hold the ostectomy closed and place two or three bicortical screws through the distal arm of the plate (Fig. 107.46).

Before closing the wound, perform a subcutaneous fascial release of the anterior compartment muscles off the tibial crest. Then reapproximate the muscles to the tibia periosteous by interrupted, absorbable tacking sutures. This covers the plate and ostectomy site. Close the wound in layers over a drain. Apply a soft knee wrap in the operating room.

**POSTOPERATIVE MANAGEMENT**

Start continuous passive motion in the recovery room at 0° to 60°, and advance as tolerated to 90°. Administer antibiotics over 24 hours, and remove the drain on the first or second postoperative day. Place the patient in a hinged knee brace and encourage knee range of motion. The brace is worn for 8 to 12 weeks. Allow partial weight bearing and crutch ambulation. Full activity can be resumed once there is radiographic evidence of healing. Early motion helps avoid patella infera (68).

We recommend removal of the implant 1 year after surgery.

**COMPLICATIONS**

Complications after HTO are relatively uncommon. Early complications include tibial plateau fractures, superficial wound infections, deep venous thrombosis and pulmonary emboli, peroneal nerve palsy, and anterior compartment syndrome (6,19,20,22). Hemigou et al. (19) reported 10 inadvertent plateau fractures followed for 10 years or more. All fractures were treated conservatively, healed uneventfully, and did not seem to affect the results of the surgery. If peroneal nerve palsy develops, rule out compartment syndrome. Catastrophic complications reported in the literature are very rare. Coventry (6) reported one arterial thrombosis leading to limb amputation.

The one study that compared results of staples and plates (21) found a much higher rate of wound infection with the plate fixation (18). Late complications include nonunion, loss of correction, and disease progression in the remaining knee compartments (6,19,22). The method of fixation does not seem to affect the rate of late complications (18).

**TOTAL KNEE ARTHROPLASTY AFTER PROXIMAL TIBIAL OSTECTOMY**

Several groups have reported reliably good results from HTO up to 10 years after surgery (6,19,24,38,45). Failures increase with time owing to progression of arthritis into the remaining joint compartments or recurrence of varus deformity. We advise patients to anticipate 8 to 10 years of pain relief following tibial ostectomy. Failed HTO is best addressed with total knee arthroplasty. Unfortunately, proximal tibia ostectomy can compromise the result of total knee arthroplasty (35,38,49). Nizard et al. (38) compared patients who underwent knee replacement after HTO with a matched group of patients undergoing primary knee replacement. More pain was reported in those who had a previous HTO. Functional scores were similar. Patella baja, lateral soft-tissue scarring, and abnormal proximal tibia anatomy have all been problems in arthroplasty patients who have had an HTO (35,38,49). These results must be considered when advising patients who are considering tibial ostectomy.

**ALTERNATIVE METHODS OF PROXIMAL TIBIAL OSTECTOMY**

Several alternative methods of performing and stabilizing the ostectomy have been proposed. The dome ostectomy, attempts to allow correction with minimal bone loss, and maintenance of tibial length (29,31,1). Forming the hemispherical ostectomy can be technically difficult. More extensive exposure of the tibia is needed, and the resulting bone segments can be less stable because all cortices are involved in the ostectomy.

The proximal ostectomy may be angled upward, placing the apex of the wedge proximal and medial, and the lateral segment more distal (23,34). This technique leaves more bone in the proximal segment. The proximal tibiofemoral joint is not exposed, and a fibular ostectomy is required to allow compression of the tibial ostectomy.

Puddu et al. (43) has introduced the opening wedge medial ostectomy with the addition of a specialized fixation plate. The defect created is filled with iliac crest bone graft. The ostectomy is then held with a specially designed bone plate. Early results are encouraging. This technique is bone conserving but may place greater loads on the proximal fragment because the graft acts like a wedge under the proximal plateau segment.

Another new method uses the Orthofix dynamic external fixator (11,13).

- Apply the fixator pins medially with two cancellous threaded pins in a transverse array proximally and two bicortical pins distally.
- Then perform a medial corticotomy 4 to 5 cm below the tibial plateau without violating the lateral cortex. Apply the fixator and hold the corticotomy closed for 10 days until early callus has formed.
- At 10 days, start distraction at 1 mm a day until the desired correction is obtained. Then lock the frame for 3 to 4 weeks until consolidation occurs. When the lengthening site is stable, unlock the frame to allow compression across the ostectomy site and advance weight bearing. Remove the frame 12 to 14 weeks after application.

This method allows early knee motion and may avoid the extensor mechanism seen with traditional methods of ostectomy fixation. Also, all implants are removed at the completion of treatment. This method may compromise future arthroplasty by introducing bacteria to the bone adjacent to the pins (37). Initial reports of knee replacement after use of the Orthofix fixator have not included any joint infections (19,30). This technique requires close attention to detail and a cooperative patient. Complications include pin track infection, loss of position, delayed consolidation, and nonunions. These can be difficult to treat.

**PROXIMAL TIBIAL OSTECTOMY FOR LATERAL COMPARTMENT ARTHRITIS**

Jackson and Waugh (26) reported poor results with a medial closing wedge tibial ostectomy for lateral compartment arthritis. Coventry (7) also had limited success with this method. Patients did well clinically; however, technical considerations made the surgery less than satisfactory. An excessively large wedge of bone was required for correction beyond 12°. Also, the joint line remained in valgus, potentially complicating future procedures. Supracondylar femoral ostectomy was recommended for correction of larger deformities.

**DISTAL FEMORAL VARUS OSTECTOMY**

Valgus deformity of the knee may lead to arthritis affecting the lateral compartment predominately. The defect is not in the tibial plateau but is caused by hypoplasia of the lateral femoral condyle. Preoperative planning for the suprapatellar ostectomy is similar to the tibial ostectomy. Use standing long-leg films of the lower extremities to calculate the degree of valgus deformity. Plan correction to obtain neutral anatomic alignment, although the degree of correction is not well established (22). Both Coventry (6) and Morrey and Edgerton (38) recommend fabrication of a triangular metal plate, with the two long sides reproducing the desired angle of correction as calculated from preoperative films (Fig. 107.54). Sterilize the triangular plate and use it as a template at the time of surgery. Use a 95° blade plate to hold the ostectomy. Staples are not adequate (6,38). The angle of the template must be increased by 5° if a 95° blade plate is to be used.

---

*Figure 107.4: A: Pins have been removed, and the L plate and the proximal cancellous screws have been placed. A ratcheded clamp is in place to close the ostectomy. B: Fluoroscopic view of completed ostectomy with fixation plate.*
Approach the distal femur either medially or laterally. The femoral vessels must be protected if the medial approach is selected. An anterior skin incision can be used; however, most authors prefer to approach the operated side directly. The medial approach with slight variation, has been described by Morrey and Edgerton (36) and by Healy et al. (17) (see also Chapter 3).

Make a medial longitudinal skin incision 10 cm in length or longer, if needed. Reflect the vastus medialis muscle anteriorly. Expose the femoral cortex from the insertion of the joint capsule to a point sufficiently proximal to accommodate the side plate.

Under fluoroscopic guidance, drill a guide pin for the blade plate chisel across the femur 2.5 cm proximal to the condyles (107.5A.1). Direct the pin at a gentle angle from anterior to posterior to keep it centered within the condyles. Place a second, proximal Steinmann pin perpendicular to the femoral shaft proximal to the osteotomy site (107.5A.2). Use a third pin to reproduce the desired angle of correction in relation to the perpendicular, proximal pin (Fig. 107.5A.4). Place this pin between the first two pins. The prefabricated angle template can help with proper placement of this pin. It is important to prepare for easy blade plate placement by seating the chisel fully into the condyles before the actual osteotomies are performed.

Perform the osteotomy with an oscillating saw. Keep the distal side of the osteotomy proximal to the adductor tubercle. Guide the transverse, proximal cut by visually referencing the pin placed perpendicular to the femoral shaft. A fourth pin may be placed coincident with the proximal osteotomy line to act as a guide for the saw (107.5A.3). The angle of the wedge should be kept slightly less than the desired angle of correction. The proximal segment can be impacted into the distal segment to obtain the desired correction. Converge the two osteotomies to a point several millimeters medial to the lateral cortex.

Before completing the osteotomy, seat the blade plate in the distal fragment. Take care to align the blade plate along the posterior femoral cortex. Use a varus force to close the osteotomy site. The side plate can be used as a lever to assist in closing the osteotomy. An osteome may be used to perforate the lateral cortex, if needed. Undercutting the angle of the osteotomy allows impaction of the proximal segment into the metaphyseal bone until the desired angle is achieved. After the osteotomy is closed, the blade plate can be further impacted into the distal femoral condyles (107.5B).

Use three to four bicortical screws to fix the plate to the proximal segment; place one cancellous screw through the plate into the distal segment.

The lateral approach follows a similar sequence. Make an anterior or direct lateral incision. Use the prefabricated angle template to direct the tip of the blade into the distal femur (Fig. 107.6A). Make the osteotomy perpendicular to the shaft, above the adductor tubercle. Seat the blade. As the plate contacts the cortex of the lateral shaft, the proximal segment is impacted onto the distal segment and the correction is obtained (Fig. 107.6B).

Start the patient on early motion with protected weight bearing until there is radiographic evidence of healing (Fig. 107.7).

**PITFALLS AND COMPLICATIONS**

The most common complication is nonunion of the osteotomy (17.32.42). Avoid nonunion by ensuring that the osteotomy is rigidly fixed with good impaction of the bone fragments. If residual motion is evident after fixation, consider additional fixation such as an anteroposterior interfragmentary screw or a smaller supplementary plate. Avoid stiffness of the knee by early motion, supervised, if necessary, by a therapist to be certain that the patient regains motion.

Total knee arthroplasty (TKA) is one of the most successful and commonly performed orthopedic surgeries. In 1997, a total of 277,000 knee arthroplasties were performed, reflecting annual increases in the 1990s of more than 10%. In comparison, only 139,000 total hip arthroplasties (THA) were performed, and the yearly growth is lower (33) (Fig. 108.1). Improvements in design, standardization of operative technique, infection prophylaxis, and fixation techniques have led to extremely low rates of revision. The best results for TKA at 10 and 15 years compare to or surpass the best results of THA.

The goals of the TKA are threefold: pain relief, restoration of normal limb alignment, and restoration of a functional range of motion. A successful result demands precise surgical technique, sound implant design and kinematics, appropriate materials, and patient compliance with rehabilitation. This approach can be applied to implantation of any well-designed prosthesis.

Specifically a TKA must provide flexion and extension and resist nonphysiologic motions such as varus or valgus or supraphysiologic translation. Failure to resist nonphysiologic forces within design tolerances results in fracture of bone, progressive loss of fixation, or loss of bone or soft tissue around the prosthesis. Accurate bone cuts and soft-tissue preparation facilitate the success of the TKA.

INDICATIONS

The most common indication for primary TKA is primary and secondary osteoarthritis of the knee. The next most frequent indication is rheumatoid arthritis and other arthritic disorders, such as secondary arthritis from hemophilia and other types of arthropathy. End-stage arthritis may occur in the knee joints and lower extremities with normal alignment or may occur in lower extremities with flexion contractures, hyperextension of the knee, varus or valgus angulation either through the knee joint or adjacent to it, or rotary malalignment. These malalignments may be secondary to an underlying disease process or previous injury and, in part, are due to the arthritis itself, which can produce angulation through asymmetric wearing of the knee joint. All of these malalignments must be taken into consideration when planning for TKA. Indications for TKA include any arthritic disorder of the knee that is nonresponsive to the usual nonoperative treatment, including appropriate nonsteroidal anti-inflammatory or other arthritis medications, occasional bracing, limitation of activities such as a cane or crutches. When the patient's pain is such that he or she can no longer accomplish his or her required activities of daily living or the quality of life is such that they are willing to undertake the risks of major surgery, then TKA may be indicated. It is preferable that patients undergoing TKA have a remaining normal life expectancy of between 20 and 30 years so that the need for repeat arthroplasty for a failed TKA will be minimal. Arthroplasty may be indicated in a younger age group, but the patient must understand the limitations of the procedure, be willing to modify his or her lifestyle to prolong the life of the prosthesis, and be willing to risk the lower success rate in a revision TKA. Patients undergoing TKA in the vast majority of cases have significant arthritis involving all three compartments of the knee. TKA may be indicated with only unicompartmental arthritis itself, which can produce angulation through asymmetric wearing of the knee joint.

Contradictions to TKA include active infection in the knee, ipsilateral extremity, or elsewhere in the body that would make the risk of infection in the TKA high; inadequate bone stock due to osteoporosis or other metabolic bone disease or bone loss that cannot be replaced with an allograft or a specialized prosthesis; neurologic disease that would preclude motor control of the knee or lead to a Charcot knee; and generally poor health or systemic disease that would make the risk of major surgery and general or regional anesthetic too risky. Other than performing no surgery, the primary alternative to TKA, especially when the risk of infection is high, is knee arthrodesis, which is discussed in Chapter 109.

CLASSIFICATION

Three broad types of arthroplasty are used in uncomplicated primary TKR today: cruciate-retaining, cruciate-substituting, and mobile-bearing knees. For more complex reconstructions in which instability due to ligament failure is present, nonlinked constrained arthroplasties have been used. (Linked constrained devices such as "hinges" are rarely used or even indicated.) All of these arthroplasties are descendants of the successful Total Condylar knee (Hospital for Special Surgery, New York, NY), the gold standard for resurfacing types of total knee replacement. In the best designed of each category, long-term results are excellent in terms of fixation, function, pain scores, and motion (Table 108.1). Philosophical differences in kinematics, constraint, and methods of bone preparation, and subtle differences in postoperative results underlie the continued development of parallel designs.

CRUCIATE-RETAINING KNEE ARTHROPLASTY

The theoretical basis for retention of the posterior cruciate ligament (PCL) in TKA suggests that with a posterior tether between the femur and the tibia, stresses bypass the arthroplasty components, proprioception is maintained (49), and more normal motion (femorotibial rollback) is preserved. Preservation of quadriceps power and physiologic rollback may theoretically result in a more normal gait in walking stairs (2, 3). Whether cruciate retention or sacrifice results in an arthroplasty with greater motion has not been established. The demands of balancing the anatomic function of the PCL dictate that the normal joint line be closely restored (24, 34), possibly further improving patellofemoral kinematics. In order to facilitate the femoral rollback, tibial polyethylene components were historically kept relatively flat (Fig. 108.2) in the anteroposterior (AP) direction, with a physiologic posterior slope. This avoided the "kinematic conflict" of a dished polyethylene, preventing normal rollback (Fig. 108.3). Although some laxity is necessary to preserve range of motion (46), more anatomic posterior cruciate–sparing prostheses depend entirely on the soft tissues to resist posterior translation (20, 40, 46). Later iterations of cruciate-retaining implants have added more congruence to the articular polyethylene to improve stability and contact stresses.

Figure 108.2. The effect of posterior cruciate ligament (PCL) retention on prosthetic design. Because of the rollback enforced by the PCL (A, B), the prosthetic tibial surface has historically been flat to allow this movement. C, D: When the PCL was absent, a dished tibial plateau has been used. (From Insall JM, ed. Surgery of the Knee, 2nd ed. New York: Springer Verlag, 1991:600, with permission.)

Figure 108.3. Kinematic conflict occurs if concepts are mismatched. In this case, the posterior cruciate ligament is preserved using a dished tibial component. Impingement occurs posteriorly with flexion. (From Insall JM, ed. Surgery of the Knee, 2nd ed. New York: Springer Verlag, 1991:600, with permission.)

With retention of the PCL, the level of the joint line must be kept at or near anatomic height after resurfacing with the arthroplasty. Failure to do this will result in a tight PCL, which will produce restricted flexion, excess femur on tibia rollback (so-called “booking”) (Fig. 108.4), and a high posterior polyethylene-bearing load, potentially leading to articular failure. The technical challenge with a PCL-retaining knee design is to realign the limb and restore full motion while keeping the PCL under proper tension.

Figure 108.4. An overtight PCL causes “booking.” There is excessive rollback of the femur, and the knee hinges open. (From Insall JM, ed. Surgery of the Knee, 2nd ed. New York: Springer Verlag, 1991:602, with permission.)

Although these theoretical advantages are compelling, Lotke (18) was able to demonstrate normal physiologic tension in only 1 of 10 knees undergoing a posterior cruciate-retaining TKA. Stiehl (44) fluoroscopically visualized clinically well-functioning PCL-retaining TKAs and found nonphysiologic AP movement. Some cases demonstrated “roll forward” rather than “roll back” (Fig. 108.5). Laskin (19), Pagano (20), and Waslewski (50) showed clinical evidence of late failure of the PCL with sagittal laxity. Other authors with large series show no evidence of this phenomenon (9, 19). The risks of excessive laxity include gait abnormality with eccentric loading, secondary soft-tissue attenuation, and edge loading with resultant high contact stresses on polyethylene components. Progressive weakening or elongation of the PCL...
and subsequently the capsule and collaterals could lead to osseous deformity and frank joint subluxation.

Figure 108.5. Medial condyle contact positions for five randomly selected subjects having a posterior cruciate-retaining design with a posterior lipped insert. Note that some knees roll forward and others roll back, and that magnitude and starting points vary. This is a stochastic process. (From Dennis DA, Clayton ML, O'Donnell S, et al. Posterior Cruciate Condylar Total Knee Arthroplasty. Average 11-year Follow-up Evaluation. Clin Orthop 1992;168:52, with permission.)

**CRUCIATE-SUBSTITUTING KNEE ARTHROPLASTY**

Sacrifice and substitution for the PCL gives predictable femorotibial kinematics and may facilitate balancing knees with greater angular deformity, especially when secondary changes in the PCL contribute to the deformity. The function of the PCL is partially replaced by using a more congruent articular surface and commonly a tibial spine and femoral cam mechanism (Fig. 108.6). Historically, the most popular designs had a higher rate of patellofemoral complications. Impingement of fibrous tissue proximal to the patellar component or in the notch can cause "patellar clunk" (48). Patellar pathology may be partially due to the relative elevation of joint line (Fig. 108.7) that can occur using the gap technique of bone preparation, and the relative patella baja that this produces. The femoral profile of early models was boxy in the AP plane without recession of the trochlear groove, increasing tension on the patellar retinaculum (Fig. 108.8). Recently improved designs more physiologically duplicate patellofemoral anatomy and mechanics.

Figure 108.6. The cam mechanism of the posterior stabilized knee simulates the function of the PCL and causes a rollback of the femur on the tibia with flexion. The resulting vector of forces passes distally through the fixation peg. (From Insall JN, Lachiewicz PF, Burstein AH. The Posterior Stabilized Condylar Prosthesis. A Modification of the Total Condylar Design. Two to Four Year Clinical Experience. J Bone Surg [Am] 1982;64:1317, with permission.)

Figure 108.7. Spatial position of the joint line. A: The normal joint line is indicated by the dotted line. B: The joint line has been abnormally lowered (solid line) owing to overresection of the proximal tibia and underresection of the distal femur. C: The joint line has been abnormally elevated (solid line) owing to underresection of the proximal tibia and overresection of the distal femur. (From Laskin RS, ed. Total Knee Replacement. New York: Springer Verlag, 1991:58, with permission.)

Figure 108.8. Effect of a tight patellar retinaculum: A: A tight lateral capsule causes patellar subluxation and loss of flexion. B: A good lateral release corrects this problem. (From Insall JM, ed. Surgery of the Knee, 2nd ed. New York: Springer Verlag, 1991:646, with permission.)

**MOBILE-BEARING KNEE ARTHROPLASTY**

The mobile-bearing total knee, although implanted in a minority of knees in the United States at present, is attracting interest because of its distinct potential design advantages. These designs rely on highly congruent femoral and tibial articular surfaces to produce very low contact stresses, theoretically reducing polyethylene wear. Allowing the tibial articular surface to "float" by a combination of gliding, rotating, or sliding mechanisms mitigates the kinematic conflict created by highly congruent surfaces. Fluoroscopic information suggests that in vivo kinematics may imperfectly replicate design goals (43). To date, only one mobile-bearing design (Depuy LCS, Warsaw, IN) has been approved by the U.S. Food and Drug Administration (FDA) (Fig. 108.9), although there has been considerable early experience overseas with
other novel implants.

Figure 108.9. The Depuy LCS knee.

Contemporary use in the United States is approximately 45% each for cruciate-retaining and cruciate-substituting designs, and 10% for mobile-bearing designs, with the cruciate-substituting and mobile-bearing designs increasing in popularity. All three implant types are viable and have proven long-term results. All have theoretical and practical pluses and minuses (Table 108.2).

Table 108.2. Advantages and Disadvantages of Types of Tibial Knee Implants

TECHNICAL CONSIDERATIONS

The design goal of the knee arthroplasty is to relieve pain and restore normal function to the arthritic knee. The shapes of the reconstructed femur and tibia, particularly in the sagittal plane, dictate the kinematics of the reconstructed knee. The soft tissues are physiologic restraints with limited elasticity. Within the range of patient sizes and limitations of ligaments, a variety of sizes is needed. The contours of the articulating surfaces create constraint, and in some cases, a more constrained articulation can substitute for ligamentous deficiency.

Accurate limb alignment minimizes stresses on bearing and fixation interfaces. The main goal of instrumentation is to provide consistent accurate alignment by referencing from osseous landmarks. Alignment may be assessed as “anatomic” or “mechanical.” The mechanical axis of the limb is defined by a line that passes through the hip center and through the center of the ankle. It typically falls on the medial side of the center of the knee joint. Although the consistent reproduction of a mechanical axis that passes through the central area of the knee is a goal, the landmarks are difficult to measure accurately in the operating room. Anatomic axis landmarks, by contrast, are readily available, easy to instrument, and can reasonably approximate the mechanical axis. Most contemporary arthroplasty instrumentation references from the anatomic axes. The relationship of the longitudinal axes of the femur and tibia define the femorotibial angle or anatomic axis (Fig. 108.10).

Figure 108.10. Comparison of the anatomic and mechanical axes. The mechanical axis usually corresponds to a femorotibial angle of about 7° and intersects the medial femoral cortex 12 to 18 cm proximal to the knee.

Precision is paramount because an asymmetry of only 5% can lead to lift-off of the femoral component on the tibia, with compressive forces all on one side and tensile forces on the other. Subtle malalignment can magnify with time as soft tissues attenuate under excessive forces (Fig. 108.11). Specifically, varus alignment of the tibial component has been associated with a higher rate of radiolucency about the prosthesis and a higher rate of loosening (Fig. 108.12).

Figure 108.11. Edge loading between the femoral and tibial components can occur owing to AP instability or varus valgus forces in a TKA design with a flat tibial bearing surface as shown in C. A: Dished tibial component with central contact points. B: Dished tibial component with varus stress maintains central contact and loading. C: Flat tibial component with varus stress can result in edge loading medially. (From Laskin RS, ed. Total Knee Replacement. New York: Springer Verlag,
Fixation of TKA components has been reliably achieved with both cemented and cementless techniques, but the use of methacrylate cement remains the standard and generally the most widely used technique.

**SURGICAL PROCEDURE**

**PREOPERATIVE EVALUATION**

Take good-quality radiographs on large cassettes in both the AP and lateral planes. AP weight-bearing films demonstrate better any potentially dynamic instability. They also accentuate joint space narrowing. A Merchant view (or other similar radiograph) is useful to evaluate patellofemoral mechanics (23). A tunnel view may be useful to evaluate for osteonecrosis.

Fixed angular deformities and contractures need to be released at the time of surgery either through soft tissue or bony maneuvers. The stiff knee can present a challenge for exposure alone. Any knee with gross ligamentous instability, particularly in the medial-lateral plane, may need to have specially stabilized components or ligamentous augmentation for a successful procedure.

Rule out and evaluate for potential serious vascular disease in the lower extremity. A consultation with a vascular surgeon may be necessary. Prior vascular surgery, particularly with the use of a prosthetic graft, may be a contraindication for use of a tourniquet.

Assessment of the skin is also important in arthroplasty. There is nothing more discouraging after undertaking a technically successful arthroplasty than to have a skin slough that leads to infection and dismal failure. Try to avoid flaps and undermining of the skin, particularly laterally over the patella to avoid potentially devastating problems. In general, old incisions performed for prior medial or lateral meniscectomy, which are either oblique or behind the midline, can be ignored. Cross transverse incisions for patellectomy or high tibial osteotomy at 90°. More recent parapatellar incisions are problematic. In general, include recent parapatellar incisions in the line of the main incision if practical. Use the most lateral longitudinal incision if it will allow adequate access to the knee for arthroplasty. Give special consideration to patients with local skin problems such as psoriasis. Preoperative dermatology consultation can significantly improve local skin lesions and reduce the risk of infection.

In the absence of long bone and hip deformities, standard 36-inch radiographic films with the patient standing are adequate for preoperative planning. Three-foot films may be used to assess mechanical axis versus anatomic axis, but they usually are needed only to assess angular deformity away from the knee joint or unusual hip offsets.

Template for the size of prosthetic components on the radiographs with acetate overlays that are compensated for radiographic magnification. Preoperative templating is only an approximation of the required prosthetic sizing—never use templating to determine the precise size used at surgery. Often, the exact size determined in surgery will vary from templating by plus or minus one size. Templating provides the opportunity to consider the surgical plan, including correct techniques to address deformities and need for soft-tissue releases. Occasionally, templating reveals the need for a very small or very large component, which requires—if not a custom device—at the least a special request before surgery. Prior surgical procedures may significantly alter the normal anatomic landmarks. Prior proximal tibial osteotomies may make conventional tibial component difficulties to use owing to an offset of the tibial axis relative to the plateau. Prior hardware, such as staples or screws, may have to be removed. Severe bone deficiencies, such as those that result from marked valgus deformity or a long-standing varus deformity, may require modular prosthetic augmentations (28) or grafting (29).

**SURGICAL PREPARATION**

After templating of radiographs, it is imperative that the appropriate surgical instruments be available for the procedure. These instruments may include special jigs, measuring devices, or cutting tools. Administer a dose of prophylactic antibiotics before inflation of the tourniquet. A first-generation cephalosporin is an appropriate choice. If there is an allergy to a first-generation cephalosporin, the alternatives include vancomycin or clindamycin (4).

1. Position the patient carefully in the supine position on the operating table. Take great care to prevent peripheral nerve palsies, which can occur during the prolonged positioning in the recumbent position in the anesthetized patient. Protect the elbows with foam pads and gently flex them approximately 30°. Elevate the patient’s buttck on the operative side with a soft roll to produce a stable upright positioning of the knee. Occasional sciatic nerve palsy has been seen from prolonged positioning on a hard buttock roll. When the patient is rolled to the opposite side using the buttock roll, the contralateral leg often lies in external rotation. To avoid pressure on the peroneal nerve on the nonoperated side place the heel on a soft elevation pad and pad the lateral side of the knee.

2. Secure two separate bumps to the table on the operated side as leg positioners. Position them such that the knee is in full extension when the leg lies on top of the bumps, in approximately 30° of flexion when the foot is placed on the first bump, and in 100° of flexion when the second bump is used. These are the three main positions of the knee used when the surgical procedures are set (Fig. 108.13). These bumps stabilize the knee and free the surgeon’s and assistant’s hands. Once the patient is positioned and the bumps are set, the extremity should be stable with the patella pointing directly at the ceiling. There may be a tendency for the limb to roll into external rotation. If this occurs, gently rotate the table toward the opposite limb until the knee is in a stable position straight up and down. Secure the patient with a strap.

3. Finally, take a “walk around” the patient just before scrubbing. Check all peripheral nerve sites for appropriate padding. The tourniquet should have been placed...
on the thigh as high as possible and the skin protected with soft webrib padding. If the patient is obese or short limbed, a sterile tourniquet may be used to ensure adequate access to the surgical field. Place protective vinyl draping distal to the tourniquet to prevent dripping of potentially caustic scrub solutions under the pressure tourniquets. Confirm with the anesthesiologist that preoperative antibiotics have been given.

Reaffirm that the correct limb is being prepared. Although it is rare, wrong limb side surgery does occur and is disastrous for patient and surgeon. The American Academy of Orthopedic Surgeons has made recommendations to minimize this complication (47). Whatever system is used, it is the attending surgeon's ultimate responsibility to confirm that the operation is performed on the correct knee.

Shave the skin around the knee immediately before the procedure to limit compromise of the skin surface. Extended time between shaving and surgery promotes colonization of small nicks with bacteria.

The regimens for prepping and draping the patient vary among hospitals and among surgeons. However, particularly in TKA, the margins of the surgical field are subject to compromise unless very careful preoperative draping is done. Now surgically scrub the limb and do a final skin prep with an antibacterial solution. Take meticulous care during draping. Drape the skin sterility as high as possible, to avoid drape creep, and to at least 4 inches below the tibial tubercle. Apply an adherent sterile vinyl dressing (preferably iodine-impregnated 3M Ioban, Minnesota Mining Co, Minneapolis, MN). Leave at least 1 inch of plastic adhesive drape above and below the planned or extended incision to ensure that the drapes do not lift up during the procedure, thus preventing irrigation fluid and other fluids from the surgical site from entering areas of contamination and vice versa. Always use a wide prep and drape to provide for an extensive exposure. It will be frustrating to find oneself "prepped out of the field" or to have the field contaminated by an inadequate level of prepping.

Avoid excessively bulky drapes on the lower extremity. Precise alignment in total knee replacement depends on the ability to palpate the tibial spine, the maloeil, or bones of the foot. A bulky drape on the foot obscures landmarks and makes surgery more difficult. Use a plastic-impregnated stockinet that covers the lower extremity, stops over an elastic Coban wrap (3M, Minneapolis, MN), which effectively walls off the foot from the sterile upper leg, holds the stockinet on precisely, and provides a graded compression for prophylaxis against venous stasis. Most important, it does not mask the palpable subcutaneous landmarks of the lower extremity, thereby allowing more accurate bone cuts.

**OPERATIVE TECHNIQUE**

- With the patient prepped and draped, flex the knee to a 30° position and mark the surgical incision. Flexion produces tension on the anterior tissues, which allows a more precise surgical exposure. A midline longitudinal incision is preferred unless otherwise dictated by prior skin incisions. The exposure should be extensive, extending approximately five fingerbreadths above the superior patella and five fingerbreadths below the inferior patella.
- The technique of arthroscopy, soft-tissue handling, and initial exposure is key to preventing problems. Put a thumb on one epicondyle and a finger on the other epicondyle, and visualize the knee in 30° of flexion to mark a center point. This is not necessarily the center of the patella; often, the center of the patella can be misleading. Mark the center of the femur proximally at the appropriate length and distally place your finger over the tibial tubercle and make a mark on the medlal aspect of the femur. The incision must be perpendicular to the skin at all skin contours. This means that proximally the belly of the blade should be as parallel to the limb as possible.
- Carry the incision through the midpoint of the knee and distally just medial to the tibial tubercle, with the blade angled perpendicular to the tibia so that it internally rotates as the incision is carried distally. This will minimize skin flap compromise and potential necrosis.
- Carry your index finger deep into the prepatellar bursa. Inspect to ensure that you can palpate the prepatellar bursa above the patellar tendon and below the tibial tubercle. Preserve this for later closure; if a careful incision is made, it makes a very nice layer for later closure.
- Perform a medial arthrotomy with a new knife blade. The location of the quadriceps tendon can be very deceiving proximally. The most superior portion of the tendon is very obvious, but if fascia is used, this may lead the surgeon to transect more tissue than actually is required.

![Figure 108.14](image)

**Figure 108.14**. The exposure of the proximal superficial quadriceps tendon may deceive the surgeon as to its true location. Palpate the tendon to be certain that the incision is along its medial border.

- Use a #10 blade perpendicular to the tendon, through its full thickness, and carry the arthrotomy longitudinally in a gentle curve, which will start at the midpoint of the quadriceps tendon proximally, curve around the patella so that it intersects a point (just medial to the patella) and then curve back to a point on the tibial tubercle laterally. It is important that the arthrotomy be gently curving and transect a minimum of quadriceps muscle fibers. Incorporate a millimeter or two of the most medial portion of the patellar tendon distally. When a medial soft-tissue sleeve is raised around the tibia, the closure toward the tibial tubercle is often precarious. Incorporating an inconsequential amount of the patellar tendon distally helps secure this layer and again lower the risk of infection.
- In the arthrotomy, split the fat pad with the medial bulk of fat maintained. This facilitates the exposure of the intercondylar notch. The medial fat pad is especially important in more difficult tight knees or heavy patients. This leaves a fair amount of fat pad for closure even when the lateral fat pad is removed to expose the difficult knee.
- Do not compromise the patellar tendon.
- Avoid the patellar tendon in the inferior region of the arthrotomy, bring the incision parallel to the shaft of the tibia and carry it distally for a few more millimeters.
- Place a right angle retractor medially and transect the anterior horn of the medial meniscus. Elevate a medial soft-tissue sleeve with electrocautery or a sharp #10 blade. Release the soft-tissue sleeve from proximal to distal, staying strictly at the subperiosteal level to maintain the vascularity of the medial flap of tissue. The medial flap is critical for covering the medial aspect of the knee joint.
- The extent of the medial dissection depends at this point on pre-existing angular deformities. For a severe varus knee, the medial exposure can be extended into a medial release. The medial collateral ligament is a tight band on the medial aspect of the knee and can be easily transected by slight malposition of the scalpel during dissection along the anteromedial and posteromedial tibia. It is best to proceed with a subperiosteal stripping of the medial aspect of the joint with a Cobb-type elevator to ensure that the collateral ligament is protected. Once the deep portion of the medial collateral ligament (MCL) has been elevated, place the Cobb-type elevator between the MCL and the joint capsule to expose the medial osteophytes at this point as part of the medial release.
- Elevate the patella, with the knee extension and pulled toward the surgeon. Release tight bands in the patellar retinaculum or plica with electrocautery and avoid the patella.

- Place a retractor along the medial joint line and flex the knee to 90° or 100°. The potential for patella tendon avulsion exists in the tight knee. As the knee is flexed, carefully watch the insertion of the patella tendon to avoid any excessive flexion that may avulse the patella tendon. If the patella cannot be easily everted without the risk of patella tendon avulsion, obtain more extensile exposure either by extending the arthrotomy proximally, doing more distal soft-tissue releases, or combining a release or lateral tibial osteotomy. This situation most often occurs in the very obese patient or the patient with prior knee surgery, such as proximal tibial osteotomy, in which the patella tendon is scarred and tight. Once patella tendon avulsion occurs, it is very difficult to treat, so this complication is best avoided. Favor a tibial talar osteotomy over proximal soft-tissue releases.

- At this point, flex the knee greater than 90°. The patella should be everted, both femoral condyles should be evident, and the tibial plateau should be at least partially visualized. Next, inspect the entire knee and identify and make a note of the intraoperative pathology.

- The anterior cruciate ligament is generally resected for all arthroplasties, and this enhances exposure. Place a hemostat behind the anterior cruciate ligament from the lateral to the medial direction and transect the ligament by electrocautery. It is best to remove the stump of the anterior cruciate ligament off its femoral insertion on the lateral side.
- In knees with advanced arthritis, the PCL may be partially or totally obliterated by notch osteophytes. Using a 1-inch osteotome, remove medial and lateral osteophytes to expose the PCL attachment to the femur. Most knees will have an intact PCL. In some cases, it may be anatomic in structure but have abnormal function.
- If the PCL is being intentionally sacrificed for surgical technique, it is best done at this point. The PCL lies immediately in front of the posterior capsule, which lies in front of the posterior cruciate ligament. The PCL should not be sacrificed in a cavalier fashion, but it should be done precisely. Place a curved clamp behind the PCL to define its substance and direction, then take electrocautery and remove the PCL subperiosteal from the femoral attachment. Once it is completely detached from the femur, retract the detached end forward and transect it at its insertion on the tibia.
- Now transect the anterior horn of the lateral meniscus. Separate the remaining fat pad beneath the patellar tendon from the patellar tendon using a hemostat down to the level of the lateral joint line, and transect it with electrocautery. This frees the lateral meniscus. Then place a Kocher clamp on the lateral meniscus and use electrocauterity along the margin of the lateral meniscus anteriorly. Then place the meniscus under tension with the clamp, and release the lateral periosteum of the meniscus with a #15 blade in a precise curvilinear fashion along to its insertion next to the PCL. Branches of the lateral geniculate artery are just outside the insertion of the lateral meniscus and can be easily transected during the removal. These branches commonly bleed if they are not cauterized at this time.
Once the lateral meniscus is removed, place a Z-type retractor in the corner overlying the lateral tibial condyle to gain extensile exposure of the flexed knee.

**Principles of Balancing: Measured Resection versus Flexion Gap**

Most modern knee instruments are quite precise. They generally rely on intramedullary alignment for the femur. The tibia may use either intramedullary or extramedullary alignment guides (11). It is important to follow the manufacturer’s instructions and at the same time to understand the underlying mechanical principles of TKA so adjustments can be made to suit the pathology encountered at surgery.

Contemporary instrumentation uses either measured resection or flexion or extension gap balancing methods to determine the location, depth, and angulation of bone cuts. The techniques are more similar than different and ultimately result in the same or nearly the same anatomical outcome. Measured resection uses trials as spacer blocks, whereas blocks are typically used in the gap measurement method.

The gap technique of bone preparation typically begins with tibial resection perpendicular to the tibial axis.

- Make the cut 5 to 9 mm below the articular surface of the more normal side. Check ligament balance.
- The femoral flexion gap is created by sizing the anterior posterior diameter of the femur from the anterior cortical surface, selecting the appropriate size, and adjusting the rotation for ligament tension before the cuts are made to create the femoral flexion gap. After the flexion gap is created, measure it with spacers and use this information to create the extension gap (Fig. 108.15).

**Figure 108.15.** After resection of the distal femur and proximal tibia, the extension gap (B) must equal the flexion gap exactly (A). (From Insall JM, ed. *Surgery of the Knee*, 2nd ed. New York: Springer Verlag, 1991:626, with permission.)

The gap technique is simple and widely applicable, but has the possible disadvantages of midrange laxity (only 0° and 90° are checked) and possible elevation of the joint line. Elevation most commonly occurs in a knee with a preoperative flexion contracture, and an aggressive flexion gap cut on the femur results in a femoral component that is relatively undersized (34).

The femur is usually resected first when proceeding with the so-called measured resection technique of TKA. Proponents suggest that the femur is more readily accessible upon first exposure. The measured resection technique works by resecting a measured amount of bone from both the femoral and tibial condyles. This resected bone is to correspond as closely as possible to the amount of implant being replaced (Fig. 108.16). This is also known as a joint line technique because the joint lines are fairly well maintained and the normal anatomy is essentially resurfaced. This is particularly important when the implant is designed to retain the PCL.

Slight elevation of the joint line in PCL-retaining designs can have adverse effects on knee kinematics (24).

**Figure 108.16.** Flexion cuts forming equal resection when combined.

Close matching of the AP dimensions on the femoral side and consistent femoral rollback without the “booking” phenomenon avoids increased posterior stresses and the limited flexion associated with a tight PCL or excessive translation with a loose PCL. In the case of a tight PCL, recession (37,57) from the tibial side after the tibial cut and balancing can allow interpolation between sizes. Flexion contracture can be addressed with posterior capsular release (Fig. 108.17).

**Figure 108.17.** Posterior capsular release from the femur to reduce a flexion contracture. A: The posterior capsule is adherent. B: The original recess is re-established. (From Insall JM, ed. *Surgery of the Knee*, 2nd ed. New York: Springer Verlag, 1991:643, with permission.)

**Preparation of the Distal Femur for Cuts**

The goal of the femoral preparation is to resurface the abnormal femur with a femoral implant articulating surface. The distal level of the femoral implantation is critical to preserve the proper level of the joint line. The flexion and extension gap must be correct. The varus and valgus alignment and proper external rotation are critical. At least four directions for spatial relations must be carefully maintained or reproduced to result in a good arthroplasty: joint level, rotation, coronal plane angulation, and sagittal plane angulation. Initial preparation of the distal femur to ensure correct rotation includes marking a line in the sulcus of the trochlear groove, the so-called Whiteside’s line, or the AP axis (53). The AP axis of the distal femur is defined by a line through the deepest part of the patellar groove anteriorly and the center of the intercondylar notch posteriorly. This line defines the center of the femoral condyles and the plane to which the knee component must be perpendicular.
Rotation of the Femoral Component

Rotation of the femoral component is key for a number of reasons. The patellofemoral mechanics are altered dramatically by femoral component rotation. An excessively internally rotated femoral component will have much higher rates of patellar subluxation and altered patellofemoral mechanics. In general, some external rotation of the femoral component is desirable. Also, because tibial resections are performed perpendicular to the long axis—not the normal 3° medial inclination of the tibial plateau—an externally rotated femoral component is necessary to make the flexion gap equal. (Fig. 108.19).

The order of cuts depends on the instrumentation. The distal cut is typically made in a preset angle of varus or valgus from the mechanical axis, marked by the intramedullary guide. Most surgeons select 5° or 6° of valgus, altering this for special circumstances when the anatomic axis departs from the mechanical axis.

Determining External Rotation

Three distinct anatomic landmarks are used to determine the external rotation of the femoral component. No one landmark by itself is always reliable. Use all three in combination to reach a consensus as to what is the proper external rotation alignment.

- The transepicondylar axis is the most reliable from the anatomic point of view, but the epicondyles may be difficult to palpate. The posterior condylar axis is generally reliable but suspect in valgus knees or in rheumatoid arthritis. A deficient lateral condyle may produce false external rotation. In cases of severe arthritis with marked anterior osteophytes, the intratrochlear groove may be abnormal. We prefer checking three landmarks and making a final determination on their confluence, erring on the side of external rotation. In the case in which a tibial cut is made first, an additional reference for a balanced flexion gap is available. Some instrumentation sets are able to reference the tibial cut and use soft-tissue tension to determine the rotation of the femoral cuts. This can be dangerous, depending on the extent of soft-tissue contractures and which structures have been released before using the instruments.

Anterior and Posterior Sizing

After the distal femoral cut is made and the external rotation has been determined, make the anterior and posterior femoral cuts. In general, there are two references or approaches that may be used at this point. One is the anterior referencing technique, whereby the anterior cut is made first by referencing from the anterior cortex. This approach ensures that no notching of the femur for anterior femoral flange occurs. The difficulty with this technique is that the exact location of the posterior femoral condyles is somewhat indeterminate because of the finite number of component sizes that are available. In general, take care in measuring the size of the femoral component. The other method of measurement, used by most systems, is some type of caliper or jig system to measure the distance between the posterior condyles and the anterior cortex. If the size registers between two sizes, which it often does, in general the smaller size is preferable to avoid “overstuffing” the knee. Overstuffing the knee is a phenomenon that occurs when too large a femoral component is placed. If the component is placed too far posteriorly, a tight flexion gap and decreased flexion will occur. If an oversized component is placed too far anterior, the extensor mechanism may impinge on the femoral flange, creating a tight knee.

In the so-called “greyhound knee,” named for its resemblance to canine anatomy, there is a mismatch between the AP diameter of the knee and the narrower medial-lateral dimension of the femoral condyle. After selecting the proper AP dimension of the component, an overhang on the medial and lateral sides becomes apparent. Proper implant system selection can minimize this phenomenon.

An important intermediate step is to check the bone cuts for evidence of the appropriate rotations. The anterior cut on the femoral condyles should leave a higher and longer prominence laterally, and the removed bone fragment typically looks like a mountain, called the Matterhorn sign. (Fig. 108.20). The posterior cuts should show similar asymmetry, with more medial than lateral bone resected in most cases.
Many systems require some additional bony preparation, such as a box for a PCL cam or a recessed trochlear groove for improved patellar articulation.

**Removing the Posterior Osteophytes**

Remove posterior osteophytes after the chamfer and other finishing cuts. The posterior osteophytes not only act as a mechanical block to limit flexion but also tent the posterior capsule and limit full extension.

1. With the knee held in extreme flexion, retract the femur superiorly with a blunt bone hook placed in the intercondylar notch. Use a 1-inch sharp, curved osteotome to resect posterior osteophytes from the medial, lateral epicondyles. Take care to avoid injury to the neurovascular structures.
2. Once these osteophytes are resected, remove adherent capsular attachments by either curettage or rongeur. A soft sulcus should result behind the posterior condyles and in front of the posterior capsule. This approach will maximize the potential extension and flexion of the knee (Table 108.3).

**Oversized femoral component**

- Improper external rotation
- Notching of the femur
- Improper axial alignment

**Table 108.3. Pitfalls of Femoral Preparation**

After the appropriate anterior, posterior, and distal femoral cuts, turn your attention to the tibia. It may be appropriate at this point to check the extension and flexion gaps again. The flexion gap is determined by the space between the femur and the tibia at 90° flexion, and the extension gap is determined by the space between the femur and the tibia at full extension. This can be a guide to the amount of resection needed on the tibial side and, equally important, to the need for future ligamentous release.

**Tibial Resection**

The tibia is generally resected perpendicular to its long axis. The anatomic axis of the tibia is in 3° of varus. Implant systems initially attempted to replicate this slight varus profile. Because of the inability to reproduce angular cuts about the knee precisely, often an attempt to produce a slight, 2° to 3° varus will produce a 5° to 6° varus cut, which has been shown to lead to early component loosening. Therefore, attempt a perpendicular cut with the knowledge that a slight varus cut plus 2° to 3° should not significantly alter clinical results. We prefer to use an extramedullary technique.

- Select a tibial cutting guide that allows for multidirectional orientation, including rotation resection height, varus-valgus alignment, and posterior-tibial tilt. In general, place the rotational alignment of the tibial cutting edge such that the profile of the cutting guide is centered on the medial edge of the tibial tubercle. This is best determined by sighting down on top of the tibia in the so-called "bird's-eye view" (Fig. 108.21). Once the rotation used for the cutting guide is determined, provisionally pin it in place.

**Figure 108.21.** Overhead view of the right tibia. To establish correct rotation, the tibial component should align just medial to the tibial tubercle. (From Insall JM, ed. *Surgery of the Knee*, 2nd ed. New York: Springer-Verlag, 1991, with permission.)

- Next, secure the yoke of the distal end of the tibia cutting guide above the ankle. Place care not to put the yoke of the distal portion of the tibial guide at the ankle joint. Because of the fibula and widening of the ankle joint, this will produce an offset that can produce a varus deformity. Place the yoke approximately two thirds of the way down on top of the tibia in the so-called "bird's-eye view" (Fig. 108.21). Once the rotation used for the cutting guide is determined, provisionally pin it in place.

**Figure 108.22.**...
Figure 108.22. Position of tibial cutting jig: In A, the guide is aligned with the anterior tibial tendon and first web space of the toes, producing an appropriate cut. In B, the alignment jig is centralized on the ankle joint, which is too lateral, resulting in excessive varus in the cut of the tibial plateaus.

After the varus-valgus position has been determined, set the tibial height. A variety of guides are available that can confirm the position of the cutting jig relative to the tibia, including thin flat curved wing-shaped devices, or jigs that can measure from the cutting surface to fixed points above the tibial surface. In general, in most knees, there is one so-called “normal” tibial plateau; the other is worn. We prefer to take 10 mm off the “normal” side. This usually results in only slight subchondral resection on the “abnormal” side. Avoid putting the tibial plate into extension, which can produce a tight flexion gap and decreased motion (Table 108.4).

Table 108.4. Pitfalls of Tibial Preparation

- Size the tibial component to provide the largest possible area to reduce force per unit of area while avoiding overhang of the tibial plateau, particularly posterolaterally. The rotation should match the femur in extension, which typically is at the medial third of the tibial tuberosity.

Saving the Posterior Cruciate Ligament

Several steps can be taken to preserve the PCL.

- Make a slot just in front of the PCL using a reciprocating saw. Place an osteotome with parallel sides in front of the PCL. With the osteotome in place, use a reciprocating saw to cut on the medial and lateral aspects of the insertion of the PCL, thus preserving a bone block to which it is attached.
- Then resect the proximal tibia, protecting the medial collateral ligament on the inside of the knee, the patellar tendon on the outside of the knee, and the posterior vascular structures.
- Then lift off the tibial plateau in one piece after releasing it from the soft-tissue attachments along its periphery.

Balance of the Knee

At this point, perform rigorous medial and lateral ligament balancing, and flexion and extension gap balancing using appropriately sized blocks. Alternatively, if the femoral preparation has been completed, trial components may be inserted and ligament balance checked. In general, balance the knee with soft-tissue releases rather than by bony cuts.

Ligament Balancing

Depending on the complexity of the knee replacement, ligament balancing can be straightforward or complex. Plan to have more constrained implants available if the preoperative deformity is excessive. Specifically, in patients with greater than 15° of varus or valgus deformity, it may be necessary to move to a more constrained implant. These implants can make up for deficient medial or lateral collateral ligaments. However, remember that constrained knee implants have had poor longevity.

There are seven main points of ligament balancing that must be achieved for an arthroplasty to be successful. These are listed in Table 108.5. Surgical techniques of reconstruction can differ widely. In the patient with minimal to moderate deformity, with acceptable surgical instrumentation from a modern TKA kit, balancing can be as simple as placing the trial components and checking the seven points of balancing (Table 108.5) to ensure that the jigs did their work. More complex knee deformities may require release of the posterior capsule, the posterolateral corner, lateral collateral, iliotibial band, or the MCL from its tibial insertion. At this point, balancing may require conversion from a posterior cruciate–retaining prosthesis to a posterior cruciate–sacrificing and replacing prosthesis, because the PCL can at times contribute to deformity, particularly in the patient with severe pre-existing deformity.

Table 108.5. Seven Points of Ligament Balancing

Varus Deformity

Varus is the most common and often the simplest deformity to correct. However, in extreme cases, it can be as challenging as any knee deformity.

- Varus deformity can be resolved by making the tibial cut perpendicular to the axis of the tibia and taking a minimal cut medially. However, commonly there is still medial tightness, particularly in extension, after appropriate bone cuts.
- Further steps include removing medial osteophytes on the femur and tibia, and releasing the joint capsule at the medial side of the tibia with careful attention to preserve the continuity of the MCL. If this does not achieve balance, the MCL can be released from its distal insertion on the tibia. Use a subperiosteal dissection of the medial collateral ligament from the tibia. It can be either partially or completely released from its insertion on the tibia with a very low amount of force to break up any remaining Sharpey's fibers connecting the ligament to bone (Fig. 108.23).
Additional releases can include the pes anserina as a secondary constraint medially. Release the posterior capsule and PCL if further correction is needed, and finally, the origin of the medial gastrocnemius can be released (Table 108.6).

![Figure 108.23.](image) A: Completed varus release. B: The superficial medial collateral ligament can be detached if necessary.

Table 108.6. Techniques of Sequential Varus Release (Do These in Sequence from 1 to 6)

The Valgus Knee

The valgus knee is technically more difficult to realign and balance. After appropriate resection of the femur and tibia, a persistent valgus deformity due to ligamentous imbalance requires a release of the lateral structures.

- The tightest structure is usually the iliotibial band with the knee in full extension. Release this from the inside out using a #15 blade perpendicular to the long axis of the iliotibial band at the joint line. In the more severely valgus knees (greater than 15° degrees), more extensive lateral releases may be necessary.
- Starting from the anterior direction, subperiosteally take the supporting lateral structures off the femoral condyle. The popliteus tendon inserts just anterior to the lateral epicondyle.
- Then remove the lateral collateral ligament from its epicondylar insertion in a subperiosteal fashion. This dissection can be carried down to the posterior lateral aspect of the capsule. The biceps femoris is rarely released.
- The iliotibial band can be released at Gerdy’s tubercle. It is important to perform these releases sequentially, releasing structures only as necessary (Fig. 108.24).

![Figure 108.24.](image) Valgus release to balance the knee. (A) First, release the iliotibial band with the knee in extension from the inside out, perpendicular to the long axis of the band and at the joint line with a #15 blade. It may also be released at Gerdy’s tubercle. (B) If the knee is still tight, release more by detaching the structures (1, 2, and 3) attaching to the lateral epicondyle using subperiosteal dissection. The biceps femoris rarely requires release.

With severe valgus deformity, a more stabilized arthroplasty should be available in case posterolateral instability results from excessive lateral release or medial instability results from MCL incompetence. In general, more severe lateral and medial corrections are more easily dealt with using cruciate-substituting devices because of the potential for a contracted PCL, which in itself may be the limiting factor in deformity correction (Table 108.7).

Table 108.7. Soft Tissue Release for Valgus Deformity (Do These in Sequence from 1 to 6)

Combined deformities, specifically valgus flexion contractures, are often the most challenging and require careful evaluation of the anatomy of the knee. A more aggressive distal femoral resection combined with lateral and posterior releases and perhaps a more constrained knee prosthesis may be the best solution.

Flexion and Extension Gap

At this point, it is imperative to recheck the flexion and extension gaps of the knee. With the knee in full extension and with gentle traction on the heel, place a spacer block to judge the relative tightness of the extension gap that was produced. At final fit, the limb should be near an anatomic 7° of valgus at the knee. Both the medial and lateral ligaments should be under equal tension and the leg should be in full extension. In the ideal situation, both the medial and lateral ligaments will be equally
Unequal gap size is a frequent technical error (Fig. 108.25). Three situations exist in which imbalance of the flexion and extension gaps may occur. Test the patient for these imbalances intraoperatively, and correct whatever problem is detected.

1. Too tight in flexion and too tight in extension. This situation usually can be best corrected by either decreasing the thickness of the tibial insert or, if necessary, recutting the proximal tibia.

2. Too tight in flexion and satisfactory in extension. This situation may occur for several reasons. Too large a femoral component, especially on anterior reference knee systems, overstuff the flexion gap. In this case, the femoral component can be downsized by one. A tight PCL will show five signs (Table 108.8). The PCL itself will have "bowstring" tension, excess rollback of the femur on the tibia produces "booking," the tibial component tends to sublux anteriorly in its tray, and the femoral component subluxes off the femur. To correct this condition, recess the PCL off the femur or tibia, increase the slope of the tibial component, or increase the flexion gap by downsizing the prosthesis.

3. Tight in extension and satisfactory in flexion. This situation is produced either by a posterior capsular contracture, which can be released, or by posterior osteophytes. If this maneuver does not work, more distal femur can be resected to produce equal extension and flexion gaps.

Patella

Patella preparation usually follows the application of femoral and tibial trial components after ligament balancing has been achieved. This should not be interpreted, however, as reducing the importance of the patellofemoral articulation, which has been the source of the majority of complications in TKA. This is particularly true with earlier, boxier femoral components or when the importance of patellar tracking was not as highly appreciated as it is now. The complication known as the patella clunk (49) (Fig. 108.26) results from fibrosis on the quadriceps tendon that catches on the anterior aspect of the femoral component.

Because the typical surgical exposure is medial parapatellar, the surface of the patella is easily accessible for cutting. Replace the resected articular surface so that the thickness of the patella stays roughly the same and the patellofemoral joint is not overstuff. Avoid resection of too much bone, which can result in fracture of the patella. Position the patella medially on the flat resection surface to enhance tracking. Appropriate external rotation of the femoral and tibial components, along with lateral translation of the femoral and tibial components, can diminish the tension on the lateral retinacular structures and improve tracking.

- Begin preparation of the patella with reflection of the fat pad and synovium from around the periphery. Remove all osteophytes. Visualize the margin of the patella without compromising the patellar and quadriceps tendons.
- Cut the patella freehand or with one of many cutting jigs, the goal of which is to make a flat cut of the patella (Fig. 108.27). Asymmetric cuts can produce patellar tilt. Most components have pegs that are inserted into drill holes in the patella.
POSTOPERATIVE CARE

Resurfacing of the patella is controversial. There are several situations for which there is general consensus on the need to resurface. Most surgeons would agree that all knees with inflammatory arthritis should be treated with patellar resurfacing. People with severely arthritic, deformed patellae may benefit from patellar resurfacing. Some surgeons resurface the patella routinely.

Preparation for Cementing

- In preparation for cementing, remove the trial components and lavage the bone surfaces to be cemented with normal saline. The attention paid to draping at the beginning of the case pays off now. A tight seal of the adhesive plastic drapes proximally and distally can ensure that fluid does not flow between nonsterile and sterile areas of the field.
- Clear the bone surfaces of debris. In addition, prepare sclerotic bone with a pick or drill point to produce multiple small shallow holes to encourage interdigitation of cement. Holes made in a line may predispose the bone to fracture, so make them random.
- After all bone surfaces are lavaged and debris has been removed, mix the cement. Then bring the final components into the field. Cement the tibia first. Vigorously pressurize the cement, in a doughy state, into the tibial plateau. After the cement is pressured, add a 1-mm-thick flat layer of cement on the tibial plateau. This uniform surface will ensure an adequate cement mantle in spite of tibial bone irregularities, which may not be apparent.
- Apply the tibial component and impact it into position. Vigorous impaction may improve cement pressurization, but take care not to fracture the tibia. Remove excess cement, particularly anterior to the posterior tibial tray.
- For the femur, apply a donut-shaped piece of cement to the dry distal femur starting on both distal condyles and then onto the anterior femur. Pressurize the cement with a sponge and finger to ensure uniformity and smoothness. Do not allow cement to extrude or enter the knee.
- Place a small amount of cement on the posterior rails of the femoral component and pressurize manually with the thumb. Remove excess cement before applying the femoral component.
- The femoral component must be applied neither in flexion nor in extension. Often, a pair of guiding posts or a notch, or both, aid the placement of the femoral component. Then impact the component into position and remove excess cement.
- Place a trial articular surface on the tibial component and extend the knee fully. It may find its own balance while the cement remains doughy. Flex the knee, remove excess cement, and bring the knee back to extension and keep it there until the cement has cured completely.
- Use an osteotome or a reciprocating saw to make a cut parallel to the joint line and approximately 2 cm distal to it at a 45° angle to meet the initial osteotomy site. This allows for a smooth transition of the bone and cement to extrude or enter the knee.
- The patellar component can be cemented with the knee extended. Apply the cement to the patella with tuberculin syringes that are cut off and have liquid cement aspirated into them. Use these syringes to pressurize the cement peg holes.
- Apply an even layer of cement to the undersurface of the patellar component with the inferior portions of the three pegs visualized. Place the patellar component onto the three holes in the patella and apply a patella clamp (Figure 108.27). Pressurize evenly and remove excess cement.
- After the cement has hardened, flex and extend the knee, and check the balance. Verify the seven points of ligament balancing (Table 108.5) and patellar-femoral tracking. If the patella lifts laterally while tracking, patellar bone beyond the polyethylene component can be removed on the lateral side. The effect is similar to that of a lateral release without the deleterious side effects of a soft-tissue release. If the patella still tracks poorly, then a full lateral patellar retinacular release can be performed.

Wound Closure

- Irrigate all of the soft tissue, and prosthetic and bony surfaces of the knee joint vigorously. Deflate the pneumatic tourniquet and electrocautery bleeding points. In the posterior knee and the posterior lateral corner, the lateral genicular vessels may bleed vigorously. It is important to perform pulsatile irrigation hemostasis to eliminate cement and other particles that cause rapid wear.
- After the knee has been irrigated, exchange the trial tibial articular insert for the final polyethylene liner. This is a good time to reassess knee balance, particularly in extension, and to determine whether moving up or down one size in tibial thickness may improve stability in flexion and extension. It is vital to check behind the posterior condyles of both the medial and lateral sides of the femur to ensure that extraneous cement has been removed. This cement can limit motion, or break off and cause third-body wear.
- Now close the knee. We prefer to close the extensor mechanism with a running monofilament resorbable suture. Closure of the extensor mechanism should be full thickness, with adequate purchase of soft tissue on both sides producing a watertight seal of the joint. This is easily achieved on the quadriceps side but can be very challenging distally. That is one of the reasons why the initial incision is so important. A small amount of patellar tendon incorporated into the most distal portion of the incision of the arthroscopy gives a good purchase of the medial soft tissue and can ensure a watertight seal distally. A proficient closure helps prevent infection.
- After closure of the extensor mechanism, use another running monofilament to close the deep fat layer, which also includes the peritenon but not the deep dermis. Close the skin with staples. Dress the wound.

Tibial Tubercle Osteotomy

Difficulty with exposure can be encountered in patients with severe angular deformity, with bone deficiency, or with prior surgery, or in obese patients. In these patients, we prefer to perform a tibial tubercle osteotomy rather than a quadricepsplasty. Our technique allows early mobilization, has excellent healing, and has a low complication rate.

The tibial tubercle osteotomy helps when the patella cannot be everted or when exposure is particularly poor. The tibial tubercle osteotomy is useful for treating other disorders around the knee as well.

- Perform a trial patellofemoral tracking using the rule of “no thumb,” or touch-free central patellofemoral tracking. There should be no subluxation. Removal of lateral patellar bone beyond the prosthesis may decrease tension laterally. Verify final tracking with the actual components, with the tourniquet down and before a lateral release is performed. With modern implants, the need for lateral release should be less than 5% of cases. A tibial tuberosity transfer or medial capsulorrhaphy, or both, may be necessary in extreme cases.

Figure 108.27. Level of patella resection. (From Insall JM, ed. Surgery of the Knee, 2nd ed. New York: Springer Verlag, 1991:645, with permission.)
Begin motion according to your preferences and the clinical situation. Early motion can improve recovery and shorten the hospital stay. The continuous passive motion (CPM) machine is useful for obtaining early motion. The intent is to achieve extension early and then to advance the CPM by 10° or more each day to achieve 90° by the time of discharge from the hospital. Allow the patient to bear weight on the first postoperative day. Use a knee immobilizer only until sufficient quadriceps control has returned.

**PITFALLS AND COMPLICATIONS**

Long-lasting complications of TKA are rare, and long-term success is generally the rule. Complications can be divided into mechanical and nonmechanical etiology.

### NONMECHANICAL COMPLICATIONS

The most common nonmechanical complications of TKA are thromboembolism and postoperative anemia.

Thromboembolism occurs in approximately 50% of patients mainly at or below the level of the knee; 10% are proximal to the knee. Pneumatic compression devices (12) and low-molecular-weight heparin (6) may lower this incidence somewhat. Prophylaxis against heparin-induced thrombocytopenia is the mainstay of current treatment regimens (51), and pharmacologic and mechanical intervention should be routine postoperatively. Deep venous thrombosis is largely asymptomatic, and patients may be treated empirically after hospital discharge or undergo screening studies, the most popular of which is Doppler ultrasound.

Although TKA can be performed entirely under tourniquet to minimize intraoperative blood loss, calculated estimates of perioperative blood loss using hematocrit suggest a blood loss of 1500 ml for a cemented procedure, and 2000 cc for an uncemented procedure (17). Dropping the tourniquet for hemostasis before closure or use of a postoperative drain may actually increase overall blood loss (6,33). Although omission of these steps is considered by some surgeons to be contrary to general surgical principles, elimination of these steps rarely results in a surgically significant hematoma. Appropriate strategies for blood conservation include preoperative autologous blood donation (66), preoperative use of erythropoietin, and postoperative blood salvage (14,21).

Vascular injury during knee replacement is extremely rare and potentially disastrous (22,28,36).

Neurologic injury after knee arthroplasty is most common in the presence of valgus deformity, especially the flexion valgus deformity of severe rheumatoid arthritis (35). This is almost entirely restricted to peroneal nerve injuries and occurs less than 1% of the time.

Wound problems are often found in the multiply operated or medically compromised patient. Careful surgical approaches and aggressive treatment of postoperative wound problems can prevent infection. Local or free muscular flap coverage may be necessary for loss of soft tissues (15).

The infected TKA is a costly complication that occurs in approximately 1% of all knees (54). Preoperative antibiotics, carefully controlled operative environments, and meticulous surgical technique are required to minimize incidence. Host factors such as diabetes or corticosteroid treated inflammatory arthritis, surgical factors such as complexity of the procedure or postoperative drainage, and late exposure to hematogenous seeding by dental or urologic manipulation or infection elsewhere in the body may predispose the patient to infection (54). In the early postoperative infection, perform an open or arthroscopic lavage of the knee and administer systemic intravenous antibiotics. This approach may salvage the prosthesis. The standard of care for treating late or established infection is resection of the prosthesis, followed by a period of intravenous antibiotics and then reimplantation of a new prosthesis (see Chapter 159) (65).

### MECHANICAL COMPLICATIONS

The majority of the mechanical complications of total knee replacement can be minimized with careful attention to proper soft-tissue balance in all planes. Patients with more challenging preoperative deformity or motion restriction should be counseled about possible postoperative shortcomings. This is especially true with preoperative motion deficits. If a knee passes the seven points of ligament balancing intraoperatively, late instability should be uncommon. Minimizing the risk of instability as a complication is discussed in the technique segment of this chapter.

Aseptic loosening of the TKA is typically different from aseptic loosening of the total hip arthroplasty. Polyethylene debris-induced, macrophage-initiated osteolysis is considerably more rare. This problem is thought to be due to the different wear environment of the TKA. Threefold larger wear particles are produced in a shearing, less-conforming environment. These larger particles are less likely to induce a macrophage response and lead to a lower rate of aseptic loosening (39). Malalignment, especially of the tibial component in varus (69), can lead to mechanical subsidence of the tibial component and loosening.

Supracondylar femur fracture above TKA may occur owing to the inherently elevated loads at the proximal end of the anterior flange of the femoral component, owing to intraoperative notching of the anterior femur (10), or owing to the osteopenia of stress shielded bone under the femoral component. Rarely, osteolysis may contribute. Special cases include diaphyseal fracture above a stemmed femoral component or fracture through the stress riser between total hip and TKAs. Stable internal fixation with either a fixed angle device or a retrograde nail through an open notch is generally preferred (10,41) (see Chapter 20).

Tibial fracture is associated with malalignment or component loosening (30). The fracture may be bypassed with a stemmed prosthesis.

Prosthetic failure in contemporary arthroplasties is limited to delamination (39) or fracture of tibial polyethylene components or failure of metal-backed patellae (45). In the compromised environment with either mechanical imbalance or secondary to polyethylene failure, a tibial metal backing may rarely crack. This type of mechanical failure may often lead to particulate-induced synovitis and mechanical symptoms.

Extensor mechanism complications are the most common reason for revision knee arthroplasty. These complications were addressed in the technique section.

### AUTHORS' PERSPECTIVE

The modern TKA has instrumentation that facilitates reproducible alignment and proper ligament balance, and materials and design that permit functional and durable recovery of motion. When implanted in closely monitored and maintained surgical and rehabilitation environments, it has a remarkable and predictable record of success. Most of the mechanical and some of the nonmechanical complications of knee replacement are preventable by meticulous surgical technique with careful cross checking of anatomic landmarks and soft-tissue tensions with appropriate jigs.

### CHAPTER REFERENCES

Two Ways to Avoid Wrong Site Surgery. AAOS Bul 1998;46.

Revision knee arthroplasty surgery is distinctly different from primary reconstructions of the arthritic joint. Although it is essential to master the principles and techniques of primary surgery before tackling revisions, primary surgery will not, by itself, prepare the surgeon to cope with the failed prosthetic knee joint.

Primary total knee replacement (TKR) usually follows a well-choreographed routine with a coherent sequence of steps that are easily performed with well-designed instruments. The bone is usually solid, ligaments are usually intact, and skin is adequate to cover and protect the reconstructed joint. Revision surgery does not offer this. Whereas in a primary arthroplasty, the surgeon can depend on instruments that refer to particular osseous landmarks, neither the landmarks nor good instruments are available for revisions.

The failed knee is in disarray. The failure must be explained at several levels: Why is there pain? Why has a component broken? Why is the joint unstable? If these questions are unanswered prior to revision, a suitable mechanical plan for the revision will not be apparent and the patient will not benefit from the revision.

Once the reasons for failure are clear, it is essential to plan the procedure carefully. Anticipation of problems mandates familiarity with the failed and revision implants. Wariness and improvisation are important in revision surgery. Alternative plans must be available. We seek perfection in the primary, and the "perfect compromise" in the revision.
The successful approach to revision knee arthroplasty includes adherence to general principles, an operative plan that addresses the cause of failure, and an orderly sequential plan for performing the surgery. I use a three-phase approach, as described later.

Long operations, extended hospital stays, and costly implants make revision surgery expensive (30). An increased incidence of complications increases costs as well. The latitude for errors—of both judgment and technique—is less than with primary TKR. In the final analysis, revision surgery is best avoided by a well-conceived and precisely executed primary knee replacement. Table 109.1 lists the steps to be taken in evaluating and planning for revision of a failed knee arthroplasty.

<tr>
<td>3</td>
<td>Their paper was significant because they analyzed the results of revision arthroplasty according to excellent results from revision arthroplasty. By contrast, the patients in whom no definable problem could be ascertained before their operations were not improved, Jacobs, working with Hungerford and Krackow (129), reported in an important paper that 83% of their patients who had definable mechanical problems achieved good or excellent results.</td>
</tr>
<tr>
<td>4</td>
<td>As uni- and bicondylar resurfacing arthroplasties supplanted hinges, revision arthroplasty became feasible. In general, however, revision meant little more than a repeat of the original operation (73,131,149). Polycentric and interposition prostheses such as the McIntosh were poorly suited for revision arthroplasty (125,166). Later, tricompartmental resurfacing designs, without customization or specific adaptation, still led to disappointing results when used for revisions (32,58,85,124), except in selected cases (65,55,126). The incomplete understanding of the unique problems of revision surgery is obvious in articles that combined primary and revision knee arthroplasties in the same series.</td>
</tr>
<tr>
<td>5</td>
<td>Revision knee surgery was soon recognized as a distinct challenge. Rand and Bryan (124), in reviewing 427 revision knee arthroplasties performed between 1970 and 1980 with a wide range of implants, established three criteria to qualify the result as successful: (a) mild or no pain, (b) knee flexion to 90°, and (c) mild or no instability. Two years after revision surgery, only 59.6% of patients had “successful” results.</td>
</tr>
<tr>
<td>6</td>
<td>The kinematic rotating hinge (KRH) was conceived as a device that had less than full constraint (it had full rotational freedom) but could still stabilize a knee in the absence of collateral ligaments. Rand et al. (129) described 23 revision arthroplasties with the KRH at 29–78 months (mean, 50 months) after surgery. The complication rates were high and the surgeons advised that the implant be limited to patients without functional collateral ligaments, whose knees could not be managed by soft-tissue reconstruction. Essentially, this was a prosthesis of last resort. It eventually became apparent that even very bad cases could be revised with specially adapted resurfacing or nonlinked constrained implants (136).</td>
</tr>
<tr>
<td>7</td>
<td>A single 1982 issue of the journal Clinical Orthopedics (19,75,146) made the point that revision surgery demands special principles, techniques, and implants. “Repeat primary replacement” is inadequate. Early revision was advised once evidence of component loosening appeared to avoid further bone loss. The patellar “turn-down” surgical approach, skeletonization of the bone ends, and a special axial slap-hammer extractor were developed for exposure and implant removal. Custom resurfacing designs with augmented metal trays and a central stem could substitute for bone defects and provide good fixation to compromised bone (2). Constrained condylar implants, which were stable to varus and valgus stresses but were unlinked, were recommended for knees without competent collateral ligaments. In this 1982 volume, Insall and Dethmers (75) stated that there was no longer an indication for hinge prostheses.</td>
</tr>
<tr>
<td>8</td>
<td>True understanding of revision surgery means diagnosing the cause of failure and reporting results accordingly. “Failed total knee arthroplasty” is not a diagnosis. Jacobs, working with Hungerford and Krakow (76), reported in an important paper that 83% of their patients who had definable mechanical problems achieved good or excellent results from revision arthroplasty. By contrast, the patients in whom no definable problem could be ascertained before their operations were not improved, emphasizing this important principle of revision knee arthroplasty. Their paper was significant because they analyzed the results of revision arthroplasty according to the cause of failure. Failed linked devices, comprising a minimum of cases (3/28), were all revised for loosening and presented considerable technical challenges. Instability and malrotation accounted for fewer cases but were easier to revise. Flexion was generally good, with mean values of 97° after revision from a preoperative mean of 86°.</td>
</tr>
<tr>

### PRINCIPLES OF TREATMENT

Establish a specific diagnosis. The diagnosis or cause of failure must be established specifically prior to revision. Revision knee arthroplasty performed without a diagnosis is unlikely to help the patient. Jacobs et al. (77) described four types of failure; Vince and Long (158) added four more causes of knee arthroplasty failure, and a ninth, fracture, can be included (Table 109.2). Thus, eight of nine causes of knee arthroplasty are amenable to revision surgery. A knee may exhibit facets of more than one type of failure. For example, a prosthesis with catastrophic failure of polyethylene with consequent osteolysis may also be loose. An infected knee may have developed loosening, and a loose arthroplasty may have become unstable. Try to distinguish the primary reason for failure.
Table 109.2. Nine Types of Failure That Are Indications for Revision TKR

Figure 109.1. A: Patellofemoral radiograph of patient who presented with symptoms of “giving way.” Reconstruction of medial collateral ligament was performed by her surgeon, but in fact the buckling was caused by patellar dislocation. B: Intraoperative photograph showing that the patella tracks directly over the lateral femoral condyle. The patellar tracking problem resulted from malrotation of the femoral and tibial components.

Instability may result from a host of causes including collateral ligament incompetence, component subsidence, pain that causes muscle inhibition, and extensor mechanism problems. Problems are often related, such as component malrotation and patellar instability. In fact, it would be fair to hypothesize that all patellar complications result from maltracking, which in turn is caused by malrotation of either the tibial or femoral components (Fig. 109.1B).

Inexplicable pain is a distinct cause for concern and caution but not an indication for surgery. A patient with pain in the presence of otherwise unremarkable findings may have had inappropriate expectations of the primary surgery and is unlikely to benefit from revision. Evaluate such patients thoroughly for infection, reflex sympathetic dystrophy (RSD), and component malrotation (Fig. 109.2).

Figure 109.2. Computerized tomography (CT) scan of distal femur showing internal rotation of the femoral component. In most cases, this leads to patellar complications. In some cases, the knee is painful and stiff without enough flexion for dislocation to occur. Internal rotation of the femoral component, difficult to diagnose on plain radiographs, presents as painful “mystery knees,” which are caused by internal rotation of the femoral and/or tibial components.

Breakage of prosthetic components was a major cause for revision in the early 1990s when earlier, flawed designs began to fail. After identifying which type of failure has occurred, determine the cause to ensure that the scenario is not replicated in the revision. The temptation in dealing with worn modular articular polyethylene is to replace it. This would however, simply reestablish the original environment of failure.

Stiffness is perhaps the best example of revision requiring a complete evaluation of the failed arthroplasty. There is rarely a quick or easy fix for this problem. The analysis must be very specific as to whether the knee lacks flexion, has a flexion contracture, or is globally tight. Each scenario requires a different approach.

Do not perform a “repeat primary arthroplasty.” The original cause of failure must be rectified and the damage caused by the failure must be reconstructed. Bone loss is common to most revisions. Fixation, which may have been straightforward in the primary procedure, can be achieved in the revision only with the use of bone graft and special implants if there are defects and the bone is too sclerotic for conventional cement techniques (Fig. 109.3).

Figure 109.3. A: Intraoperative photograph of the proximal tibia after removal of components. The bone is sclerotic, is covered with a fibrous membrane, and lacks the normal cancellous surface of bone seen in primary knee arthroplasties. B: Intraoperative view of healthy cancellous bone at the time of primary knee arthroplasty. Bone cuts have been made and the knee is ready for implantation.

Pay attention to all aspects of reconstruction. Once you have opened the failed knee arthroplasty and face the complete disarray and destruction, the course of action may be unclear. Although bone defects, for example, present an immediate challenge, they cannot be reconstructed without attending to joint stability and prosthesis fixation, and ultimately restoring functional kinematics to the joint. Skin and soft-tissue coverage problems are prevalent and require attention. Preoperative planning must take all of these issues into consideration.

Use appropriate implant technology. There is an unfortunate although understandable response by the surgeon faced with a badly failed knee arthroplasty: “This is such a bad-looking failure that I will certainly need a large, constrained implant if not a hinge!” This response is misguided. There are specific reasons to use built-in constraint in a prosthesis, to supplement fixation, and to add modular augmentations (components); these become apparent during the course of the revision. It is
inappropriate to simply use a “revision implant”—there are systems available that offer many options.

Plan the surgery. Planning ensures preparedness. It requires anticipation of all possible eventualities to avoid costly surprises in surgery. A thorough plan for revision TKR (Table 109.3) provides a way to ensure that the necessary equipment, instruments, graft material, and implants will be available at surgery, as well as a sequential intraoperative guide to what should be accomplished in the revision.

### Table 109.3. Critical Components of a Plan for Revision Knee Arthroplasty

A specific mechanical plan that identifies each shortcoming of the failed knee and describes a solution must be part of the plan. The tight knee with a flexion contracture, for example, will require an aggressive release of the posterior capsule and probably resection of additional distal femoral bone. This would not be appropriate for the unstable knee that needs to have the deforming forces (malalignment) eliminated, and stabilizing forces (ligament reconstruction or constraint) reconstituted. The sequential plan indicates when each part of the procedure should be carried out, and the mechanical plan describes what has to be accomplished.

### CLINICAL ASSESSMENT OF PAIN IN THE FAILED TKR

Most problem knee arthroplasties present with pain; clues for the cause of the pain are the time of onset and the nature of the pain (Table 109.4).

NO PAIN RELIEF AFTER ARTHROPLASTY

**Same Pain Persists**

If there was never any pain relief after surgery and essentially the same pain persists, consider referred pain from the hip or spine, preexisting sepsis, a tight arthroplasty, or failed bone ingrowth. Carefully evaluate the ipsilateral hip and the spine. Internal rotation of the ipsilateral hip that is limited on physical exam and reproduces the knee symptoms is very important. Treat an arthritic hip prior to knee arthroplasty, as much of the knee pain may be referred from the hip. A technetium (Tc) bone scan and injection of local anesthetic into the hip joint are helpful in the differential diagnosis.

Sometimes the preoperative pain is caused by a joint effusion. Pain accompanied by a general feeling of tightness or fullness, or pain that is perceived in the popliteal region, may be associated with a tense effusion. A postoperative effusion can reproduce this same pain.

Perhaps the most trying situation of all is the patient who, in retrospect, was suffering from sympathetically mediated pain (RSD). The characteristic history of inordinate pain relative to physical findings may be present, but cardinal symptoms such as skin hypersensitivity and intolerance to light touch, for example of bed sheets, may be absent. Awareness of the possibility is important to avoid unnecessary surgery. Consultation with a pain-management expert will help the patient cope with understandable frustration and anger. Lumbar sympathetic blocks are helpful to diagnose and treat this very difficult clinical situation.

**New and Different Pain**

Postoperative pain that differs from the preoperative pain requires a workup for infection. Culturing an aspirate of the knee, with the patient off antibiotics, is essential to establishing the diagnosis. The infected knee replacement may present with only slight warmth and swelling, or with frank drainage and soft-tissue loss. Some factors in the history create particular risk. Prior osteomyelitis adjacent to the knee, although dormant for many years, has been associated with a 15% infection rate in knee arthroplasty. Prior surgery (especially with implants), antimetabolite medications (including corticosteroids), and some medical conditions (notably rheumatoid arthritis) are suspected of increasing the risk of infection. The data, all from small series, are inconclusive.

A different pain that has been present ever since the surgery implies that the arthroplasty or the technique of insertion may be at the root of the problem. Knees that have been implanted with a greater degree of stability and tightness than the patient can tolerate may be painful. Malrotation of the components can also create a painful situation, with tightness and binding of the components.

Uncemented arthroplasties in which bone ingrowth has not occurred will usually be painful from the outset. During the recovery phase, as postoperative pain recedes, the patient is left with discomfort that is worse on weight bearing and that never really abates. Careful fluoroscopic examination of all the interfaces allows accurately directed plain radiographs that will illustrate this situation (44).

Reflex sympathetic dystrophy may also occur for the first time after knee arthroplasty surgery. The prospects for prompt resolution of the RSD are improved by early referral to a pain management specialist.

**Different Pain with Stiffness**

The knee that moved well prior to surgery but became stiff and painful afterward may be difficult. A knee prosthesis that is tight, for whatever mechanical or surgical reason, is likely to be painful. Conversely, a knee that is painful may hurt too much for the patient to participate in physical therapy. RSD is a frequent companion to the tight painful knee.

INITIAL PAIN RELIEF
New Pain Months to Years Postoperatively

The appearance of a new or different type of pain after a period of pain relief may indicate late infection. It is, however, the typical presentation for any number of mechanical failings in the knee, most commonly loosening and breakage. Breakage, or extensive wear of components, is probably encountered more commonly than loosening in the current era. Mechanical failure may also be accompanied by symptoms of lost motion, buckling, instability, or catching and grinding.

New Onset of Pain at Rest

Pain of mechanical origin is usually present with activities. The loose prosthesis hurts more with weight bearing and the tight knee hurts more when flexion is attempted. Pain from a patellar fracture is worse with activities, such as stair climbing, that increase the force on the extensor mechanism.

Unremittent pain of new onset, present at rest and worse with activities, is characteristic of sepsis. RSD, which also produces rest pain, is unlikely to have a late onset. The presence of an effusion, from whatever cause, may result in pain at rest.

MECHANICAL SYMPTOMS PLUS DISCOMFORT

Some patients describe mechanical symptoms that are accompanied by but are more serious than their pain. Instability may take different forms: The patient may experience buckling, caused by giving way of the extensor mechanism, in turn caused by either pain or subluxation of the patella. True varus–valgus instability is generally apparent and accompanied by malalignment when severe. The patient easily demonstrates catching or grinding that usually accompanies catastrophic polyethylene wear.

PHYSICAL EXAMINATION

Use the physical examination to evaluate the patient fully, with attention to the spine and hips as well as the knees. Evidence of infection or catastrophic polyethylene wear may lead to lymphadenopathy, particularly at the groin. Check the dentition and sinuses, as they may be sources of sepsis. Examine gait for evidence of instability and limp. The characteristic walk of a patient with hip pathology, dipping of the shoulder ipsilateral to the painful hip, may indicate referred hip pain.

Observation Swelling may affect the entire limb or just the knee joint. Local swelling may result from chronic scarring in a tight joint, extensive thickening of synovium, or an effusion. The entire leg may be affected by edema or lymphedema. Instability to fully extend the knee may result from an effusion or a fixed flexion contracture. There can be sympathetically mediated pain without the characteristic waxy pallor that is sometimes mimicked by tight swelling in the early postoperative period. Many normally healing knees will have a characteristic neurodermatitis rash that accompanies an area of paresthesia lateral to the skin incision (138).

Palpation Begin palpation of the knee with gentle stroking of the skin, which may reveal the hypersensitivity that is often associated with RSD. Increased warmth is common during the first 3 months after surgery and may be exacerbated by overly aggressive physical therapy. Increased warmth out of context of the patient’s recovery from surgery, however, is suggestive of sepsis. Palpate for specific areas of tenderness that may indicate a mechanical problem between the prosthesis and bone or the prosthesis and soft tissues. Palpate the posterior aspect of the knee to detect a popliteal or Baker’s cyst, which reflects a large effusion, which may come from a failed arthroplasty. Palpate the pulses and evaluate for circulation to eliminate peripheral vascular disease as a possible cause of the patient’s pain and to be certain that there is adequate circulation for reconstructive surgery.

Motion Motion must be quantified, with clear distinctions established between passive and active motion. The average flexion of most arthroplasties by 3 months following surgery will be about 115°. This is influenced heavily by the preoperative motion, so it is important for you to know what that was. It is unrealistic to expect that a patient who flexes to only 60° but had near normal motion prior to the primary surgery may benefit from timely revision before the soft tissues contract.

Strength Pain or neurologic disorders may compromise apparent strength. The patient with spinal stenosis who has quadriceps weakness may behave like the polio patient who must “back knee” to walk. This may create looseness, wear, and instability in the arthroplasty.

Look for an “extensor lag,” which is due to extensor strength that is inadequate to extend the knee through its full passive extension. This can be caused by muscle weakness, inhibition due to pain, and anatomic and mechanical problems in the extensor mechanisms. Carefully palpate the extensor mechanism to look for sites of discrete tenderness or gaps, which may suggest patellar fracture or tendon rupture. Although some of these problems are treatable, chronic extensor lags can be difficult to eliminate completely with revision surgery.

Instability Most patients can demonstrate, if not describe, their knee instability. Determine precisely what type of instability is present and what the mechanical remedy will be. Many patients whose knees are buckling or giving way will use the term instability when the problem is in the quadriceps mechanism. See Table 109.5 for interpretations of instability symptoms and Table 109.6 for causes of buckling.

**Table 109.6. Anatomic Causes of Giving Way (Buckling) of the Knee**

Knees may dislocate in the anteroposterior (AP) plane, which occurs most commonly in flexion. The patient will be able to demonstrate this phenomenon, and you can confirm it with a conventional drawer test and posterior sag sign. Other methods of assessing instability, so useful in the normal knee, are not applicable to the arthroplasty. An arthroplasty with posterior or anterior instability in extension is likely to manifest global instability. The patient will probably walk in marked...
Varus–valgus instability is disabling. The patient falters with each step and usually depends heavily on assistive devices. This type of instability is usually accompanied by significant malalignment, which has either been the cause or the result of the instability. Comparing the physical examination with the radiographs will reveal whether instability is from collateral ligament failure, loosening and subsidence of components, or destructive wear of polyethylene (Fig. 109.4).

The unstable knee arthroplasty may be deceptively stable to varus and valgus stress testing when locked in full extension, because of tension on the posterior structures. This knee, when flexed to about 30°, reveals significant instability. The medial collateral ligament (MCL), so crucial to good arthroplasty function, should be assessed for strength prior to revision. A knee may be unstable with a structurally intact but unbalanced ligament. It can be made to be functional with the appropriate releases or advancement. The knee in which the MCL has suffered complete failure becomes a far larger challenge.

Extensor Mechanism Palpation may reveal quadriceps or patellar tendinitis, or a fatigue fracture of the patella. Catches, clicks, or “jumping out of place” may result from subluxation or patellar dislocation. The patellar “clunk” occurs when scar under the quadriceps tendon catches under the anterior edge of the femoral component when the knee flexes deeply. This may initially be a small piece of synovium, which hypertrophies with each subsequent episode of catching. Eventually, the patient notes a dramatic “catch” when trying to rise from a seated position. The scar catches and with further effort escapes from the notch with an audible and sometime painful “clunk” (10,72). The offending scar may be excised arthroscopically or with a limited arthrotomy (Fig. 109.5).

Patellar subluxation is usually a dynamic phenomenon that requires careful observation of the functioning knee to diagnose. Patellae that dislocate are more easily diagnosed. Dislocation generally occurs with flexion, and the extensor mechanism often reduces with extension. Because component malrotation is usually at the root of the problem, there may be apparent differences in the amount of internal rotation of the flexed hip joints, only because the femoral component itself is internally rotated (Fig. 109.6). Internal rotation of the tibial component can be appreciated by looking at the externally rotated position of the foot with the patient sitting with his legs hanging over the edge of the examining table. Confirm any suspicion of malrotation with a computed tomography (CT) scan of the arthroplasty, which will allow comparison of the position of the prosthesis relative to the transepicondylar axis.

INVESTIGATION OF THE FAILED TKR

ASPIRATION OF JOINT FLUID

Aspirate the joint and send fluid for a leukocyte count and for culture and sensitivity of aerobic, anaerobic, and fungal organisms (49,97). More than 25,000 leukocytes per cubic millimeter indicates sepsis, especially if a majority of the cells are polymorphonuclear cells. Repeat cultures if there is a negative culture from the aspirate of an arthroplasty suspected to be infected. Barrack et al. (7) found preoperative aspiration to be reasonably sensitive (75%) and highly specific (96%) for the detection of infection. Early work with biochemical evaluation of polymerase chain reactions of aspirated fluid promise a high degree of sensitivity and specificity (68). This assay,
however, is not yet widely available for the diagnosis of infection in knee arthroplasties.

**RADIOGRAPHS**

**Plain Films**

For evaluation of the problematic knee arthroplasty, take plain radiographs using 18-inch (45 cm)-long cassettes with the patient bearing full weight on the limb of concern. This usually reveals the extent of subsidence and of ligamentous laxity. Take the lateral projection with the patient standing and then with the knee flexed maximally. This technique reveals subluxation in extension as well as recurvatum and flexion contractures. The lateral flexed view helps the technician obtain a true lateral projection and reveals tibial femoral instability that may not occur in extension. The tibial slope is displayed best in this view, and flexion can be measured. Posterior osteophytes that may impede flexion are apparent, and the size of the femoral component is easy to measure.

The greatest technical challenge in obtaining accurate radiographs is control of rotation. Failure to do so creates studies with limited value. When it seems impossible to obtain a true AP projection of both components—on one radiograph the tibia is viewed correctly but on another it is rotated while the femur is viewed accurately—the diagnosis of malrotated component is established (Fig. 109.7).

![Image](image)

**Figure 109.7.** A: AP radiograph of an uncemented knee arthroplasty that has failed because of pain, stiffness, and patellar subluxation. While this shows a symmetric view of the tibial component, the femoral component is clearly viewed obliquely. B: The lateral radiograph shows that the femoral component has been translated posteriorly, further contributing to a tight flexion gap and poor motion. C: Patellofemoral view showing subluxation of the patella that has resulted from malrotation. This subluxation, creating the sense of impending dislocation with further flexion, causes the patient to stop knee flexion during physical therapy and contributes to poor motion.

Evaluate the patellofemoral joint with either “sunrise” or Merchant views (108) (Fig. 109.8). These projections assess patellar bone cuts and tracking. Component wear and breakage, bone fracture, and patellar dislocation are apparent.

![Image](image)

**Figure 109.8.** Patellofemoral (Merchant) radiographs showing a range of patellar pathology: dislocation (A), fracture with component loosening (B), and lateral tracking and (C) catastrophic wear of a metal-backed button.

Plain radiographs of the contralateral knee, if no arthroplasty is present, may be of use to estimate revision component size. Do not commit to a component size at this point, because derangements in the soft tissues of a failed knee arthroplasty, whether abnormally tight or loose, may necessitate the choice of larger or smaller devices. Evaluation of serial radiographs of the failed knee arthroplasty are helpful to understand precisely what has led to the current situation. Finally, radiographs of the arthritic knee immediately prior to the primary arthroplasty are helpful. If these do not show very extensive arthritic changes, then search for other sources of referred pain. In the absence of these, the arthroplasty may have been performed prematurely, before serious arthritis had developed.

**Fluoroscopic Views**

When tibial components were manufactured exclusively of polyethylene, radiolucent lines between the cement interface and the bone or component were much easier to visualize (Fig. 109.9A, Fig. 109.9B). Metal-backed tibial baseplates frequently obscure the interface so that fluoroscopic views are necessary to ensure that the x-ray beam is parallel to the interface (34).

![Image](image)

**Figure 109.9.** A: AP radiograph of a painful, stiff total knee arthroplasty with ostensibly good alignment and well-fixed tibial component. B: Lateral radiograph of a painful, stiff, uncemented total knee arthroplasty with some radiolucency anteriorly. The component is slightly oversized. When templating for revision, use a slightly smaller femoral component to improve flexion. C: Fehring’s (44) lateral fluoroscopic view of the anterior interface, showing extensive radiolucency and a limited ingrowth. D: Lateral fluoroscopic radiographs demonstrate complete radiolucencies in the posterior flange. This femoral component is loose. Attempts at flexion are painful because the tibia rocks the femoral component anteriorly. E: Intraoperative photographs demonstrating the ease of removal of the loose femoral component. F: Intraoperative picture of the uncemented femoral component, where there has been very little if any bone ingrowth.

When cemented femoral components loosen, progression to subsidence is usually rapid. Failure of bone ingrowth into the uncemented component can be a source of
pain that is difficult to visualize without fluoroscopic views (109). These may have to be oriented to each of the three major interfaces of the femoral component (anterior, distal, and posterior) (Fig. 109.9C, Fig. 109.9D, Fig. 109.9E and Fig. 109.9F). Fehring and McAvoy (44) evaluated 20 painful knee arthroplasties with this technique and identified 14 that appeared loose. At revision, all 14 were loose and improved by revision surgery.

**Stress Views**

Stress radiographs are not usually necessary for the assessment of problem knee arthroplasties, especially if standing films have been obtained. They can be useful, however, to quantify varus or valgus instability or when there is doubt as to whether fractures adjacent to the arthroplasty have healed.

**BONE SCAN**

Technetium bone scans are highly sensitive but lack specificity in the evaluation of a painful knee arthroplasty (33,133). Hofmann et al. (79) found that these scans frequently demonstrate mild to moderate activity during the first year after surgery, whether cemented or uncemented fixation has been used. High variability has been noted. Loosening cannot easily be distinguished from bone remodeling in this period. Henderson et al. (64) studied three groups in whom they performed Tc bone scans: asymptomatic knees undergoing scans for other reasons, septically or aseptically loose arthroplasties, and painful knees without radiographic evidence of loosening. They concluded that sequential 99m-Tc-MDP and 67-gallium (67-Ga) citrate scintigrams are useful for demonstrating the presence of aseptic and septic loosening in knee prostheses, and that pain with a normal scan appearance is probably not caused by loosening or infection. Gallium scans alone are not generally reliable, but indium-labeled (In-111) white cell scans—more specifically, In-111-labeled immunoglobulin G (In-111-IgG) scintigraphy—has been regarded as highly sensitive and fairly specific for detecting late infection (79,106). Scans, however, are never substitutes for aspiration of the joint.

**COMPUTED TOMOGRAPHY SCAN**

Rotational malalignment of femoral and/or tibial components has been revealed as a cause of patellofemoral complications (16). There is agreement that the femoral component should be aligned parallel to the transepicondylar axis of the distal femur, defined as a line passing between the two attachment points for the collateral ligaments. CT scanning would be ideal to evaluate the rotational position of the femoral component relative to the epicondylar axis, were it not for its expense and the artifact created by the chrome cobalt in most femoral components. Nonetheless, many arthroplasties can be imaged sufficiently well with modern scanners to identify the epicondyles on the femur and the prosthesis, despite scatter of the beam. A plain radiographic method has also been described by Eckoff et al. (35,36).

**INDICATIONS FOR REVISION TKR**

Revision knee arthroplasty may be recommended to a patient dissatisfied with his present knee arthroplasty when a specific mechanical diagnosis is made and a coherent plan for surgery to correct the problem can be established. Do not consider revision for trivial problems. Do not do a revision unless the benefits clearly outweigh the risk of complications.

Some indications are compelling. Treat the infected knee, except in highly unusual circumstances or when the infection is of very recent onset, promptly and aggressively with a two-stage implantation protocol. Revise a loose prosthesis because it will continue to damage bone. Patients with poor flexion or a flexion contracture deserve an adequate time period following surgery in which to work aggressively on rehabilitation. However, stiffness combined with obvious mechanical impediments to motion requires revision as early as 3 months after the primary arthroplasty. Patellar tracking problems, especially if symptomatic, inexorably lead to greater complications. They should be treated by a surgeon who is willing to revise the entire arthroplasty if necessary to correct underlying rotational problems (Fig. 109.10).

Figure 109.10. AP radiograph of a painful, stiff uncemented total knee arthroplasty. The components appear large and there are circumferential radiolucent arcs around the tibial component. B: Lateral radiograph showing oversized femoral component, loose tibial component that has subsided anteriorly, and extensive osteophyte formation posteriorly. Calcification is also present in the patellar tendon. This knee had minimal flexion.

**STUDIES OF CONTEMPORARY REVISION KNEE ARTHROPLASTY**

**GENERAL RESULTS**

Despite improvements in knee revision knee arthroplasty, the results are inferior to primary knee replacement. It is difficult to compare the published series of revisions (38), because techniques and causes of failure differ widely. There is no large series with a minimum 10-year follow-up. The general dependence on constrained devices emphasizes the importance of a long-term study, given the high risk of late loosening with these implants.

There are three series that may be compared, using similar although not identical implants and techniques. Vince and Long (158) reported early loosening in a group of 44 revisions when nonlinked constrained implants had been implanted with press-fit modular stem extensions in patients with poor-quality bone. They reported good functional results without failures due to loosening when (nonconstrained) posterior stabilized implants were used, but a failure rate approaching 20% when constrained implants were necessary. In a follow-up to this study (159) that described 98 revisions, the use of constrained implants decreased. The overall failure rate was 7%, with instability a greater problem than loosening.

Haas et al. (60) described the results of 76 (nonseptic) revision knee arthroplasties with an average follow-up of 3.5 years (range, 2–9 years) with this modular system. Their overall failure rate was 8%.

Peters et al. (118) from Rush-Presbyterian Hospital in Chicago reported their experience with 57 revisions evaluated at an average follow-up of 62 months (range, 36–120 months). Four (7%) clinical failures were reported, three of which were due to instability after the implantation of a posterior stabilized implant. In this series, the surgeons resorted to nonlinked constrained implants in an unusually high percentage of cases, when compared to the experiences of Vince and Long (158) and Haas et al. (60).

**RESULTS OF DIFFERENT FIXATION OPTIONS**

**Stems**

Use modular stem extensions in revision surgery when bone quality is poor, defects have been reconstructed, or a constrained implant has been used. Many surgeons limit the use of methacrylate cement by using modular stems that can be applied to the femoral and tibial components and that achieve a tight fit in the medullary canal.

Fully cemented stems have been advocated by Rand et al. (114) at the Mayo Clinic, who reviewed 40 revision knees in 35 patients with the Kinematic Stabilizer (Howmedica, Rutherford, NJ) prostheses implanted with fully cemented stem extensions in one or both long bones. Radiolucentstics did not progress, and no failures of fixation were reported. Although the superiority of fixation with full cementation is not generally disputed, there is still concern as to how destructive removal may prove
if one of these reconstructions becomes infected. Various intramedullary stem extensions are shown in Figure 109.11.

**Figure 109.11.** Intramedullary stem extensions. A,B: Fully cemented nonmodular stem with the original Total Condylar III (Howmedica, Rutherford, NJ) femoral component, used here because of poor bone quality with a posterior stabilized nonmodular tibial component. C: Fully cemented fixed stem extension with a constrained articulation. D: Press-fit modular stem extension with methacrylate cement applied only to the component. Note the nonconstrained posterior stabilized prosthesis. The femoral stem extension is underramed relative to the medial side of the endosteal canal—it does not, however, compromise the alignment of the prosthesis. The tibia, by contrast, fills the canal but as a result lies in valgus. E,F: AP and lateral radiographs of fully cemented, 145 mm stem extensions. Note the constrained articulation. These are indicated in the presence of poor quality bone when constrained prostheses are used. G,H: AP and lateral radiographs of a constrained articulation, necessitated by medial collateral ligament incompetence with fully cemented, short or “stubby” stem extensions. I: Loose noncemented femoral stem extension. Note the constrained articulation, which most likely contributed to the loosening and the increased valgus alignment resulting from the tight press-fit of a straight stem in an asymmetric bone. J: Offset stems, used without cement. Note the tight fit in the canal without compromising the alignment of the arthroplasty. This revision was performed for instability, and accordingly, a larger femoral component was selected. K,L: Extremely long uncemented stem used in a second reimplant for sepsis in a patient who had already failed one two-stage reimplantation. These very long stems have been used to stabilize large structural allografts and should never be fully cemented.

**Uncemented Revision TKR**

Several investigators continue to evaluate un cemented revisions. Mow and Weidel (113) described 15 revisions in selected cases, of which eight had both components implanted without cement. Two required revision for tibial component loosening. In a later study with un cemented porous-coated anatomic (PCA) revision components, 6 (16.6%) of 36 revisions failed. Three of these were for tibial component loosening.

Cementless primary and revision knee arthroplasties have been developed by Whiteside over the last two decades. In 1993, Whiteside (167) reported the results of 56 cementless knee arthroplasties followed for a minimum of 2 years after surgery. The technique is based on rigid fixation of the implants into the remaining shell of distal femur and proximal tibia. Morcellized cancellous bone was employed to fill all defects. There were two failures of fixation. Uncemented revision knee arthroplasty is appealing but technically demanding.

**General Bone Defects**

Numerous techniques have been developed to reconstruct deficient bone in revision surgery. There may be fundamental differences between bone defects—what works for one patient may not work for another, and proven techniques for primary arthroplasty are not always useful in the revision. Elia and Lotke (37) described their experience with 40 revision arthroplasties in the presence of significant bone loss. They reported good results but wisely commented in their conclusions on the importance of (a) restoring the mechanical alignment of the knee with accurate component positioning; (b) filling all bone defects with bone, cement, or modular spacers; (c) using stems to assist in component support; and (d) adherence to soft-tissue balancing.

**Modular Augmentations**

Modular prosthetic systems have become widely available for revision knee arthroplasty, enabling surgeons to deal with the numerous different problems that present at revision. Typical systems include augmentation for tibial and femoral components. Although these are usually regarded as a means of reconstructing defective bone, each has a specific kinematic implication that can be exploited. For example, the distal femoral components can tighten the extension gap of the knee selectively and if used on one condyle alone will alter alignment. A medial distal femoral augmentation increases valgus alignment. This effect is most dramatic on the posterior condyle, where symmetric medial and lateral augmentation will tighten the knee in flexion and an augmentation on one side will change the rotation of the component. Internal malrotation of the femoral component, observed commonly in knee arthroplasty, can be corrected with a posterior lateral augmentation. The proximal tibia can be reconstructed reliably with augmentation blocks and wedge-shaped augmentations. Rand (122,123), reporting 41 consecutive revision arthroplasties with cruciate retaining or posterior stabilized prostheses, supported the reliability of modular augmentation in revision knee arthroplasty.

**Allograft**

The failed knee arthroplasty is often so destructive of bone that innovative approaches are required. Large custom prostheses, highly regarded in tumor reconstructions, have not been as successful in revision total knee arthroplasty. Massive structural allografts have, however, been used extensively, with surprisingly good results (Fig. 109.12). Mow and Wiedel (112) described 15 revision knee arthroplasties with large segmental, cavity, or combination defects that were reconstructed with structural allografts. These were followed for 30–101 months, with one failure directly related to the graft.

**Figure 109.12.** Structural allografts. A: AP radiograph of a failed revision total knee arthroplasty. The amount of missing bone would have been better managed with structural allografts. Failure occurred due to loosening and instability. Note the excess valgus alignment despite the femoral stem extension. B: Lateral radiograph of failed revision total knee arthroplasty. C: Intraoperative photograph of a distal femoral structural allograft applied to the second revision. D: Intraoperative photograph of a proximal tibial allograft shaped and ready to be applied to the proximal tibia. Fixation is achieved by the interlocking sculpted shape that maximizes contact area, and by the intramedullary stem on the tibial implant. E: AP radiograph of a second revision knee arthroplasty with distal femoral and proximal tibial allografts. F,G: Lateral radiograph of second revision in extension and flexion.

One of the most extensive experiences with allograft reconstruction of the knee has been at the University of Toronto. Ghazavi et al. (63), reporting the surgical experience of Gross et al. (57), found that of 50 knees with either distal femoral or proximal tibial allograft reconstruction, seven (33%) ended as failures at an average of 50 months (range, 24–132 months) of follow-up. The failures were due to infection in three, tibial component loosening in two, fracture of the graft in one, and nonunion of the graft in one. They concluded that “properly applied allograft can be used to reconstruct massive bone defects, provide stability and support for
implants, and restore bone stock in the event that additional operative treatment is necessary."

Whiteside (167) has avoided the use of large structural allografts by packing defects with cancellous bone. Even large structural defects have been reconstructed this way, applying 6-inch medullary stems to bypass the defects. Whereas the stems were smooth and uncemented, the components themselves were porous coated. Generally good results were described in a series of 20 knees, with persistent pain requiring revision in only one patient.

Tsahakis et al. (148) described structural allografting for large uncontained defects in 19 cases. The results were good at an average of 2.1 years, representing a preliminary experience with the technique.

An innovative approach, borrowed from hip arthroplasty surgery, is that of impaction grafting (Fig. 109.13). Some surgeons have used this term to describe compaction of cancellous bone in small contained defects, but Ullmark and Hovelius (156) have employed the technique in the medullary canal in three patients. Their results are promising at 28 months of followup.

Figure 109.13. Impaction grafting. A: AP radiograph of a loose revision arthroplasty that was performed 4 years earlier as a reimplantation after infection. The constrained component has contributed to loosening, which has been further complicated by a fracture of the femur. B,C: AP and lateral radiographs of second revision total knee arthroplasty with impaction grafting of the femur, further secured with medial and lateral strut allografts because of a fracture. D: CT scan of the femur, proximal to the femoral component, showing consolidated impaction grafting and strut allografts in place. E: CT scan of proximal tibia showing a press-fit stem extension without impaction grafting.

Constrained Prosthesis

There have long been attempts to stabilize difficult knee arthroplasties using constrained and even hinged prostheses. There is a general, although not universal, preference for unconstrained implants where feasible. This places greater demands on the surgeon, who must reestablish stability and motion with the patient's own soft tissues. There are times in the operating room when soft tissues are lacking and it is difficult to stabilize the arthroplasty without resorting to mechanical constraint. When mechanical substitution for soft tissues is needed, what devices are available and to what extent are they reliable and effective?

Although constrained prostheses promise stability, they do so at the risk of an increased incidence of loosening. Linked, constrained devices (hinges) have enjoyed popularity in some centers (13) but generally have been abandoned because of poor results (62,74). Rotating hinges, although still linked devices, have been employed as an alternate (128,142).

The nonlinked constrained devices have held more promise. They are constrained to rotation and provide stability to varus and valgus forces and also resist posterior dislocation in flexion. However, they lack the hyperextension stop that is integral to the hinge. The Kinematic Total Condylar III prosthesis (Howmedica, Rutherford, NJ) was the original nonlinked constrained device. Mechanical substitution for collateral ligament function was provided by a prominent tibial eminence that rested between the femoral condyles. Both tibial and femoral components featured nonmodular, narrow-diameter intramedullary stems that were fully cemented into the medullary canal. The results with these implants proved surprisingly good (24,71,92,121,132).

To avoid the introduction of methacrylate cement deeply into the medullary canal, modular stem extensions were added to achieve a press-fit inside the canal, and cement fixation could be reserved for the cut bone surface of the tibia and femur. Haas et al. (80) with 76 cases concluded that there was no significant difference in the failure rates when uncemented stems were used with 57 (75%) posterior stabilized or 19 (25%) constrained implants. They did not study revisions for sepsis. They reported a total of six failures, two of which were the result of aseptic loosening. One failure was in the posterior stabilized articulation group (1.75%), and the other was in the constrained condylar group (5.3%). The experience of Vince and Long (158) revealed that of 44 revisions (which included revisions for sepsis), all three (23%) failures occurred in the group of 13 with constrained articulations.

See Table 109.7 for a comparison of three series by Haas et al. at the Hospital for Special Surgery in New York (60), Peters et al. at Rush-Presbyterian Hospital in Chicago (118), and Vince et al. at Los Angeles (159).

REOPERATION AFTER REVISION TKR

The results of revision knee arthroplasty may be summarized in the Mayo Clinic experience with reoperations after revision knee arthroplasty surgery (145) (Table 109.8). Loosening is not the major cause of failure. The more frequent problems require reoperations without revision. The Mayo Clinic group reviewed 655 revision knee arthroplasties and discovered that 46 (7%) of them required a total of 60 (9%) additional surgeries. The extensor mechanism was the most common site of problems leading to reoperation in 19 knees (41%).

The series by Vince et al. (159) (Table 109.8) included revisions for sepsis, which the Mayo series did not. Again, the extensor mechanism was the most common site of problems requiring additional surgery, not all of which were complete revisions. Whereas tracking problems and fractures of the patella may have roots in the surgical technique, extensor lag, which is one of the most perplexing complications of revision arthroplasty, is difficult to predict. It may be improved in some cases by a shortening of the extensor mechanism, accomplished with a distal advancement of the vastus medialis. Figure 109.14 shows distal advancement of the rectus femoris.

Extensor mechanism allografts are new treatments that show promise.

**TREATMENT OF INFECTION**

Two-stage reimplantation protocols, although taxing for patient, surgeon, and health care system, have been recognized in North America as the most reliable means of eradicating infection (50,170). The original protocol, from the Hospital for Special Surgery in New York, has been followed for many years (171). Other series have described results with antibiotic-impregnated polymethylmethacrylate (PMMA) spacers that were implanted when the prosthesis was removed (14,59,65) (Fig. 109.15). Spacer blocks that allow some knee motion have been studied (69). Although most surgeons prefer spacer blocks because they provide local delivery of antibiotics, the maintenance of tissue planes, and improved stability during the period of explantation of the prosthesis, other surgeons have reported bone loss associated with the spacers (18). One-stage reimplantations, popular in some centers with extensive experience, do not yield the same high success rate (161). To reduce the number of surgeries, it may be argued that using a one-stage revision, and reserving a two-stage revision for the failures, makes sense (140).

Figure 109.15. A: Cement spacer block seen on an AP radiograph of a primarily infected knee arthroplasty that has been removed. Originally, the patient had posttraumatic arthritis from a motorcycle accident. A spacer block, impregnated with antibiotic, was inserted between the deformed tibia and the femur. B: Templates for the fabrication of a custom tibial baseplate that will accept modular stem extensions. C: AP radiograph after reimplantation with custom-fabricated tibial baseplate and standard, fully cemented, short-stem extensions.

In the original reports, patients were selected for entry into the two-stage protocol. Other institutions have published experiences with unselected infected knee arthroplasties that have not been as good. In one of the most recent large studies, Hirakawa et al. (68) noted a 92% success rate when the infection complicated a primary knee arthroplasty in a patient who had no previous surgery (Table 109.9). This dropped to 41% when there had been multiple previous surgeries.

Staphylococcus epidermidis is the most common organism in most series (50).

When infection recurs after a two-stage reimplantation, the patient may be treated according to the protocol a second time. In their experience with 12 such patients, Backe et al. (5) at the Hospital for Special Surgery elected to arthrodese and not reimplant three of them. Infection did not return in the nine repeat reimplantations and...
three fusions.

REVISION OF UNICOMPARTMENTAL REPLACEMENT

The failed unicompartmental replacement poses a specific, controversial situation. Whether this represents a relatively easy revision is debated, although there is agreement that the failed unicompartmental replacement cannot reliably be reconstructed with another unicompartmental prosthesis. Figure 109.16 shows revision of a unicompartmental replacement.

![Figure 109.16](image)

**Figure 109.16.** Revision of a unicompartmental arthroplasty. A: Failed medial unicompartmental knee replacement in a 48-year-old male laborer. There is extensive osteolysis. B: Revision was performed with impaction grafting of a contained defect of the entire proximal medial tibial. Arrows indicate the extent of graft material. Closer to the knee, a thin layer of methacrylate cement can be seen.

Surgeons working at the Brigham Hospital in Boston (8) have presented data supporting the idea that the unicompartmental replacement may be used as a temporizing measure because it is an easier revision. As such, it might be an option for the younger patient who realizes that additional surgery is inevitable given a normal lifespan. The original study has been updated with similar conclusions (88).

Padgett et al. (117), collaborating with colleagues from the Hospital for Special Surgery in New York, have reported a different experience, and they feel that revision of a failed unicompartmental replacement presents much the same challenge as a failed tricompartmental replacement. They found significant osseous defects in 76% of failed unicompartmental replacements, with 62% of revisions exhibiting radiolucent lines. They reject the concept that the unicompartmental replacement is a more conservative surgery.

PREOPERATIVE PLANNING

Preoperative autologous blood donation has been recommended for arthroplastic surgery in general, and this includes revision procedures. Thorough medical evaluation is, of course, essential, especially because the average age of revision patients is even older than that of primary patients in most series (68). The essential elements of planning, however, are the diagnosis of the failure and a detailed mechanical plan to rectify the causes of the failure (153).

THE ROLE OF ARTHROSCOPY

Arthroscopy has been used with limited success to rectify the problems of knee arthroplasty (78,110,163). It has virtually no role in the treatment of the infected knee arthroplasty, despite occasional reports of short-term success (47). Acute infections, at times amenable to open debridement with exchange of the polyethylene, often ultimately require a two-stage reimplantation protocol.

Some surgeons have used arthroscopy to release adhesions prior to manipulation of a stiff arthroplasty. This is not necessary when the manipulation is done within 6–8 weeks after surgery. The chronically stiff knee will generally require a well-planned complete revision. Some benefit has been described from arthroscopic resection of the posterior cruciate ligament (PCL) in the stiff cruciate-replacing arthroplasty. In one series, 10 knees gained an average of 40° of flexion with this approach (169).

Patellar tracking problems are invariably the cause of patellar fracture, catastrophic wear, and component loosening. In turn, the tracking problems are generally the result of malrotation of the femoral or tibial components that require full revision surgery (16). Accordingly, arthroscopic intervention, limited to lateral patellar retinacular release, is inadequate. Even proximal realignment, failing as it does to correct the root cause of the tracking problem, will be ineffectual.

The disorder described previously as a “patellar clunk” has been identified most commonly in early designs of posterior stabilized implants. The offending scar can easily be resected from the quadriceps tendon arthroscopically, with complete resolution of symptoms (100). The literature on arthroscopic evaluation and treatment of the problematic knee arthroplasty is summarized in Table 109.10.

![Table 109.10](image)

**Table 109.10.** Role of Arthroscopy in the Failed Total Knee Arthroplasty

PROBLEMS REQUIRING SURGERY BUT NOT TOTAL REVISION

Problems may arise in knee arthroplasties that require surgery but not revision of the components. Most problems, however, are due to malposition of all components, and require complete revision. Complete revision offers the best chance to set everything right, and to ensure that compatible components are implanted. Techniques for component removal and for fixation of new devices have markedly improved. Complete removal is rarely as destructive as it previously was, even in the worst situation in which a porous-coated component has been well fixed with methacrylate cement (172).

WEAR

Modularity was introduced as a means of limiting inventory and providing surgeons with options during surgery. There was also a hope that worn polyethylene components could simply be removed from the baseplates without disrupting the fixation interface. Although this is sometimes possible, bone may have been destroyed by osteolysis, the components may have loosened, and defects may need reconstruction, effectively eliminating simple polyethylene exchange as an option. In addition, the environment that has led to catastrophic wear should not be replicated. For example, thin polyethylene components or malalignment must be corrected by revision, not modular exchange.
Sometimes, however, alignment or instability can be corrected by exchanging the polyethylene for a custom-manufactured, angled bearing insert (Fig. 109.17). If the prosthesis permits, exchange to a more constrained insert may restore stability. The knee that is malaligned in valgus, for example, with a correctable deformity, can benefit from a polyethylene tibial insert that is manufactured on an angle so that it is thicker on the lateral side (141).

**Figure 109.17.** An 83-year-old patient with recurrent valgus instability in a primary revision and second revision. A: AP radiograph of a primary knee arthroplasty in this patient, performed for osteoarthritis with valgus deformity where soft-tissue releases were not performed. The tibial component was placed in varus, and the femoral component in slightly excess valgus. B: AP radiograph of the failed first revision, where a constrained prosthesis was implanted. The femoral component was implanted with excess valgus (note the stem against the medial cortex). The tibial component had been extensively cemented and is also in valgus. The medial soft tissues failed despite the constrained component, largely because of malalignment. C: The patient underwent a second revision arthroplasty, which also failed. This AP radiograph shows that the femoral component was revised with full cement fixation of the stem extension and repositioning (note the femoral stem tip now against the lateral cortex) to reduce valgus alignment. A proximal advancement of the medial collateral ligament was performed. The tibial component was not revised because of the extensive cement fixation. Even the combination of decreased valgus alignment, lateral ligament release, medial ligament reconstruction, and constraint have not stabilized the knee. D: This situation was complicated because the patient had an older-model total hip arthroplasty on the same side as the unstable revision knee. The acetabular component is not medialized and the stem has a valgus neck–shaft angle. Accordingly, to restore a neutral mechanical axis to the arthroplasty below it, only 2° to 3° of valgus alignment will be required in the knee. Anything more imparts a large deforming force on the revision knee. E: Schematic diagram of a custom fabricated tibial insert with a 0° varus orientation. This allows the tibial angle to be corrected without removing the well-fixed tibial component. F: AP radiograph of a third revision knee arthroplasty. The femoral and tibial components have been left in place, but the angled tibial insert has been exchanged and the medial ligament has been reconstructed with vascular dacron. This arthroplasty has remained stable at a 5-year follow-up largely because of the reduction in the valgus deforming forces.

**GLOBAL STIFFNESS OR INSTABILITY**

Global instability or tightness (equal instability or tightness in flexion and extension) can often be improved by limited revision surgery. Because the tibia has an equal effect on both flexion and extension gaps, revision of just the tibial component or even exchange of the tibial polyethylene alone may remedy the situation. However, an unacceptably thin polyethylene insert should not be inserted to increase motion. Revision of the tibial baseplate with resection of additional tibial bone and soft-tissue releases is preferred (159).

**OSTEOLYSIS**

Osteolysis may present with large cystic destruction of bone but without loosening of components. It is sometimes feasible to graft these lesions with compacted particulate bone. This should be accompanied by an attempt to eradicate the mechanical environment that led to the failure in the first place; for example, at a minimum, exchange the tibial polyethylene (81). When there is any doubt as to the viability of the fixation, a full revision is preferred. At that time, there will be superior access to bone defects with better reconstruction possible. Figure 109.18 presents an illustrative case of reconstruction for osteolysis.

**Figure 109.18.** Osteolysis treated with bone grafting. A: An unusual case of osteolysis in a well-aligned posterior stabilized knee arthroplasty 6 years after implantation. Osteolytic lesions are apparent on either side of the central tibial keel. B: Lateral radiograph of posterior stabilized knee arthroplasty at 6 years, showing a large osteolytic lesion (arrows) directly under the tibial tubercle. C: Intraoperative photograph of large osteolytic cavity viewed from the medial side of the tibial tubercle. A flap of periosteum has been elevated from the tubercle. D: The osteolytic cavity was curedtted and packed with particulate iliac crest bone autograft combined with allograft. This eventually failed when the tibial component became loose and then required revision knee arthroplasty. E: The removed modular posterior stabilized tibial insert showing very little wear. F: The patellar component showing more extensive wear on the lateral facet.

**RECURRENT EFFUSION**

On occasion, a patient may experience recurrent swelling in a knee arthroplasty. This is generally related to higher levels of activity and can be expected to subside. At times, this may be persistent and bothersome. Some result from wear debris. Debridement and synovectomy may prove beneficial, especially if the tibial polyethylene insert is exchanged and the cause of the wear is addressed. Recurrent swelling may result from hemorrhage into the knee. A series of 30 such patients has been evaluated by Kindsfater and Scott at the Brigham Hospital in Boston (86). They found that nine knees responded to conservative care alone, and that open synovectomy was curative in 14 of 15 patients whose hemarthroses recurred regularly. They attributed the bleeds to entrapment of proliferative synovium or the fat pad between prosthetic components.

**NINE MECHANICAL PLANS FOR REVISION TKR**

**LOOSENING AND PROGRESSION OF ARTHRITIS**

Prosthetic loosening results from the victory of forces that favor loosening over those that resist it. The most important force resulting in loosening is generated by malalignment, most commonly varus alignment of the tibial femoral axis. The medial side of the tibia is overloaded, bone subsides, and the component is no longer solidly attached to bone. The solution is to reestablish the desired alignment of the limb. This is generally around 7° of valgus tibial femoral angle, but more specifically it is a neutral mechanical axis, as depicted by the line running from the center of the hip through the knee and ankle.

Most prostheses that fail because of subsidence and loosening will also have bone defects that must be reconstructed. Cement, particulate bone graft, modular prosthetic augmentations, and large structural allografts all play a role. The surgeon will need to anticipate these problems and plan to have the appropriate material
available.

Most knees that fail from malalignment have never had the appropriate ligament balance performed. A knee that is in varus prior to the primary procedure and then is implanted in varus is unlikely to have had an adequate medial release. Conventional ligament releases are appropriate for the majority of these cases. Increased joint constraint and the more arcane ligament advancements and reconstructions are usually not required.

When loosening has been the cause of failure, there will generally be a need for enhanced fixation at the time of revision. This will usually take the form of intramedullary stem extensions, which are usually modular additions to the prosthesis. These may be long and achieve three-point fixation inside the medullary canal, or they may be of wider diameter with more of a press fit. In selected cases, such as poor-quality bone where a constrained implant is planned, it may be appropriate to fully cement the stem with techniques commonly used in hip arthroplasty.

The loose prosthesis that was originally implanted with a porous ingrowth surface may no longer be amenable to uncemented fixation. The same requirements in terms of correction of malalignment and augmenting fixation are appropriate.

INSTABILITY

Instability, like loosening, can be viewed as the competition between two sets of forces, those that stabilize the knee versus those that induce the instability. Instability occurs in an anterior–posterior direction, or varus–valgus, or both.

The arthroplasty with anterior–posterior instability is usually dislocating posteriorly. This is usually because of failure to achieve a balance between the flexion and extension gaps. A flexion gap that is too large requires a polyethylene insert that is thicker than can be accommodated in extension. Anterior tibial dislocation can also occur in this situation, but it is observed less often because the hamstring muscles pull the tibia posteriorly. Excessive posterior tibial slope may drive the tibia forward, and anterior slope will contribute to posterior instability. Assess the slope prior to surgery and correct it during the revision.

Late posterior instability may result from erosion or rupture of the PCL, as has been described by Laskin and O'Flynn ([16]). It presents with instability, recurvatum, and synovitis around the PCL. Late posterior instability has also been noted as a consequence of progressive wear, which usually erodes the posterior articular surface of the tibia and results in the femur “rolling off” the back of the knee.

The strategy of revision requires that the knee be made tighter in flexion. This is solved by inserting a larger revision femoral component to decrease the size of the flexion gap, it is misguided to simply insert a thicker tibial polyethylene insert, because, although this may stabilize the knee in flexion, it will create a flexion contracture. When the flexion gap is too large to be increased by stabilizing the size of the femoral component, even in conjunction with a posterior stabilized design, it may be necessary to resort to a nonlinked constrained implant, with a higher tibial spine. Ligament advancements, anteriorly on the distal femur, can selectively tighten the knee in flexion ([157]). In addition, tightening of the extensor mechanism with a distal advancement of the vastus medialis will enhance the effect of the patella as a buttress against extensor lag. It is important to prevent posterior dislocation before a patellectomy is present, it may be necessary to perform this advancement. In the patient with a patellectomy, posterior tibial instability, and an extensor lag, implantation of an allograft extensor mechanism may prove very useful.

Varus–valgus instability can be exceedingly difficult to overcome. Valgus instability is most common and results from an incompetent or stretched-out MCL and valgus malalignment. Varus malalignment generates huge forces that stress the soft tissues on the medial side. Correction of alignment is an essential first step in trying to stabilize these knees. All attempts at stabilization, whether through the use of constraint in the prosthesis or soft-tissue reconstruction, are doomed without the appropriate alignment.

The preferred alignment of most arthroplasties may have to be reduced to less valgus when competence of the MCL is in question. Even though this may risk overload of the medial tibial bone, and loosening, it may be essential to decrease the valgus moment arm to stabilize the knee.

The desired alignment in these knees must be calculated carefully from full-length films that show the hip, knee, and ankle. Special attention is required when the patient has a hip arthroplasty in which the neck–shaft angle of the prosthesis is quite valgus, and especially if the acetabular component has been implanted in a somewhat lateralized position. This patient may require as little as 2° of valgus tibial femoral angle at the knee to achieve a neutral mechanical axis.

Constrained arthroplasties intended to stabilize the knee may paradoxically be responsible for instability if they compromise alignment. These devices are commonly manufactured with a fixed bearing angle between the femoral component and the intramedullary stem extension that is required with most constrained devices. The asymmetry of the tibia combined with the goal of inserting larger-diameter intramedullary stems often results in up to 5° of valgus at the tibial component. In addition, if the femoral stem extension sits against the medial intramedullary wall, often the result of deficient lateral femoral condylar bone, there may be up to 12° of valgus in a knee that needs only 2°. The forces favoring valgus instability are huge and can shred a collateral ligament or dislocate a constrained implant. Correct alignment is paramount. No hinge can be expected to stabilize a malaligned prosthesis.

Just as the deforming forces must be eliminated, stabilizing forces must be restored through intact collateral ligaments or a constrained implant. When conventional releases are inadequate to stabilize the implant, mechanical constraint, ligament advancement, or ligamentous allograft reconstruction is required.

It will never be adequate to simply insert thicker polyethylene to restore stability to a knee where the collateral ligaments are either unbalanced or incompetent.

Consider the MCL that has undergone plastic failure with elongation. If the knee is lengthened in an effort to equalize the lateral side with the pathologically long medial side, as progressively thicker polyethylene is inserted, the posterior structures remain intact and begin to limit flexion. This ultimately creates a knee with persistent valgus instability (due to failure of the MCL) in conjunction with a flexion contracture.

Instability can occur in conjunction with strong and healthy collateral ligaments. This usually is the result of loosening and subsidence of the components. When they are restored to a normal position, by reconstruction of bone defects and reestablishment of fixation, the knee is stable. Apparent varus instability is often from subsidence of the tibial component that protects the MCL. Instability associated with patellar dislocation is associated with malrotation of components. This must be corrected.

Global instability is often associated with gross loosening of the components and rupture of the extensor mechanism, all of which require treatment. Consider inherent soft-tissue deficiencies, such as Ehler-Danlos syndrome, or neurologic diagnoses, such as polio or spinal stenosis, which leave the patient with a weak quadriceps. This causes "back-kneed" gait in recurvatum, which accelerates loosening. Hinges are sometimes considered in the treatment of the unstable knee, but they are only very rarely required. Greater attention to alignment, component size, and reconstruction of available soft tissues is usually more successful.

MALROTATION AND PATELLAR INSTABILITY

Malrotation of the components and patellar instability are usually linked ([16]). The internally rotated femoral component has a lateral femoral trochlea that is higher but more medial. The patella is likely to snap up and over it during flexion. In addition, the articular groove will be displaced medially, distant from the track the patella needs to follow.

All patellar complications may be related to maltracking, which can lead to fracture of the bone or loosening of the polyethylene button. Wear of metal-backed buttons is accelerated by lateral tracking because the joint reaction force is focused on the lateral side where the patellar polyethylene is likely to be thin. Surgery for any patellar complications must consider the possibility of maltracking as a cause. Complete revision arthroplasty may be necessary.

The most common solution for internal rotation of the femoral component is the use of the posterolateral femoral component augmentation, which drives the component out of internal rotation. The epicondylar axis is the most reliable guide to proper femoral component orientation.

UNDIAGNOSED PAIN

The patient with undiagnosed pain should not be subjected to revision arthroplasty ([17]). Not knowing the cause of failure, the surgeon is unlikely to be able to achieve a cure. Some pain is the result of problems unrelated to the knee arthroplasty, such as referred pain from the spine or hip or sympathetically mediated pain. Infection must be considered. Aspirate the knee for cultures, cell count, and differential analysis. Internal rotation of the femoral component, difficult to diagnose on plain radiographs, can easily be quantified with CT. Discussion of such cases with an experienced colleague will benefit surgeon and patient alike. A precise diagnosis and mechanical plan will be necessary for all these patients.
BREAKAGE AND WEAR

Catastrophic wear of knee arthroplasty components must be revised in such a way that the destructive environment is not replicated. Complete revision is usually required to correct the malalignment that may have been at the root of the problem, and to ensure that adequate polyethylene thickness can be accommodated. In this respect, the mechanical plan will resemble that for failure due to loosening. Revision to an updated prosthetic design in which adequate contact areas are provided to reduce wear is appropriate. The inevitable areas of osteolysis require graft reconstruction. Synovectomy is often important to eliminate wear particles and decrease persistent swelling.

SEPSIS

Infections are multifactorial problems that are not easily treated (13). Open debridement of acute infections within 2 weeks of surgery or within a short period after the presentation of an acute infection in an established arthroplasty can be justified. Arthroscopic intervention is less likely to be successful in curing the infection. One-stage reimplantation is possible for the infected knee arthroplasty, but clearly the risk of recurrent infection is higher with this approach.

Two-stage reimplantation protocols are the most reliable method for the eradication of infection in knee arthroplasties. The best results of two-stage protocols are obtained after appropriate patient selection. Some infected knees, either because of the type of organism, the condition of the soft tissues, or the condition of the patient, inevitably lead to resection arthroplasty. Windsor et al. (171), with Insall, reported 1 of 38 infected knees with a recurrence of the same infecting organism at 4 to 10 years. Three other patients suffered recurrence with different organisms attributed to a compromised immune system. More recently, work from Cleveland identified specific risk factors that are associated with relatively poor results from the two-stage protocol (68).

The two-stage protocol is not simply a removal of the prosthesis. Rather, it is a detailed and disciplined medical and surgical approach to the problem that requires an aggressive debridement of the infected knee joint. The original protocol of leaving the knee devoid of foreign material has been supplanted by the insertion of a PMMA spacer block, loaded with antibiotics. This delivers high-dose local antibiotics, and it preserves tissue planes for later total joint reimplantation. In an effort to maintain motion, articulated spacers have been employed.

EXTENSOR MECHANISM RUPTURE

Extensor mechanism rupture may be the worst problem in knee arthroplasty surgery, regarded by many as more difficult to treat than sepsis. Repairs of the torn tissue are notoriously ineffectual, but there has been a report of good results after transferring the semitendinosus, attached to its origin, as a means of reestablishing the integrity of the mechanism (17). Emerson et al. (53,43) have employed extensor mechanism allografts and reported excellent results. These grafts must be implanted with surprising tension, often at the cost of some flexion, for the patient to regain useful extensor strength. At the time of grafting, the tension of the extensor reconstruction can be checked by lifting the thigh. Passive flexion should be about 60°. Most patients will eventually gain motion of 90° or more.

As with so many other problems that require repeat surgery in knee arthroplasty, it is essential to consider what factors and forces may have led to the rupture initially. These must be corrected. The most common constellation of problems are those that increase the tensile forces in the extensor mechanism, such as an oversized femoral component, malrotation, excessively thick patellar construct, and so on. Figure 109.19 shows radiographs and intraoperative photographs of an extensor allograft.

STIFFNESS

The stiff total knee arthroplasty has long been considered inappropriate for revision, as these knees often become stiff because of the patient's aggressive healing response. More frequently, however, the scar that is observed in these knees is the result of the stiffness and not the cause of the problem.

If the patient cannot easily bend at the knee fairly quickly after surgery, he is at risk for loss of motion and resultant scarring. This includes patients who are unwilling or unable to comply with physical therapy. Those whose pain is simply too severe after surgery to allow movement of the knee will undoubtedly suffer stiffness. Adequate analgesia and even readmission to the hospital for epidural analgesia under which motion can be initiated may be appropriate. Medical complications that make physical therapy difficult, as well as wound problems or a hemorrhhrosis, predispose the patient to stiffness.

Look for referred pain from either the spine or the hip that may preclude comfortable knee flexion, and treat the underlying problem. After this is resolved, revision to increase motion may be indicated.

Occult infection may lead to stiffness because of the associated pain and swelling. Aspiration is key to establishing the diagnosis. RSD may be difficult to diagnose. Lumbar sympathetic blocks are useful for diagnosis and treatment. These patients may respond to revision to increase motion, performed under continuous epidural anesthesia that is used for several days after surgery. Failure of bone ingrowth may cause pain throughout the rehabilitation period that precludes successful therapy. These patients benefit most often from revision to a cemented implant.

Mechanical factors may be responsible for the stiffness; these can be resolved during the revision to ensure that maximum motion is achieved. Like instability, poor motion may be caused by poor flexion, a flexion contracture, or global stiffness. The former two require different approaches, and the last a combined approach.

The mechanical factors that contribute to poor flexion are largely those that determine the dimensions of the flexion gap and the tension in the extensor mechanism. Oversized femoral components or those that are implanted too posteriorly may make the knee tight and lead to stiffness. The PCL that was tight and should have been released or resected at the time of primary surgery may need to be revised to a cruciate substituting design. Tibias that have inadequate posterior slope or, worse, anterior slope, require attention. Malrotation, causing the components to bind and jam painfully with flexion, may be responsible for poor motion. In addition, internal rotation of the femoral component may predispose to dislocation of the patella. The patient, sensing that a dislocation is about to occur as the knee flexes, will resist flexing, much like a patellar apprehension sign. This leads to scarring and the inability to flex.

The patella that has been cut obliquely or that has become too thick as the result of resurfacing makes it difficult to bend the knee. At the time of revision, this problem is easy to solve because there is adequate bone for removal of the prosthesis, resection of additional bone, and repeat resurfacing. Ultimately, the limiting factor to the improvement of flexion will be the extensibility of the quadriceps muscle. When poor flexion is chronic, it may be impossible to gain motion, because the muscle itself is
challenges in the event removal is required and should not be implanted with full cement fixation. Stacked on top of each other, is the classic technique. A reciprocating saw also works well. Long intramedullary stems and porous-coated devices pose serious bone will be damaged. The Gigli saw fits easily into the interface and was originally recommended for the removal of well-fixed, uncemented implants. The saw, however, may drift, in which case well-fixed components must be removed without damage to the underlying bone. A Thompson quadricepsplasty may improve motion but at the risk of sacrificing quadriceps strength. Flexion contractures are more easily improved by revision surgery. Exchanging the polyethylene for a thinner insert can be dangerous, risking instability in flexion. Revision surgery is preferred, with removal of the distal femur and aggressive posterior soft-tissue releases.

**FRACTURE**

Revision knee arthroplasty is rarely performed for the treatment of fractures, but this can be a very successful approach. Most common is a supracondylar femoral fracture. Most of these require treatment with conventional plates or locked intramedullary rods introduced either retrograde or antegrade (see Chapter 20). At times, however, the distal femoral fragment may be highly comminuted or osteoporotic. Revision with a distal femoral allograft will be appropriate. Proximal tibial fracture or osteotomies (performed in an effort to correct arthroplasty alignment) that have not healed respond well to revision of the tibial component with an intramedullary stem extension across the fracture site.

**PLANNING: SKIN AND SOFT TISSUES**

Many catastrophic wound problems may be prevented with prophylactic reconstruction of soft tissues. Tissue expanders have been used successfully in knees with multiple previous scars and adherent skin. Surgical transfer of muscle has the added appeal of enhancing blood supply to the compromised area; it can be performed prior to the revision or after removal of an infected component but prior to reimplantation. The gastrocnemius is the most easily transferred, but free flaps, although technically more difficult to transfer, have some added advantages.

**SURGICAL EXPOSURE**

A standard anterior midline approach is effective in the majority of revision knee arthroplasties (see Chapter 3). Careful attention to detail in the release of scar and reconstruction of the "gutters" along the intermuscular septae adjacent to the femur are the secrets to a gentle patellar eversion without rupture of the extensor mechanism. A lateral patellar retinacular release facilitates exposure. More difficult cases may require an extension of the exposure either proximally or distally. Tibial tubercle osteotomy frequently is associated with complications. Proximal soft-tissue releases are easily performed. A patellofemoral "turn-down" is the most radical and is rarely required in even the most difficult revisions. Currently, a limited, very proximal transection of the quadriceps tendon, referred to as a snip, is favored. More aggressive exposure of the distal femur, to the point of skeletonizing, may be necessary for the stiff knee arthroplasty.

---

![Figure 109.20](image1.png)

**Figure 109.20.** Thompson quadricepsplasty. Isolate the rectus femoris tendon from the vastus medialis and vastus lateralis and release the medial and lateral quadriceps retinaculum as necessary. Lyse adhesions in the knee and excise the intermedius muscle, which is scarred down to the femur.

Flexion contractures are more easily improved by revision surgery. Exchanging the polyethylene for a thinner insert can be dangerous, risking instability in flexion. Revision surgery is preferred, with removal of the distal femur and aggressive posterior soft-tissue releases.

**component removal**

Well-fixed components must be removed without damage to the underlying bone. Several techniques have been developed, all requiring patience. The Gigli saw fits easily into the interface and was originally recommended for the removal of well-fixed, uncemented implants. The saw, however, may drift, in which case well-fixed components will be damaged. High-speed metal-cutting burrs have been employed to facilitate removal. Slow advancement of narrow osteotomes, which may be stacked on top of each other, is the classic technique. A reciprocating saw also works well. Long intramedullary stems and porous-coated devices pose serious challenges in the event removal is required and should not be implanted with full cement fixation.

![Figure 109.21](image2.png)

**Figure 109.21.** Surgical approaches. A: The classic patellar turn-down arthrotomy derived from the Coonse Adams surgical approach to the knee. Some surgeons have advocated its use as a means of lengthening the extensor mechanism to increase flexion. This may produce a disabling extensor lag. B: Intraoperative photograph showing the unparalleled exposure with a full patellar turn-down. This technique is rarely if ever required. C: The modified quadriceps snip approach. Many surgeons angle the proximal transverse cut from more distal on the medial side to more proximal on the lateral side. This maneuver may not be necessary if the approach is made slowly, with careful attention to detail and the release of scar. D: Intraoperative photograph of the closure of the quadriceps snip, showing the sutures transversely across the quadriceps tendon. Clearly, these alone will not be adequate to resist the tensile forces in the extensor mechanism. The strength of the closure comes from the standard side-to-side closure of the arthrotomy. E: Lateral radiograph of a revision knee arthroplasty, in which a tibial tubercle osteotomy has been performed and secured with cerclage wires. Placing these wires poses a danger to the neurovascular structures behind the knee. F: Intraoperative photograph of the tibial tubercle osteotomy demonstrating excellent exposure but with compromise to the cylinder of the tibia with potential compromise of tibial component fixation.

---

**Component removal**

Well-fixed components must be removed without damage to the underlying bone. Several techniques have been developed, all requiring patience. The Gigli saw fits easily into the interface and was originally recommended for the removal of well-fixed, uncemented implants. The saw, however, may drift, in which case well-fixed components will be damaged. High-speed metal-cutting burrs have been employed to facilitate removal. Slow advancement of narrow osteotomes, which may be stacked on top of each other, is the classic technique. A reciprocating saw also works well. Long intramedullary stems and porous-coated devices pose serious challenges in the event removal is required and should not be implanted with full cement fixation.
THREE-STEP REVISION TECHNIQUE

The planning and execution of a revision knee arthroplasty must follow a coherent program. The three-step technique is a path that the surgeon can follow during revision knee arthroplasty (Fig. 109.23). The cause of failure will dictate what is to be accomplished at each of the three stages (155).

Figure 109.23. Three-step revision knee arthroplasty. A: Step 1: Reconstruct the tibial platform. This establishes a foundation to use as a reference for all other work. The tibia is selected first, because its surface is always in contact with the femur regardless of the position of flexion. B: Step 2: Stabilize the knee in flexion by confirming the correct rotational position of the femur (step 2a), selecting the femoral component size that will stabilize the soft tissues in flexion (step 2b), and then selecting a combination of femur and tibial polyethylene that provides a reasonable joint line height (step 2c). C: Step 3: Stabilize the knee in extension by seating the femoral component either more proximally (only in rare cases of extreme flexion contracture) or more distally with the use of distal femoral augmentations or structural allografts.

Instruments, except for very general devices that help ascertain alignment and component position, are not generally useful. Trial components, especially those attached to intramedullary stems, are very useful. Even spacer blocks, used so widely in primary knee arthroplasty, may be misleading in revision surgery where asymmetric bone loss precludes meaningful insertion of blocks into the flexion and extension gaps.

STEP 1: RECONSTRUCT THE TIBIAL PLATFORM

The tibial articular surface is always in contact with the femur, whether the knee is flexed or extended. By contrast, only the posterior articular surface of the femur articulates in flexion, and the distal surface is in contact with the tibia in extension. The tibia serves as the foundation for the reconstruction of the knee joint (Fig. 109.23A).

Accordingly, in the first step, reestablish the tibial baseplate (but not the articulating surface) surface by inserting a trial component. Bone-graft reconstruction of defects may be necessary. Frequently, some sort of intramedullary stem extension to enhance fixation is needed. Several good classification systems exist for bone defects, which may be contained or noncontained, or they may be a massive structural defect (Table 109.11). Contained defects can be managed with particular graft or even cement, noncontained defects are best reconstructed with modular prosthetic augments; and massive defects require allograft.

![Table 109.11. Classification and Treatment of Bone Defects](image)

STEP 2: STABILIZE THE KNEE IN FLEXION

Phase 2 of the reconstruction, rebuilding the knee in flexion, is when the most important work is done. Three important goals must be satisfied in this step:

- Step 2a: Determine the correct rotational position of the femoral component relative to osseous landmarks.
- Step 2b: Choose the femoral component size and position it to stabilize the knee in flexion.
- Step 2c: Pair the most appropriate femoral component and tibial polyethylene component to place the joint line at the desired level.

**Step 2a: Rotation**

Establishing the rotational position of the femoral component on the femur is perhaps one of the most important steps in knee arthroplasty surgery, although its importance has only recently been appreciated. Most instrument systems for primary surgery easily take their reference from the posterior articular condyles, but these condyles do not exist at revision. Furthermore, although the articular surface is easily appreciated in the primary and it usually resides in a predictable relationship to the transepicondylar axis (103), this is not always the case. There is agreement that the transverse axis of the femoral component should correspond to the transepicondylar axis (11,119).

**Step 2b: Femoral Component Size**

Align the rotational position of the femoral component with the distal femur anatomically to ensure comfort, central patellar tracking, good motion, and stability. This is the key to restoring the mechanics of the knee. The AP dimension of the component is the most important dimension to consider, and it must be chosen according to the tightness of the soft tissues about the knee. The femoral component must be chosen to stabilize the knee in flexion and never to simply fit the existing bone, which will be unpredictably smaller than normal. The largest size that can be employed will reach the medial and lateral sides of the distal femur—if something larger is required to stabilize the flexed knee, then either the collateral ligaments have failed from plastic deformation or there is significant bone loss from the upper tibia that necessitates bone graft reconstruction.

**Step 2c: Joint Line Position**
The knee may be stabilized in flexion with more than one size of femoral component—a larger component may do well with a thinner tibial polyethylene insert, a smaller one with a thicker polyethylene insert. The difference between these two will be the level of the joint line. The location of the anatomic joint line proximal to the fibular head can be predicted to be a portion of the width of the transepicondylar axis (119). Assuming that the patellar tendon has not been stretched or detached, this is a readily available indicator of the desired joint line. If the joint line is below the inferior pole of the patella, you can assume that the reconstruction is near anatomic and that joint line height will not compromise extensor mechanism function.

STEP 3: STABILIZE THE KNEE IN EXTENSION

With the knee reconstructed in flexion, it is relatively easy to extend the joint and seat the femoral component against the tibial polyethylene insert to stabilize the knee in extension (Fig. 109.25). The relative position of the femoral component in the femur should be maintained and modular augmentation blocks or distal femoral allograft added to finalize the revision.

In more difficult revision surgery, you may find that the flexion gap gapes open and cannot be stabilized with even the largest femoral component and a very thick tibial insert, or the knee may have varus or valgus instability in extension. In these circumstances, decide whether to use constrained articulation that will compensate for soft-tissue deficiency or to reconstruct the deficient ligaments (90,157).

THE PATELLA—A FOURTH STEP

Leave in place a well-fixed all-polyethylene component that tracks well and is compatible with the revision component, but remove a loose polyethylene component or a well-fixed metal-backed component. If adequate bone remains, do revision resurfacing with an all-polyethylene device. If the bone is inadequate to accept a patellar prosthesis, trim the bone to fit the femoral component and leave it unresurfaced. Patellectomy is a poor choice because it leads to rupture of the extensor mechanism. The scaphoid-shaped patella that results from extensive osteolysis is a source of problems. It tends to hug the lateral femoral condyle, risking dislocation, yet it is too thin to either support a patellar implant or to be trimmed into a functional piece of bone.

A vertical osteotomy may be performed from the inferior pole to the superior, from the inside of the patella. This leaves the anterior soft tissues intact. The medial and lateral parts of the patella can then be cracked “up” away from the knee into the shape of a gull’s wing. This “gull-wing osteotomy” (Fig. 109.24) is used rarely, it does not disrupt the extensor mechanism, and it allows even a very small fragment of bone to articulate well against the femur (154). Small pieces of bone graft can be added through the osteotomy to the ventral surface. These consolidate well with time. The technique for the gull-wing osteotomy is shown in Figure 109.25.

Figure 109.24. Gull-wing patellar osteotomy. A: Lateral radiograph of failed TKR. B: AP radiograph of revision knee arthroplasty with stem extensions, compacted bone graft in contained tibial defects, and a (nonconstrained) posterior stabilized articulation. C: Sagittal gull-wing patellar osteotomy 1 month after revision for extensive patellar bone loss and a residual scaphoid shell of patella that would not track centrally and could not be resurfaced. Patellectomy risks extensor mechanism rupture. D: Gull-wing osteotomy with bone graft 3 years after revision arthroplasty, showing consolidation of medial and lateral fragments.

Figure 109.25. Gull-wing osteotomy technique. A: The normal patella should track centrally between the femoral condyles as viewed on a Merchant-type patellofemoral radiograph. B: The resurfaced patella is also expected to track centrally. C: When very little bone is left because of osteolysis, the shell of bone often tracks laterally, hugging the lateral femoral condyle and risking dislocation. D: Plan a sagittal osteotomy, from the superior aspect of the patella to the inferior pole. E: With the patella everted, complete the osteotomy with a saw. F: Crack the medial and lateral halves of the patella ventrally and place a bone graft ventrally. G: This new gull-wing shape will track centrally between the two condyles. H: The everted patella, demonstrating where the osteotomy is planned.

POSTOPERATIVE CARE AND REHABILITATION

I no longer use the bulky, cotton-padded Jones compression dressing. I now prefer a simple sterile absorbent dressing held in place by a tubular elastic fishnet gauze. The small dressing seems to convey to the patient that the knee is ready to use, a psychological factor that accelerates rehabilitation. Immobilization is rarely advantageous except to allow excessive swelling to subside. The goals of revision knee arthroplasty should be to create a stable, mobile, well-fixed arthroplasty ready for physical therapy (Fig. 109.26).

Figure 109.26. A: Postoperative dressing as described in text. B: Completed dressing with comfortable elevation on a pillow.
INDICATIONS

reported in most series as discussed later, primarily because the arthrodesis usually eliminates the pain and instability that necessitated the procedure (immobilization of the knee in a cast or brace so they will have a realistic picture of what their function will be like after arthrodesis. Satisfaction rates of 80% to 90% are

function. Arthrodesis of the ankle or hip produces almost imperceptible changes in gait, whereas fusion of the knee produces an obvious stiff-legged gait with significant pain in the knee caused by disabling arthritis, infection, or other disorders. A knee fusion is quite disabling, as it eliminates the most important joint for lower extremity

Arthrodesis of the knee is a salvage procedure to be used only when other alternatives, such as total knee arthroplasty, cannot resolve problems of instability and/or

original technique described Küntscher. Fusion of the neuropathic knee is difficult. Lucas and Murray (101) modified Küntscher's technique by inserting the nail through an anterior window in the femur, obtaining fusion in 85% of his patients. Because of the risk

failed arthroplasty, especially if there has been extensive bone loss. The best technique is difficult to discern, given the relatively few cases that require this treatment. The subject has been reviewed extensively (27,89). The preferred method, in terms of the mechanics, is undoubtedly the intramedullary nail (29,38,63,66,69,120) (Fig. 109.27). Unfortunately, the knee that is likely to be considered for arthrodesis is the failed, infected arthroplasty for which there is concern over dissemination of the infection inside the bone with an intramedullary device. External fixators have been used (61,127). Plating would seem to have little to recommend it because it lacks the mechanical advantages of the intramedullary rod and yet still introduces metal into an area of previous sepsis (116).

Figure 109.27. Arthrodesis. AP (A) and lateral (B) radiographs of postrumatic arthritis of the knee after a gunshot wound and femur fracture. The knee was stiff, painful, and deformed. AP (C) and lateral (D) radiographs of knee arthrodesis with a long intramedullary rod. The anterior bow has been rotated to create a few degrees of valgus alignment.

PITFALLS AND COMPLICATIONS

Failure to establish a clear mechanical diagnosis is the most common pitfall in revision knee arthroplasty. Failure to recognize that malrotation may be at the root of many knee problems—all patellar complications, the stiff knee, instability, and the painful "mystery knee"—is relatively frequent. Regarding the revision as simply a repeat primary, without acknowledging that special concepts, skills, implants, and instrumentation are required, produces poor results. Depending on instruments that rely on osseous landmarks that no longer exist does not work well. Venturing to achieve a solid press fit inside the asymmetric tibia or femur with stem extensions often leads to malalignment.

The most common reasons for poor results and reoperations after revision lie in the extensor mechanism. Femoral and tibial component malrotation may be at the root of the problem, but often bothersome extensor lags limit the function of the knee. This problem has not been solved satisfactorily. Constrained components are often overused in situations when nonconstrained implants would suffice, and at times there may be too much reliance on constraint even when it is needed. The constrained component will fail if the revision is malaligned or if soft-tissue releases and reconstructions have been ignored.

ALTERNATIVES TO REVISION TKR

The alternatives to revision knee arthroplasty are not good. In the face of true mechanical failure, revision is indicated. It should not be deferred if bone stock is being damaged by loosening, infection, or osteolysis. In very destructive failures, with extensive bone loss, keep in mind that revision knee arthroplasty is easier to accomplish than a solid fusion.

ARTHRODESIS

Sound arthrodesis can be difficult to achieve after failed arthroplasty, especially if there has been extensive bone loss. The best technique is difficult to discern, given the relatively few cases that require this treatment. The subject has been reviewed extensively (27,89). The preferred method, in terms of the mechanics, is undoubtedly the intramedullary nail (29,38,63,66,69,120) (Fig. 109.27). Unfortunately, the knee that is likely to be considered for arthrodesis is the failed, infected arthroplasty for which there is concern over dissemination of the infection inside the bone with an intramedullary device. External fixators have been used (61,127). Plating would seem to have little to recommend it because it lacks the mechanical advantages of the intramedullary rod and yet still introduces metal into an area of previous sepsis (116).

RESECTION ARTHROPLASTY

An arthroplasty that has failed, either because of incurable infection or perceived impossibility of bone reconstitution, may simply be left as it is, producing a resection arthroplasty. The functioning capability of these patients is usually poor (43,81,146).

AMPUTATION

Above-knee amputation is rarely necessary at any time after knee arthroplasty (82,76). Chronic infection that is active and a threat to the patient's general health, and that has not responded to multiple surgeries, is the most common indication for amputation. Bone loss alone, unless colossal, can usually be reconstituted in the healthy patient with allograft, as can the extensor mechanism. Indeed, combined proximal tibial allografts with the extensor mechanism included may be a solution.

ARTHRODESIS OF THE KNEE

Technical Contributor: Michael W. Chapman

Christan and Donley (25) state that the first reported arthrodesis of the knee was performed by Professor Albert of Vienna in 1878 for instability of the knee due to residual of poliomyelitis. Fusion of the knee was the only surgical solution for a painful or unstable knee until the introduction of arthroplasty of the knee joint in the last quarter of the 20th century. Hibbs treated tuberculosis of the knee with arthrodesis in 1911 (66,67). Key (83) first used external fixation with compression for arthrodesis of the knee in 1932, and in 1937 (84) he used a large central autogenous bone peg to achieve fusion of the knee. Charnley (21) refined the technique of arthrodesis with compression using external fixation in 1948, and the general principles he established continue to be used for arthrodesis utilizing external fixation (61,22 and 23).

Küntscher (91) in 1948 described arthrodesis of the knee by inserting his intramedullary nail from the tip of the greater trochanter across the knee into the tibia. Chapchal (29) modified Küntscher's technique by inserting the nail through an anterior window in the femur, obtaining fusion in 85% of his patients. Because of the risk of fracture at the cortical window, the latter technique has never become popular and intramedullary nailing for arthrodesis of the knee today is modeled after the original technique described Küntscher. Fusion of the neuropathic knee is difficult. Lucas and Murray (101) described arthrodesis of the knee by double-plate fixation in 1961, demonstrating that fusion of a Charcot knee was feasible.

Arthrodesis of the knee is a salvage procedure to be used only when other alternatives, such as total knee arthroplasty, cannot resolve problems of instability and/or pain in the knee caused by disabling arthritis, infection, or other disorders. A knee fusion is quite disabling, as it eliminates the most important joint for lower extremity function. Arthrodesis of the ankle or hip produces almost imperceptible changes in gait, whereas fusion of the knee produces an obvious stiff-legged gait with significant increases in energy expenditure in walking. Climbing or descending stairs and walking on hills or rough terrain are always a problem. Patients with arthrodesis of the knee have difficulty using public transportation because of the need to bend the knee to sit. They must usually sit on the aisle in theaters and may have difficulty getting up after falling. Dressing is more difficult. Patients must be warned about these problems prior to arthrodesis of their knees. Patients benefit preoperatively by immobilization of the knee in a cast or brace so they will have a realistic picture of what their function will be like after arthrodesis. Satisfaction rates of 90% to 90% are reported in most series as discussed later, primarily because the arthrodesis usually eliminates the pain and instability that necessitated the procedure (135).

INDICATIONS

Protected motion is required in the early phases after extensor mechanism allograft. Although motion is important, it should probably be passive, without proceeding past a point that risks rupture of the mechanism. Use a dial-lock hinge brace, set to limit flexion to about 60° initially, with additional droplocks to keep the knee extended during ambulation. Let the patient bear weight to a comfortable level. Implant structural allograft with sufficient stability to allow early weight bearing. These grafts rarely become stronger with time.
Indications for arthrodesis of the knee include the following:

- Postinfectious destruction of the knee
- Posttraumatic destruction of the knee in a young, active individual who desires to continue vigorous activity
- Paralytic conditions with severe deformity
- Neuropathic arthropathy
- Occasionally in malignant conditions about the knee
- After failed arthroplasty, when an attempt at revision arthroplasty is unforeseeable for the patient or not possible

The knee may be fused in children as early as age 6 or 7 years, but the risk of growth arrest by surgical procedures around the physis is significant. If possible, fusion should be delayed (by the use of braces and crutches) until full growth has been obtained.

The most important principle in fusion of the knee is the use of compression, either by external fixation, or by internal fixation with the addition of load bearing when possible. This increases the stability and area of bone contact.

Green and Kolsnick (56) achieved a 78% rate of fusion when noncompression arthrodesis (resection of the joint plus internal fixation with or without bone graft) was used and a failure of fusion when crossed Steinmann pins were used.

Occasionally, in untreated tuberculosis or hemophilia, spontaneous fusion occurs in a poor position. Deformity is often severe after the disease has subsided, and the extremity is usually fixed in flexion, abduction, and external rotation. Also, the tibia is frequently subluxated or dislocated on the femur. If the deformity is mild, enough bone can be removed from the condyles of the tibia and femur to allow approximation of the osseous surfaces in the most anatomic and functional position. If the deformity is severe, however, capsuloplasty, as well as other soft-tissue releases, may be necessary before the bones can be approximated and fused in the most functional position.

With arthrodesis of the knee, some length is lost because of the resection of the joint surfaces as well as the positioning of the fusion in 10° to 15° of flexion. Shortening of up to 2 cm is of some benefit, in that it allows better clearance of the foot during walking, assists in dressing, and relieves tension in the hamstring tendons and sciatic nerve. Shortening of more than 2.5 cm may require the use of a small shoe lift, but the entire leg-length discrepancy should not be compensated for.

INFECTION

Arthrodesis can be obtained in the presence of active infection (26). Principles for obtaining arthrodesis in the presence of infections include thorough debridement of all infected and necrotic tissues, stable external fixation, and good postoperative drainage of the wound. Staged surgery is usually advisable, with initial eradication of the infection followed by fusion. If the wound is left open at the time of arthrodesis, drainage usually ceases when the fusion becomes solid (26).

Arthrodesis of the knee for tuberculosis is frequently performed in children. There may be partial destruction of one condyle without destruction of the other. It is important to excise all the tuberculous material and necrotic bone and to administer combined antimicrobial therapy (see Chapter 176). Soft-tissue releases also may be indicated.

In cases of failed arthroplasty caused by infection, remove all implant materials and necrotic bone before fusing the knee. Knee fusions after failed unicompartamental arthroplasties have a relatively high fusion rate (about 90%), whereas fusions after TKRs are difficult, with a first-time rate of fusion of only 50% (89). Staged surgery is advisable when gross pus is present around the prosthesis. First, remove the prosthesis, bone cement, and necrotic tissue. Treat the infection with intravenous antibiotics. Consider using an antibiotic-impregnated spacer or beads. After the acute infection has resolved, perform an arthrodesis, usually with bone graft and external fixation.

ARTHROTHESIS

In most patients with arthritis, total knee arthroplasty is the procedure of choice. There is an occasional young adult, particularly a young man who desires to continue working at heavy labor, for whom an arthrodesis, despite its functional limitations, may be the best choice in view of the fact that a total knee arthroplasty would not be expected to last for very many years under these circumstances. The alternative would be to perform a total knee joint arthroplasty, recognizing that if the knee joint and subsequent revisions were to fail, arthrodesis would be necessary. As discussed later in this chapter, arthrodesis following failed total joint arthroplasty has a lower success rate than primary knee fusion, and it usually does not give as good a functional result, as substantial shortening may be necessary. Treatment of hemophilic arthropathy, which may require fusion, is discussed in Chapter 136.

NEUROPATHIC JOINTS

Arthrodesis of the knee for neuropathic joint disease is difficult and unusual. See Chapter 124 for a full discussion of Charcot neuroarthropathy.

Successful fusion of the neuropathic knee joint requires complete debridement of joint surfaces down to viable bleeding bone, and thorough debridement of the joint debris including complete synovectomy (31). Supplemental autologous bone graft may be indicated. Solid fixation of the arthrodesis with biplar external fixation, intramedullary nailing and compression, or double-plate fixation is necessary until solid radiographic union is evident. Intramedullary nailing, when feasible, is probably the fixation of choice, as a nail is not as susceptible to fatigue failure in bending as plates are, and the problem of loosening of external fixation pins in osteoporotic bone is avoided. Union rates of 100% have been described using intramedullary fixation (31,151). Double-plate fixation (101) works well, but weight bearing must be avoided and external support utilized until solid fusion is obtained.

SURGICAL TECHNIQUES

POSITION OF THE ARTHRODESIS

- In the AP plane, place the knee in anatomic position relative to the opposite normal extremity (5° to 7° of valgus), and in about 10° of external rotation. The position of flexion and extension depends on relative leg lengths and other coexisting problems, such as muscle paralysis. With only knee disease, arthrodesis in 10° to 15° of flexion allows clearance of the foot when walking and is the most efficient position for walking. However, with bone loss of more than 2.0 cm, fusion in full extension may be indicated to gain more length.

EXTERNAL FIXATION, COMPRESSION ARTHRODESIS

Compression arthrodesis of the knee with external fixation was first described by Key and is now commonly used (48,56,111,174). The technique was popularized by Charnley (21,22), who developed the Charnley clamp, which is used as an initial compression device followed by a plaster cast. Charnley and Lowe (23) reported a 98.8% fusion rate in 171 patients treated with an average of 9 weeks of external fixation and a plaster cast. Stewart and Bland (143) obtained solid fusion in 100% of 30 knees that were externally fixed for an average of 15.5 weeks.

External fixation has been used to obtain fusion after failed TKRs, particularly when infection has occurred (6,134,162). External fixation is the best technique for previously infected knees, because it avoids implants in the infected bone. Pin track infections and fixation pin failure are disadvantages of external fixation. Green and Kolsnick (56) reported successful fusions in 13 of 16 patients using external fixators, but pin track infections occurred in six.

- Position the patient supine on a radiolucent operating table and prepare and drape the entire affected extremity. A sterile tourniquet is useful to control hemorrhage.
- Through a long anterior median parapatellar incision, reflect the patella laterally, and expose the knee joint.
- If necessary, perform a thorough debridement of the knee, excising all nonviable bone and debris, and perform a synovectomy, particularly if fusing a neuropathic knee or a knee that was previously infected. Send the debrided deep tissues for culture and sensitivities. Debride the articular surfaces of the tibia, femur, and patella down to bleeding subchondral bone.
- Using the alignment jig system from any standard total knee arthroplasty system (Fig. 109.28), make the distal femoral and proximal tibial cuts to obtain 0° to 15° of flexion, 5° to 7° of valgus, and 10° of external rotation. Shape the underside of the patella to match the patella to the denuded patellofemoral groove. The patella can also be excised.
Intramedullary nailing for fixation of a knee arthrodesis has the advantages of more limited soft-tissue dissection, the potential for immediate weight bearing, an absence of pin track complications, easier rehabilitation, and a high rate of fusion. Intramedullary nailing is particularly useful when bone loss at the knee does not permit compression fixation, and where large allografts or autografts have been used to bridge an area of bone deficiency (such as following tumor resection or failed total knee arthroplasty). The major disadvantages are that nailing can be technically challenging, additional blood loss from the medullary canals can be a problem, and it is more difficult to obtain optimal alignment.

In many patients, the knee appears to be radiographically fused on the immediate postoperative radiographs because of the excellent apposition and compression across the broad bone surfaces between the femur and tibia. Although solid union of an arthrodesis in our hands has occurred as early as 6–8 weeks, I recommend leaving the external fixator in place until at least 12 weeks unless pin problems require earlier removal of a portion or all of the external fixator frame and pins. When radiographic and clinical union is evident, remove the external fixator and apply a removable long leg orthosis (some prefer a cylinder cast) and allow the patient to bear full weight for an additional 4 weeks. Then it is usually possible to allow the patient to resume normal activities without external protection. In the arthrodesis of neuropathic joints, or in situations where intercalary bone graft has been utilized to maintain leg length (such as after failure of knee arthroplasty), prolonged external protection may be necessary to ensure that the arthrodesis does not fail.

**ARTRODESIS WITH INTRAMEDULLARY NAILS**

Intramedullary nailing for fixation of a knee arthrodesis has the advantages of more limited soft-tissue dissection, the potential for immediate weight bearing, an absence of pin track complications, easier rehabilitation, and a high rate of fusion. Intramedullary nailing is particularly useful when bone loss at the knee does not permit compression fixation, and where large allografts or autografts have been used to bridge an area of bone deficiency (such as following tumor resection or failed total knee arthroplasty). The major disadvantages are that nailing can be technically challenging, additional blood loss from the medullary canals can be a problem, and it is more difficult to obtain optimal alignment.

In many patients, the knee appears to be radiographically fused on the immediate postoperative radiographs because of the excellent apposition and compression across the broad bone surfaces between the femur and tibia. Although solid union of an arthrodesis in our hands has occurred as early as 6–8 weeks, I recommend leaving the external fixator in place until at least 12 weeks unless pin problems require earlier removal of a portion or all of the external fixator frame and pins. When radiographic and clinical union is evident, remove the external fixator and apply a removable long leg orthosis (some prefer a cylinder cast) and allow the patient to bear full weight for an additional 4 weeks. Then it is usually possible to allow the patient to resume normal activities without external protection. In the arthrodesis of neuropathic joints, or in situations where intercalary bone graft has been utilized to maintain leg length (such as after failure of knee arthroplasty), prolonged external protection may be necessary to ensure that the arthrodesis does not fail.
tibia to within 2–6 cm of the ankle joint. Recent experience, however, with newer interlocking intramedullary nails has shown that the nail in the tibia need be inserted only down to the isthmus where good stability can be obtained by cross locking the nail (personal communication, MW Chapman, 2000). This makes the nailing technically easier to do.

Since knee arthrodesis today is most frequently done for failed total knee arthroplasty, the following technique is described for locked intramedullary nail arthrodesis following failed knee arthroplasty.

Operative Technique

- Preoperatively, take full-length AP and lateral radiographs of the involved extremity to include the hip joint and ankle. On these radiographs, carefully inspect the medullary cavity of both bones to be certain that they will accommodate the nail to be used. Use appropriate templates to determine the length and diameter of the nail required. In most cases, the nail should extend from the tip of the greater trochanter of the femur to the isthmus of the tibia. If there are problems in the tibia or osteoporosis, plan to have the nail extend down to within 2–3 cm of the ankle joint. Average-sized individuals will require an intramedullary nail 50 cm or more in length, which usually must be ordered from the manufacturer ahead of time (hospitals rarely stock nails this long). The diameter of nail used depends on the size of the bones and the condition being treated. Try to use a nail that is 11 mm or more in diameter in order to have sufficient strength.

- These procedures tend to be rather long and require significant manipulation and moving of the patient, so a general anesthetic is usually recommended. Positioning of the patient is challenging: A direct anterior approach to the knee and a posterior or lateral approach to the buttck are both necessary to accomplish the procedure. The patient can be placed in the supine position on a fracture table, which facilitates imaging, but I prefer the supine position on a fully radiolucent operating table. Place a bump under the buttck and position the patient so that the incision required to insert the nail through the buttck can be safely made. To improve exposure of the buttck, it is sometimes useful to place the patient in the lateral decubitus position, prepare and drape the entire lower extremity and buttck, and then roll her into the supine position for the majority of the procedure. She then can be rolled partially toward the lateral decubitus position as necessary for the insertion of the nail in the buttck. A sterile tourniquet can be used on the proximal thigh during the debridement of the knee to limit hemorrhage, but this is not desirable during the nailing.

- Expose the entire knee joint through an anterior longitudinal medial parapatellar incision, utilizing the old surgical scar in most cases.

- Once the distal femur, proximal tibia, and total knee joint are exposed, mark the femur with an osteotome or electrocautery to provide reference lines for determining rotation and length after the prosthesis is removed.

- Utilize the instrumentation appropriate for the total knee, remove all total knee components, and cement. Remove all debris from the soft tissues and bone, preserving as much viable bone stock as possible. If the patella has decent bone stock, preserve it for use as a bone graft; otherwise, excise it.

- Submit debrided bone for culture and sensitivities, and initiate intravenous antibiotics. If the culture proves to be positive, prolonged treatment with intravenous antibiotics may be indicated.

- In most cases, it is now possible to place the rough ends of the tibia and femur into apposition. Their irregular surfaces often provide a good interlock. The driving of the intramedullary nail automatically determines alignment in both the anteroposterior and lateral planes. Be certain that the foot is at the proper progression angle, which is usually about 10° of external rotation.

- Asymmetrical loss of bone may limit bone contact and require recutting of the joint surfaces with total knee instrumentation to obtain good bone apposition. Although this may be necessary, it is not generally recommended, as it results in excessive shortening.

- Insert a ball-tipped reaming guide pin into the medullary canal of the femur. In most cases, this is best done through a short buttck incision using the standard technique for intramedullary nailing of the femur (see Chapter 11 and Chapter 20). An alternative technique that allows percutaneous insertion of the nail into the proximal femur is to run a sharp-tipped, flagged Kuntscher guide pin retrograde up the medullary canal to exit the proximal femur and come to lie beneath the skin in the buttck. To avoid injury to the sciatic nerve, and to have an appropriate skin incision, it is essential to flex and adduct the hip so that the guide pin exits the skin as close to the tip of the greater trochanter as possible. It is important to visualize this carefully on the fluoroscope, so that the guide pin exits at the pyriform fossa on the femur. An incision 2–3 cm long can then be made on the buttck in line with the fibers of the gluteus maximus to expose the tip of the guide pin. Then use a guide-pin exchange tube to exchange the Kuntscher guide pin for a ball-tipped reaming guide pin.

- Ream the medullary canal of the femur to obtain a diameter 2 mm wider than that of the nail to be used. This can be done antegrade or retrograde.

- Ream the medullary canal of the tibia over a ball-tipped guide pin antegrade from the knee joint. Ream through the isthmus so that passage of the nail will not be impeded if the length has been mismeasured.

- Save contents of the medullary canal and bone reamings for bone graft around the arthrodesis.

- With the knee in the appropriate position for arthrodesis, insert the femoral guide pin into the tibia and measure to be certain that the appropriate-length nail has been selected.

- Drive the medullary nail antegrade down the femur, taking care to avoid fracture of the femur or incarceration of the nail. The nail should move down the femur easily with each blow of the mallet. If significant resistance is encountered, inspect the nail and femur carefully under fluoroscopy to be certain the orientation of the nail is correct. Ream the medullary canal larger if necessary. Drive the nail until it protrudes from the distal end of the femur about 2 cm.

- Now position the tibia over the end of the nail in apposition with the femur and using the previously drawn reference lines be certain that the position of the articular facets is correct. The overall curvature of the nail will generally produce about 10° to 15° of flexion in the knee fusion. Position the tibia for proper valgus and rotation.

- Complete the driving of the medullary nail into the tibia. As in the femur, the nails should drive easily with minimal resistance.

- Ensure good compression across the arthrodesis site by placing a small drill hole in the femur and another one in the tibia and inserting into these the tines of a pointed fracture-reduction forceps, which then can be used to compress the arthrodesis site. Often, two are needed, one anteriorly and one laterally.

- Place two transverse locking screws through the distal end of the nail in the tibia, and lock the nail in the proximal femur using the jigs provided by the manufacturer.

- Fill any gaps in the arthrodesis site with the reaming materials and, if necessary, autologous bone graft harvested from the iliac crest.

- Close the wounds in layers over a suction drain and apply a sterile dressing incorporating the extremity with a soft compression dressing to the toes of the groin.

Postoperative Care Mobilize the patient as soon as possible postoperatively. When the bone quality is good, and if the arthrodesis site has excellent contact and is in compression, immediate weight bearing with assistive devices is usually possible. Where there is osteoporosis or poor bone contact at the arthrodesis site, limit weight bearing to the weight of the leg until fusion occurs. Solid fusion is usually evident at 12–16 weeks, at which time the use of ambulatory aids can be discontinued. External immobilization of any type is usually unnecessary. See Figure 109.27 for a typical case.

**ARTHRODESIS WITH PLATE FIXATION**

Lucas and Murray (101) described knee arthrodesis using anterior and medial plates resulting in successful fusion in 17 of 18 knees. This fusion is useful in difficult situations, such as Charcot's joints and where significant bone loss between the femur and tibia requires large bone grafts. These may be autografts from the iliac crest, sliding grafts from the anterior femur or tibia, or large allografts. The strong dual plates are necessary to protect the graft during healing and remodeling (Figs. 109.30, 109.31).

**Figure 109.30.** Plate fixation of a large allograft placed between the femur and tibia. Protection of the bone graft by the plate is needed in this type of fusion for many years until the allograft has been incorporated.
Nichols et al. (118) used dual medial and lateral dynamic compression plates to successfully fuse 11 knees. Although medial and lateral plates are not biomechanically as strong as two plates at 90° to each other, these authors felt that eliminating the anterior plate reduced the incidence of wound problems. In addition, they suggested using plates of two different lengths to avoid the stress riser that might occur at the end of two plates of equal length.

The primary advantage of plate fixation is that it avoids the pin complications of external fixation. Also it is easier for the patient during the postoperative period. When compared to intramedullary nailing, it requires less surgical exposure and less surgery time, and it is technically easier for most surgeons. It is particularly useful when large intercalary bone grafts are used, as better fixation and better bone apposition is usually possible. The major problem with plate fixation is the increased incidence of soft-tissue problems that result from the bulk of the implants and their position immediately beneath the skin flaps. There is a risk of fracture of the tibia or femur at the end of the plates, which is more likely with a fused knee.

Stiehl and Hanel (134) described the combination of intramedullary nail and medial compression plate fixation in eight difficult knees, all of which united. They recommend their technique for difficult salvage situations, when segmental allografts may be required.

Operative Technique

- Place the patient in a supine position on a radiolucent operating table, and prepare and drape the extremity from the toes to the groin. Prepare the iliac crest if bone graft is required.
- Make a long longitudinal medial parapatellar incision to expose the knee joint. Incise the periosteum in a similar line on both the femur and the tibia, and expose the distal femur and proximal tibia subperiosteally.
- Cut a V in the anterior femur to accept the patella, and cut a similar V underneath the patella to create a good fit with the depression in the anterior femur. The patella can also be excised.
- Debride the knee joint, and leave the PCL in place. Prepare the surfaces of the distal femur and proximal tibia using a TKR jig. Use templates to establish the contours for anterior and medial, large, broad plates and use plate benders to fit them to the anterior and medial surfaces.
- Use 12- to 16-hole plates and secure the plates to the femur and tibia with at least five bicortical screws through each plate in each fragment using compression techniques.
- If the patella is retained, fix it to the femor with two screws.
- Pack any defects of the joint margins with cancellous bone from the iliac crest.
- Close the wounds in layers over a drain and apply a soft supportive dressing.

Postoperative Care

After surgery, place the patient in a cylinder cast and allow touch-down weight-bearing with crutches until 12 weeks, when partial weight-bearing is begun if the radiographs demonstrate evidence of early union. Full healing on radiographs is usually evident by 16–24 weeks, at which time full weight-bearing is possible.

PITFALLS AND COMPLICATIONS

The complications of arthrodesis of the knee are the same as those of any major orthopaedic surgery for complicated conditions. As noted previously, the incidence of complications is significant, as knee fusion is usually a salvage procedure for multiple failed surgeries of the knee, for severe infection, or for bone loss resulting from tumor resection. A problem with knee arthrodesis using external fixation is loosening or infection of the fixation pins followed by nonunion of the arthrodesis. The pin problems can be minimized using the meticulous technique described in Chapter 11, and by avoiding full weight-bearing until solid arthrodesis is present.

A risk of nonunion can be minimized by the use of biplanar or multiplanar fixation utilizing compression applied across broad viable bone surfaces at the site of arthrodesis. Excessive shortening may be unavoidable, but it can be minimized by avoiding unnecessary resection when the arthrodesis follows failed total knee arthroplasty, and by using intercalary bone grafts when necessary. Another approach is to perform limb lengthening with Ilizarov techniques after successful knee fusion.

The risk of infection can be minimized by performing staged arthrodesis when fusion is being performed for infection or when the suspicion of infection is high. If infection occurs in the presence of stable fixation, then irrigation and debridement, with maintenance of the fixation, combined with appropriate intravenous antibiotics, will often control the infection until fusion occurs. Once fusion is present, the infection may spontaneously resolve, or removal of the implants will then result in the resolution of the infection. Infection in the presence of an unstable arthrodesis and implants usually requires the removal of the implants, irrigation and debridement, and treatment with antibiotics, followed by repeat fusion when the infection has completely resolved, usually utilizing multiplanar external fixation.

AUTHOR’S PERSPECTIVE

The most common indication for knee arthrodesis in my practice, and in that of most surgeons, is failed total knee arthroplasty. My preferred technique for this is fusion with intramedullary fixation. I reserve external fixation arthrodesis for primary arthrodesis when there is infection, and where infection has been a significant problem in a failed total knee arthroplasty. Double-plate arthrodesis of the knee is most common in the practices of surgeons treating malignant tumors of the knee that are not amenable to total joint arthroplasty and require intercalary allograft for reconstruction. This is not a common procedure in my practice, nor in the practice of most community surgeons, so careful attention to the details outlined in this chapter are necessary for a high rate of success.

TALUS FRACTURES

PATHOPHYSIOLOGY

Although fractures and dislocations of the talus account for less than 1% of all fractures, they are fraught with serious complications, including skin necrosis, infection, avascular necrosis, malunion, nonunion, ankle and subtalar arthrosis, and posttraumatic arthritis (18,23,51,52,61). Injuries range from osteochondral fractures of the dome to fractures of the talar neck and body, with or without subluxation or dislocation of the ankle and subtalar joints. With advances in methods of treatment, morbidity is decreasing and complications are being managed more effectively.

Anatomy and Blood Supply

The talus is made up of the body posteriorly, which articulates with the tibia, posterior subtalar facet, and lateral malleolus; the head anteriorly, which articulates with the navicular, anterior and middle subtalar facets, and calcaneonavicular ligament; and the neck, which has no articulations.

The talus is unique because its external surface is 60% articular cartilage and it has no muscular attachments (46). Because of its large articular surface and lack of muscular attachments, the talus has a limited surface area for vascular supply. Although it has a rich blood supply, with contributions from all three main arteries of the lower limb, the limited access makes its blood supply particularly vulnerable to injury. The three main extraosseous vascular sources are arterial branches to the dorsal neck arising from the anterior tibial and peroneal arteries, the artery of the sinus tarsi arising from the anterior tibial and peroneal arteries, and the artery of the tarsal canal arising from the posterior tibial artery (Fig. 110.1). Additionally, the deltoid branch of the artery to the tarsal canal supplies blood to the medial talar body (46,62).

Numerous smaller channels enter through capsular and ligamentous attachments.

In addition to the extraosseous blood supply, a rich network of intraosseous anastomoses has been described (54). Peterson et al. (71) demonstrated injury to the intraosseous arterial network in nondisplaced, experimentally produced talar neck fractures, with progressive damage to the main extraosseous arterial channels as fracture displacement progressed.

Mechanisms of Injury

Talar neck fractures are high-energy injuries caused by major traumatic events. They make up 50% of all major injuries to the talus (23). Once termed aviator’s astragalus, talar neck fractures are no longer caused primarily by flying accidents; motor vehicle accidents and falls from heights are now more common mechanisms of injury. These fractures initially were thought to be caused by forced dorsiflexion of the talus against the anterior margin of the tibia, but laboratory studies have shown that they are more likely caused by a dorsally directed shear force exerted against the sole of the foot with the body of the talus fixed between the tibia and calcaneus. Fractures occur in a vertical or slightly oblique plane between the middle and posterior subtalar facets, and the distal fragment is characteristically displaced dorsally and medially (18). The force required to fracture the talus is roughly twice that required to fracture either the calcaneus or the navicular (74). With additional force, the body of the talus is dislocated posteriorly out of the ankle mortise, usually medial to the Achilles tendon.

Classification

Talus fractures were classified by Coltart (23) into chip and avulsion fractures, compression fractures of the head, fractures of the neck, and fractures of the body.
Dislocations and fracture-dislocations were further subdivided into those associated with dislocations of the ankle, subtalar, and midtarsal joints.

Hawkins (41) further subdivided talar neck fractures into three types (Fig. 110.2). Type I fractures are nondisplaced and disrupt only those blood vessels entering the body via the dorsal talar neck in addition to intraosseous vessels crossing the neck. Type II fractures are displaced with subluxation or dislocation of the subtalar joint. These fractures disrupt the dorsal neck arterial branches and the branches entering inferiorly from the sinus tarsi and tarsal canal, leaving undisturbed only the vessels entering through the deep deltoid ligament and medial talar body. Type III fractures are displaced with dislocation of the talar body from both the ankle and the subtalar joints. The body of the talus is usually displaced posteriorly and medially, stretching and compressing the neurovascular bundle. All three main sources of blood supply to the body of the talus are disrupted in these injuries. Canale and Kelly (20) added type IV, which are fractures associated with complete dislocation of the talar body and subluxation or dislocation of the talar head from the talonavicular joint.

**Figure 110.2.** Modified Hawkins (41) classification of talar neck fractures. A: Type I, nondisplaced. B: Type II, displaced with subluxation or dislocation of the subtalar joint. C: Type III, displaced with dislocation of the talar body from both ankle and subtalar joints. D: Type IV, subluxation or dislocation of talar head in addition to dislocation of talar body. (From Delee JC. Fractures and Dislocations of the Foot. In: Mann RA, ed. Surgery of the Foot, 5th ed. St. Louis: Mosby, 1986:656, with permission.)

**RADIOGRAPHIC EVALUATION**

Take high-quality anteroposterior (AP), lateral, and oblique radiographs of the ankle and foot. Canale and Kelly (20) described a pronated oblique view of the midfoot to better visualize the talar neck and head (Fig. 110.3). Look for associated injuries. Tomograms or computed tomography (CT) scans are occasionally required to assess the fracture configuration and displacement.

**Figure 110.3.** Pronated oblique view of midfoot to better visualize the talar neck. Ankle is in maximal equinus, with foot pronated 15°. Direct the roentgen tube 75° from the horizontal. (From Delee JC. Fractures and Dislocations of the Foot. In: Mann RA, ed. Surgery of the Foot, 5th ed. St. Louis: Mosby, 1986:656, with permission.)

**FRACTURES OF THE NECK OF THE TALUS**

**Principles of Treatment**

Nonoperative treatment is usually appropriate for nondisplaced (type I) talar neck fractures. Treat in a short-leg, non-weight-bearing cast for 6–8 weeks. Once union occurs, begin progressive weight bearing and mobilization of the ankle and subtalar joints.

Operative treatment is generally reserved for displaced talar neck fractures (types II, III, and IV). Reduction is difficult to maintain using closed methods because of tearing of the talocalcaneal interosseous ligament (33). Type II fractures require anatomic reduction to correct subtalar incongruity. Fractures of type III or IV require prompt reduction of the talar body to reduce the risk of pressure necrosis of the overlying skin. Early reduction and rigid internal fixation reestablishes soft-tissue circulation, enhances bony revascularization, and allows early motion, which reduces the risk of persistent edema, soft-tissue atrophy, stiffness, and osteoporosis (i.e., "fracture disease") (24,83,86). Open injuries require immediate and thorough irrigation and debridement of the wound, anatomic reduction, internal fixation, and appropriate antibiotics.

Whereas most type II fractures can be reduced by closed methods using fluoroscopic guidance, most type III and IV fractures require open reduction. Reduction of the talar body into the mortise is often facilitated by equinus positioning of the foot and axial traction through a calcaneal pin. Reduce the body as gently as possible to prevent further damage to the blood supply and articular cartilage. Osteotomy of the medial malleolus may facilitate reduction of the dislocated talar body; it also protects the deep deltoid blood supply to the talus (32).

Use smooth wires or guide pins for preliminary fixation and rigid screw fixation for definitive fixation. Screws prevent fracture displacement and malunion, and they enhance bone union and early mobilization of the ankle and subtalar joints. Screws placed anterior to posterior allow visualization of the fracture, but often they must be placed through the weaker talar neck or talar head articular surface (38,86). Screws placed posterior to anterior avoid disruption of the talonavicular joint and further damage to the dorsal blood supply to the talar neck, but they do not allow direct visualization of fracture reduction (30,49,93) unless a combined anterior and posterior exposure is performed. A mechanical study by Swanson et al. (85) demonstrated that posterior screw fixation gives more rigid fixation than anterior screws, and both are superior to Kirschner wire (K-wire) fixation. The choice of surgical approach ultimately depends on the presence and location of traumatic wounds, the condition of skin, fracture classification and configuration, and the presence of adjacent fractures (85). Cannulated screws are now available for percutaneous fixation of fractures accurately reduced using closed methods (20).

**SURGICAL TECHNIQUES**

**Posterior Fixation**

Posterior screw fixation can be completed through either a posterolateral or a posteromedial approach. The posterolateral approach avoids the neurovascular bundle and is generally recommended for type II fractures.

- Place the patient in the prone or lateral decubitus position with the affected extremity uppermost. Make a 4 cm longitudinal incision just lateral to the Achilles tendon, taking care to protect the sural nerve, which is anterior (Fig. 110.4).
Make the skin incision for the posterolateral approach to the talus just lateral to the Achilles tendon.

Locate the posterior process of the talus through the peroneus brevis and flexor hallucis longus tendons (Fig. 110.5).

Next, perform a closed reduction by plantar-flexing and abducting the forefoot under fluoroscopic guidance. Use a 2.0 mm K-wire as a “joystick” to manipulate the fracture if needed. If you cannot obtain an adequate closed reduction, make a small anterior incision to facilitate the reduction.

Drive two K-wires from the nonarticular aspect of the talar body into the talar head to hold the reduction, and reassess the reduction with standard radiographs if needed (53).

Achieve rigid fixation with dual 4.0 mm cancellous screws, entering just lateral to the posterior process (Fig. 110.6). Be certain that threads extend past the fracture site but not into the talonavicular joint. Try to place screws perpendicular to the fracture plane for maximal compression. With the advent of cannulated screws, talar neck fractures can be rigidly fixed percutaneously using a single 6.5 mm cancellous screw entering through the posterior, nonarticular part of the talus (20).

The posteromedial approach is useful for talar body dislocations because it allows osteotomy of the medial malleolus, facilitating reduction of the dislocated body (or fixation of concomitant medial malleolar fractures).

Place the patient in the supine position with a sandbag under the contralateral buttock and with the affected extremity in a figure-four position. Make a 6 cm longitudinal incision between the medial malleolus and the Achilles tendon (Fig. 110.7), taking care to carefully isolate the neurovascular bundle (Fig. 110.8). Carry dissection posterior to posteromedial neurovascular structures.

Place the patient in the supine position with a sandbag under the contralateral buttock and with the affected extremity in a figure-four position. Make a 6 cm longitudinal incision between the medial malleolus and the Achilles tendon (Fig. 110.7), taking care to carefully isolate the neurovascular bundle (Fig. 110.8). Carry dissection posterior to posteromedial neurovascular structures.

Make the skin incision for the posteromedial approach to the talus between the medial malleolus and Achilles tendon.

Posteromedial approach to the talus. (From Hoppenfeld S, deBoer P. Surgical Exposures in Orthopaedics: The Anatomic Approach. Philadelphia:
To reduce the dislocated talar body, place a Steinmann pin in the calcaneus for axial traction if needed. If you still cannot reduce the dislocated body, dissect subcutaneously and perform a medial malleolar osteotomy. To osteotomize the medial malleolus, predrill screw holes for reattachment. Perform the osteotomy at 30° to 45° from the plane of the articular surface, toward the medial corner of the tibial plafond. Take care not to disrupt the tenuous deltoid ligament blood supply.

After reducing the talar body, develop the interval between the flexor hallucis longus and the peroneus tendons. The flexor hallucis longus occasionally needs to be dislocated medially out of its groove.

Proceed with reduction and fixation of the fracture as described for the posterolateral approach. Reattach the medial malleolus with dual 4.0 mm cancellous screws (30).

Anterior Fixation

Anterior fixation can be done through either an anteromedial or an anterolateral incision. The anteromedial approach is most widely used and can be combined with medial malleolar osteotomy to improve exposure, or it can be used to fix concomitant medial malleolar fractures.

Make a curvilinear incision just medial to the tibialis anterior tendon (Fig. 110.9). Take care to avoid the saphenous vein and nerve. Carry the dissection down to the ankle joint capsule and neck of the talus.

![Figure 110.9](image)

**Figure 110.9.** For the anteromedial approach to the talus, make a curvilinear incision just medial to the tibialis anterior tendon.

Dissect subcutaneously to perform a medial malleolar osteotomy, if necessary (Fig. 110.10).

![Figure 110.10](image)

**Figure 110.10.** Anteromedial approach to the talus. A: Skin incision in relationship to the deep structures. B: Incise the deep fascia and open the ankle joint capsule. C: Osteotomize the medial malleolus with a sharp osteotome just distal to the plafond of the tibia if further exposure is required. (From Mayo KA. Fractures of the Talus: Principles of Management and Techniques of Treatment. Tech Orthop 1988;3:42, with permission.)

Next, identify the talar neck fracture, and reduce it using small K-wires placed in the individual fragments for manipulation, if needed. Take care to correct any dorsomedial displacement or angulation of the distal fragment.

Achieve rigid fixation using 4.0 mm cancellous screws placed through the nonarticular talar neck, or directly through the talar head after countersinking (Fig. 110.11).

![Figure 110.11](image)

**Figure 110.11.** Anterior screw fixation of a talar neck fracture. A: Screws placed through the articular cartilage must be countersunk below the articular surface. B: The preferred fixation, if possible, is through the neck of the talus. (From Grob D, Simpson LA, Weber BG, Bray T. Operative Treatment of Displaced Talus Fractures. Clin Orthop 1965;199:88, with permission.)

The anterolateral approach provides better visualization of the lateral talar neck and sinus tarsi.

Make a slightly curved incision from 2 cm anterior to the distal aspect of the fibula toward the fourth metatarsal base (Fig. 110.12).

![Figure 110.12](image)

**Figure 110.12.** For the anterolateral approach to the talus, make a curvilinear incision just anterior to the lateral malleolus, toward the fourth metatarsal base.

Incise the fascia and extensor retinaculum, taking care to preserve any branches of the superficial peroneal nerve.
separately.

Because of its crucial role in the ankle and subtalar joints, any residual incongruity may cause symptoms. Although the mechanism of injury and the general morphology of these fractures are similar to those of talar neck fractures, the prognosis is generally worse, and therefore we consider these fractures separately.

FRACTURES OF THE BODY OF THE TALUS

Postoperative Care and Rehabilitation

Support the extremity in a well-padded splint until wounds are healed. If rigid fixation has been achieved, institute early ankle and subtalar motion using a removable fracture brace or splint once soft tissues are healed, generally by 10–14 days. Begin progressive weight bearing in a removable brace when fracture union is evident, usually by 6–8 weeks.

Complications

Acute complications of talar neck fractures include skin necrosis and infection. Skin necrosis is generally seen only with type III and IV fractures, and it can be minimized by prompt reduction of the talar body. Infection may occur after open injuries but can often be avoided by early irrigation and debridement, rigid fracture fixation, delayed wound closure, and prophylactic antibiotics. However, if the talar body is completely avascular, an established osteomyelitis may be resistant to treatment.

Late complications include avascular necrosis, nonunion, malunion, and posttraumatic arthritis. Absence of avascular necrosis can often be recognized at 6–8 weeks by the presence of subchondral atrophy in the dome of the talus (Hawkins’ sign) (41). Its absence, however, is not a definite indicator of avascular necrosis (18), nor does its presence rule out small areas of necrosis. Magnetic resonance imaging (MRI) is the most useful modality for diagnosing avascular necrosis. However, MRI requires the use of nonferromagnetic screws because its presence rules out small areas of necrosis. Magnetic resonance imaging (MRI) is the most useful modality for diagnosing avascular necrosis. However, MRI requires the use of nonferromagnetic screws (1) because it cannot be used after internal fixation with stainless steel screws (53).

The incidence of avascular necrosis depends on the amount of vascular disruption. Type I fractures have minimal arterial disruption, with rates of avascular necrosis of 0% to 13%. Some authors have postulated that avascular necrosis in this group is caused by an occult, displaced injury that spontaneously reduces (83). Type II fractures have moderate disruption of vascular channels and avascular necrosis rates of 20% to 50%. Type III and IV fractures have disruption of most arterial sources, with avascular necrosis rates of up to 100%.

The wide variation in reported incidences of avascular necrosis is probably the result of differences in methods of detection and methods of acute fracture management. Several series (17,24,32,38,86) report lower rates of avascular necrosis with open reduction and internal fixation (ORIF).

Controversy regarding treatment of avascular necrosis stems from the finding that not all avascular tali go on to collapse, and that those destined to collapse often do so only after a number of years (18,41). Although no study has unequivocally proved that protected weight bearing reduces the likelihood of collapse, many authors (30,53,63) recommend use of a patellar tendon-bearing brace until the revascularization process is complete. Davis et al. (29) showed a decrease in weight transmitted across the ankle joint with this brace. If the avascular process involves only a portion of the talar body, allow full weight bearing in a cast or brace that neutralizes varus–valgus ankle stress (23).

For severe collapse of the avascular talar body, alternatives include tibiocalcaneal fusion with or without interposition iliac crest bone grafting, and the Blair tibiotalar fusion (8,31,50,59,58,77). The Blair fusion is generally preferred because it preserves heel height, maintains the medial longitudinal arch, and allows for some hindfoot motion (30,53,81). However, if the talus head cannot be salvaged, tibiocalcaneal fusion with interposition iliac crest bone grafting provides a stable hindfoot in most cases.

Delayed union has been reported in up to 15% of talar neck fractures, but nonunions are rare, generally occurring in less than 1% of fractures (71). The incidence is even lower when rigid internal fixation is used (24,53,81). Malunions are more common, reported in up to 27% in some series (18,20). Most are either dorsal or varus malunions, and anatomic reduction with rigid internal fixation reduces the incidence (18,20,55). Dorsal “beak” resections have been successful for symptomatic dorsal malunions, and triple arthrodesis has been used to treat varus malunions (20).

The incidence of ankle and subtalar posttraumatic arthritis varies from 40% to 90% (18,20,48,51,70). Causes are initial traumatic damage to the articular cartilage, avascular necrosis, and fracture malunion. Arthrofibrosis and loss of motion can be minimized by promoting venous drainage with elevation of the extremity in the early postoperative period, and by early mobilization of the ankle and subtalar joints (55). Subtalar or triple arthrodesis is indicated for symptomatic subtalar arthritis, and tibiotalar arthritis is best managed by ankle arthrodesis. Take care to accurately localize the symptomatic joint before proceeding with arthrodesis (19).

FRACTURES OF THE BODY OF THE TALUS

Fractures of the talar body make up 10% to 25% of all injuries to the talus, depending on which fracture subtypes are included (23,83). Large forces are required to fracture the body. Because of its crucial role in the ankle and subtalar joints, any residual incongruity may cause symptoms. Although the mechanism of injury and general morphology of these fractures are similar to those of talar neck fractures, the prognosis is generally worse, and therefore we consider these fractures separately (23,57,83).

Classification

Fractures of the talar body were initially classified by Snepen et al. (83). This classification was modified by Delee (30) into five groups: I, transchondral dome fractures; II, shear fractures; III, posterior tubercle fractures; IV, lateral process fractures; and V, crush fractures (Fig. 110.14). Shear fractures can be further subdivided into coronal, sagittal, and horizontal fractures. Only shear (II) and crush (V) fractures are discussed in this section; groups I, III, and IV will be considered separately.
Surgery of the Foot

Figure 110.15. Classification of talar body fractures. (From Delee JC. Fractures and Dislocations of the Foot. In: Mann RA, ed. Surgery of the Foot, 5th ed. St. Louis: Mosby, 1986:656, with permission.)

Nonoperative Treatment

Manage shear and crush fractures of the talar body with closed treatment when displacement is minimal (less than 2 mm). Apply a short-leg, non-weight-bearing cast for 6–8 weeks or until union is apparent. If the fracture fragments appear stable, begin cautious early motion using a removable fracture brace or splint before this time, if desired. Thereafter, begin progressive weight bearing in a removable fracture brace. Manage displaced horizontal shear fractures with closed treatment if a satisfactory closed reduction can be obtained using a combination of calcaneal pin traction and manipulation (6). Immobilize in a short-leg, non-weight-bearing cast until union occurs.

Operative Technique and Postoperative Care

Perform operative fixation of displaced talar body fractures when comminution is limited. For shear fractures in the coronal plane, operative approaches, fixation techniques, and postoperative management are essentially identical to those described for talar neck fractures (1). Because of the larger anterior fragment, these fragments are more amenable to posterior screw fixation than are neck fractures. Shear fractures in the sagittal plane can be fixed with screws through an anteromedial or anterolateral approach. Medial malleolar osteotomy may be necessary for adequate visualization and internal fixation (32). Irreducible horizontal shear fractures can be managed by open reduction with or without pin or screw fixation. Be certain that pins or screw heads are countersunk below the articular surface. Herbert screws through the articular surface provide satisfactory fixation of these fractures.

Displaced, comminuted fractures of the talar body are occasionally not amenable to ORIF. Various authors (6,11,31,33,50,59,69) have recommended primary takedown, tibiocalcaneal fusion, pantalar arthrodesis, and Blair fusion for irreparable fractures. Primary takedown should rarely be performed acutely because it may compromise subsequent reconstruction, and no harm results when definitive treatment is delayed. Tibiocalcaneal fusion results in loss of heel height and medial longitudinal arch, whereas pantalar arthrodesis precludes hindfoot motion. With severe collapse of the talar body, the Blair tibiotalar fusion maintains heel height, preserves the medial longitudinal arch, and allows for some biplanar motion (1,6,30,31,50,59,61).

Complications

Complications of talar body fractures are similar to those seen with talar neck fractures: avascular necrosis, nonunion, malunion, arthrosis, and posttraumatic arthritis of the ankle and subtalar joints. However, the incidence of these complications is higher with talar body fractures, leading to a larger proportion of poor results.

The incidence of avascular necrosis with coronal shear fractures is about 25% for nondisplaced fractures, 40% to 50% for displaced fractures, and 90% for displaced fractures with complete dislocation of the body (30,57,83). Because these fractures occur more posteriorly than talar neck fractures, and because the fracture line may exit medially through the deltoid ligament attachment, even minimal displacement may result in complete avascularity of the talar body. In horizontal shear fractures, the incidence of avascular necrosis of the dome is even higher due to complete isolation from all vascular sources (5).

Delayed union is most common in displaced fractures and in those developing avascular necrosis; nonunion is rare after talar body fractures (57). Malunion can develop in up to one third of displaced fractures when reduction is inadequate (63).

Posttraumatic arthritis is extremely common after talar body fractures because the fracture line passes through both the talar dome articular surface and the posterior facet of the subtalar joint. Other causes of arthritis include acute cartilaginous injury, malunion, and avascular necrosis (11,23,63). Sneppen et al. (83) found a 75% incidence of degenerative arthritis in fractures that healed without displacement.

FRACTURES OF THE HEAD OF THE TALUS

Fractures of the head of the talus account for only 5% to 10% of all talus injuries. These fractures result from longitudinal compression of a plantar-flexed foot, with or without a simultaneous abduction or adduction force (23,69). Fractures are either a compression type or a split in the longitudinal or oblique plane. Because the head of the talus is well vascularized, avascular necrosis is uncommon (1).

Manage nondisplaced fractures in a short-leg, non-weight-bearing cast with a well-molded arch for 6–8 weeks until union occurs. Displaced fractures often require surgical intervention. If the fracture fragment involves more than half of the articular surface, ORIF through an anteromedial approach is usually preferred, whereas if the fracture involves less than half of the articular surface, excision is often the best treatment. Late problems include talar head depression and instability.

TRANSCHONDRAL DOME FRACTURES

Transchondral fractures of the talar dome are extremely uncommon injuries, making up only 0.09% of all fractures (7). Known by several terms (transchondral fracture, osteochondral fracture, flake fracture, osteochondritis dissecans), these lesions are most likely traumatic in origin (7,64,65,75,76). Many affected patients are treated originally for sprains or more serious ankle injuries (2,4). Characteristic locations are the anterolateral and posteromedial talar dome, with roughly equal proportions in each location (7,19,26). Lateral lesions are typically wafuer like or flake like, whereas medial lesions are often cup-shaped (19) (Fig. 110.15).

Classification

Berndt and Harty (7) originally classified transchondral dome fractures. Stage I lesions involve a small area of subchondral compression of the talar dome. Stage II lesions are partially detached osteochondral fragments. Stage III lesions are completely detached, with the fragment remaining within the crater formed by its detachment. Stage IV lesions are completely detached, with the fragment displaced from its original location (Fig. 110.16A). Recently, with the advent of better imaging techniques, including CT and MRI, Fisher et al. (35) have added stage V, the radiolucent defect (subchondral cyst) (Fig. 110.16B). They found, using these imaging techniques, that 80% of osteochondral lesions were purely cavitary, with no associated bony or cartilaginous fragments in the joint.

Figure 110.16. Classification of transchondral dome fractures. (From Canale ST, Belding RH. Osteochondral Lesions of the Talus. J Bone Joint Surg Am 1980;62:97, with permission.)

Radiographic Evaluation

Before the advent of CT and MRI, transchondral dome fractures were largely evaluated using plain radiographs and tomograms. Plain radiographs, although mandatory in the evaluation of these lesions, are often negative (4,35). Bone scanning is an excellent screening tool because it has a sensitivity for these lesions approaching 100% (35). Further evaluation requires MRI when radiographs are negative, or CT scans when bony involvement is seen on radiographs (4,35). MRI can detect cartilaginous lesions or areas of subchondral compression (stage I lesions), and CT scanning can delineate cavitary lesions (stage V) or assess displacement of osteochondral fragments (stage II, III, and IV lesions).

Nonoperative Treatment

Controversy exists regarding the best form of treatment for various stages of transchondral dome fractures. Most authors (7,19,30,75,81) recommend at least 6 weeks of cast immobilization for acute, nondisplaced lesions. Some (30,75) recommend a trial of immobilization even for chronic, nondisplaced lesions. Operative treatment is indicated for persistent symptoms after an adequate trial of conservative treatment or when the osteochondral fragment is displaced.

Operative Technique

Operative intervention usually involves removal of the fragment when present and drilling of the defect to promote revascularization and fibrocartilaginous metaplasia (28,64,76,81). Only acute lesions involving at least one third of the medial or lateral dome are treated by ORIF. Fibrin adhesives and absorbable pins have recently been developed for this use.

Medial lesions can be approached either through an anteromedial approach with osteotomy of the medial malleolus or through a posteromedial approach without osteotomy of the medial malleolus (35). Lateral lesions can be reached through a standard anterolateral approach.

Recently, arthroscopy has been used to treat transchondral dome fractures. Arthroscopic removal of loose fragments, curettage, debridement, and drilling of the defect greatly reduce postoperative morbidity as compared to open treatment (2,94) (see Chapter 93).

Postoperative Care and Rehabilitation

A period of 6–12 weeks of non-weight-bearing and early ROM exercises is recommended after arthroscopic or open treatment of transchondral dome fractures (2,30,94). After internal fixation of larger transchondral dome fragments, delay weight bearing until fracture union is present (81).

Complications

The most commonly reported complications after treatment of transchondral dome fractures are limitation of ankle motion and posttraumatic arthritis. Results are influenced by the stage, location, and size of the lesion; weight and activity level of the patient; type of treatment; and extent of delay in treatment (75,76,81). In general, nondisplaced lesions have a more favorable prognosis than displaced lesions, with results of medial lesions being superior to lateral lesions in some series (75). A delay in treatment longer than 12 months may worsen the prognosis (65). Several authors (2,7,19,65,76) suggest that surgically treated lesions have a better prognosis than those that are not surgically treated.

Although Canale and Belding (19) reported a 50% incidence of degenerative ankle arthritis at 11 years regardless of the type of treatment, Bauer et al. (6) reported only 2 of 30 patients with degenerative changes at a mean of 21-years follow-up.

FRACTURES OF THE LATERAL PROCESS

The lateral talar process is the most lateral aspect of the talus (Fig. 110.17). It articulates with both the distal fibula and the posterior facet of the calcaneus and serves as the attachment point for several ligaments, including the anterior talofibular and lateral talocalcaneal ligaments. Fractures of the lateral talar process account for 24% of talus body fractures (81).

Figure 110.17. Lateral talar process fracture. Note the involvement of the articular surfaces for both the talofibular and subtalar joints. (From Delee JC. Fractures and Dislocations of the Foot. In: Mann RA, ed. Surgery of the Foot, 5th ed. St. Louis: Mosby, 1986:656, with permission.)
Lateral process fractures are most likely caused by a combination of forced dorsiflexion and inversion, a mechanism similar to that causing lateral ankle sprains (40,60). Indeed, the signs and symptoms of lateral process fractures and lateral ankle sprains are almost identical. Therefore, this injury should be considered when any patient complains of posttraumatic lateral ankle pain.

Radiographic Evaluation

Standard radiographs include AP, lateral, and mortise views of the ankle. A 20° internal oblique view of the ankle best demonstrates this fracture (68). Tomograms and CT scans are also useful in delineating fracture fragment size and displacement (60).

Nonoperative Treatment

Most authors recommend conservative treatment for nondisplaced fractures. Because the lateral process involves a weight-bearing surface, 4–6 weeks in a short-leg, non-weight-bearing cast is generally recommended (49,81,83). Some recommend attempted closed reduction of displaced fragments, and others recommend open reduction because of the difficulty in obtaining a satisfactory closed reduction (30,40,81).

Operative Technique and Postoperative Care

Open reduction and internal fixation are indicated for large, displaced fragments; small or comminuted fragments are best treated by excision (40,60). Lateral process fractures can be successfully reached through a modified anterolateral approach. Begin the incision 5 cm proximal to the ankle joint, curving just distal to the tip of the fibula (30). Rigid internal fixation with a cancellous screw is generally preferred.

After either ORIF or fragment excision, immobilize the ankle for 2–3 weeks. Thereafter, allow ROM exercises using a removable splint. After ORIF, allow weight bearing when union is demonstrated radiographically, usually by 6 weeks. After excision, allow progressive weight bearing at 3 weeks (30).

Complications

Even nondisplaced fractures can result in restricted subtalar motion, pain, and arthritis (47,83). Bony overgrowth in the region of the sinus tarsi can cause impingement with the fibula or calcaneus (49). Delay in diagnosis and treatment worsens the prognosis (40,81). Nonunion, malunion, or impingement are indications for exploration and fragment excision or subtalar arthrodesis if significant arthritis is present (40,81).

FRACTURES OF THE POSTERIOR PROCESS

The posterior process of the talus consists of medial and lateral tubercles separated by a groove for the flexor hallucis longus tendon (Fig. 110.18). The lateral tubercle serves as the attachment for the posterior talofibular ligament. Lateral tubercle fractures are much more common than medial tubercle fractures and must often be distinguished from a commonly found accessory bone, the os trigonum (54). The mechanism of injury for fractures of the lateral tubercle of the posterior process is either forced plantar flexion with impingement against the tibial plafond or forced dorsiflexion with avulsion of the tubercle by the posterior talofibular ligament (59).

Radiographic Evaluation

Lateral and 30° oblique radiographs best demonstrate the lateral tubercle. An acute fracture can be distinguished from a normal os trigonum by technetium bone scanning (68).

Nonoperative Treatment

Most acute posterior process fractures are successfully treated by 6 weeks of cast immobilization. Most authors recommend non-weight-bearing because the inferior surface normally articulates with the calcaneus. Symptomatic chronic injuries can often be successfully treated with a course of cast immobilization (30,68).

Operative Technique

If symptoms persist longer than 4–6 months, surgical excision of the posterior process fragment is indicated. This can be done through either a posterolateral or a posteromedial approach. ORIF can be considered for acute fractures of large fragments (30,68).

PERITALAR DISLOCATIONS

Peritalar (subtalair) dislocation involves simultaneous dislocation of both the talonavicular and talocalcaneal joints, resulting in disruption of joint capsules, the interosseous talocalcaneal ligament, and additional supporting structures both medially and laterally. These injuries are rare and result from high-energy mechanisms (12).

Classification

Peritalar dislocations are classified as medial, lateral, anterior, or posterior, depending on the direction of displacement of the foot with respect to the talus. Medial dislocations are by far the most common, making up 80% of all subtalar dislocations (12). The talus may also rarely undergo total dislocation from the subtalar and ankle joints.

Radiographic Evaluation

Subtalar dislocations can easily be missed if AP, lateral, and oblique radiographs are not obtained and carefully studied. An AP view of the foot often discloses a medial or lateral subtalar dislocation by the absence of the talar head in the concavity of the navicular (5).

Nonoperative Treatment

Most subtalar dislocations can be treated by closed reduction and cast immobilization. Reduce the dislocation by flexing the knee, applying gentle traction to the forefoot, accentuating the deformity to unlock the dislocation, and reversing the deformity. Digital pressure over the talar head may aid in reduction of medial or lateral
dislocations (13). After reduction, immobilize the foot in a short-leg, non-weight-bearing cast for 4–6 weeks, followed by progressive weight bearing and range of motion (ROM) (81).

**Operative Technique**

Irreducible dislocations are usually secondary to buttonholing of the talar head through the joint capsule or tendons. Medial dislocations are most commonly entrapped by extensor tendons, whereas lateral dislocations may be entrapped by the posterior tibial tendon (47) (Fig. 110.18). When you cannot reduce these injuries closed, perform open reduction through a longitudinal incision over the talar head, followed by gentle unlocking of the involved structures and reduction of the dislocation. Postoperative management is similar to that for closed reduction.

**Figure 110.19.** This lateral subtalar dislocation is irreducible because of entrapment by the tibialis posterior tendon, which has slipped out of its normal position in the groove of the posterior tibia. (From Leitner B. Obstacles to Reduction in Subtalar Dislocations. *J Bone Joint Surg Am* 1954;36:36304, with permission.)

**Complications**

Although most subtalar dislocations result in variable degrees of subtalar arthrosis and loss of motion, instability can be an even greater clinical problem, particularly in younger patients (12–95). Recurrent dislocation during cast immobilization has been reported (44). Therefore, some authors recommend a full 6 weeks of cast immobilization for young, active patients, whereas 4 weeks may be adequate for older patients. Symptomatic subtalar arthrosis can be managed by subtalar or triple arthrodesis (44). Avascular necrosis occurs in less than 5% of these injuries (95).

**AUTHOR'S PERSPECTIVE**

Decisions for treatment of displaced talar neck fractures are difficult. The nondisplaced neck fracture can be treated nonoperatively; however, serial radiographs must be frequently and closely examined. Minimal degrees of displacement affect adversely the force distribution in the subtalar joint. A minimally displaced type II fracture can be treated successfully by closed reduction and posterior screw placement. Laboratory studies have confirmed better mechanical stability by posterior screw placement, and, by placing the screws in the central axis of the bone, no medial or lateral gaping occurs. Types III and IV fractures are probably best treated by combined approaches and dual fixation. This technique allows anatomic reduction and debridement of the subtalar joint with placement of stable fixation. New minimally constructs placed medially and laterally just inferior to the articular surface may provide the most rigid fixation.

Avascular necrosis in the presence of a healed talus fracture frequently is incomplete and asymptomatic. Positive imaging studies should not be of major concern. It has been shown that small areas of focal avascular necrosis are well tolerated by the joint and can result in an excellent, functional outcome.

Avascular necrosis with painful collapse and loss of joint function is still best treated with ankle arthrodesis. Creative hindfoot fusions are required because obtaining a fusion in the presence of avascular bone can be difficult. Therefore, techniques such as interpositional bone grafting, calcaneal–tibial arthrodesis, and bone transport techniques have all been described.

Finally, talar-dome defects are one indication for ankle arthroscopic techniques. Utilizing ankle distraction, visualization of the talus is excellent enough to allow drilling and fixation. Biodegradable pins are useful.

**CALCANEUS FRACTURES**

**Technical Contributor: Michael W. Chapman**

Anatomic reduction is the goal of the operative treatment of fractures of the calcaneus whenever it is possible and advisable. However, frustration in treatment of these fractures has led many to abandon attempts at open reduction, and instead to treat these difficult fractures by elevation of the foot, compression dressing, and early motion. The end result is usually a bulbous heel that will not fit a shoe properly; a short heel in valgus with a relatively short heel cord; a mass of bone laterally producing impingement on the peroneal tendons; and disruption of the subtalar joint, which may result in traumatic arthritis.

Although not all these fractures have bad results, the results of treatment of calcaneus fractures over the years have not been good. It is logical to assume that patients are better off with an anatomic or near-anatomic reduction than to be left with the deformities. The more anatomic the reduction, the better the functional results you can expect. Regardless of the fracture type and method of treatment, always try to restore the normal width of the heel as well as the length and height of the calcaneus.

**PATHOLOGIC ANATOMY**

The calcaneus is the largest of the tarsal bones and its articular surfaces are located on the dorsal aspect of its anterior half (59). The posterior half, the tuberosity, provides the site of insertion of the Achilles tendon. It inserts about midway down the posterior aspect of the tuberosity with a small bursa located between the tendon and the calcaneus in the superior portion. The plantar fascia originates from the medial and lateral processes located on the plantar aspect of the tuberosity. The calcaneal portion of the subtalar joint is made up of a posterior facet, which is the largest and is convex in shape; it is separated by the tarsal sinus and the tarsal ligament from the middle and anterior facets, which are concave in shape and usually contiguous with each other. The middle facet is located on the prominent medial projection of the anterior calcaneus, called the sustentaculum tali. The anterior surface provides a saddle-shaped articular surface for the cuboid. The calcaneus is composed of dense cancellous bone covered by a very thin cortical shell. On a lateral radiograph of the calcaneus (Fig. 110.20), two important angles are used to help determine the quality of reduction after fractures. Böhler's tuber angle, measured by a line drawn from the posterior superior prominence of the tuberosity to the superior apex of the posterior facet to the superior aspect of the anterior process, measures between 25° and 40° in most individuals. Gissane's angle, also known as the critical angle, is directly beneath the lateral process of the talus and is where axial compressive forces are applied by the talus during vertical loading, which is the most common mechanism of injury for fractures of the calcaneus.
The most common mechanism of injury in fractures of the calcaneus is a direct blow to the plantar aspect of the heel from either a fall or a severe deceleration injury such as in high-speed motor vehicle accidents. Twisting forces are more likely to produce extra-articular fractures such as those of the anterior process, the sustentaculum, and the medial process. Fractures of the tuberosity are usually caused by avulsion of the Achilles tendon insertion. Bilateral fractures are usually caused by vertical loading of both lower extremities. Remember that the calcaneal fractures are often associated with fractures of cancellous bone in other portions of the skeleton, particularly the thoracolumbar spine.

Essex-Lopresti (34) described two common types of intra-articular calcaneus fractures: tongue-type and joint depression–type fractures (15) (Fig. 110.21).

The oblique sharp posterolateral edge of the talus produces the fracture (Fig. 110.21A). It drives down across the calcaneus like an axe, producing a corresponding oblique fracture line through the calcaneus. The center of the tuberosity is slightly offset lateral to the center of the talus, so if a force is applied to the top of the talus with the tuberosity fixed to the ground, a shear line develops, as shown in Figure 110.21B. This shear line consistently produces a sustentacular fragment (S in Fig. 110.21B) and a tuberosity fragment (T in Fig. 110.21B). The front half of the calcaneus is firmly bound to the underside of the talus by the talocalcaneal ligaments. Therefore, the sustentacular fragment remains attached to the talus and descends with it (Fig. 110.21C), while the tuberosity fragment, which has no ligamentous attachments, is unstable and moves laterally and upward. The star in Figure 110.21C shows production of either a tongue-type or a joint depression–type fragment by the descending posterolateral edge of the talus.

The tongue-type fragment is long and extends to the back of the tuberosity (star in Fig. 110.21D). The fracture line runs through the lateral part of the posterior facet. The fragment (star) is long and extends to the posterior part of the tuberosity. The joint depression–type fragment is short and extends just posterior to the posterior facet (star in Fig. 110.21E). The fractures are quite similar both in the shape of the sustentacular fragments and in the path of the fracture line through the lateral part of the posterior facet. The major difference in the fractures is the length of the superolateral fragments.

The sustentacular spike is shown by the X in Figure 110.21D and Figure 110.21E. The spike is important in locating the sustentacular fragment during surgery.

The small drawings below Figure 110.21D and Figure 110.21E show the displacement of the fragments. The tongue-type fragment is depressed in front and elevated to the rear, and the joint depression–type fragment is pushed straight down and rotated so that the articular cartilage of the fragment faces forward. Figure 110.21F shows the tongue-type fracture from above. The fracture line runs through the lateral part of the posterior facet and parallels the posterolateral edge of the talus. The front of the tongue is depressed, leaving an offset in the posterior facet surface. Figure 110.21G shows the short joint depression–type fragment depressed into the body of the calcaneus, leaving an offset in the posterior facet surface. This fragment is also rotated diagonally downward in front.

Radiographic Assessment

The standard radiographic views obtained to assess calcaneus fractures are the lateral, tangential, and Broden's views. Broden's views are oblique views made with the leg internally rotated 45°. Four views are made, at 10°, 20°, 30°, and 40° distal to the perpendicular with the x-ray beam centered on the sinus tarsi. Figure 110.22A, Figure 110.22B, Figure 110.22C and Figure 110.22D show these views of a normal foot. The 10° view (Fig. 110.22A) shows the posterior aspect of the joint. The 20° and 30° views show the central part (Figs. 110.22B and Fig. 110.22C), and the 40° view shows the anterior aspect (Fig. 110.22D). The location of the fracture line in relation to the posterior facet can be determined from these views.

Figure 110.22. A: Broden's view of a normal heel made at 10°. B: Broden's view of a normal heel made at 20°. C: Broden's view of a normal heel made at 30°. D: Broden's view of a normal heel made at 40°. E–H: Classification of the tongue-type and joint depression-type fractures is made according to the location of the fracture line in relation to the posterior facet, as shown in the 30° Broden's views. I: The fragment is depressed, leaving a step in the posterior facet surface. J: The fragment has slipped upward and from under the talus to lie at the tip of the lateral malleolus. K: Fracture with comminution of the sustentacular fragment.
Several authors (21, 27, 37, 39, 42, 43, 80, 82) have investigated the usefulness of CT scans in evaluating calcaneal fractures. Allon and Means (3) concluded that two-dimensional CT scans tend to overestimate the degree of comminution, whereas conventional radiographs provide an underestimate. Three-dimensional reconstructions from CT scans were superior, except in their somewhat poor resolution of intra-articular pathology. Carr et al. (21) proposed that three-dimensional CT reconstructions were most useful in preoperative planning to assist an inexperienced surgeon in learning to interpret the standard plain films. An experienced surgeon can analyze the fracture pattern and plan a procedure based on the standard lateral, tangential, and Broden's views without the need for CT. The surgeon must be familiar with Broden's views and must be able to interpret them, because they are used in surgery to determine whether the depressed fragment has been elevated properly; the CT scan cannot be used in surgery.

Classification

Fractures of the calcaneus can be classified into extra-articular and intra-articular fractures. Extra-articular fractures make up 25% to 30% of all calcaneal fractures (25, 26) and include fractures of the anterior process, beak or avulsion fractures of the tuberosity, medial process fractures, and fractures of the sustentaculum tali and body (Fig. 110.23).

Classification of the joint depression–type and tongue-type fractures can be made according to the location of the fracture line in relation to the posterior facet (14). The fracture line may run lateral to the posterior facet (Fig. 110.22E), producing no damage to the joint. If the fracture line runs through the lateral part of the posterior facet (Fig. 110.22F), it produces a classic joint depression–type or tongue-type fracture, as described by Essex-Lopresti (34). Because the tongue-type or joint depression–type fragment is relatively small and contains only a small part of the articular facet, it is not always depressed into the body of the calcaneus (Fig. 110.22I). It may slip laterally out from under the talus and displace upward (Fig. 110.22J).

The fracture line may run through the center of the posterior facet (Fig. 110.22G), but it still produces a classic tongue-type or joint depression–type fracture, but with a larger fragment containing more of the posterior facet cartilage.

If the fracture line is far medial, it may miss the posterior facet and produce a large tongue- or joint depression–type fragment, which will contain the entire posterior facet (Fig. 110.23H).

Any of these fractures with sufficient displacement are candidates for open reduction (Fig. 110.22E, Fig. 110.22F, Fig. 110.22G, Fig. 110.22H, Fig. 110.22I and Fig. 110.22J). Before beginning surgery, obtain Broden's views or a CT scan so that you will know what type of fracture you are dealing with.

PRINCIPLES OF TREATMENT

Calcaneal fractures are among the most difficult fractures to operatively reduce and internally fix. There has been great debate in the literature as to whether combinations of medial approaches, lateral approaches, or dual approaches provide the best opportunity to attain anatomic reduction (46, 50, 66, 67, 84). Treatment options for calcaneal fractures include the following:

- No reduction, with elevation of the foot, compression dressing, and early ROM.
- Closed reduction, with elevation of the foot, compression dressing, and early motion.
- Percutaneous reduction techniques such as Essex-Lopresti (34).
- Open reduction and internal fixation as popularized by Palmer (67) and McReynolds (56).
- Primary arthrodesis.

The goals of nonoperative treatment are to restore the overall shape of the calcaneus to as close to anatomic position as possible. Anatomic restoration of the articular surface is rarely possible by closed techniques, but it is worth trying as it is occasionally successful. The goals of ORIF are to safely restore the anatomy of the hindfoot. This includes anatomic reduction of the articular facets (61), reconstitution of hindfoot height, width, and length; and realignment of the tuberosity to appropriate axial alignment. The entire osseous morphology of the hindfoot must be anatomically reduced to provide the best chance of good long-term outcomes.

The difficulties of ORIF include the difficult exposure, the complex three-dimensional shape of the bone, ever-changing fixation devices, open fractures, and osteopenic bone disease. Patients with diabetes mellitus, hypertension, or peripheral vascular disease, and tobacco chewers and smokers, have an increased incidence of wound complications. Surgery in these patients may be contraindicated despite the degree of injury to the calcaneus.

McReynolds (56) popularized the medial approach to fixation and stated that the key to a successful reduction is restoration of the medial wall of the calcaneus by realigning the medial cortex of the tuberosity fragment with the medial cortex of the stable sustentacular fragment (14, 15, and 16). Although this helps to restore height and axial alignment, it is difficult to reduce the posterior facet or address anterior calcaneal–cuboid pathology from the medial side.

The advantage of the lateral approach is the wide-open exposure (73). The calcaneal–cuboid joint and distal comminution can be addressed, as well as the reduction of the posterior facet, the axial tuberosity alignment, and the height and width of the hindfoot. Some surgeons (84) have advocated mini-open medial approaches to assist in the reduction of the tuberosity to the sustentacular fragment, then a more extensile exposure laterally for the remainder of the pathology, including bone grafting and lateral wall reduction. Because of the complications from open approaches, there has recently been increased interest in percutaneous reduction techniques with joysticks, small elevators, and percutaneous cannulated screws, which are modifications of the original Essex-Lopresti technique (94).

SURGICAL TECHNIQUES

Closed Reduction

Closed reduction of fractures of the calcaneus, without the insertion of any pins or fixation, is indicated in minimally displaced fractures or in displaced fractures where percutaneous reduction techniques or ORIF is contraindicated. Examples are in patients with massive swelling and blood-filled fracture blisters on the foot; for calcaneal fractures in patients with multiple injuries, where only the minimum can be done initially because of the patient's unstable condition; in patients with systemic disease contraindicating any type of intervention; or for local conditions of the foot, such as skin ulcers or active infection, that contraindicate any type of operative intervention. In addition, even when ORIF is anticipated to occur eventually, if it cannot be done immediately, then closed reduction under anesthesia may be useful to obtain initial alignment, which improves venous and lymphatic return from the foot, decompresses associated neurovascular structures, eliminates tenting of the skin, and generally improves the condition of the foot for the subsequent ORIF. However, remember that in general, except in neglected injuries or after extremely severe crushing type injuries with major soft-tissue damage, the earlier ORIF is carried out, the better the results. The technique is as follows:

- Administer a general or regional anesthetic and perform the reduction under fluoroscopic control with a C-arm. This is most easily done with the patient in the supine position and the C-arm positioned with the flat surface of the receiver at the foot of the table. By externally rotating the extremity at the hip, the foot then
can be placed in the lateral position on the C-arm for visualization of the reduction.

- If there is a tongue depression–type fracture, or the tuberosity is displaced superiorly, restoration of Böhler's angle and restoration of the tuberosity to its normal position is the first step. In displaced fractures, this requires grasping the tuberosity of the calcaneus in some manner. The simplest technique is to prepare the heel and grasp the tuberosity percutaneously through the skin with a large AO tenaculum-type bone-holding forceps, or large tenaculum pelvic-reduction clamps. An alternative is to temporarily insert either a K-wire or a Steinmann pin and attach to it the appropriate bow for applying traction. To reduce the tuberosity and restore Böhler's angle, simultaneously pull plantarward the forefoot and the tuberosity of the calcaneus while visualizing the reduction on the fluoroscope. This requires axial alignment.

- Next, grasp the calcaneus between the bases of both palms with your fingers interlocked beneath the heel. Apply strong manual compression to reduce the lateral wall fragments back into position, and position the tuberosity beneath sustentaculum tali. Ensure that axial alignment is restored.

- Small 2.0 mm K-wires can be placed temporarily or long term for stabilization.

Usually it is not possible with closed reduction alone to restore displaced articular fragments. Although occasionally with the maneuvers described here some intra-articular fractures will reduce if the intra-articular fragments are attached directly to the major fragments manipulated in the closed reduction.

Because of the soft-tissue swelling that usually follows these fractures, it is not feasible to hold reduction with a cast. Fortunately, a significant majority are reasonably stable after closed reduction if not subjected to forces that would displace them. After completion of the reduction, take AP, lateral, axial, and Broden radiographic views to document the reduction. Then apply a well-padded U-type short-leg splint along with a posterior splint to maintain the foot in a neutral position. Overwrap the splints with bias-cut stockinet.

Postoperatively, elevate the extremity 10 cm above the level of the heart and observe closely for excessive swelling. The dressings and splint often need to be split down to skin anteriorly within the first 24 hours because of excessive swelling. Once the swelling has resolved and prior to discharge from the hospital, overwrap the splint. Between 2 and 3 weeks after injury, the swelling will have subsided sufficiently, and a well-molded short-leg cast can usually be applied. When sufficient consolidation has occurred (usually by 6–8 weeks), the cast can be removed and the patient placed in a prefabricated orthosis such as a Cam-walker. At this point, institute ankle and foot joint ROM exercises. Delay weight bearing in most cases until 10–12 weeks after injury.

If patients have significant intra-articular involvement, they typically lose 50% or more of subtalar joint motion. If the overall external anatomy of the calcaneus has been restored, however, they will be able to successfully wear most types of shoes, and the average urban dweller who usually walks on flat surfaces will not complain of the loss of subtalar joint motion.

**Modified Essex-Lopresti Technique**

Essex-Lopresti in 1952 (34) described a percutaneous technique for the reduction of fractures of the calcaneus. It worked best for tongue-type fractures with minimal intra-articular involvement, and it utilized a spline inserted into the posterior aspect of the calcaneus to perform the reduction. Tornetta (93) described its use for tongue-type fractures of the calcaneus. I have modified this technique utilizing percutaneous manipulation of the fracture fragments and internal fixation with percutaneous K-wires and/or cannulated screws. This technique is indicated for displaced fractures of the calcaneus when there is minimal or no intra-articular involvement, or when formal ORIF is contraindicated. Elderly patients with displaced fractures, if they are sedentary and will place limited demands on their lower extremities, are excellent candidates for this technique, particularly if they have any associated systemic diseases or local extremity problems that would increase the risk of complications after open reduction.

Complete understanding of the anatomy of the fracture prior to surgery is essential. You must have a good feeling for the three-dimensional anatomy of the fracture, in particular the size and the position of the sustentaculum tali and the displaced articular fragments. Stability is achieved by the insertion of a pin or cannulated fixation screw from an intact tuberosity fragment into the sustentaculum tali. This fixation usually enters on the posterolateral surface of the tuberosity of the calcaneus and passes across the fracture site in an anterior-to-medial direction into the sustentaculum. The preferred fixation is into the sustentaculum, as this avoids crossing the mid-foot joints. If the sustentaculum is too small or is comminuted, which is usual, fixation can be extended into the talus, navicular, or cuboid. I try to avoid this, however, as it transfers the intervening joints and damages somewhat the articular cartilage. This technique is difficult on the severely swollen foot, but it is achievable, particularly if the foot is overwrapped with a compression dressing and a foot pump applied preoperatively to "milk" edema out of the foot and heel. In addition, this technique is most successful when the fracture hematoma is liquid, so it should be done as soon as possible after the fracture occurs, preferably within the first 12 hours. As time passes, the effectiveness of this technique gradually diminishes; after 7 days, it may be ineffective because of the firm organization of the fracture hematoma.

The surgical technique follows:

1. **Administer a general or regional anesthetic and place the patient in a supine position on a radiolucent fracture table.** Place a tourniquet on the upper thigh. This is usually not required but is handy to have in place in case there is excessive bleeding from the puncture wounds used for the technique. An alternative technique is to use a lateral decubitus position, particularly if implants will be inserted from the lateral side.

2. **As for the closed reduction technique previously described, position a C-arm adjacent to the side of the foot of the table on the affected side, with the large flat surface of the receiver head level with the tabletop. Prepare and drape the extremity from the tourniquet distally.**

3. **First, perform a closed reduction as described previously, as the initial repositioning of the fragments makes the remainder of this procedure easier.**

4. **Externally rotate the extremity at the hip and flex the knee to place the foot in the lateral position on the C-arm (49).**

5. **Begin 1 cm proximal to the insertion of the Achilles tendon into the calcaneus (note that this is about 50% distalward on the posterior aspect of the calcaneus), make a vertical midline posterior incision through the skin and subcutaneous fat approximately 2 cm in length.**

6. **Under fluoroscopic control, insert a ½-inch (6 mm) threaded Steinmann pin at or somewhat distal to the proximal insertion of the Achilles tendon, slightly to the lateral side of the midline of the calcaneus. Drill this in slowly under fluoroscopic control, keeping the pin parallel to the superior surface of the tuberosity fragment and directing the pin in an anteromedial direction toward the sustentaculum tali. Since the fracture is not fully reduced, this is technically the most challenging part of the procedure.** Insert the pin until it just exits the tuberosity fragment into the fracture site (Fig. 110.244).

**Figure 110.24. Modified Essex-Lopresti technique. Reduction aided by plantar-flexing the foot. A: Insert a Steinmann pin into the tuberosity up to the fracture. B: Plantar-flex the forefoot. C: Distract and lever the tuberosity distalward while maintaining forefoot plantar flexion. D: Use the pin in the tuberosity to also correct the axial alignment. E: Line up the medial cortex and insert the pin across the fracture into the sustentaculum fragment. F: Where the lateral joint surface of the posterior facet is displaced, the pin–tuberosity fragment unit can sometimes be used to manipulate and elevate the articular surface. G: After reduction, insert the pin into the sustentaculum as described.**
The reduction maneuver now involves traction on the tuberosity fragment to pull it distalward to restore Böhler’s angle and to restore the length of the calcaneus, while the forefoot is plantar-flexed. While holding the foot in this position, pull the Essex-Lopresti pin plantarward to reduce the tuberosity and help reduce the posterior facet. If necessary, use an elevator beneath the facet to aid in the reduction (Fig. 110.25). Once the reduction is achieved on the lateral view, gently pick the foot up off the C-arm and compress the calcaneus laterally and medially to reduce the lateral wall and line up the tuberosity with the sustentaculum tali (Fig. 110.26).

In my experience, however, with closed reduction and the percutaneous techniques described, the need for subtalar joint fusion for subsequent subtalar joint pain has led to wound complications and loss of fixation. Therefore, I immobilize the patient for 6 weeks in a short-leg cast. At 6 weeks, all the protruding wires and pins can be removed in an outpatient setting and an additional short-leg cast applied for 2 weeks more. At 6–8 weeks, remove the cast and apply a removable orthosis such as a cam-walker, and begin active ROM exercises for the foot and ankle. Delay weight bearing until 10–12 weeks. Neither the closed reduction technique described previously nor this one permits early motion in the subtalar joint, which is a disadvantage. The primary goal of this treatment is to restore the overall shape of the calcaneus as opposed to preserving subtalar joint motion.

**Open Reduction: Lateral Approach**

Most fracture surgeons today have adopted the extensile, lateral approach to ORIF of calcaneal fractures (see Chapter 3). The J, or lateral, approach with the subperiosteal dissection of a full-thickness flap off the lateral calcaneal wall is used for the exposure from the calcaneal tuberosity to the calcaneal cuboid joint. The principles of reduction include stabilization of the calcaneocuboid joint, the critical angle of Gissane, and the posterior facet; realignment of the calcaneal tuberosity to the sustentaculum; and finally replacement of the lateral wall. Bone grafts are used for large defects and fixation utilizes either a custom 3.5 or a 2.7 plate that has been specifically designed for calcaneal fracture fixation. The surgery can be difficult and tedious, but it is the best method for restoring the anatomy of the calcaneus, in particular the articular surfaces.

- Place the patient in a lateral decubitus position on a radiolucent fracture table with the foot to be operated uppermost. The surgery can be prolonged, so carefully position the upper extremities and pad bony prominences and neurovascular structures. Pad the down leg well and create a well-padded platform to operate on. With the legs in a slightly scissored position, lateral radiographs are easy to obtain. With external rotation, the tuberosity view can easily be obtained to check hindfoot alignment.
- Start the incision 6–7 cm above the lateral malleolus, and posterior along the lateral edge of the Achilles tendon. Extend it distally parallel to the Achilles tendon almost to the weight-bearing skin on the heelpad; then gently curve it forward and extend the transverse limb to the base of the fifth metatarsal (Fig. 110.27). Carry dissection directly down to the calcaneus, avoiding injury to sensory nerves. Then sharply elevate this entire full-thickness flap at a subperiosteal level, which includes the peroneal tendons, the calcaneal fibular ligaments, and the sural nerve. Full development of this exposure provides access to the calcaneal cuboid joint, the subtalar joint, the sinus tarsi, and the retrocalcaneal tuberosity. Place several folded towels under the tibia to allow the foot to be adducted, thereby increasing the exposure. For retraction of the flap, place K-wires in the lateral process of the talus, the fibula, and the cuboid, and bend them away from the surgical field to hold the flap. Avoid excessive tension and kinking of the flap, which can lead to marginal necrosis of the tip of the flap.
Figure 110.27. Skin incision for open reduction of the calcaneus from a lateral approach.

- After this exposure, inspect the fractures and bulge of the lateral wall of the calcaneus. Reflect the lateral wall posteriorly to visualize the interior of the calcaneus and the facet joints. An osteotomy of the lateral wall is sometimes necessary. The lateral posterior facet usually is depressed deep into the midbody of the calcaneus and rotated clockwise as visualized in this approach. The tuberosity fragment is short and in varus. Anteriorly, expose and examine the calcaneus–cuboid joint for fracture or displacement, as the reduction generally starts from the anterior aspect of the calcaneus and progresses posteriorly.
- Address the anterior calcaneus and the calcaneus–cuboid joint first. Use multiple 1.6 or 2.0 K-wires to reduce and fix the anterior body of the calcaneus and then the calcaneus–cuboid joint.
- Reduce and temporarily fix with K-wires the depressed posterior facet fragment. If the fracture line is lateral and noncomminuted, fixation can be fairly easy, whereas a more medial fracture line or comminution can make this quite challenging. Access to the articular fragments can be improved by distracting the tuberosity fragment to restore the length of the calcaneus, which displaces the tuberosity fragment inferiorly, medially, and posteriorly. Reduction often requires a combination of techniques. Insert a small osteotome or elevator into the primary fracture line and displace the body of the calcaneal tuberosity. In addition, a “Gissane spike” (a 6.5 mm, fully threaded distraction bolt) or a transverse or a longitudinal Steinmann pin can be placed into the tuberosity to manipulate the tuberosity, provide traction, and aid with the reduction.
- Now elevate and rotate the depressed posterior facet joint fragments into anatomic position. Fix the posterior facet fragments to the intact portions of the facet and to the sustentaculum. Do all of this under fluoroscopic visualization to ensure anatomic reduction and appropriate placement of the wires. At this point, check Broden's views to be certain that the posterior facet joint is anatomically restored. It is usually best to complete the fixation of the articular surface by inserting 3.5 mm lag screws with washers prior to final reduction of the calcaneal tuberosity and placement of the calcaneal plate.
- Complete the reduction and fixation of the tuberosity. This is usually the most difficult part of the reduction and frequently takes more than one attempt before satisfactory hindfoot alignment is achieved.
- Use the pins or spike previously placed in the tuberosity to align it with the remainder of the calcaneus. Try to line up the medial cortex with the sustentaculum. At this point, a defect in the cancellous bone of the calcaneus beneath the posterior facet joint is usually evident. Stability of the reduction can be improved by packing this defect with autologous cancellous bone graft, morcelized allograft, or a synthetic bone graft substitute (45). Obtain temporary fixation of the reduction with K-wires.
- Reduce the lateral wall of the calcaneus back into position. If it is intact, it provides a good guide to reduction, as it should fit anatomically into place.
- Obtain final fixation by applying a specially designed calcaneal plate or a combination of mini-fragment or small fragment plates utilizing 2.7 and/or 3.5 mm screws.
- I prefer the AO calcaneal plate (Synthes, Paoli, PA), which must be carefully molded to fit the entire lateral surface of the calcaneus so that the fracture is not displaced with insertion of the screws. This plate provides many alternative locations for screws, not all of which need to be used. Insert screws where necessary to obtain as solid a fixation of the fracture as possible (45). Obtain final plain radiographs, including AP, lateral, tuberosity, and Broden's views (Figs. 110.28).

C: Postoperative lateral radiograph showing restoration of Böhler’s angle and fixation with a low-profile titanium calcaneus plate. D: Axial view. (Courtesy of C. Finkemeier, Sacramento, CA.)

- The wound closure is critical to help prevent wound complications. Insert a small drain. Use interrupted figure-eight sutures from the periostial flap to the deep tissues, including the fascia of the abductor digiti minimi. Place all deep sutures prior to tying and then tie from anteriorly to posteriorly. This provides even tension on the flap. Close subcutaneous fat and then the skin with either Allgöwer-type subcuticular vertical nylon mattress sutures or staples. Apply a well-padded short-leg splint incorporating bulk cotton to allow for swelling, holding the foot and ankle in a neutral position.

Open Reduction: Medial Approach

A full medial approach can be used alone for fixation, or a small medial approach can be combined with a lateral approach to assist in the reduction of the calcaneal tuberosity to the sustentaculum tali, especially in fractures that are more than 3 weeks old.

- Begin the skin incision halfway between the medial malleolus and the bottom of the heel using a curvilinear incision that is parallel and posterior to the posterior tibial tendon and the neurovascular bundle. Reflect this flap in a subperiosteal manner superiorward to expose the calcaneous. Try to identify and preserve the sensory nerves.
- Identify the fracture lines, in particular the spike of bone of the sustentaculum fragment, which is the key to the reduction.
- The techniques of reduction and fixation are similar to those already described for the lateral side. Level the body of the tuberosity posteriorly and medially; the fracture fragments usually key into an anatomic position. Insert multiple K-wires through the calcaneal tuberosity into the sustentaculum or mid foot to hold the tuberosity fragment. Obtain fixation with staples, wires, screws, and/or small plates. As mentioned earlier, the lateral approach is necessary for reduction of the calcaneus–cuboid joint, the angle of Gissane, and the posterior facet joint.
- Wound closure is as described for the lateral side.
- Postoperatively, continue intravenous antibiotics for 24 hours. Keep the foot elevated 10 cm above the heart. Foot pumps may help to prevent edema (89).
- Discharge patients in the bulky dressing and splint, and see them for a follow-up at approximately 10 days. Continue elevation at home. If the flaps are healthy without drainage, convert to a removable splint to allow early ankle and hindfoot motion. Keep them non-weight-bearing. If the patients are unreliable, place the foot in a short-leg cast and see them regularly in the office for supervised active and passive ROM exercises. At 6–8 weeks, at least 50% of the motion should have returned to the ankle and hindfoot. If radiographs show healing, initiate partial weight bearing up to 50 pounds. By 12–14 weeks, allow full weight bearing, and begin strengthening exercises.

Have patients walk each day in good, well-cushioned shoes, using elastic hose to control edema. They must practice walking until they can walk across the room on tiptoe. If they fail to make sufficient progress, send them to a physical therapist for supervised exercises. They begin by walking on a combined treadmill–trampoline machine and progress as tolerated. Full recovery requires a full year, and some patients show additional improvement in the following year.

Primary Subtalar Arthrodesis

When the articular facets on the calcaneus are so comminuted that anatomic reduction is not possible and posttraumatic arthritis is inevitable, some authors (13,78) advocate calcaneal-subtalar arthrodesis at the time of internal fixation of the calcaneus, feeling that the overall long-term recovery is shortened and a second operation avoided. In addition, this makes the fixation of the calcaneus easier as implants can be placed into the talus across the subtalar joint. To add subtalar arthrodesis to the internal fixation of the calcaneus, remove the cartilage from the joint surfaces on the talus when the subtalar joint is exposed and curet the subchondral bone to expose bleeding cancellous bone. Be certain that the calcaneus is well aligned and in good position and pack autologous bone into the subtalar joint. Assuming the tuberosity of the calcaneus will provide good fixation, a long screw inserted from the plantar surface of the tuberosity through a stab wound on the heel can be angled up through the posterior facet joint into the body of the talus to obtain good fixation. Place a washer on the screw to prevent it from sinking into the calcaneus.

After swelling subsides, apply a short-leg cast, and keep it in place until union of the calcaneus and subtalar joint occurs. During this period, keep the patient non-weight-bearing. After 8 weeks, patients can be progressed toward full weight bearing either in a short-leg cast or with a removable orthosis such as a Cam-walker until solid union occurs, usually around 12 weeks.
Wound Necrosis  Necrosis of the superﬁcial wound margin can occur both medially and laterally. This is potentially very serious, as it can lead to secondary infection and exposure of the bone and ﬁxation hardware (10-36). If not well managed, or if it occurs in the presence of peripheral vascular disease or systemic disease such as diabetes mellitus, deep bone infection can occur, which can result in amputation. Avoid this complication by careful patient selection, maintaining a full-thickness ﬂap, using gentle retraction of the ﬂap (which avoids the kinking of the ﬂap), and avoiding prolonged operating times.

A tension-free closure utilizing suture techniques that preserve the blood supply to the skin is essential. If swelling occurs during surgery, so that a tension-free closure is not possible, leave the wound open; cover it with a biological dressing and return the patient to surgery for a delayed primary closure when the soft-tissue swelling has resolved. Necrosis of the tip of the superior ﬂap of 5 mm or less can usually be treated by debridement on an outpatient basis, and with wet-to-dry dressing changes, allowing the wound to heal by secondary intention. If the wound necrosis is so large that bone and/or ﬁxation will be exposed, consult with an orthopaedic or plastic surgeon with experience in local or free microvascularized ﬂaps, so that the wound can be debrided back to viable tissue and closed as soon as possible.

Infection  Deep infection, although uncommon, may manifest as a cellulitis, which can be treated with deep cultures and administration of appropriate intravenous bactericidal antibiotics. For deep infection with abscess formation, irrigate and debride the wound as soon as infection is detected, obtain deep cultures, and begin culture-speciﬁc bactericidal intravenous antibiotics. Usually, the wound needs to be left open, but it should be closed secondarily as soon as the acute infection resolves, if the construct remains stable and hardware ﬁxation is solid, the implants can be left in place. If deep infection with osteomyelitis occurs with loosening of the implants, then removal of all implants and debridement of nonviable bone may be necessary to resolve the infection. This usually leads to an unsatisfactory outcome: a scarred, shortened heel with signiﬁcant loss of function.

Maldirection of the Fracture  Residual malposition of the calcaneus commonly occurs after any of the described methods of reduction because of the difﬁculty in treating these challenging fractures. The most frequent problem in my experience is residual shortening, with proximal migration of the tuberosity and residual valgus. This can lead to weakness in push-oﬀ, diﬃculty with shoe-wear, and impingement on the peroneal tendons or tip of the ﬁbula, which can lead to chronic pain and tendinitis. Reconstruction for late deformities of the calcaneus are very diﬃcult and are beyond the scope of this chapter (see Chapter 115).

Subtalar Joint Arthritis  Posttraumatic arthritis in the subtalar joint occurs to some extent in the majority of these fractures. It is primarily the result of the original trauma itself, although inadequate reduction can hasten the onset of arthritis. According to McReynolds (56), about 20% of calcaneal fractures will require subtalar arthrodesis for traumatic arthritis. This is much higher than in my experience, where less than 5% ever require arthrodesis, probably because many go on to stable pain-free ﬁbrous ankylosis of the subtalar joint. If the overall anatomic shape and alignment of the calcaneus is restored, this minimizes the stresses on the subtalar joint and keeps the necessity for subsequent arthrodesis low. See Chapter 115 for a discussion of arthrodesis of the subtalar joint.

AUTHORS' PERSPECTIVE

There have been few published randomized prospective studies comparing ORIF of calcaneal fractures to less invasive methods that have shown better functional outcomes with ORIF (87,91). There is an ongoing large randomized study in Canada, which is unpublished, that suggests that ORIF may provide a slightly better long-term result in certain displaced types of fractures. There is general agreement among fracture surgeons that anatomically reconstructing the calcaneus produces acceptable functional outcomes in the majority of selected patients, and that there is a tremendous advantage to subsequent reconstruction if the hindfoot anatomy is reasonably normal (87,91).

I prefer the extensile, lateral approach to the calcaneus. As mentioned, there are limited indications for small open medial approaches to assist in the reduction. Popularity is gaining for more aggressive percutaneous reduction techniques; however, these will probably not be universally applied in community practice settings until the techniques are better developed. Long-term results of this method are lacking. I prefer the lateral position using ﬂuoroscopic control and the extensile lateral approach when the soft-tissue envelope is healthy. Calcaneal plate ﬁxation with or without bone grafting provides the best opportunity for anatomic reconstruction by most general orthopaedic or fracture surgeons.

If patients eventually develop hindfoot arthritis, most can be well managed by using a rocker-bottom shoe and oral anti-inﬂammatories prior to recommending a hindfoot fusion. In the event of a failed calcaneal fracture, a reasonable salvage approach is a subtalar arthrodesis (22,83). Occasionally, the hindfoot will require bone block distraction to realign the hindfoot and the talonavicular joint with or without calcaneal osteotomy (79).

INTRODUCTION AND GENERAL CONSIDERATIONS

Recently, research on the impact of foot injuries in the rehabilitation of polytrauma patients has documented that patients with foot injuries often had more long-term morbidity (39). This research suggests that more attention needs to be paid to what may have been seen as less serious injuries. Recent publications provide excellent reviews of this important topic (1,18,29,30,37,40).

ANATOMY

The bones discussed in this chapter include the navicular, cuboid, three cuneiforms, metatarsals, phalanges, and sesamoids. The joints discussed are Chopart's joint, Lisfranc complex, metatarsophalangeal (MTP) joints, and the interphalangeal joints. It is important to recognize the close relation of nerves and blood vessels to the bones and joints in the foot (33). In particular, the dorsalis pedis artery and the deep peroneal nerve are at risk in both injuries to and surgery for the Lisfranc complex. Incisional neuromas are relatively common complications of surgery in the foot and ankle. A variable number of compartments have been described in the foot (22,35) that must also be understood in these injuries. See Chapter 3 on surgical approaches to the lower extremity.

SOFT-TISSUE MANAGEMENT

Although they are not limited to the foot, crush injuries and lawnmower injuries make up a significant subset of injuries to the foot and ankle (28). Crush injuries may be combined with degloving when the foot is run over by a heavy vehicle, but they also occur with direct impact such as dropping a heavy object on the foot. Lawnmower injuries are heavily contaminated open wounds with or without fractures and often some soft-tissue avulsion. These injuries not only damage bones and joints but also nerves and vascular structures, and can lead to skin necrosis, which is not evident acutely. Therefore, these wounds often need repeated debridements and delayed primary closure of the skin. Lawmower injuries require urgent treatment, with thorough debridement and irrigation, and then reassessment of the viability of the affected part (29). Early administration of intravenous antibiotics is essential. The principles of management of open fractures are discussed in Chapter 12.

Vascular injuries, even forefoot gangrene, have been described following Lisfranc's injuries (8,13). This makes reduction of a displaced dislocation in this area urgent. Compartment syndrome in the foot has been well described by Manoli (22), Shereff (35), and others. Diagnosis and investigation of compartment syndrome are discussed in Chapter 13. Compartment syndrome can occur without bony injury in the foot, but when it is associated with a Lisfranc fracture dislocation, the surgical approach for decompression needs to take into consideration the approach for internal fixation of the underlying bony injury. Compartment syndrome release can be performed through a single medial incision, but my preference when it is associated with Lisfranc's fracture dislocation is to combine a medial incision with one or two dorsal incisions. There may be a role for foot pumps to decrease the incidence of foot compartment syndrome. Patients with calcaneal and more proximal fractures tolerate this treatment modality more readily.

Reflex sympathetic dystrophy (RSD) may be a complication of soft-tissue injuries as well as bony injuries of the foot (13). See Chapter 7 for more information of RSD.

NEUROPATHIC MIDFOOT FRACTURES

It is important to recognize that in patients with peripheral neuropathy, particularly in diabetics, a forefoot or midfoot fracture can lead to the development of a Charcot arthropathy. This is discussed in detail in Chapter 116 and Chapter 124. In some acute injuries, the underlying neuropathy may not be recognized; in other cases, the patient may present with a well-established neuropathy and advanced deformity so that the diagnosis of neuropathy is obvious.

STRESS FRACTURES

The principles of stress fractures are addressed in Chapter 96. In the midfoot and forefoot the most common sites for stress fractures are the navicular, the base of the fifth metatarsal, the shaft of the second and third metatarsals, and the sesamoids. Those most resistant to treatment are the navicular and base of the fifth metatarsal. Fractures of the sesamoid and middle metatarsals are addressed elsewhere in this chapter.

FIXATION TECHNIQUES IN THE MIDFOOT AND FOREFOOT

The role of various fixation techniques is presented in Table 111.1.
Table 111.1. Applications, Advantages and Disadvantages of Foot Fixation Techniques

KIRSCHNER WIRES VERSUS SCREWS

Kirschner wires (K-wires) have been frequently used to stabilize forefoot fractures. They are particularly useful where their role is short-term fixation, particularly of a metatarsal or a toe. Their role in Lisfranc injuries remains controversial, however. The disadvantages of using smooth K-wires are migration if they are left buried and infection if they are left through the skin for prolonged periods. Therefore, when I repair primarily ligamentous injuries that require 3 months of immobilization, I prefer to use either a screw or a threaded K-wire and bury it beneath the skin.

The advantages of screws are the ability to provide compression and more solid fixation, which is particularly important for rigid stabilization of the medial three tarsal-metatarsal joints and for those fractures in which inadequate fixation is likely to lead to nonunion or delayed union. Cannulated screw systems allow percutaneous insertion of the implant. When a screw is placed across a joint, which is particularly relevant in Lisfranc’s injuries, the other concerns are damage to the articular surface by the larger diameter and the need to remove the implant. If the screw is placed across a joint that is essential to the function of the foot, removal is indicated; otherwise, removal remains controversial unless the implant causes symptoms. Details of the recommended methods of fixation for individual injuries are discussed later in this chapter.

BIORESORBABLE IMPLANTS

Pins and screws made of polylactic acid (PLA), polyglycolic acid (PGA), and substances that are absorbed over time are now available (5). These implants initially caused some concern because of local soft-tissue reactions, particularly seromas. The more recent implants produce less reaction and do have a role, especially for intra-articular fractures or for temporary (i.e., 6-week to 3-month) fixation of joints such as Lisfranc’s injuries. Their role in long-term fixation of the foot and ankle, however, remains to be seen.

ROLE OF EXTERNAL FIXATION

The midfoot contains a variety of small bones (e.g., the cuneiforms, navicular, and cuboid), which when fractured, may be comminuted and difficult to stabilize with internal fixation. It is occasionally useful to bridge the area with an external fixator, such as medially from the talar neck to the first metatarsal (Fig. 111.1C, Fig. 111.1D) (11,15) to restore the length of the column and reduce the fractures using ligamentotaxis. External fixation may be used as a temporary device to provide the reduction. The fracture can then be stabilized by internal fixation or percutaneous fixation as the definitive method of treatment, or the fixator can be left in situ. I have found this particularly helpful in a comminuted navicular fracture for which such extensive comminution occurred that stripping the soft tissues to allow adequate reduction might have led to avascular necrosis. The other role for external fixation is when the soft tissues are compromised, such as an open fracture or severe crushing, to provide temporary fixation while the soft-tissue situation is resolved.

INJURIES TO MIDFOOT AND FOREFOOT BY REGION

The algorithm for assessing injuries to the midfoot and forefoot is shown in Figure 111.2.

Figure 111.2. Algorithm for assessment of midfoot and forefoot injuries.

CHOPART’S JOINT-FRACTURE DISLOCATIONS

The algorithm for treatment of Chopart’s joint injuries is shown in Figure 111.3.
Mechanism of Injury, Investigation, and Classification

Chopart's joint is an unusual injury site, but because of its importance to the function of the foot, particularly in linking the hindfoot to the forefoot, damage in this area can have significant consequences to the function of the foot. Main and Jowett (21) classified midtarsal joint injuries based on the direction of the force of injury and the deformity that occurred. They described five patterns of injury; within each, the injuries varied in severity. However, their classification is not helpful in prognosis or management decisions.

The main concern is that the extent of the injury may be initially missed (10, 21, 27). A dislocation with spontaneous relocation may be associated with only minor avulsion fractures (10). Take a careful history, and ask about the amount of force applied, the direction of the force, and whether the patient felt a “clunk” as the joint dislocated or relocated. These injuries are often found in polytrauma patients, in whom the details of the injury may not be available; therefore, any polytrauma patient with a swollen foot needs careful assessment. Localize sites of maximum tenderness; test motor and sensory function, if possible, and gently stress the transverse tarsal joints to look for excessive mobility.

Take anteroposterior (AP), lateral, and a medial-oblique radiographs of the foot. Findings may include avulsion of the navicular tuberosity, fractures through the body of the navicular, compression of the cuboid, or anterior calcaneus. Hermel and Gershon-Cohen (17) applied the term “nutcracker fracture” to the compression fracture of the cuboid. True dislocations may be seen on plain radiographs, but most often, spontaneous reduction of the transverse tarsal joint has occurred. For this reason, examination under anesthesia is occasionally warranted if the patient is undergoing surgery for other injuries. Alternatively, if the patient does not have other major injuries and it is clinically indicated, local anesthetic injection may allow weight bearing or stress films to be taken. Further investigation such as computerized tomography (CT) may be warranted if a significant intra-articular fracture requires documentation or if the plain radiographs are not diagnostic. If the patient is seen late with persistent medial midfoot pain, a bone scan may be warranted to document an otherwise unrecognized injury (7, 12).

Principles of Treatment

The goal of treatment in the transverse tarsal joint is to restore the normal anatomy and stability without producing excessive stiffness. As shown in Figure 111.2, assess whether immediate treatment is warranted. Treatment may consist of closed reduction, external fixation, open reduction and internal fixation, or late reconstruction.

Immediate Treatment If the injury is primarily to soft tissues, or is a dislocation or subluxation, then treat immediately with closed reduction (Fig. 111.4A and Fig. 111.4B). If closed reduction is not possible owing to a trapped tendon, capsule, or bony fragments, perform an open reduction (Fig. 111.4C and Fig. 111.4D). Once the reduction is completed, assess the stability (Fig. 111.3).

Most often, a transverse tarsal joint dislocation without a major fracture is relatively stable. Immobilize with a splint, and elevate (no weight bearing) for 1 to 2 weeks to allow pain to resolve. I recommend using a removable splint or removable cast to allow range of movement while protecting the foot from loading. If, however, there is a fracture associated with a dislocation, particularly a fracture of the navicular, then the injury may be unstable. If a fracture of the navicular is undisplaced and if closed reduction produces satisfactory alignment, splint until the swelling is reduced, followed by a period of immobilization in a short-leg cast for approximately 6 weeks. Weight bearing depends on the stability of the fracture. Then encourage range of movement.

For displaced fractures of the navicular, such as avulsion of the navicular tuberosity, open reduction and anatomic fixation are warranted. Immobilize for 6 weeks until fracture healing occurs. Weight-bearing status depends on the stability of the fracture and the fixation but is generally non-weight bearing for 6 weeks.

Fractures of the lateral column are less likely to be unstable, but a compression fracture of the cuboid may shorten the lateral column, which will have a long-term effect on foot function. When the lateral column fractures are minor avulsions, such as the anterior process of the calcaneus or the dorsal lip of the cuboid, treat symptomatically. Occasionally, late excision of bony fragments is necessary if they are problematic. If there is a crush injury of the lateral column with loss of height of the cuboid, however, then reduction and stabilization are indicated. The same pattern of cuboid injury may be seen with Lisfranc’s dislocations. The principles of the different methods of treatment are discussed in relation to the different fracture patterns.

External Fixation I use external fixation on the medial side only when there is significant loss of medial column length, and when other methods of fixation are not an option. It is more common to have lateral column shortening. External fixation may be used if the fragments are too small to obtain stable reduction with internal fixation.

- Plan the insertion of two pins in the calcaneus and two in the fifth metatarsal.
- Make stab incisions in the skin; be careful to avoid injury to the sural nerve.
- Insert two pins in a half pin fashion into the calcaneus and two into the fifth metatarsal using the technique appropriate for the external fixator that is being used.
- Apply the fixator and distract the fracture.
- Expose the fractured bone through a short longitudinal incision and elevate the articular surface, which can usually be elevated and aligned to the remaining medial or plantar articular surface.
- Use a small amount of bone graft, which can be harvested locally from the calcaneus or malleoli, to fill any resulting defect and stabilize the fragment.
- Stabilize the fracture with one or two small threaded K-wires running in the subchondral bone into the remaining cuboid. Cut the wires off just outside the bone.

Figure 111.3. Algorithm for Chopart's joint injuries.

Figure 111.4. AP (A) and lateral (B) radiographs of residual subluxation following closed reduction of a Chopart's fracture and dislocation in a 9-year-old girl. AP (C) and lateral (D) radiographs of post-open reduction and K-wire fixation. The dorsal capsule was blocking reduction.
Postoperatively, leave the external fixator in place for at least 6 weeks to keep all compressive forces off the cuboid.

Occasionally the fragments are simply too small for any fixation, in which case simply elevate the fracture, pack in bone graft, and use external fixation to control the fracture. If the fracture fragments are large enough, a screw may be used to stabilize the fracture fragments. In this case, the external fixator may be removed or a plate may be applied (see the next section), depending on the stability of the construct.

**Open Reduction and Internal Fixation**

On the medial column, open reduction and internal fixation are used for displaced fractures of the navicular tuberosity or displaced fractures of the body of the navicular. The most common injury is an avulsion fracture of the navicular tuberosity, which can be treated by the following technique:

- Make a longitudinal medial incision, centered over the navicular tuberosity. Dissect along the line of the incision straight down to the navicular.
- Identify the talonavicular and naviculocuneiform joints. Owing to the curved shape of the navicular, screws or pins placed from the medial aspect of the foot may inadvertently transgress one or both of these joints.
- If the fracture is not comminuted, reduction can often be achieved by inverting the foot. The navicular tuberosity is not primarily articular, so the main concern is restoration of the insertion of the tibialis posterior tendon and restoring medial stability.
- Once stabilization and reduction are achieved, insert a screw from proximal to distal using compression technique to stabilize the fracture.

Postoperatively, immobilize the foot in a splint in mild inversion and plantar flexion for 2 weeks and then reapply a splint or cast in neutral alignment. Time to weight bearing depends on the size of the fragment and the stability of the fixation, but most patients can bear full weight by 6 to 8 weeks.

Fractures that involve the navicular, particularly those with severe comminution, are discussed in this chapter under the section titled *Isolated Navicular Fractures*, but in this context, it is important to note the initial aim in treatment is to restore normal forefoot–hindfoot alignment and to maintain the lengths of the medial and lateral columns. Many of these patients may require later arthrodesis, which will be much easier if the anatomy is preserved. Primary arthrodesis is occasionally indicated (11,12,15); however, my preference is to attempt to obtain healing in appropriate alignment in order to maintain the function of the transverse tarsal joints and perform arthrodesis only as a later reconstruction if symptoms cannot be controlled with nonoperative methods.

For lateral column injuries, open reduction and internal fixation are less frequently warranted.

- Make a longitudinal lateral approach to the anterior calcaneus, cuboid, and base of the fourth and fifth metatarsals with variations in the exposure depending on the fracture pattern in the cuboid and whether the anterior calcaneus is involved.
- The cuboid is generally crushed between the calcaneus and the metatarsals. The injury may be simple to the lateral half of the cuboid and often is primarily dorsal. Similar to talus plateau fractures, the articular surface has been driven into the body of the cuboid with a thin rim of subchondral bone preserved.
- An alternative to using an external fixator for the previously discussed “nutcracker” fracture of the cuboid is to use a plate spanning from the calcaneus to the fifth metatarsal to distract and unload the cuboid fracture. Leave the plate in situ for approximately 3 months and then remove it (Fig. 111.4).

**Late Reconstruction and Role of Arthrodesis**

Late presentation of injuries to Chopart's joint injuries may be due to initial misdiagnosis of the injury as a minor sprain. The more severely displaced injuries are generally recognized immediately. Treat late presentation of a primarily soft-tissue injury with in-shoe devices combined with shoe modifications. Medial or lateral column shortening combined with degenerative changes in the affected joints is more serious and generally requires surgery.

For lateral column shortening and arthrosis of the calcaneocuboid joint and subluxation of the talonavicular joint, lengthen the lateral column and perform an arthrodesis of the calcaneocuboid joint.

In medial column shortening, generally both the talonavicular and naviculocuneiform joints are affected. Plan an arthrodesis for the entire medial column from the talus to the medial and intermediate cuneiforms. Quite commonly all three cuneiforms must be included in the arthrodesis to form a solid block with the navicular. There is relatively little motion between the cuneiforms, and it is easier to get a solid fusion by involving all three. If alignment is satisfactory, perform an in situ arthrodesis (29).

If the medial column has been shortened, restoration of length is necessary and will require tri cortical iliac crest graft (12). The aim is to restore the longitudinal axis of the foot so that the second metatarsal bisects the angle between talus and the calcaneus on an AP radiograph of the foot. Comparison radiographs of the other foot are helpful. Arthrosis of the medial column is much more difficult to achieve than for the lateral column. Good-quality bone graft is essential, combined with rigid internal fixation, generally using multiple screws occasionally supplemented by a plate followed by non-weight bearing for 6 weeks and total immobilization of 3 months.

**ISOLATED NAVICULAR FRACTURES**

Injuries to the navicular range from minor to severe. Stress fractures can be a complex problem and are discussed in Chapter 96.

**Dorsal Avulsion Fractures**

Dorsal avulsion fractures are most commonly seen with a forced plantarflexion injury or a direct blow to the foot and are essentially a dorsal midfoot sprain (7,9,11,41). An avulsion fracture may be an indicator of a more serious fracture dislocation. If the mechanism of injury is relatively clear, symptoms and signs are localized at a small area on the dorsum of the foot, and there is no tenderness over the calcaneocuboid or navicular tuberosity, the fracture can be considered a localized injury. Check the function of the deep peroneal nerve, which generally lies immediately adjacent to this fracture. The tibialis anterior tendon does not insert in this area, but isolated ruptures of the tibialis anterior do occur, so look for this injury. Plain AP and lateral radiographs are usually sufficient. A typical avulsion fracture has sharp edges and irregular margins. Look for a fractured dorsal osteophyte. Do not mistake an accessory ossicle for a fracture.

Initially, manage the injury in a dorsiflexion splint for 1 to 2 weeks. Once the acute pain and swelling have resolved, apply a walking cast or removable orthosis (“cam-walker”) for another 3 to 4 weeks, followed by mobilization. Warn patients at the onset of treatment that the small fragment may not heal, and that the aim of the treatment is to allow the ligaments and soft tissues to heal. If the bony fragment is symptomatic, particularly irritation of the deep peroneal nerve, then surgical excision (“cam-walker”) for another 3 to 4 weeks, followed by mobilization. Warn patients at the onset of treatment that the small fragment may not heal, and that the aim of the treatment is to allow the ligaments and soft tissues to heal. If the bony fragment is symptomatic, particularly irritation of the deep peroneal nerve, then surgical excision is indicated. My preference is to attempt to obtain healing in appropriate alignment in order to maintain the function of the transverse tarsal joints and perform arthrodesis only as a later reconstruction if symptoms cannot be controlled with nonoperative methods.

Avulsion of the navicular tuberosity may occur with resisted forceful contraction of the tibialis posterior or forced eversion (7,9,11,41). It is important to rule out a more complex associated injury. Take a good history to make sure the mechanism of injury is consistent with the clinical findings. Rule out other associated injuries, particularly to Chopart's and Lisfranc's joints. Assess the tibialis posterior tendon for continuity.

Take AP and lateral radiographs, but to visualize the navicular tuberosity, a reverse oblique will demonstrate a fracture better than the normal medial oblique view. It is
important to differentiate between an acute fracture and an accessory navicular. An accessory navicular usually has smooth edges rather than the sharper, irregular margins of an acute fracture. It is possible, however, for the fibrous syndesmosis between the accessory navicular and the navicular body to become disrupted, and that area may be symptomatic. An ultrasound scan may also be useful to assess the tendon at its insertion.

A fracture of the navicular tuberosity is often nondisplaced or minimally displaced. If so, initially splint the foot into slight inversion to take the tension off the posterior tibial tendon and ease pain, followed by a period of 4 to 6 weeks in a short-leg walking cast. Base the total treatment time on evidence of clinical and radiographic union. In athletes, some recommend simple bandaging (41). Because of the continuous pull of the tendon, nonunion may occur, but it is often asymptomatic.

An accessory navicular may become symptomatic, especially in the adolescent, in which case, 6 weeks in a short-leg walking cast is recommended to determine whether the syndesmosis will heal. If the nonunion of an accessory navicular produces persistent pain or loss of function of the tibialis posterior tendon, surgical intervention is indicated. For displaced fractures, surgical repair is warranted.

**Open Reduction and Fixation**

- Make a medially slightly curved longitudinal incision centered on the navicular tuberosity, curving proximally along the posterior tibial tendon and extending longitudinally distally along the plantar border of the medial cuneiform.
- By blunt dissection, expose the wide insertion of the tibialis posterior tendon with its extensive ligamentous insertion medially and plantarward.
- For acute fractures, clean the fracture ends, reduce the fracture, and generally fix it with a simple compression screw.
- K-wire fixation may be necessary if the fracture is comminuted and no individual fragment is large enough to take screw fixation. If the bony fragment is small, an alternative is to excise the fragment and repair the remaining tibialis posterior tendon to the navicular.

Following any of these surgical procedures splint the foot in inversion and plantarflexion for 7 to 10 days, followed by a short-leg non-weight-bearing cast in neutral for 4 to 6 weeks and then a removable weight-bearing orthosis for up to 12 weeks.

**Fractures of the Navicular Body**

Acute fractures of the body of the navicular are seen frequently in the longitudinal stress pattern described by Main and Jowett (21). Typically, vertical splits occurring in line with the cuneiform. The pattern varies, depending on the amount of plantar flexion the foot is in at the time of injury. Sangeorzan (31) described three fracture patterns in 1989:

- **Type I fractures** have a fracture line parallel to the sole of the foot (i.e., the transverse plane separates it into dorsal and plantar fragments). This fracture pattern is generally benign with very little displacement of the forefoot in relationship to the hindfoot.
- **Type II fractures** are oblique fractures with fracture lines running dorsolateral to plantarmedial and the forefoot is displaced medially. More extensive comminution is noted.
- **Type III fractures** are comminuted with the main damage being centrally or laterally and the forefoot is displaced laterally.

Take AP, lateral, and oblique radiographs. A CT scan may be helpful in distinguishing type II and type III fractures if that influences the surgical decision making.

The talonavicular joint is one of the key joints maintaining the length of the medial column and foot function. Therefore, the goals of treatment are to restore an anatomic alignment of the taloarticular surface of the navicular and to restore medial column length. Nonoperative treatment would be indicated only for an undisplaced fracture. If the fracture is a longitudinal split, consider a stress fracture.

**External Fixation**

A mini-external fixator may be useful in medial column injuries for comminuted type II or III fracture patterns. For type II fractures in which there is primarily lateral comminution of the navicular with one relatively large dorsal medial fragment, two incisions may be indicated.

- Make a medial incision running from the navicular tuberosity toward the medial malleolus, above the tibialis posterior tendon, avoiding the saphenous nerves and veins, to expose the talar neck. The incision can be continuous, or separate incisions can be made distally over the medial cuneiform, or depending on the fracture pattern, the base of the first metatarsal.
- Then under direct vision, place external fixator pins in the talus neck and medial cuneiform, apply longitudinal traction, and tighten the external fixator while applying distracting forces across the navicular (Fig. 111.1). If the fracture is fixable, then either through the same medial incision or a second dorsal lateral incision, reduce and fix the fracture.
- If the lateral fragment is too comminuted for fixation, then reduce the dorsal medial fragment between the cuneiforms and transfix the talus in that position with either K-wires or fully threaded cortical screws. An alternative is to fix the fragments only to the cuneiforms to try and preserve talonavicular motion (11,15,31).
- For type III fractures in which the extent of comminution is such that stable internal fixation cannot be achieved, use the external fixator and apply longitudinal traction. By direct pressure, attempt to manipulate the fragments into satisfactory alignment, particularly aiming to align the forefoot to the hindfoot and maintain the medial column length.
- When there is widespread comminution of the fracture, do not expose it because it simply devascularizes the fracture fragments and may predispose the patient to avascular necrosis. Percutaneous fixation may add to the stability.

**Open Reduction and Internal Fixation**

Open reduction and internal fixation is primarily used in the displaced type I and type II and some type III fractures. With comminuted type II and III fractures, open reduction and stable internal fixation are difficult to achieve and may need to be combined with some form of external fixation.

- Make a dorsomedial longitudinal incision through the tibialis anterior tendon sheath, down through the inferior margin of the sheath, and onto the navicular, being careful to identify the talonavicular joint and the medial cuneiform.
- Retract the tendon either medially or laterally to better visualize the fracture.
- Reduce the fracture and, if possible, fix it with screws inserted dorsally. It is important to remember the curve of the navicular and identify the joints on either side to avoid the screw impinging on either joint.

Postoperatively splint the foot and keep the patient non-weight bearing for at least 6 to 8 weeks and occasionally for 12 weeks. Patients, particularly those with type II and III fracture patterns, should be advised that there is a high likelihood of a fair to poor outcome (9,10,11 and 12,15,21,27,31) due to degenerative changes, malunion, nonunion, or avascular necrosis, that even with good fracture healing, stiffness is a likely outcome.

**Late Reconstruction**

Late reconstruction of fractures of the navicular are primarily for degenerative arthritis of the talonavicular joint due to avascular necrosis or shortening of the medial longitudinal arch causing dysfunction of the forefoot. The primary reconstruction option for all of these problems is arthrodesis, extending from the talar neck into the cuneiforms. If alignment is satisfactory, an in situ arthrodesis can be performed. Two techniques are described for this.

**Medial Column Arthrodesis**

- Expose the involved joints through a longitudinal medial incision.
- In the first technique, create a longitudinal channel in the bones and joints to be fused. Take iliac crest graft, split it, and reverse it so that the cancellous surfaces face out. Place them in the channel in the talar neck, navicular, and into the cuneiforms. Fix with either screws or K-wires.
- In the second technique, excise a portion of the navicular and replace it with tricortical iliac crest bone graft to lengthen the medial column and form a more solid wedge. Fix it with screws.

When alignment is not satisfactory and medial column lengthening is required, then the second technique is preferred because the tricortical iliac crest struts are strong enough to lengthen the medial column. Both of these techniques are described in the article by Ferris et al. (12).

**ISOLATED CUBOID FRACUTRES**

Isolated cuboid fractures are rare. More commonly, cuboid injuries are associated with either Chopart's joint fracture dislocations or as part of a Lisfranc injury. Both of these injuries produce a “nutcracker” type of fracture (17), as described in the previous section. Isolated fractures can occur with a direct blow; these fractures are generally minimally displaced and can be treated in a short-leg cast. As long as the plantar and medial cortices are intact, a walking cast used for approximately 6 weeks is sufficient. Other isolated cuboid fractures are some of the minor avulsions seen with inversion or plantarflexion injuries (7). These fractures generally can be treated symptomatically. It is important to be aware of the os peroneum because it can be mistaken for a fracture of the cuboid. The os peroneum is a sesamoid bone.
in the peroneus longus tendon as it curves around the cuboid. It can be painful.

There have been reports of calcaneocuboid subluxation as a source of pain in the lateral foot that is not usually due to acute trauma but is seen primarily in athletes and dancers (23).

**ISOLATED CUNEIFORM FRACTURES**

As an isolated entity, cuneiform fractures are most commonly an avulsion fracture due to plantar flexion force or from a direct blow. The most severe isolated cuneiform fractures are from direct trauma, particularly from gunshot wounds or propellers (26), which produce open fractures with bone loss. Otherwise, any injury to the cuneiform needs to be a warning sign to look for injury to the Lisfranc complex in particular. Note that Lisfranc's variants can extend to the intercuneiform joints (3,11,25). Isolated dislocations of the cuneiforms have been described (6,11). Charcot's arthropathy can result in isolated injuries as well.

Take AP, lateral, and oblique radiographic views of the foot. If there is suspicion of a Lisfranc injury, a CT scan may identify the small plantar fractures associated with disruption of the strong plantar ligaments. Manipulation of the foot under anesthesia may be necessary to detect instability.

Isolated fractures are treated according to the severity of the fracture. Treat isolated dorsal avulsion fractures with initial splinting, followed by a walking cast or a removable cast boot. Treat fractures of the body of the cuneiform non-weight bearing for at least 6 weeks and longer if severe comminution delayed healing, or undetected ligament injury (9,15). Treat open fractures as described in Chapter 12 and use external fixation if necessary to stabilize the foot (60). If bone loss has occurred, then late arthrodesis and bone grafting may be required. Even some apparent minor injuries may eventually require arthrodesis to treat a painful joint (12).

**TARSOMETATARSAL (LISFRANC) FRACTURE DISLOCATIONS**

The mechanisms for Lisfranc fracture dislocations have changed historically (2,3 and 4,6,9,11,13,14,15,16 and 17,21,24,25,28,32,36,41). The frequency of this injury is increasing owing to motor vehicle injuries and falls secondary to sports and work activities. Although it was thought to be a rare injury, this was because the injury is difficult to diagnose. Injuries that were previously undetected are now being recognized. Still today, approximately 20% of these injuries are undiagnosed at initial presentation, particularly in the polytrauma patient (13,39). Variants of the Lisfranc injury involving the cuneiforms has increased so that now the term “Lisfranc's complex” rather than “Lisfranc's joint” is more appropriate. Lisfranc's fracture-dislocations can include the tarsometatarsal (TMT) joints, cuneiforms, cuboid, and occasionally even the navicular.

Direct trauma, is less common. In significant crush injuries, management of the soft tissues may be the most challenging aspect of treatment. Indirect trauma is more common. Generally, a longitudinal or axial load is applied to a plantarflexed foot such as in a football player being tackled, or from windsurfing and snowboarding. More severe injuries result from the high-energy forces of motor vehicle or motorcycle accidents (39).

Knowledge of the anatomy of the Lisfranc complex is important to the investigation and classification of this injury (33). The base of the second metatarsal is the “keystone” of the Lisfranc complex, being inset so that the medial and lateral cuneiform bones provide support on either side of the base of the second metatarsal, locking it in place. The other four metatarsals have relatively little bony support. It is also important to understand that the dorsal TMT ligaments and capsule are relatively weak compared to the plantar ligaments. The Lisfranc ligament itself is a strong oblique ligament from the lateral aspect of the medial cuneiform to the base of the second metatarsal (33). Anatomically and radiographically, Stein (30) described five features that are radiographic constants and are helpful in assessing this area.

- The medial border of the fourth metatarsal always forms a continuous straight line with the medial border of the cuboid on the medial oblique view.
- The intermetatarsal space between the third and fourth metatarsals is continuous with that between the lateral cuneiform and the cuboid.
- On the medial oblique view, the intermetatarsal space between the second and third metatarsals is a continuous straight line with the open space between the lateral and medial cuneiform.
- On the AP view, the medial border of the second metatarsal forms an unbroken line with the medial border of the middle cuneiform.
- On the AP view, the space between the first and second metatarsals matches that between the medial and intermediate cuneiforms.
- On a lateral view, the bases of the metatarsals should not be more dorsal than the adjacent cuneiform or cuboid (Fig. 111.6 and Fig. 111.7).

Assessment must include a good history and physical examination because this injury may be missed, particularly in someone complaining of an “ankle sprain.” A history that suggests forced plantarflexion of the foot with axial loading needs to be examined very carefully. If there is tenderness dorsally over the TMT joints and it is not clear whether this is superficial or deep, then stress the Lisfranc complex by grasping the appropriate metatarsal head and applying plantarflexion and dorsiflexion forces to the metatarsal, with the hindfoot stabilized. Pain indicates TMT joint pathology. Similarly, rotational or mediolateral forces applied to the foot produces pain in the midfoot suggests injury to the Lisfranc complex. Take AP, lateral, and medial oblique radiographic views. In addition to the key features listed earlier, other significant signs include:

- A small fracture from the base of the second metatarsal or intermediate cuneiform.
- Compression fracture of the cuboid on the AP or oblique radiograph (17).
- Any indication of overlap between the metatarsal bases and the adjacent tarsal bones, suggesting complete dislocation.

Stress views are generally painful in the acute circumstance but can be obtained under either general anesthesia or occasionally with an ankle block or local anesthetic.
directly infiltrated into the TMT joints, depending on the clinical situation. A CT scan is not usually necessary to make the diagnosis, but if there are comminuted fractures, particularly of the cuboid, it may assist in assessing the fracture pattern.

Multiple injuries in the foot are not uncommon. Lisfranc’s injuries can be associated with fractures of the shafts or necks of the metatarsals or dislocation of the MTP joints. Longitudinal forces can produce more proximal injuries, including navicular fracture. It is always important to visualize the entire foot radiographically in a patient with polytrauma with a swollen foot because an obvious fracture such as a calcaneus or ankle fracture may lead to missing a more subtle injury in the midfoot or forefoot (Fig. 111.6).

**Principles of Treatment**

The range of presentations of acute Lisfranc’s injuries is from the “midfoot sprain” to severe displaced fracture-dislocation, occasionally with overlying soft-tissue injuries. In the polytrauma patient, the more subtle forms may be missed; therefore, clinical suspicion is important. See Figure 111.2 for an assessment algorithm.

**Immediate Treatment**

When significant displacement exists, particularly when there is significant plantar or dorsal displacement of the metatarsal bases, neurovascular compromise is a possibility and urgent closed reduction should be attempted. Compartment syndrome is also possible with this injury, and fasciotomy is occasionally required. If fasciotomy is required, the incisions for the fasciotomy should be planned based on the incisions necessary for open reduction and internal fixation of the underlying injury. Other aspects of immediate treatment include assessing the rest of the foot for any associated injuries, particularly the MTP joints. If the major displacement cannot be reduced immediately, whether by direct manipulation or by application of toe traps and ankle traction, then perform immediate open reduction and internal fixation. This approach will decrease pressure on the skin and tension on the neurovascular bundle. Associated swelling is unlikely to resolve in the presence of persistent displacement.

For patients with more subtle or less severely displaced injuries who are not medically stable for immediate intervention, splinting, ice, and elevation are appropriate in the interim. Once the injury has been diagnosed and the patient otherwise stabilized, the choices for a displaced Lisfranc’s fracture-dislocation are either closed reduction and percutaneous fixation or open reduction and internal fixation.

When the patient has symptoms and signs consistent with injury to the Lisfranc complex with no demonstrable displacement or fracture on plain x-ray studies, further investigation is warranted because a purely ligamentous injury may appear to be anatomic on plain x-ray studies and yet be unstable. Stress views or examination under anesthesia, or both, may demonstrate instability. If that is not possible, then splint the foot and do not allow the patient to bear weight for a few days until the foot can be reassessed clinically and radiographically. One method of obtaining a stress view in a patient who presents late (i.e., 2 weeks or more after injury) is to perform a weight-bearing x-ray and compare it with the opposite side, particularly looking at the gap between the first and second metatarsals and the medial and intermediate cuneiforms.

**Closed Reduction and Percutaneous Fixation**

It is now widely agreed that anatomic reduction is essential in Lisfranc’s injuries, even though the results are still disappointing (3,4,9,11,13,15,16,24,25,26). In the majority of cases in which significant displacement is visible on initial radiographs or intraarticular fractures exist, closed reduction is not sufficient. Closed reduction is feasible for subtle injuries that are detected only on stress views. Commonly, this is seen as a gap between the medial ray (first metatarsal and medial cuneiform) and the second ray. Closed reduction and percutaneous, cannulated screw fixation is an option.

- Use a large bone tenaculum, such as a pelvic reduction clamp placed through two small stab wounds to compress the medial cuneiform to the base of the second metatarsal under radiograph control.

**HINTS AND TRICKS**

Use of K-wires to stabilize minimally displaced Lisfranc’s injuries has largely been superseded by percutaneous screw fixation (3) because it takes 3 months for the ligaments to heal. Smooth K-wires tend to cause problems with skin irritation or infection (4) and, therefore, generally are not suitable if they need to be left in place for longer than 6 weeks. They are frequently used for the lateral TMT joints in an effort to avoid stiffness.

Problems with cannulated screws include the fact that the guide pins are of small diameter and prone to shear off, leaving a portion in situ. Therefore, if you are using cannulated screws, it is safer to stablize the construct with a parallel K-wire of at least 1.6 mm diameter so that when the screw hole is drilled and tapped, there is no micromotion between the bones. Guide pins can still break. An alternative when fluoroscopy is available is to use the drill bit for initial fixation; having stabilized the construct with a tenaculum, check the position under fluoroscopic control, and then insert a 3.5 mm cortical screw.

These injuries are a diastasis of a joint and, therefore, provided adequate reduction has been achieved, compressive force is not necessary. A more recent option is that of bioabsorbable screws, which can be inserted in a similar fashion (Fig. 111.6).

- Position the image until it is perpendicular to the plane of the intercuneiform and intermetatarsal joint because that view is necessary to assess the reduction. Achieve an anatomic reduction. Then insert a screw from the medial cuneiform into the second metatarsal base, generally starting from plantar medial going to dorsal lateral. If the third metatarsal is also involved in the injury, then this screw can also fix the third metatarsal shaft. If the fourth and fifth metatarsal joints are not involved, then that single screw may be sufficient to stabilize the medial column. If in doubt, insert a second screw from the first metatarsal base into the second cuneiform to supplement the fixation. There are multiple options for internal fixation, depending on the pattern of injury (6,11,15).

**Open Reduction and Internal Fixation**

This is my preferred option in the majority of injuries in which significant displacement or articular fractures are evident on initial films. The majority of authors support this approach, although the choice of technique varies (3,4,9,11,13,15,16,24,25,26). Careful preoperative assessment is important in planning the surgical incisions. A C-arm fluoroscope is useful. Before prepping the foot but after induction of anesthesia reassess the stability of each column of the foot under fluoroscopy. If the fourth and fifth tarsal metatarsal joints are stable to fluoroscopy, then an incision over these joints may be avoided. Much less commonly, the injury is isolated to the lateral TMT joints, sparing a medial incision. A variety of surgical approaches have been used (3,4,9,11,15,24,25). A frequent choice is a dorsal longitudinal incision just lateral to the extensor hallucis longus, extending to the first metatarsal space. Many authors supplement this incision with a second parallel incision extending from the third web space proximalward between the lateral cuneiform and the cuboid.

My preference to expose the complete Lisfranc complex is to use any combination of the following three incisions as the fracture pattern dictates (12) (Fig. 111.9D, Fig. 111.9E).
The term “fracture of the metatarsals” covers a diverse group of injuries. The neurovascular bundle is retracted laterally to demonstrate the base of the second metatarsal and intermediate cuneiform. The bases of the fourth and fifth metatarsals are dislocated dorsally. D, E, F: Medial and dorsal surgical incisions with an extended medial exposure and provisional fixation with K-wires.

- Make the first incision medially from the navicular tuberosity centered along the midportion of the medial cuneiform to the midpoint of the first metatarsal. Dissect down to bone. Lift the neurovascular bundle and being careful not to avulse it using a 3.5 mm screw. This can be cut off to lie just under the skin. It generally is easily palpated and removed in clinic through a stab incision under local anesthetic at 3 months’ follow-up. Document the fact that the K-wire is threaded so that needle-nose pliers or heavy-duty needle holders used to unscrew it.
- Make the two or three incisions to expose the area adequately (Fig. 111.7 and 111.9). Reduce the fracture dislocations working through the multiple exposures, and obtain temporary fixation with K-wires.
- Check the alignment with radiographs or fluoroscopy before placing any permanent fixation. Often, it is not possible to reduce each portion of the injury accurately until all of the joints have been approximately aligned.
- If the MTP joints are dislocated, it may be necessary to reduce the MTP joint before the metatarsal base can be anatomically relocated (Fig. 111.7). When metatarsal neck fractures have occurred they usually do not prevent reduction of the metatarsal base, but it is possible to extend the dorsal incisions distally to expose the metatarsal bases and transfix these fractures with longitudinal K-wires.
- Once all the fractures or dislocations are adequately reduced and stabilized, insert permanent fixation. My preference is fully threaded cortical screws, preferably not cannulated. Screws can be stainless steel, titanium, or bioresorbable. When screws are not possible because of comminution, then use either smooth or threaded K-wires (Fig. 111.6 and 111.7). Smooth K-wires are often satisfactory when stabilizing fractures with minimal ligamentous injury because generally by 6 weeks, fractures consolidate sufficiently to remove the K-wire.
- The pattern of screw fixation varies depending on the injury pattern. In particular, the injury may extend proximally between the cuneiforms or into the navicular, in which case transverse screws may be necessary to stabilize these injuries. The lateral cuboid may impact on the articular surface, particularly the dorsal lateral corner. If this is 25% or less of the articular surface, it is generally possible to stabilize the fourth metatarsal cuboid to the medial half of the cuboid and insert a screw from the base of the fifth into the fourth metatarsal to stabilize the construct further. In this way, the articular surface of the cuboid can then be reduced, and occasionally bone grafted and fixed with a pin, a bridging plate, or an external fixator if the cuboid has a nutcracker-type injury that needs to be held out to length (Fig. 111.9).
- Once the entire construct is stabilized and any small loose bony fragments have been removed, close the wounds. If wounds cannot be closed owing to a compartment syndrome or massive swelling, then apply dressings and bring the patient back for a delayed closure in 3 to 5 days.

The postoperative regimen includes rest, elevation, and splinting for 7 to 10 days and then the application of a non-weight-bearing cast. At approximately 6 weeks, remove any K-wires that have been left out through the skin for either a metatarsal or shaft fractures. Provided that the patient is reliable and will remain non-weight-bearing, it is reasonable to place the patient in a removable cast to start range of movement to the ankle and subtalar joints. At 3 months, if clinical and radiographic findings show a K-wire in the middle third of the fracture and healing, the patient may commence weight bearing in a cane-walker. Schedule surgery for removal of the screws 3 to 4 weeks later. Whether removal of all of these screws is necessary under review, but certainly any screw or hardware across the fourth and fifth TMT joints must be removed. I prefer to remove any screws that cross a joint. Some authors advocate leaving the screws in the medial three columns or even performing a screwless fixation. The key screw is from the plantar medial aspect of the medial cuneiform to the base of the second metatarsal.

When the second metatarsal has a significant intra-articular fracture (e.g., the corner fracture of the medial aspect of the second metatarsal), the purpose of the screw is not to transfix that fracture but to stabilize the majority of the second metatarsal in appropriate alignment. An alternative fracture pattern, when there is a transverse fracture of the second metatarsal, leaves the base intact. Obviously, there are a wide variety of fracture patterns that can occur in the metatarsals, but these two are commonly seen.

- In the latter case, fix the screws into the base of the second metatarsal and a longitudinal K-wire can stabilize the shaft of the metatarsal to the base.
- If the articular surface is comminuted, remove any small fragments, particularly those without a blood supply. If there remain any articular fragments too small for a screw, then use a smooth or threaded K-wire for fixation.
- In some circumstances, it is possible to stabilize the second ray by placing screws on either side (i.e., the first and third rays). Occasionally, supplementary screws are needed from the medial cuneiform into the intermediate or through into the lateral cuneiform.

If the fourth and fifth TMT joints are involved, then curve the third incision to match to the steep angle of the fourth and fifth TMT joints (Fig. 111.9).

- Start distally in the fourth interspace and curve laterally and inferiorly proximalward to allow adequate exposure of the fourth and fifth TMT joints.
- For fixation across this joint, make a separate small stab wound over the base of the fifth metatarsal just distal to the flare. Again, there is a choice of K-wire or screw fixation in this area. More recently, there has been a move away from using screws across the fourth and fifth TMT joint because stiffness of these joints is more problematic. Therefore, insert a 0.062 in. (1.6 mm) threaded K-wire because it provides adequate stability with less damage to the articular surface than a 3.5 mm screw. This can be cut off to lie just under the skin. It generally is easily palpated and removed in clinic through a stab incision under local anesthetic at 3 months’ follow-up. Document the fact that the K-wire is threaded so that needle-nose pliers or heavy-duty needle holders used to unscrew it.
- Make the two or three incisions to expose the area adequately (Fig. 111.7 and 111.9). Reduce the fracture dislocations working through the multiple exposures, and obtain temporary fixation with K-wires.
- Check the alignment with radiographs or fluoroscopy before placing any permanent fixation. Often, it is not possible to reduce each portion of the injury accurately until all of the joints have been approximately aligned.
- If the MTP joints are dislocated, it may be necessary to reduce the MTP joint before the metatarsal base can be anatomically relocated (Fig. 111.7). When metatarsal neck fractures have occurred they usually do not prevent reduction of the metatarsal base, but it is possible to extend the dorsal incisions distally to expose the metatarsal bases and transfix these fractures with longitudinal K-wires.
- Once all the fractures or dislocations are adequately reduced and stabilized, insert permanent fixation. My preference is fully threaded cortical screws, preferably not cannulated. Screws can be stainless steel, titanium, or bioresorbable. When screws are not possible because of comminution, then use either smooth or threaded K-wires (Fig. 111.6 and 111.7). Smooth K-wires are often satisfactory when stabilizing fractures with minimal ligamentous injury because generally by 6 weeks, fractures consolidate sufficiently to remove the K-wire.
- The pattern of screw fixation varies depending on the injury pattern. In particular, the injury may extend proximally between the cuneiforms or into the navicular, in which case transverse screws may be necessary to stabilize these injuries. The lateral cuboid may impact on the articular surface, particularly the dorsal lateral corner. If this is 25% or less of the articular surface, it is generally possible to stabilize the fourth metatarsal cuboid to the medial half of the cuboid and insert a screw from the base of the fifth into the fourth metatarsal to stabilize the construct further. In this way, the articular surface of the cuboid can then be reduced, and occasionally bone grafted and fixed with a pin, a bridging plate, or an external fixator if the cuboid has a nutcracker-type injury that needs to be held out to length (Fig. 111.9).
- Once the entire construct is stabilized and any small loose bony fragments have been removed, close the wounds. If wounds cannot be closed owing to a compartment syndrome or massive swelling, then apply dressings and bring the patient back for a delayed closure in 3 to 5 days.

The postoperative regimen includes rest, elevation, and splinting for 7 to 10 days and then the application of a non-weight-bearing cast. At approximately 6 weeks, remove any K-wires that have been left out through the skin for either a metatarsal or shaft fractures. Provided that the patient is reliable and will remain non-weight-bearing, it is reasonable to place the patient in a removable cast to start range of movement to the ankle and subtalar joints. At 3 months, if clinical and radiographic findings show a K-wire in the middle third of the fracture and healing, the patient may commence weight bearing in a cane-walker. Schedule surgery for removal of the screws 3 to 4 weeks later. Whether removal of all of these screws is necessary under review, but certainly any screw or hardware across the fourth and fifth TMT joints must be removed. I prefer to remove any screws that cross a joint. Some authors advocate leaving the screws in the medial three columns or even performing a primary arthrodesis (11.14.15.32). The use of bioresorbable implants eliminates the need for a secondary procedure.

**Late Reconstruction** If the injury is less than 6 weeks old and has significant displacement, then perform an open reduction and internal fixation as in an acute fracture. If the injury is between 6 weeks to 6 months old, base your decision of which procedure to perform on the patient's age and general health, the severity of disability, activity level, and whether it is purely a soft-tissue or bony injury. In some cases, repairs for an acute injury may be successful. After 6 months, acute repair is unlikely to be successful, and the choices are nonoperative treatment or reduction and arthrodesis (11.12.15.32). Realignment and arthrodesis may lead to development of degenerative changes in adjacent joints (12). The presence of diabetes and, particularly, diabetic neuropathy makes success of any surgery less likely. Advise the patient that late treatment of a Lisfranc injury likely will result in long-term problems with persistent pain and possible progression of deformity.

**METATARSAL FRACTURES**

The term “fracture of the metatarsals” covers a diverse group of injuries (7.9.15.19.34.38.41). The fifth metatarsal in particular is subject to a variety of injuries, including:

- Fractures of the tuberosity, often associated with inversion ankle injuries
- Jones' fracture, which is a transverse fracture of the diaphysealmetaphyseal junction
- Spiral fractures of the shaft associated with rotational foot injuries
• Oblique or transverse fractures of the metatarsal neck

Management of the metatarsal must be appropriate to the site of the fracture in the metatarsal, especially whether the metatarsal is one of the middle metatarsals, which behave differently than the first and fifth. Similarly, multiple metatarsal fractures are treated differently than an isolated metatarsal fracture. Apart from Jones’ fracture, there has not been much scientific study of metatarsal fractures, and authors have varied significantly in recommendations about management. A variety of opinions exist on the indications for reduction and internal fixation of these fractures (9,15,34,38).

First Metatarsal Fractures

The first metatarsal is less commonly fractured, but it does require special consideration. Any shortening of the first metatarsal or plantar or dorsal displacement of the metatarsal head will have an adverse effect on foot function as a whole. In addition, any articular fracture causing loss of movement in the first MTP joint will interfere with the normal progression of gait. Therefore, any displaced fracture of the first metatarsal that allows shortening or angular displacement or impacts the MTP joint requires reduction, either closed or open, and fixation. The choice between closed reduction and K-wire or external fixation versus open reduction and internal fixation depends on the site and comminution of the fracture and possibly related soft-tissue injuries.

Fifth Metatarsal Fractures

Fractures of the fifth metatarsal are common (23% of metatarsal injuries), particularly those associated with inversion injuries. Jones’ fracture, although less common, is of clinical and academic interest because of its poor prognosis. The fifth metatarsal is the most mobile of the five, so a small amount of shortening or angular deformity may be less problematic because the fifth metatarsal itself is more adaptable.

Two common fracture patterns that usually do not require surgery are the fracture of the tuberosity of the fifth metatarsal, which is commonly an avulsion fracture, and the spiral fracture of the fifth metatarsal shaft. Nonoperative treatment of metatarsal fractures, include using a stiff-soled shoe, strapping, or a short-leg non-weight-bearing cast for 4 to 6 weeks.

I prefer to treat fractures of the styloid of the fifth metatarsal like an ankle sprain. Spiral fractures of the fifth metatarsal shaft produce significant pain and swelling, and benefit by a few days of rest, elevation, splinting, and crutches. Once the acute pain and swelling have subsided in both of these injuries, a removable cast device, preferably with some means to control swelling, will enable the patient to walk relatively pain free. A hard-sole shoe does not give sufficient support for the ankle and is moderately uncomfortable for walking.

Jones’ fracture and stress fractures of the fifth metatarsal are discussed in Chapter 96. In brief, such fractures of the fifth metatarsal have a propensity for nonunion. For low-demand patients, if seen immediately after the injury, treat non-weight bearing for 6 weeks in a short-leg cast. Immobilization may be needed for 3 months or more with still no guarantee that the fracture will unite. For those patients with an established nonunion or those who are considered high demand, particularly athletes, it is recommended to perform intramedullary fixation of the fifth metatarsal shaft (9,15,34,38). In the acute instance, internal fixation alone may be sufficient. In established nonunions, opening the fracture site, debridement of the sclerotic bone, and bone grafting combined with internal fixation are warranted.

Second, Third, and Fourth Metatarsal Fractures

If a single metatarsal fracture occurs, it is usually of lower violence, and if the transverse metatarsal ligament is intact, most often there is minimal displacement and closed management is indicated. However, this is one area where authors differ widely. Shereff (34) believes that any displacement of more than 3 to 4 mm or more than 10° of angulation requires open reduction and internal fixation.

In cases of multiple metatarsal fractures, a higher level of energy has been dissipated in the foot. More than likely, the ligaments are disrupted and significant shortening or displacement will occur. These metatarsal fractures are often associated with other injuries in the foot and, as previously noted, the amount of morbidity associated with the metatarsal fractures has been underestimated. Dorsal displacement of the metatarsal head or shortening produces transfer metatarsalgia, which can lead to significant disability (Fig. 111.10). It is less clear cut whether medial or lateral displacement will cause interference with the adjacent metatarsal or interdigital nerve (34), although anatomically it is certainly feasible. If palpation of the forefoot demonstrates enough displacement of the affected metatarsal head to alter the mechanics of weight bearing, then reduction and fixation are indicated. Closed reduction of a metatarsal without some form of fixation is unlikely to be stable (15,34).

Figure 111.10. Patient with persistent metatarsalgia after a “neuroma” was excised. AP (A), oblique (B), and sesamoid (C) views show healed metatarsal fractures. The fifth metatarsal is asymptomatic; pain is due to the overload of the third metatarsal from the dorsally angulated second metatarsal.

Open Reduction and K-Wire Fixation

Metatarsal shaft fractures often require open reduction and internal fixation. Fractures of the first metatarsal may require fixation with screws or a plate and screws. Metatarsal neck fractures, particularly of the middle metatarsals, usually can be reduced and fixed with K-wires.

Closed reduction and pinning of multiple metatarsal fractures rarely results in anatomical position therefore I favor open reduction.

- Expose a fracture of the metatarsal neck through a 2 to 3 cm longitudinal dorsal incision. For multiple neck fractures, a somewhat larger incision over the first and third or second and fourth web spaces, depending on which metatarsals are fractured, provides adequate exposure. Identify and protect the extensor tendons and neurovascular structures.
- Expose the fracture and insert a 1.6 mm or 2 mm K-wire into the medullary canal of the distal fragment and exit on the plantar aspect of the foot. Keep the toe dorsiflexed to avoid penetration of the proximal phalanx.
- Then attach the drill to the exposed K-wire outside of the foot, reduce the fracture anatomically, and drill the wire retrograde into the medullary canal of the 2nd or 3rd metatarsal, securing the fracture. Verify the position and orientation of the wires and fix.
- Cut the K-wire to leave 1 to 1.5 cm exposed and apply pin caps or bend the end of the wire to prevent migration.

Postoperatively, do not allow patients to bear weight in a splint. K-wires can be removed at 4 to 6 weeks, and weight bearing is then permitted. Sometimes, a cam-walker is useful for a couple of weeks.

Open fractures can be stabilized in a similar manner. Rarely is external fixation appropriate for the metatarsal (28).

METATARSOPHALANGEAL JOINT DISLOCATIONS

First Metatarsophalangeal Joint and Sesamoid Injuries
First MTP dislocation is generally associated with hyperextension and is an extreme example of the "turf toe" type injury. It can also occur with severe direct trauma, such as in motor-vehicle accidents. Jahss (19) classifies the injury as type I or II, depending on whether the intersesamoid ligaments are intact or whether one of the sesamoids has a transverse fracture. In the type I dislocation, the ligament and sesamoid are intact, and if the lesion is irreducible by closed means, it will require an open reduction and sometimes K-wire fixation. In the type II injury, there is either disruption of the intersesamoid ligament or a transverse fracture of one of the sesamoids. Closed reduction is usually successful, but when the sesamoid is fractured, the distal fragment usually requires excision. These are uncommon injuries. These can be approached dorsally, medially, or through a plantar incision. My preference is a direct medial approach, which allows access to both the dorsal and plantar aspects of the joint which avoids the neurovascular structures and a plantar scar (18). Be sure to preserve the continuity of the flexor hallucis brevis tendon if partial or complete excision of the sesamoid is indicated.

**Lesser Metatarsophalangeal Dislocations**

Lesser MTP dislocations are easily missed, particularly in children. The most common mechanism is a hyperextension injury. The toe usually sits in a hyperextended position at the MTP joint with some associated clawing, the metatarsal head having button holed through the plantar plate. Closed reduction is often possible, but direct traction on the toe may further trap the metatarsal head and be ineffective. If closed reduction is ineffective, perform open reduction through a dorsal incision adjacent to the extensor tendon. These dislocations are usually stable after reduction. Chronic dislocations generally require open reduction and K-wire fixation through a dorsal approach. Sometimes, a metatarsal condylectomy is necessary to achieve reduction.

**SESAMOID FRACTURES**

The medial sesamoid is more commonly injured or symptomatic. Although acute fractures of the sesamoids may occur with either direct trauma or hyperextension, it is also possible to have stress fractures of the sesamoids, symptomatic bipartite sesamoids, and also avascular necrosis of the sesamoids (7, 9, 15, 19, 41). Clinical and radiographic differentiation of these conditions may not be clear cut. A bone scan is not likely to differentiate between a stress fracture, an acute fracture, avascular necrosis, or even sesamoiditis. A bipartite sesamoid generally does not appear hot on a bone scan.

When acute injury is recognized, initial treatment includes no weight bearing and immobilization of the MTP joint for at least 4 to 6 weeks. This is followed by a further period of at least 4 to 6 weeks with protected weight bearing by relief padding or a removable cast-brace for a total of 3 months immobilization. Lack of healing is generally treated by sesamoidectomy. Occasionally, if one fragment is small, excision of a single pole is possible. The application of a bone graft to an undisplaced fracture site may encourage union.

**PHALANGEAL FRACTURES AND INTERPHALANGEAL JOINT DISLOCATIONS**

Except for an intraarticular fracture of the proximal phalanx of the great toe, generally treat phalangeal fractures by strapping to the adjacent toe and using a stiff-soled shoe until pain and swelling settle. Similarly, generally treat dislocations of the interphalangeal joint, when closed, by closed reduction, strapping to an adjacent stable toe, and stiff-soled shoes (Fig. 111.11).

![Figure 111.11](image)

Residual displacement after closed reduction of interphalangeal dislocation of the great toe. The patient declined further surgery.

Because of the importance of the great toe to foot function, and the size of the bones that makes them more suitable for internal fixation, displaced intra-articular fractures are generally treated with open reduction and internal fixation with mini-screws. Treat shaft fractures of the proximal phalanx with a longitudinal K-wire, screws, or a miniplate if closed reduction and a splint or cast does not give adequate alignment and stability.

For noncontaminated open phalangeal fractures, debride and irrigate the wound, stabilize the fracture with an intramedullary K-wire running lengthwise down the toe to maintain length and medial and lateral stability, and give antibiotics. Interphalangeal joint dislocations are often open on the plantar aspect and, once they are reduced, are usually stable.

In lawnmower and similar high-energy injuries, the viability of the toe must be assessed in terms of neurovascular damage and the degloving component of the injury. Salvage of the toe risks infection, and poor function must be compared with the effects of loss of the toe through amputation on foot function.

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

PATHOPHYSIOLOGY

The hallux valgus deformity is characterized by lateral deviation of the proximal phalanx on the metatarsal head. In the majority of patients, the deformity is due to improper shoe wear. It occurs almost 10 times more frequently in women than in men.

As a result of this lateral subluxation of the proximal phalanx on the metatarsal head, several secondary changes occur:

- Contracture of the lateral joint capsule
- Attenuation of the medial joint capsule
- A medial eminence of varying size
- Pronation of the hallux as the deformity becomes more severe
- Medial deviation of the first metatarsal, giving rise to an increase in the intermetatarsal angle. This leads to an uncovering of the sesamoids, which are anchored in their lateralward position by the adductor hallucis.

As the hallux valgus deformity becomes more severe, the impingement of the hallux against the second toe can lead to destabilization of the second metatarsophalangeal joint, resulting in an overlapping of the hallux by the second toe. Occasionally, underlapping may occur.

As the deformity increases, the weight bearing of the hallux and first metatarsal is diminished, resulting in increased weight bearing by the second metatarsal head, which results in metatarsalgia, sometimes associated with a callus. The decreased weight bearing is due to the lack of plantar flexion of the first metatarsal in the last half of stance phase due to the decreased function of the windlass mechanism of the plantar fascia.

In 3% to 4% of cases, there is instability of the first metatarsocuneiform joint, resulting in hypermobility. When this condition is present, a first metatarsocuneiform joint fusion should be carried out in conjunction with the hallux valgus repair.

PRINCIPLES OF TREATMENT

HISTORY

It is important to obtain the patient's chief complaint with regard to the hallux valgus deformity. As a general rule, the chief complaint is pain over the medial eminence, although sometimes, despite a severe deformity, the patient's main complaint is a second toe deformity and associated symptoms.

Important aspects of the history involve degree of disability, lifestyle, and management of the disability. The history should answer questions such as the following:

- Is the primary problem that the patient cannot wear certain dress shoes or even a wide soft shoe?
- At work, how much time does the patient spend standing each day?
- Does the patient participate in athletics?
- Has the patient tried conservative care such as changing shoes or using a bunion splint?

Do not consider surgery unless the patient is significantly disabled from work or athletics.

PHYSICAL EXAMINATION

- Begin with the patient standing.
- Observe the alignment of the foot and lower extremity. Note the deformity of the great toe and lesser toes.
- Seat the patient and measure the range of motion of the ankle, subtalar, and transverse tarsal joints with particular attention to the first metatarsophalangeal joint.
- Note any pain about the metatarsophalangeal joint, synovial thickening, or crepitation. If pain is persistent, it is important to localize this pain to the dorsal or plantar aspect of the joint because a sesamoid problem may be present.
- Carefully assess the neurovascular status of the foot. If there is any question about the vascularity, obtain an arterial Doppler study.

RADIOGRAPHIC EVALUATION

- Always obtain anteroposterior (AP) and lateral radiographs of the foot weight bearing.
- Measure the first metatarsophalangeal joint angle, which should be less than 15°. The intermetatarsal angle should be less than 8°.
- Note the position of the sesamoids and the size of the medial eminence (Fig. 112.1).
Look for arthrosis in the first metatarsophalangeal joint and assess whether the joint is congruent or incongruent. A congruent joint is one with no lateral deviation of the proximal phalanx on the metatarsal head. An incongruent joint is one with lateral deviation of the proximal phalanx on the metatarsal head (Fig. 112.2).

Figure 112.2. A: A congruent metatarsophalangeal joint is one in which there is no lateral subluxation of the proximal phalanx on the metatarsal head. B: An incongruent metatarsophalangeal joint is one in which there is lateral subluxation of the proximal phalanx on the metatarsal head.

Measure the distal metatarsal articular angle (DMAA), which is the relationship of the articular surface to the long axis of the metatarsal. Normally, this should be less than 10° of lateral deviation (Fig. 112.3).

Figure 112.3. Radiograph demonstrating the distal metatarsal articular angle, which measures the relationship between the articular surface of the metatarsal and the long axis of the first metatarsal. Normal should be less than 10° of lateral deviation.

CONSERVATIVE MANAGEMENT

- Explain the nature of the problem to the patient. Try to talk the patient into using broad, soft-soled shoes, preferably with a low heel, that provide adequate room for the great toe and the medial eminence. Many patients can be made comfortable with just a change of shoe style. Some women, particularly young women, enjoy wearing stylish shoes and have difficulty with this type of conservative management; not infrequently, they will request surgery.
- Advise the patient that, after bunion surgery (in our experience), only two thirds of patients can wear shoes in an unrestricted manner, leaving a third requiring restricted shoe wear. People in this latter group typically have broad, wide feet, so that even after corrective surgery, even though they now have straight metatarsophalangeal joints, their feet still cannot fit into small, narrow, pointed-toe shoes.

DECISION MAKING

One of the most important factors in the outcome of bunion surgery is the correct selection of the operative procedure. Not all bunion deformities are alike. Therefore, a single operative procedure will not result in a satisfactory outcome for all types of deformities.

The first consideration is whether the deformity is in a congruent or an incongruent joint. This is important because if the joint is congruent, the proximal phalanx cannot be rotated on the metatarsal head to correct the deformity; if the deformity is incongruent, however, the proximal phalanx can be rotated on the metatarsal head to correct the deformity. The algorithm in Table 112.1 can help in the decision-making process.

Table 112.1. Algorithm for Treating Hallux Valgus

In a congruent joint, use a chevron procedure to correct the deformity.
If the DMAA is increased, use a medial closing wedge with a chevron osteotomy, rotating the metatarsal head medially and thereby correcting the DMAA (14).

Other procedures include a distal soft-tissue procedure or an Akin procedure (osteotomy of the proximal phalanx) along with excision of the medial eminence.

If the hallux valgus deformity is associated with an incongruent joint, the operative procedure depends on the severity of the deformity. The numbers presented in Table 112.1 should be used as suggested values: They are not etched in stone.

- If the hallux valgus is mild with a hallux valgus angle of less than 30°, and the intermetatarsal angle is less than 13°, use a chevron osteotomy or distal soft tissue procedure to correct the deformity.
- If the deformity is moderate with a hallux valgus of 40° or less, and the intermetatarsal angle is 20° or less, use a distal soft-tissue procedure and a proximal metatarsal osteotomy to correct the deformity. Note that a chevron osteotomy cannot correct a deformity of this magnitude.
- If the deformity is severe with a hallux valgus angle of more than 40° and the intermetatarsal is greater than 20°, use a distal soft-tissue procedure with proximal osteotomy if there is minimal arthrosis. If arthrosis is present or the deformity is too severe, then consider an arthrodesis.
- If there is significant arthrosis of the metatarsophalangeal joint, an arthrodesis is probably the procedure of choice. Place the hallux at about 15° of valgus and 10° to 15° of dorsiflexion in relation to the ground.

**SURGICAL TECHNIQUES**

**AKIN PROCEDURE**

An Akin procedure is a medial closing-wedge osteotomy of the proximal phalanx (1) (Fig. 112.4). It can be utilized as an isolated procedure or in conjunction with excision of the medial eminence. Do not perform this procedure if the metatarsophalangeal joint is incongruent. It is a useful salvage procedure for a mild recurrent hallux valgus deformity with a stable metatarsophalangeal joint. It is the procedure of choice to correct a hallux valgus interphalangeus.

![Akin procedure](image)

**Figure 112.4.** The Akin procedure. A: Location of the osteotomy in the base of the proximal phalanx. Be sure the base of the osteotomy is distal to the concavity of the articular surface. B: Closure of the osteotomy site and plication of the medial capsule.

- Perform the Akin procedure through a medial incision starting along the medial aspect of the proximal phalanx and carried proximally to the metatarsal head. Create dorsal and plantar full-thickness skin flaps, exposing two thirds of the proximal phalanx and the medial eminence.
- Approach the metatarsophalangeal joint through a vertical capsulotomy and excise approximately 2–3 mm of capsule.
- Make a dorsomedial capsular incision to expose the medial eminence by hinging the capsule plantar medially.
- Expose the medial eminence by sharp dissection and excise it with a sharp thin osteotome. Begin at the sagittal sulcus in line with the medial aspect of the metatarsal shaft. Take care not to cut into the shaft.
- Close the capsule, pulling the toe into correct alignment. Avoid a varus position.

A valgus deformity is corrected by the Akin procedure in the proximal phalanx.

- Make the osteotomy of the proximal phalanx about 4–5 mm distal to the proximal articular surface. Keep in mind that the articular surface of the proximal phalanx is concave. Be certain that the osteotomy is distal to this concavity.
- Remove a wedge of proximal phalanx measuring 2–4 mm in thickness, depending on the deformity. Once the toe is straight, fix the osteotomy with crossed Kirschner (K-) wires or heavy suture material placed through drill holes in the proximal phalanx.

**Postoperative Care**

The postoperative management is important. Keep the foot in a dressing for 8 weeks, holding the hallux in a slight varus position. Use 2-inch Kling and half-inch adhesive tape to firmly hold the hallux in correct alignment. This permits the patient to ambulate more comfortably in a postoperative wooden shoe (Fig. 112.5).

![Radiograph after an Akin procedure](image)

**Figure 112.5.** Radiograph after an Akin procedure. The osteotomy site is often visible for many months, but it is clinically healed in 6–8 weeks.

**Complications**

The main complication following an Akin procedure is subluxation of the metatarsophalangeal joint. If the joint is subluxed preoperatively, as a rule it will tend to sublux even further following the procedure (18). Therefore, subluxation is the main contraindication to an Akin procedure. Only rarely does a nonunion occur in the proximal phalanx.

**CHEVRON PROCEDURE**

Utilize the chevron procedure for mild to low-moderate hallux valgus deformity (2). If it is used for a deformity that is too severe, complete correction is not possible and a recurrence may develop.

- Make a medial midline incision starting at the medial side of the midportion of the proximal phalanx extending 1 cm proximally to the medial eminence.
- Develop full-thickness dorsal and plantar skin flaps. Retract the digital nerves out of the way.
A procedure that is technically challenging and needs to be meticulously carried out to achieve the best clinical results. The distal soft-tissue procedure with and without a proximal crescentic metatarsal osteotomy is indicated for a wide range of deformity from mild to severe. It is a procedure that is technically challenging and needs to be meticulously carried out to achieve the best clinical results.

Possible complications include arthrofibrosis, which is a stiffening of the metatarsophalangeal joint, and varus deformity, usually due to overcorrection of the medial joint capsule or inadvertent tilting of the metatarsal head into lateral deviation. This is possibly due to loss of fixation of the osteotomy site or a recurrence of the deformity because the preoperative deformity was too severe.

HINTS AND TRICKS

When there is an increased DMAA, the correction produced by the chevron procedure may be inadequate. To correct, remove more bone from the proximal limb of the chevron cut. Remove 2–3 mm of bone, which includes the width of the saw blade, from the medial aspect of the metatarsal, allowing the head to be angulated in a medialward direction, thereby correcting the abnormal DMAA. Some authors believe that release of the lateral joint capsule can be carried out with a chevron osteotomy, and the literature seems to support this. If a capsule release is carried out, it should be at the level of the joint and distally to avoid the blood supply coming into the metatarsal head through the joint capsule.

Avascular necrosis of the metatarsal head is an unusual complication but certainly can be disastrous. The incidence is low, probably 1% or 2%. Exactly why this occurs in some cases is unknown. It may be due to excessive stripping of the lateral joint capsule, thereby disrupting the blood supply to the metatarsal head. If there is complete avascular necrosis of the head associated with significant collapse, severe disability results. Minor radiographic changes are usually not of any clinical significance. If a patient develops avascular necrosis, treat it conservatively for as long as possible until a painful joint requires arthrodesis. Treat arthrofibrosis of the metatarsophalangeal joint with vigorous physical therapy.

Probably the most common complication is incomplete correction of the hallux valgus deformity. This results from treating too severe a hallux valgus deformity, or from failure to recognize an increased DMAA, so that it was not corrected at the time the chevron osteotomy was done.

DISTAL SOFT-TISSUE PROCEDURE

The distal soft-tissue procedure with and without a proximal crescentic metatarsal osteotomy is indicated for a wide range of deformity from mild to severe. It is a procedure that is technically challenging and needs to be meticulously carried out to achieve the best clinical results.
Figure 112.8. Distal soft-tissue procedure. A: The adductor tendon inserts into the lateral aspect of the fibular sesamoid and into the base of the proximal phalanx. B: The adductor tendon is released from its insertion into the lateral side of the fibular sesamoid and base of the proximal phalanx. C: The transverse metatarsal ligament passes from the second metatarsal into the fibular sesamoid. D: The transverse metatarsal ligament is transected. E: The three contracted structures on the lateral side of the metatarsophalangeal joint are released. F: The medial capsular incision begins 2–3 mm proximal to the base of the proximal phalanx, and a piece of tissue 3–8 mm is removed. A dorsal medial incision is then made to create a plantar proximally based flap. G: The medial eminence is removed in line with the medial aspect of the first metatarsal shaft. (From Mann RA, Coughlin MJ. Video Textbook of Foot and Ankle Surgery. St. Louis, MO: Medical Video Productions, 1991.)

- Make the initial incision on the dorsal aspect of the first web space in the midline, avoiding the superficial branches of the deep peroneal nerve.
- Section the transverse metatarsal ligament, which inserts into the lateral aspect of the fibular sesamoid (Fig. 112.8C, Fig. 112.8D, Fig. 112.8E).
- Center the second incision over the medial aspect of the first metatarsophalangeal joint. Carry it down to the joint capsule and create a full-thickness dorsal and plantar flap. Take care to avoid the dorsomedial and plantar medial cutaneous nerves (Fig. 112.8F).
- Remove a wedge of capsule from the medial aspect of the metatarsophalangeal joint. Begin the initial capsular incision about 2–3 mm proximal to the base of the proximal phalanx. Make the second portion of the incision more proximal, between 4 and 8 mm, depending on the degree of the deformity that needs to be corrected. Dorsally, this incision ends about 1 cm medial to the extensor hallucis longus tendon and plantarly the passes through the abductor hallucis tendon, ending at the medial aspect of the tibial sesamoid.
- Expose the medial eminence either by carefully dissecting the medial joint capsule off the medial eminence or by making an incision along the dorsomedial aspect of the joint capsule to create a flap to expose the medial eminence.
- Remove the medial eminence about 1 mm medial to the sagittal sulcus and in line with the medial aspect of the metatarsal shaft (Fig. 112.8G). Smooth the edges with a rongeur.

At this point, decide if the metatarsus primus varus can be corrected without a proximal metatarsal osteotomy. This is determined by pressing on the first metatarsal to see if it can be reduced to the second metatarsal. If this occurs without the first metatarsal springing medially again, then no osteotomy is necessary. If, however, there is a tendency for the two metatarsals to spring apart, then an osteotomy at the base of the metatarsal is required. We use an osteotomy in 80% to 90% of cases (Fig. 112.9) (7).

Figure 112.9. To determine whether an osteotomy is necessary after the distal soft-tissue release has been done, push the first metatarsal head laterally. If there is any tendency for the metatarsal head to spring open, consider an osteotomy. We perform an osteotomy about 90% of the time.

- Expose the osteotomy site at the base of the metatarsal through a dorsal incision distal to the first metatarsocuneiform joint (Fig. 112.10). Do the osteotomy about 1 cm distal to the metatarsocuneiform joint. We prefer to use a crescentic osteotomy with the concavity directed proximally. The osteotomy is produced perpendicular to neither the metatarsal shaft nor the bottom of the foot, but halfway between. Cut the osteotomy with a crescentic blade by using an oscillating handpiece.

Figure 112.10. The Freer elevator is pointing at the metatarsocuneiform joint. The osteotomy site (O) is about 1 cm distal. If a screw will be used for fixation of the osteotomy site, it is placed about 1 cm distal to the osteotomy site (S).

- Next, correct the hallux valgus by placing three sutures in the first web space between the first and second metatarsals, incorporating the adductor tendon. Pass the suture through the medial aspect of the capsule of the second metatarsophalangeal joint, through the adductor tendon, and then through the dorsal capsule on the lateral aspect of the first metatarsal. Tie these sutures after the proximal osteotomy has been fixed.
- Correct the increased intermetatarsal angle by freeing all the soft tissues around the osteotomy site, so the osteotomy can be easily moved. Place a Freer elevator on the proximal portion of the metatarsal and displace it medially as the metatarsal shaft is rotated laterally. Displacement of only 2–3 mm allows rotation of the metatarsal shaft at the osteotomy site, correcting the metatarsus primus varus (Fig. 112.11). We prefer to stabilize the osteotomy site with a 4.0 mm, cannulated AO screw, although an oblique 5/64-inch Steinmann pin or multiple smaller K-wires may be used.

Figure 112.11. The osteotomy site is reduced by completely freeing the soft tissue about the osteotomy, then pushing the proximal fragment medially with a small
The Keller procedure does play a limited role in management of foot problems, however. When utilized in the less active individual, it can bring about adequate transfer to the second metatarsal head, often resulting in a transfer lesion. The great toe itself may drift into dorsiflexion, varus or valgus, because of its lack of mechanism of the first metatarsophalangeal joint, which brings about plantar flexion of the first metatarsal during the last half of stance phase, is disrupted, weight is the stability of the first metatarsophalangeal joint is lost and, as a result, a transfer lesion beneath the second metatarsal head often occurs. Since the windlass apparatus provides the first metatarsophalangeal joint with a strong plantar flexion force, which is important for maintaining the alignment of the hallux, the Keller procedure is often used to correct hallux valgus deformities. The outcome of this procedure is usually quite satisfactory, although the patient does lose some motion at the metatarsophalangeal joint. If the alignment of the joint is than 15° to 20° is present, usually an arthrodesis of the interphalangeal joint is added to the procedure.

Complications

The main complication was hallux varus, which occurred in 14 cases and averaged 5.4°. Nine were less than 6°, which was of no clinical significance, and five were greater than 6°. Of these, two patients were dissatisfied with the result (7,16). Bear in mind that when a severe deformity is corrected, some loss of motion of the metatarsophalangeal joint may occur. If slight undercorrection of the hallux valgus occurs, and this is bothersome to the patient, an Akin procedure can be utilized in the future to complete the correction of the deformity. If overcorrection occurs and a hallux valgus deformity results, this may be corrected by an extensor tendon transfer, as described by Johnson and Spiegel (12) and modified by Mann (13).

Hallux Varus Repair

The type of procedure chosen to repair a hallux varus deformity depends on several factors. If there is symptomatic arthrosis of the metatarsophalangeal joint, an arthrodesis is the procedure of choice. If there is no arthrosis present, then one might consider a soft-tissue reconstruction utilizing a split extensor hallucis longus repair. The principle of the repair is that all soft-tissue contracture along the medial aspect of the joint, which would include the joint capsule, abductor hallucis tendon, and the displaced tibial sesamoid, if present, needs to be sufficiently released to permit the proximal phalanx to be rotated laterally on the metatarsal head. The proximal phalanx is then stabilized in its normal position by transferring a portion of or the entire extensor hallucis longus tendon beneath the transverse metatarsal ligament and suturing it into the base of the proximal phalanx through a transverse drill hole. If an interphalangeal joint contracture of more than 15° to 20° is present, usually an arthrodesis of the interphalangeal joint is added to the procedure.

The outcome of this procedure is usually quite satisfactory, although the patient does lose some motion at the metatarsophalangeal joint. If the alignment of the joint is satisfactory, however, the clinical problem of the hallux varus deformity is usually solved.

Keller Procedure

The Keller procedure (20), once the most popular procedure for repair of hallux valgus deformity, is now used only in the patient who has limited ambulatory capacity, or possibly as an alternative to an arthrodesis in the more sedentary patient. The problem with the Keller procedure is that, in an active individual, the stability of the first metatarsophalangeal joint is lost and, as a result, a transfer lesion beneath the second metatarsal head often occurs. (Since the windlass mechanism of the first metatarsophalangeal joint, which brings about plantar flexion of the first metatarsal during the last half of stance phase, is disrupted, weight is transferred to the second metatarsal head; often resulting in a transfer lesion.) The great toe itself may drift into dorsiflexion, varus or valgus, because of its lack of ability to stabilize itself due to the excision of the proximal portion of the proximal phalanx.

The Keller procedure does play a limited role in management of foot problems, however. When utilized in the less active individual, it can bring about adequate...
decompression of the metatarsophalangeal joint and relieve pressure on the skin on the medial side of the first metatarsal.

The Keller procedure is carried out through a medial approach, exposing the medial joint capsule. This is dissected off the metatarsal head, creating a distally based flap. The medial eminence is removed, and the proximal 20% of the proximal phalanx is removed. The metatarsophalangeal joint is then usually adequately decompressed, but, if the joint still remains somewhat tight, excise a little bit more of the proximal phalanx. If the deformity is severe, the adductor hallucis insertion into the lateral sesamoid sling is released. Try to reattach the sesamoid mechanism to the base of the proximal phalanx through small drill holes; if this is not possible, however, at least suture the sesamoid mechanism into the flexor hallucis longus tendon to help prevent dorsiflexion at the metatarsophalangeal joint. A longitudinal pin is then placed retrograde through the tip of the toe and back into the metatarsal head, after which the medial capsule is sutured closed. The pin is left in place for 3 weeks and the toe is kept dressed for approximately 6 weeks. During the postoperative period, the patient is permitted to ambulate in a postoperative shoe.

ARTHRODESIS OF THE FIRST METATARSOPHALANGEAL JOINT

Arthrodesis of the first metatarsophalangeal joint is performed for arthrosis of the joint or a failed hallux valgus repair. It is carried out routinely in the rheumatoid foot.

- Make an incision over the dorsal aspect of the first metatarsophalangeal joint. Dissect through subcutaneous fat to expose the extensor hallucis longus tendon.
- Retract the tendon medially or laterally to expose the underlying joint.
- Open the joint capsule and remove the osteophytes and the surrounding synovial tissue if present.
- Remove the distal portion of the metatarsal head and the base of the proximal phalanx with a sagittal saw, keeping the bone resection to a minimum. Make the bony cuts to produce 10° to 15° of valgus and about 30° of dorsiflexion in relation to the first metatarsal shaft, or 10° to 15° of dorsiflexion in relation to the plantar aspect of the foot (Fig. 112.14). If a medial eminence is present, remove it.

Figure 112.14. Arthrodesis of a metatarsophalangeal joint. A: Shaded area represents amount of bone surface usually removed when arthrodesis is carried out. B: Lateral view of metatarsophalangeal joint demonstrating that the arthrodesis site should be placed in about 30° of dorsiflexion in relation to the metatarsal shaft. C: Anteroposterior view of metatarsophalangeal joint demonstrating that there should be about 15° of valgus at the arthrodesis site.

- I prefer to stabilize the fusion site with an interfragmentary compression screw, and a five- or six-hole quarter-tubular small fragment plate with 4.0-mm screws. After the bone cuts are made, stabilize the arthrodesis in proper alignment with 0.045-inch K-wires. Place the interfragmentary screw from the medial flare of the proximal phalanx obliquely into the metatarsal head. Usually a six-hole plate can be applied to the dorsal surface if adequate exposure is obtained; if not, use a five-hole plate. Although the plate is placed on the compression side of the fusion site, it is usually sufficient to neutralize the forces and permit fusion to occur. Secure the plate with 4.0 mm cancellous or cortical screws, depending on the quality of the bone (Fig. 112.15).

Figure 112.15. AP (A) and lateral (B) radiographs demonstrating an arthrodesis of the first metatarsophalangeal joint in a patient with rheumatoid arthritis. The fusion site should be placed in approximately 15° of valgus, and at 10° to 15° of dorsiflexion in relation to the ground.

Postoperative Care

Apply a compression dressing and ambulate in a postoperative shoe with weight bearing as tolerated. Remove the sutures in 10–14 days. Use the postoperative shoe until fusion occurs, which usually is by 10–12 weeks. The plate needs to be removed in only about 10% of patients.

Complications

Most patients have few or no complaints. In fact, after an arthrodesis of the first metatarsophalangeal joint, patients are quite functional (4,8). Women can wear shoes with 1½-inch heels. Proper alignment of the joint must be achieved, however; otherwise, abnormal stress may be placed across the interphalangeal joint. Degenerative changes at the interphalangeal joint may occur in about 20% of patients. As a general rule, although radiographic changes occur in the interphalangeal joint, they rarely become clinically symptomatic if the alignment of the first metatarsophalangeal joint is correct. If insufficient valgus or too much plantar flexion is placed at the arthrodesis site, the patient tends to vault over the toe or externally rotate the foot to prevent excessive pressure across the great toe. Occasionally, a nonunion of the arthrodesis site occurs; if symptomatic, it should be repaired.

HINTS AND TRICKS

If bone stock is insufficient (e.g., after a Keller procedure, or in the case of severe rheumatoid arthritis with osteopenic bone), use Steinmann pins to stabilize the fusion site (6). Use two threaded double-ended ½-inch or ⅞-inch Steinmann pins. Drill each pin retrograde starting in the proximal phalanx, crossing the interphalangeal joint, and passing out through the tip of the great toe. Once the first pin has been drilled out completely, place a second pin parallel to it. Hold the cut bone surfaces in apposition and drill one Steinmann pin back across the metatarsophalangeal joint. As this is being done, place compression across the joint. The pin can usually be driven in 2–3 cm. Cut the pin, leaving it protruding from the tip of the toe by about 4–5 mm. Carefully check the toe for alignment and rotation by aligning the toenails, and then drill the second pin across the metatarsophalangeal joint (Fig. 112.16). Place the patient in a compression dressing and permit walking in a postoperative shoe until the arthrodesis heals, usually 10–12 weeks. Remove the pins under digital block using a Craig pin remover.

AUTHORS’S PERSPECTIVE

Hallux valgus surgery should result in satisfactory correction of the deformity and a painless functional first metatarsophalangeal joint. The surgical procedure must be carefully selected; if one attempts to use a procedure such as a chevron when the deformity is too severe, it will provide less than an optimal result. It is extremely important to carefully select the indicated procedure and not to “stretch” indications (5).

Postoperative management must be meticulous: It is an integral part of the procedure if a satisfactory outcome is to be achieved.

If a complication such as a mild hallux varus occurs, it usually is not symptomatic. When the hallux varus is greater than 8° to 10°, it may be symptomatic and surgical correction utilizing a split extensor hallucis longus transfer may be indicated.

Fully inform the patient about possible complications of the foot surgery. This prevents surprises for the patient, which makes for a much better physician–patient relationship.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

ANATOMY AND PHYSIOLOGY

Each of the lesser toes consists of three phalanges, the proximal, middle, and distal phalanx. In the case of the fifth toe, sometimes the middle and distal phalanx fail to separate (7). Barriers to deformities include the medial and lateral collateral ligaments of the metatarsophalangeal (MP) joints, as well as the proximal and distal interphalangeal joints. The plantar plate helps to passively return the MP joints to a neutral position when the joints are dorsiflexed during ambulation.

Active motion of the joints of the lesser toes is accomplished with both the intrinsic and the extrinsic musculature (11). Dorsiflexion of the MP joint is accomplished by the extensor digitorum longus tendon, whereas flexion of that joint is accomplished by the intrinsic lumbrical and interossei musculature. The interossei attach to the dorsal hood over the proximal phalanx, and through this they work to act as extensors of the proximal and distal interphalangeal joints. The proximal interphalangeal (PIP) joint is plantar flexed by the flexor digitorum brevis, and the distal interphalangeal joint is plantar flexed by the flexor digitorum longus (FDL) tendon. Because the strength of the extrinsics is significantly greater than that of the intrinsics, deformities are most commonly that of dorsiflexion at the MP joint and plantar flexion at the proximal and distal interphalangeal joints.

The etiology of a flexible hammer toe is often a tight FDL tendon; if the deformity persists for a sufficient duration, it can become fixed. A disproportionately long lesser toe or a shoe with a tight toe box can also cause a fixed hammer-toe deformity. Further causes of hammer-toe deformity can be poor shoe wear or the formation of a hallux valgus deformity, which can push the second toe into a “hammered” or overlapped position.

RIGID HAMMER TOE

A rigid hammer toe is defined as a fixed flexion deformity of the PIP joint (10). This deformity can cause symptoms over the dorsum of the PIP joint where the toe rubs against the top of the toe box (Fig. 113.1), or at the tip of the toe where the toe hits the sole of the shoe. If the hammer toe produces sufficient distal migration of the plantar fatty cushion, pain under the metatarsal head can result. Shoe modifications, including extradepth shoes, soft insoles, and metatarsal pads, can help to alleviate symptoms.

**Figure 113.1.** A patient with a symptomatic second hammer toe. A: Oblique view. B: Top view.

Evaluation of the entire foot for related deformities, such as a tight FDL tendon or a hallux valgus deformity, is important prior to any surgical treatment. A hallux valgus deformity can reduce the space lateral to the hallux, which prevents reduction of a second toe into a reduced position. If this condition exists, a hallux valgus repair should be strongly considered as a concomitant surgical procedure.

SURGICAL CORRECTION OF RIGID HAMMER TOE

A PIP joint arthroplasty, such as described by DuVries (3,6), consists of the resection of the distal condyle of the proximal phalanx. It results in a fibrous ankylosis that allows approximately 15° or 20° of motion. An alternative is bony arthrodesis of the PIP joint.

- Make a dorsal elliptical incision over the PIP joint. Sharply remove the skin, extensor tendon, and capsule (Fig. 113.2).
Figure 113.2. Removal of an ellipse of skin above the proximal interphalangeal joint.

- Release the medial and lateral collateral ligaments, and, after exposing the distal condyle of the proximal phalanx, remove the condyle using a bone cutter (Fig. 113.3). Take care to remove the entire condyle and make the cut so that it is perpendicular to the shaft of the proximal phalanx.

Figure 113.3. The soft tissues have been elevated off the distal condyle of the proximal phalanx, and a bone cutter is about to remove the distal condyle. Note that the blades are perpendicular to the shaft of the phalanx.

- Then stabilize the toe with a 0.045-inch, double-ended Kirschner (K-) wire brought out distally from the PIP joint and then advanced in a retrograde fashion across the joint into the shaft of the proximal phalanx (Fig. 113.4). If stabilization of the MP joint is also desired, use a 0.062-inch K-wire to decrease the chance of breakage of the K-wire.

Figure 113.4. A K-wire has been placed from the PIP joint out through the tip of the distal toe, and it will be brought into the proximal phalanx in a retrograde fashion.

- Close the skin with vertical mattress sutures (Fig. 113.5).

Figure 113.5. The K-wire has been advanced to the proximal phalanx, bent, and cut. The extensor mechanism of the toe has been repaired as well as the skin.

Remove the sutures at 3 weeks, along with the K-wire. Allow the patient to ambulate with full weight bearing in a postoperative shoe 3 weeks after surgery. Splint the toe into neutral with tape for 3 weeks after removal of the pin. Advise the patient to use an open-toed shoe or one with a roomy toe box.

COMPLICATIONS

Swelling is the most common complication following hammer-toe surgery. This usually decreases over the course of 6 months. Recurrence of a hammer-toe deformity is sometimes noted, and a floppy toe can result if too much of the shaft of the proximal phalanx is removed along with the distal condyle. Migration of the intermediate pin can occur if the end is not bent or if a fixation device is not attached to the distal aspect of the pin.

FLEXIBLE HAMMER TOE

A flexible hammer-toe deformity can decrease or be completely eliminated with plantar flexion of the MP joint or of the ankle. These deformities are usually caused by tightness of the FDL tendon. Treat a flexible hammer toe with a Girdlestone-Taylor flexor tendon transfer if surgery is indicated. This transfer, often combined with the release of deforming forces at the MP joint, can produce satisfactory results. An arthroplasty of the PIP joint is sometimes combined with the tendon transfer if there is some element of a fixed component.

SUGICAL CORRECTION OF FLEXIBLE HAMMER TOE

- Make a transverse incision under the proximal aspect of the proximal phalanx and carry dissection bluntly down to the flexor tendon sheath. Then open the flexor tendon sheath with a longitudinal incision using a #11 blade.
- Identify the FDL tendon and apply gentle traction by placing a curved hemostat beneath the tendon.
- Then make a second plantar transverse incision at the level of the distal plantar flexion crease at the distal interphalangeal joint.
- Free up the FDL tendon distally, transect it near its insertion, and bring it out through the proximal plantar transverse incision. Then split the tendon along its raphe.
Surgical Correction of Claw Toe

- Make a longitudinal incision dorsally over the dorsal MP joint extending out to the distal condyle of the proximal phalanx, and release the extensor tendon and collateral ligaments if necessary.
- Excise the distal condyle of the proximal phalanx as in a fixed hammer-toe repair if there is noncorrectable deformity.
- Bring up each half of the FDL tendon from plantar to dorsal along both sides of the shaft of the proximal phalanx, and suture it into the extensor hood. Do this with the PIP joint of the toe extended and with the MP joint in slight flexion.
- Close all wounds and hold the toe in neutral position with a postoperative dressing. Fix the toe with a 0.062-inch K-wire if a fixed PIP joint deformity was treated.

Allow the patient to ambulate, with weight bearing as tolerated, with a postoperative shoe for 6 weeks.

Complications

Complications include possible neurovascular injury from pressure or swelling around the area of the tendon transfer, producing vascular or neurologic compromise. Other difficulties, such as swelling and recurrence of deformity, can also occur. Minimize these risks with gentle precise surgical technique.

Deformities of the Metatarsophalangeal Joint

Deformities or pain at the MP joint can exist along with a hammer toe (5,8,9,13). These usually consist of a fixed dorsiflexion deformity, although subluxation or dislocation of the joint can occur. Mild dorsiflexion deformities often can be treated with extensor tenotomy. Should the deformity be of such a magnitude that this treatment is not sufficient, however, an open release of the joint capsule may be necessary. An open extensor tenotomy and capsulotomy will correct many subluxation deformities, although it is important to ensure release of the medial and lateral collateral ligaments also. Take care to avoid injury to the neurovascular bundles on either side of the joint. After correcting the soft-tissue deforming forces, hold the toe in a neutral position and insert an intermediary K-wire of at least 0.062 inches in diameter. Protect the foot with a wooden postoperative shoe until the pin is removed, 2–3 weeks after surgery.

When a severe deformity is present, a soft-tissue procedure is often not adequate, and an arthroplasty of the MP joint is necessary. Decompression of the joint will allow its reduction, and the conversion of a diarthrodial joint to a fibrous joint will provide stability.

Arthroplasty of the Metatarsophalangeal Joint

- Make a dorsal longitudinal incision over the MP joint and perform a dorsal capsulotomy with release of the collateral ligaments. Do a dorsal extensor tenotomy if necessary.
- Plantar flex the toe, and resect approximately 2–4 mm of bone off the distal metatarsal head. Use a rongeur, power saw, or osteotome to bevel the plantar and dorsal surfaces of the distal metatarsal head.
- Allow the toe to return to a neutral position, and repetitively move the ankle dorsally and plantarly to check the stability of the MP joint. The amount of bone that requires resection can be estimated by evaluating the overlap seen preoperatively on a lateral radiograph of the MP joint.
- After obtaining satisfactory stability, stabilize the joint with a K-wire of at least 0.062 inches. Position the wire by inserting it into the proximal phalanx and drilling it out the tip of the toe. Then align the joint and insert the wire across the joint into the metatarsal head in a retrograde fashion. Bend the pin to prevent its proximal migration, and cut it. Hold the toe in a slightly plantar-flexed position during pin fixation.

Postoperatively, treat the patient for 2–3 weeks in a wooden postoperative shoe. Remove the pin prior to return to regular shoes, after 3 weeks or so. There will be a loss of up to 50% of normal motion. This arthrofibrosis, however, helps to provide stability and prevent dislocation.

Complications

Redlocation of the MP joint is the most common complication of this procedure. Thorough release of the soft tissues is the best method of preventing redlocation. Neurologic or vascular compromise can occur if the toe stays reduced without adequate soft-tissue release, or if the vascular supply is compromised prior to the procedure. Occasionally, removal of the K-wire may be necessary to improve postoperative vascular status. Redlocation often occurs after K-wire removal; however, this is preferable to necrosis of all or part of the toe.

Crossover Second Toe

A significant hallux valgus deformity can cause pressure on the second toe and lead to dorsal subluxation or dislocation of the second toe, placing the great toe adjacent to the third toe (1,2,3 and 4). This results in attenuation of the second MP joint’s fibular collateral ligament, and possibly even the formation of a rent in it. The tibial collateral ligament can sometimes contract. As the deformity progresses, dorsal subluxation and possibly dislocation of the second MP joint can occur.

Evaluate instability of the joint using the anterior drawer sign of the lesser MP joint, as described by Thompson and Hamilton (13). Grasp the proximal phalanx of the lesser toe between the thumb and index finger and stabilize the metatarsal with the other hand. Then manipulate the toe in a vertical fashion. If instability exists, there is subluxation at the MP joint, and pain may exist.

Nonsurgical treatment includes taping the second toe in a reduced position or using open-toed or extra-depth shoes.

Surgical Repair of a Crossover Toe

- Make a dorsal longitudinal incision over the second MP joint.
- Perform extensor tenotomy as well as dorsal capsulotomy and collateral ligament release as described in the previous paragraphs.
- Hold the toe in a reduced position with a 0.062-inch intramedullary K-wire for 4–6 weeks after surgery.
- For severe deformity of the MP joint arthroplasty, as previously described, may be necessary to both decompress the joint and allow reduction of the proximal phalanx. A Girdlestone-Taylor (11) flexor tendon transfer may also be necessary. Releasing of the lateral capsule may also be used to strengthen the reconstruction and decrease the chances of recurrence of the deformity.
- Perform correction of the hallux valgus deformity at the same time as repair of the second toe to allow for proper placement and reduction of the toe, and to prevent the hallux from again displacing the second toe (see Chapter 112).

Complications

The complications of treatment of the second toe include swelling of the toe as well as recurrence of the first and second toe deformity. Loss of motion at the MP joint from postsurgical scarring and fibrous arthrodesis is a common complication. Occasional neurovascular compromise from stretching of the neurovascular bundle with reduction of the toe at the MP joint is also a possibility. Avoid this by adequate soft-tissue release, avoiding overlengthening, and gentle surgical technique.

Claw Toe

A claw toe is a deformity of the MP joint that occurs together with a flexion deformity of either the proximal or distal interphalangeal joints. The PIP joint is involved much more frequently than the distal interphalangeal joint in a claw-toe deformity. When evaluating a claw toe, examine both the MP and the involved interphalangeal joint to determine whether the involved deformity is fixed or flexible at each joint. In addition, carefully evaluate the halluc for a valgus deformity, which could prevent reduction of the second toe into its normal position. If there is a hallux valgus deformity that might interfere with the second toe, correct it simultaneously.

Surgical Correction of Claw Toe

- At the PIP joint, make a dorsal elliptical incision and perform a resection of the distal condyle of the proximal phalanx with the creation of a fibrous arthroplasty as described for the surgical treatment of hammer toe.
- Then make a longitudinal incision over the MP joint, and perform extensor tenotomy and capsulotomy, with release of the medial and lateral collateral ligaments as necessary. This is often enough to correct all deformities; however, a flexor tendon transfer, as described in the treatment of flexible hammer toe, is sometimes also required.
- If severe subluxation or dislocation of the MP joint is present, release of the soft tissues will often be not sufficient to allow a stable reduction, and a resection arthroplasty of the MP joint might be necessary. Accomplish this by decompressing the joint with the removal of 2–3 mm of the distal metatarsal head as described previously. This is often adequate to allow reduction of the joint and produce postoperative stability. Some beveling of the dorsal and plantar condyles

Chapter 112, 9, 13. Grasp the proximal phalanx of the lesser toe between the thumb and index finger and stabilize the metatarsal with the other hand. Then manipulate the toe in a vertical fashion. If instability exists, there is subluxation at the MP joint, and pain may exist.

Nonsurgical treatment includes taping the second toe in a reduced position or using open-toed or extra-depth shoes.

Surgical Repair of a Crossover Toe

- Make a dorsal longitudinal incision over the second MP joint.
- Perform extensor tenotomy as well as dorsal capsulotomy and collateral ligament release as described in the previous paragraphs.
- Hold the toe in a reduced position with a 0.062-inch intramedullary K-wire for 4–6 weeks after surgery.
- For severe deformity of the MP joint arthroplasty, as previously described, may be necessary to both decompress the joint and allow reduction of the proximal phalanx. A Girdlestone-Taylor (11) flexor tendon transfer may also be necessary. Releasing of the lateral capsule may also be used to strengthen the reconstruction and decrease the chances of recurrence of the deformity.
- Perform correction of the hallux valgus deformity at the same time as repair of the second toe to allow for proper placement and reduction of the toe, and to prevent the hallux from again displacing the second toe (see Chapter 112).

Complications

The complications of treatment of the second toe include swelling of the toe as well as recurrence of the first and second toe deformity. Loss of motion at the MP joint from postsurgical scarring and fibrous arthrodesis is a common complication. Occasional neurovascular compromise from stretching of the neurovascular bundle with reduction of the toe at the MP joint is also a possibility. Avoid this by adequate soft-tissue release, avoiding overlengthening, and gentle surgical technique.

Claw Toe

A claw toe is a deformity of the MP joint that occurs together with a flexion deformity of either the proximal or distal interphalangeal joints. The PIP joint is involved much more frequently than the distal interphalangeal joint in a claw-toe deformity. When evaluating a claw toe, examine both the MP and the involved interphalangeal joint to determine whether the involved deformity is fixed or flexible at each joint. In addition, carefully evaluate the halluc for a valgus deformity, which could prevent reduction of the second toe into its normal position. If there is a hallux valgus deformity that might interfere with the second toe, correct it simultaneously.

Surgical Correction of Claw Toe

- At the PIP joint, make a dorsal elliptical incision and perform a resection of the distal condyle of the proximal phalanx with the creation of a fibrous arthroplasty as described for the surgical treatment of hammer toe.
- Then make a longitudinal incision over the MP joint, and perform extensor tenotomy and capsulotomy, with release of the medial and lateral collateral ligaments as necessary. This is often enough to correct all deformities; however, a flexor tendon transfer, as described in the treatment of flexible hammer toe, is sometimes also required.
- If severe subluxation or dislocation of the MP joint is present, release of the soft tissues will often be not sufficient to allow a stable reduction, and a resection arthroplasty of the MP joint might be necessary. Accomplish this by decompressing the joint with the removal of 2–3 mm of the distal metatarsal head as described previously. This is often adequate to allow reduction of the joint and produce postoperative stability. Some beveling of the dorsal and plantar condyles
with a rongeur produces a smoother surface, which permits easier dorsiflexion of the toe.

- Test the toe for stability in neutral position as well as during dorsiflexion. After treatment of all bony and soft-tissue deformities, stabilize the digit with a 0.062-inch K-wire. The technically least demanding method is to insert the K-wire from the PIP joint distally, out through the tip of the toe, and bring it back in a retrograde fashion through the proximal phalanx into the proximal metatarsal. Take care to ensure proper position of the toe while placing the internal fixation.
- Close all wounds and bend the K-wire protruding from the toe.

Remove the K-wire approximately 3 weeks after surgery. Allow the patient to ambulate with weight bearing as tolerated in a stiff postoperative shoe. At this point, begin gentle mobilization of the MP joint. Arthrofibrosis often occurs at the MP joint after this surgery, and loss of range of motion up to 50% is common. Avoid proximal phalangectomy. The stability offered by the presence of the wide base of the proximal phalanx is important. This flared area will help to form a stable fibrous joint, allowing articulation with the shortened and reshaped metatarsal head.

COMPLICATIONS

Redislocation of the MP joint is an occasional complication of this procedure. It can result from inadequate shortening of the MP head or stiffness from inadequate rehabilitation after pin removal. Incomplete soft-tissue release may also be a factor contributing to recurrence. Compromise of the vascular supply at the toe can occur from tension or spasm of the interdigital vessels, and postoperative monitoring is strongly recommended. If vascular compromise appears to jeopardize the viability of the toe, removal of the K-wire will sometimes help to improve the digital blood supply. Unfortunately, this usually also allows dislocation of the MP joint.

MALLET TOE

Mallet toe is a flexion deformity of the distal interphalangeal joint. It often causes pain because the tip of the toe rubs on the inner sole of the shoe. Mallet toe is usually a fixed deformity and is less common than hammer toe.

SURGICAL CORRECTION OF MALLET TOE

- Mallet toes that are flexible can occasionally be treated with percutaneous tenotomy of the FDL tendon.
- With a fixed deformity, it is necessary to decompress the distal interphalangeal joint. Excise an ellipse of skin from the dorsal aspect of the distal interphalangeal joint, and after release of the extensor apparatus and the collateral ligaments, excise the distal condyle of the middle phalanx with a bone cutter. This technique is similar to that described for correction of rigid hammer toe.
- Hold the toe in a neutral position with a 0.045-inch K-wire.
- Close the skin with interrupted vertical mattress sutures.

Allow the patient to ambulate with a postoperative shoe for 3 weeks, and then remove the pin and sutures. Then hold the toe in a neutral position with a half-inch adhesive tape wrapping for another 3 weeks. Take care to avoid any injury to the proximal nail matrix.

COMPLICATIONS

Complications are the same as for repair of hammer toe.

HARD CORNS

A hard corn is a thickened area of skin usually found on the dorsolateral aspect of the fifth toe (Fig. 113.6). The thickened skin is a hyperkeratotic reaction to the increased pressure between the distal condyle of the proximal phalanx of the fifth toe and the side of the shoe. Nonsurgical treatment for this problem consists of protecting the skin with a donut device made of soft material. In addition to this, wider, roomy shoes that minimize or eliminate a confined toe box are also quite effective. Shaving of the keratotic lesion can also help alleviate symptoms. If surgery is necessary, the underlying principle is to remove the offending condyle to relieve pressure on the skin.

Figure 113.6. A: A hard hyperkeratotic region over the PIP joint of the fifth toe. B: The radiograph of the toe.

SURGICAL CORRECTION OF A HARD CORN

- When the hard corn is on the dorsolateral fifth toe, make a longitudinal incision over the fifth toe and dissect around the PIP joint to expose it.
- Release the collateral ligaments and resect the distal condyle of the proximal phalanx perpendicular to the shaft using a bone cutter (Fig. 113.7).

Figure 113.7. The distal condyle of the proximal phalanx, which has been exposed. A freer elevator ensures that the soft tissues from underneath the proximal phalanx have been released.

- Make certain all remaining bony surfaces are smooth (Fig. 113.8). Use a rasp as necessary.
Figure 113.8. Radiograph of the toe after removal of the bony prominence.

- Close the skin with interrupted sutures.

Protect the toe for approximately 3 weeks after surgery, allowing full weight bearing in a postoperative shoe. At approximately 3 weeks after surgery, allow the patient to go to wide, laced shoes, and stabilize the toe by buddy taping it to the fourth toe for approximately 3–4 weeks.

COMPLICATIONS

Swelling of the toe is not uncommon, but this will usually resolve over approximately 3–6 months. Stiffness of the PIP joint often occurs but is usually not symptomatic. If excess bone is removed, a floppy toe may result. If the condyle is resected at a significant angle to the shaft, a spike of bone may cause discomfort in the adjoining fourth toe.

SOFT CORNS

A soft corn is a thickening of the skin between two lesser toes (Fig. 113.9). This hyperkeratotic skin reaction is caused by excess pressure in the web space between the toes, often caused by a constricted toe box. The moisture present in the region between the toes results in the maceration of the keratotic lesion. The location of the corn is usually at the area where one bony prominence is pushed into the adjoining toe.

To treat, prescribe open-toed shoes or a wide toe box, and place a soft material such as lamb’s wool between the toes. If this is not satisfactory, removal of the offending condyle can resolve the problem. If there is any question as to which is the offending condyle, identify it by placing a small lead marker over the soft corn, and obtain a radiograph (Fig. 113.10). This condyle may be on the toe with the lesion or on the adjacent digit.

Figure 113.10. A lead marker placed on the lesion demonstrates it to be at the level of the distal condyle of the proximal phalanx of the fifth toe.

CONDYLECTOMY FOR A SOFT CORN

Make a dorsal elliptical incision over the joint with the offending condyle, usually at the PIP joint.

- Resect the distal condyle as previously described for hammer toe.
- If surgery is done on the fifth toe, use a longitudinal incision. Surgery on two adjacent toes is occasionally necessary.

Postoperative treatment is identical to that described for hammer toe, mallet toe, or a hard corn, depending on which joint or digit is involved.

COMPLICATIONS

Swelling is not uncommon, but it often resolves within 3–6 months. Excessive resection of the proximal phalanx can result in a floppy toe, or if the remaining piece of bone is angulated, this can result in malalignment of the toe. Surgery on the wrong toe occasionally occurs; any doubt as to which digit is the offending toe should be resolved prior to surgery.

CHAPTER 114

PERIPHERAL NERVE LESIONS OF THE FOOT AND ANKLE

Martin G. Mankey

M. G. Mankey: Department of Orthopaedics, University of Washington, Seattle, Washington, 98195.

INTERDIGITAL NEUROMA

PATHOPHYSIOLOGY

The term neuroma is actually a misnomer. Most recent literature supports the theory that the condition we call interdigital neuroma is an entrapment neuropathy of the common digital nerve beneath the transverse metatarsal ligament (26,38,39,44). These studies demonstrate that almost all the histologic changes in the nerve occur distal to the transverse metatarsal ligament, and that the nerve proximal to the ligament appears normal. The histologic changes are characterized by perineural fibrosis, degeneration of the nerve fibers, deposition of an amorphous eosinophilic material, and a decrease in both the number and the diameter of thick myelinated fibers (Fig. 114.1). Although these studies seem to support the theory that the main cause of an interdigital neuroma is an entrapment neuropathy, there are anatomic factors that need to be considered.

![Figure 114.1. Photomicrographs of an interdigital neuroma (trichrome stain). A: Low-power photomicrograph of a normal nerve. B: High-power photomicrograph of neuroma. Axonal degeneration and abundant vasculature are present.](image-url)

Early reports regarding this painful entity, often referred to as Morton's syndrome, focused on the third interspace (9,46,48). Subsequent studies of the anatomy of the plantar nerves and their branches have demonstrated a communicating branch between the medial and lateral plantar nerves (9,32) (Fig. 114.2). This branch was noted to course from the common digital nerve in the fourth interspace to the third digital branch of the medial plantar nerve in the third interspace. Jones and Klenerman (32) found this communicating branch to be present in all 20 of the cadaver specimens dissected. In two of the female specimens, they found the communicating branch was enlarged, and they hypothesized that this enlargement may be a factor for the frequent involvement of the nerve to the third interspace. Mann and Reynolds (44) reported an equal distribution of interdigital neuromas in the second and third interspaces. They believed their data supported the theory that neuromas are caused by repetitive local trauma related to footwear (e.g., tight shoes, high heels, and thin soles) and shed doubt on the role of the communicating branch as the main cause of interdigital neuroma formation. Levitsky et al. (39) found the communicating branch was present in only 19 (26.8%) of 71 specimens dissected, and the incidence of third-interspace neuromas was no greater in those feet with the communicating branch as those without it. The information also questions the role of the communicating branch in the etiology of interdigital neuromas. Both Mann and Levitsky failed to identify a neuroma in the first and fourth...
principles of treatment

The principles of treatment for interdigital neuroma are threefold:

1. Make the correct diagnosis.
2. Nonoperative treatment (shoe wear alterations, metatarsal pad, corticosteroid injection, nonsteroidal anti-inflammatory medication)
3. Operative treatment (dorsal approach, plantar approach)

literature review

A review of the literature about interdigital neuromas over a span of 120 years follows (13).

- 1876—Morton (48) coined the term metatarsalgia to describe a painful affection of the forefoot suspected to involve the interdigital nerves.
- 1893, Hoadley (29) explored the digital nerves under the painful area, “found a small neuroma,” excised it, and claimed the patient obtained “prompt and perfect cure.”
- 1940, Betts (3) stated that “Morton’s metatarsalgia is a neuritis of the fourth digital nerve.” He also noted branches of both the medial and lateral plantar nerves formed the nerve in the third interspace.
- 1979, Gauthier (22) speculated that the condition represented a nerve entrapment, a theory supported by Lassman (38) and later by Graham and Graham (26).
- 1983, Mann and Reynolds (44) found an equal number of interdigital neuromas in the second and third interspaces. They theorized that repetitive local trauma related to footwear was the main etiologic factor rather than the communicating branch.
- 1984, Jones and Klennerman (32) identified the communicating branch in all 20 cadaver feet studied. They suggested enlargement of this communicating branch may be responsible for the frequent involvement of the third interspace.
- 1993, Levitsky et al. (29) found the communicating branch in only 26.8% of specimens studied. They developed a ratio of the distance between the metatarsal heads to the diameter of the nerve and found it to be significantly smaller in the second and third interspaces, suggesting neuromas are caused by an entrapment neuropathy based on mechanical force.
- 1993, Thompson and Deland (65) coined the term “second neuroma, same foot,” or SNSF, to describe the occurrence of a second primary neuroma in the same foot. They placed the incidence at under 4%. They found it more rare for the neuromas to occur simultaneously and suggested that both interspaces not be explored at the same time.
- 1995, Benedetti et al. (7) presented a comprehensive staged treatment protocol for interdigital neuromas, along with their results.
- 1996, Benedetti et al. (6) reported on 19 feet that underwent simultaneous excision of two primary interdigital neuromas in adjacent interspaces. They found a 3% incidence. Patients had dense sensory loss. The authors recommended one single dorsal longitudinal incision in the second web space to resect both neuromas.

Diagnosis

The key to a successful outcome from treatment of an interdigital neuroma is first making the correct diagnosis. The examiner needs to determine not only if the patient’s symptoms are consistent with the diagnosis of a neuroma, but also at which interspace the neuroma is located. This can be very challenging. The diagnosis is made on the basis of a patient’s symptoms and the physical examination. Certainly there are patients that present with classic symptoms and physical findings. Although magnetic resonance imaging (MRI) and ultrasound have been reported to be sensitive in diagnosing interdigital neuromas, they have not gained wide acceptance and should not take the place of a directed history and physical examination.

Symptom Complex

The most common symptoms, in decreasing order of frequency, are presented in Table 114.1, which was adapted from Mann and Reynolds’ study (44). Other studies present data without significant differences. A vast majority of the patients are women in their fifties. Most of the time, symptoms are unilateral, although bilateral neuromas occur about 15% of the time. Either the second or third interspace can be involved, with studies showing anywhere from equal involvement to predominance in the third interspace. The classic symptoms are burning plantar pain between the metatarsal heads with radiation into the toes, exacerbated by wearing tight shoes, high heeled shoes and relieved by removing the offending footwear. Patients may feel a “lump” or “mass,” as if their sock is rolled up (but it is not). Some patients feel the need to “pop” their foot to obtain relief. Runners and athletes are a group being seen more often. They note the onset of their symptoms after a certain distance or period of activity. Their pain crescendos to a peak and does not subside until they stop and remove their athletic shoes.
that a positive response to the injection is a prerequisite to recommending surgical treatment. In unsuccessful cases, the protocol helped select those patients who might benefit most from surgery. They also felt that the injection was diagnostically helpful and indicated the need for further treatment if the patient indeed has simultaneous adjacent neuromas, they should not be excised at the same time and the symptomatic one should be excised first. Benedetti et al. (15) developed a three-stage treatment protocol, the first two stages of which were nonoperative. The authors note no false positives in the patients who eventually required surgery, but they cannot comment on false negatives without histologic verification of the diagnosis. Overall, the usefulness and cost-effectiveness of MRI have yet to be determined in the diagnosis of interdigital neuromas and directing treatment. Therefore, I do not recommend routine use of MRI.

Ultrasound has also been advocated by Shapiro and Shapiro (61) as a useful study in diagnosing neuromas. The authors accurately predicted the presence, location, and size of the neuroma in 98% of cases. They feel it is particularly useful in diagnosing adjacent neuromas in the same foot; this is the situation for which ultrasound may have its greatest usefulness. The authors also admit that the diagnosis is examiner dependent, and an experienced ultrasonographer interested in foot and ankle problems is essential.

Making the Diagnosis

As mentioned earlier, some patients present with classic symptoms and physical findings, and the diagnosis seems straightforward. Many, however, are difficult to diagnose with enough confidence to suggest surgery. The best way to sort through the findings for the difficult patient is to perform a series of examinations over a period of time. Symptoms change, as do physical findings. You will either feel more confident about the presence of a neuroma or more sure that you are dealing with an entity different from a neuroma. During the time you are following the patient, different nonoperative treatments can be tried, and you may actually be able to come to a diagnosis based on the patient’s response. A reasonable time period between assessments is 6–8 weeks.

One entity that can make the diagnosis and location of a symptomatic neuroma difficult is the presence (in 28% of feet) of adjacent neuromas (39), although this problem is becoming better understood. Thompson and Deland (60) suggest the use of 1–2 ml of Xylocaine into one of the suspected interspaces, with follow-up to determine its effect. If no or partial relief is obtained, the other interspace is similarly injected, with later follow-up. The authors suggest that if you feel strongly that the patient indeed has simultaneous adjacent neuromas, they should not be excised at the same time and the symptomatic one should be excised first. Benedetti et al. (6) reported on the surgical outcome of excision of adjacent neuromas, but they did not have any specific suggestions on how to diagnose them. They did stress the importance of ruling out any other condition that could cause more diffuse forefoot pain, such as peripheral neuropathy, double crush syndrome, and synovitis of the metatarsophalangeal joints.

To reiterate, if the diagnosis is not clear, treat nonoperatively, perform repeated examinations at appropriate intervals, and do not operate.

PREOPERATIVE MANAGEMENT

Once the diagnosis is made, treat nonoperatively initially in all patients. Bennett et al. (7) developed a three-stage treatment protocol, the first two stages of which were nonoperative. The first stage included patient education about the condition. Footwear modifications were made to include a wider shoe, and a metatarsal pad was applied proximal to the involved interspace. A letter was sent to the patient to reinforce the program. If little or no improvement was seen within 3 months, the patient returned, and 2 ml of 1% Xylocaine and 1 ml of Aristocort (triamcinolone, 40 mg/ml) was injected into the interspace (stage 2). Immediate short-term pain relief was seen in all patients. They were encouraged to continue with the shoewear modifications. If satisfactory relief of the patient's symptoms was not seen 3 months later, surgical excision was carried out (stage 3). The authors' results are summarized in Table 114.3. They conclude that although the nonsurgical treatment was not successful in all patients, the protocol helped select those patients who might benefit most from surgery. They also felt that the injection was diagnostically helpful and that a positive response to the injection is a prerequisite to recommending surgical treatment.

The treatment used by Mann and Reynolds (44) was similar to stage 1 of the preceding protocol. These authors found that although the patients responded well to nonoperative management, 70% to 80% were sufficiently symptomatic and dissatisfied with the change in shoewear that they opted for surgery. Anti-inflammatory medications or injections, with or without a steroid, did not provide long-term relief and was not part of their routine management. Rasmussen et al. (55) reported on 51 feet that received a single corticosteroid injection for treatment of third interspace neuromas. They concluded that injections generally did not provide a cure for interdigital neuromas, but they did provide temporary relief and did not preclude a good surgical outcome. After 4 years, only 11% of the feet had lasting improvement. The authors felt, as did Bennett et al. (7), that injection can be useful in confirming the diagnosis and as a predictor of operative success.

Local steroid injection into superficial areas with little subcutaneous tissue, such as the interspace in the foot, can cause subcutaneous atrophy, altered cutaneous pigmentation, alopecia, and telangiectasia (56). The effects are more pronounced with the use of relatively insoluble preparations, such as triamcinolone. The more soluble preparations should be used in low volume if a corticosteroid is to be injected into the foot for treatment of an interdigital neuroma.

OPERATIVE TECHNIQUE

If the surgeon feels confident that patient's symptoms are from an interdigital neuroma, and the patient has failed nonsurgical management, surgery is indicated. There are essentially three options for surgical treatment: (a) dorsal approach, (b) plantar approach, or (c) dividing the transverse metatarsal ligament and leaving the nerve intact.

Dorsal Approach

The dorsal approach is the most common and widely used surgical treatment for interdigital neuroma. Overall, one can expect 80% to 85% good and excellent results with this surgical approach combined with the staged treatment protocol outlined previously (7,19,44). It is my preferred technique.

- Under tourniquet control, make a 3 cm incision starting in the involved webspace (Fig. 114.3). Place the incision between the metatarsals to avoid injury to a small dorsal sensory nerve. Carry out blunt dissection with a thumb or small scissors down through the subcutaneous tissue, avoiding injury to superficial nerves.

**Figure 114.3.** Dorsal incision placed between the metatarsals.

- Place a Weitlander retractor or a small lamina spreader into the wound between the metatarsal heads, and open it, placing the transverse metatarsal ligament under tension (Fig. 114.4).

**Figure 114.4.** Weitlander retractor placed between the metatarsals for exposure.

- Use a Freer elevator to bluntly dissect in line with the incision to identify the transverse metatarsal ligament and the normal interdigital nerve proximally. The nerve occasionally courses close to the metatarsal and is not always in the center of the interspace. Plantar pressure under the web space should reveal the enlarged neuroma protruding distal to the transverse metatarsal ligament (Fig. 114.5). Then sharply divide the metatarsal ligament.

**Figure 114.5.** Neuroma protruding distal to the transverse metatarsal ligament.

- Identify the nerve in the proximal part of the wound and trace it distally into the irregular mass. Look for any accessory branches coming from either metatarsal to join the common digital nerve. If one is identified, dissect it and clearly define it. I recommend leaving a divided accessory branch long and suturing the end into the interosseous muscle or capsule of the metatarsal head with a small suture. This prevents the nerve end from retracting and forming a potential painful...
neuroma stump directly under the metatarsal head.

- Trace the common digital nerve and transect it in the most proximal aspect of the wound so the cut end does not end up between metatarsal heads. Then dissect the neuroma out distally and excise it (Fig. 114.6). Preserve as much plantar fat as possible.

*Figure 114.6. Typical surgical specimen showing normal interdigital nerve (right) leading into irregular neuroma mass.*

- Close the skin with an interrupted 4-0 nylon suture and apply a compressive dressing (Fig. 114.7).

*Figure 114.7. Wound is closed with interrupted nylon suture to prevent hematoma formation.*

**Plantar Approach**

The plantar approach is used less often. Karges (34) performed 57 primary interdigital neuroma excisions through a plantar approach. He felt that the improved exposure gave better results. He reported no wound problems. There are other reports, however, of painful plantar incisions from this approach. Because there is little recourse to remedy a painful plantar scar, and because the dorsal approach provides good exposure with less morbidity, the dorsal approach is preferred for excision of a primary interdigital neuroma (42,44). Some have advocated the plantar approach for treatment of recurrent neuromas. The following is a brief description of the technique.

- Palpate the metatarsal heads on each side of the involved interspace and draw them out with a skin marker.
- Place a small-gauge needle (25- or 27-gauge) from a dorsal to plantar direction in the interspace, piercing the plantar aspect of the foot. This identifies the interspace plantarward so the incision can be made accurately. Draw the incision in line with the interspace, but proximal to the metatarsal heads.
- Carry the incision through the subcutaneous tissue. Place a Weitlander retractor. Carry out dissection with a blunt scissors in line with the skin incision. Retract slips of the plantar fascia, exposing the interdigital nerve and neuroma. Transect the nerve proximally and continue dissection distal to the neuroma. Excise the neuroma as in the dorsal approach.
- Close the skin with interrupted 5-0 nylon and apply a compressive dressing.

**Division of Transverse Metatarsal Ligament**

Good results have been reported by dividing the transverse metatarsal ligament and decompressing the interdigital nerve (22,24). When surgery has been performed for a recurrent neuroma, it appears that the transverse metatarsal ligament has completely reconstituted. This casts some doubt on the long-term outcome of an interdigital neuroma treated by this method, and it cannot be recommended at this time (42).

**POSTOPERATIVE CARE**

The postoperative management for all surgical techniques is similar. Send the patient home the same day in a postoperative shoe. Instruct the patient to elevate the foot as much as possible to decrease swelling. Allow weight bearing, but the dressing should be reapplied and kept in place for up to 3 weeks after surgery. The patient may ambulate in the postoperative shoe during this time. After 3–4 weeks, the swelling and tenderness should subside enough for him to begin ambulating in a wide, sensible shoe. Start passive and active range-of-motion exercises of the foot and ankle at that time. The patient can then slowly increase activities as tolerated, but he may experience swelling and soreness for some months with vigorous activities.

**GENERAL PITFALLS AND COMPLICATIONS**

There are many pitfalls awaiting the physician in the diagnosis and treatment of an interdigital neuroma. Making the correct diagnosis of a neuroma and its location can be challenging. Suggestions to avoid pitfalls in diagnosis have been given.

Be aware of the possibility of the presence of the second neuroma in the same foot. This condition is rare, but it could be the reason for unsatisfactory surgical outcomes. In addition, an incorrect diagnosis about the interspace in which the neuroma is located will lead to a poor surgical outcome. These two pitfalls have some overlap, which is difficult to sort through at times.

Too many injections of corticosteroids into one interspace can lead to atrophy of the fat pad and pigment changes of the skin. I recommend only one injection, if any, at this time, based on the previously presented data.

There have been few reported wound problems with the dorsal approach. If done incorrectly, or if the patient forms a keloid, it can lead to a painful incision that can be very difficult to cure. Dissection outside the line of the incision or overvigorous activities can lead to injury to the small dorsal cutaneous nerves, resulting in uncomfortable paresthesias or dysesthesias in the toes.

If surgery is carried out for excision of simultaneous neuromas in adjacent web spaces, the patient will experience dense sensory loss under the third toe that can be uncomfortable. Devascularization of the third toe due to injury to the digital arteries has been reported as well (Fig. 114.8).
RECURRENT NEUROMAS

Certainly not every patient with persistent pain following neuroma excision has a “recurrent” neuroma. Beskin and Baxter (8) noted that two thirds of the 39 patients they treated for recurrent neuroma had symptoms within 12 months of the original procedure. The other one third noted symptoms 1–4 years later. Mann and Baxter (42) hypothesized that the group with recurrent symptoms within 12 months probably had surgery for the wrong diagnosis, and that the other third had the interdigital nerve transected too far distal, and the neuroma stump from the excision ended up between the metatarsal heads and took 1–4 years to become painful. In their own experience of 11 recurrent neuromas, Mann and Reynolds (44) noted the neuroma stump to be adherent to the plantar aspect of the metatarsal head in all cases. They reported that 81% of these patients were asymptomatic after surgery through a dorsal approach. The diagnosis, nonoperative management, and surgical approach are almost identical to those for the primary neuroma. At the time of surgery, you may need to extend the incision a little more proximally to get down to virgin tissue and nerve, then follow it distally into the neuroma stump. Also, postoperatively, patients should be allowed a little longer healing time before returning to vigorous activities.

AUTHOR’S PERSPECTIVE

Interdigital neuromas can be very challenging to diagnose and treat. By following the guidelines for diagnosis, nonoperative management, and surgical treatment outlined in this section, you may be able to avoid the many pitfalls and complications. Nothing can take the place of experience. I cannot overstate the importance of patient history and physical examination. All the information needed to make the diagnosis is in the room with you and the patient—you just need to find it. Those of us who treat foot and ankle problems on a daily basis all too often see distressed patients who have had neuromas excised from multiple interspaces on both feet. Unfortunately, there is very little to offer them at that point. Remember that adjacent neuromas in the same foot are very rare. Neuromas occur bilaterally in about 15% of the patients, and even then rarely at the same time. If you think a patient has multiple neuromas, think again and again. If unsure as to the diagnosis or location, do not operate. That is the best advice I can give.

TARSAL TUNNEL SYNDROME

ANATOMY

The anatomy of the tarsal tunnel must be understood to understand tarsal tunnel syndrome. The tarsal tunnel is a fibro-osseous canal bounded by the tibia and medial malleolus anteriorly, the talus laterally, and the flexor retinaculum medially. The medial surface of the talus with the sustenaculum tali and the medial surface of the os calcis form the osseous floor. The tunnel is completed by the laciniate ligament (flexor retinaculum). The contents of the canal are, from medial to lateral, the tibialis posterior tendon and its sheath, the flexor digitorum longus tendon and its sheath, the posterior tibial neurovascular bundle, and the flexor hallucis longus muscle–tendon unit (Fig. 114.9).

The flexor retinaculum is triangular, with a proximal malleolar apex and an inferior base along the superior border of the abductor hallucis muscle. The anterior and posterior borders are difficult to define because they blend with the dorsal and superficial aponeuroses of the foot and leg, respectively. The tibial nerve divides into the medial and lateral plantar nerves and gives off its calcaneal branch within the tarsal tunnel in most cases. There is, however, great variation in this branching pattern (Fig. 114.10).

Figure 114.8. A: Patient 8 days after excision of presumed adjacent neuromas. B: Same patient 20 days postoperatively with gangrene secondary to devascularization of third toe. C: Same patient 3 weeks after amputation of third toe.

PATHOPHYSIOLOGY

Tarsal tunnel syndrome is the result of compression of the posterior tibial nerve within the tarsal canal, or of one of its terminal branches distal to the canal. Along its course, the nerve is susceptible to compression from numerous sources, both intrinsic and extrinsic. In about 60% of the patients with a tarsal tunnel syndrome, a specific cause can be identified (41). Table 114.4 lists the differential diagnosis of tarsal tunnel syndrome (16).

<table>
<thead>
<tr>
<th>Differential Diagnosis of Tarsal Tunnel Syndrome</th>
</tr>
</thead>
</table>

SYMPTOM COMPLEX

The most common presenting complaint for tarsal tunnel syndrome is “burning” dysesthesias or paresthesias on the plantar aspect of the foot. The symptoms are aggravated by prolonged standing or activity and partially relieved at rest. Many patients describe worsening of their symptoms while in bed at night, making it difficult to fall asleep. Some patients describe the Valleix phenomenon, which is proximal radiation of the pain along the medial aspect of the leg to the midcalf (16). Often the symptoms are diffuse and vague and not very well localized. Take a carefully directed history to identify any of the alternative diagnoses listed in Table 114.4. Look for a history of previous trauma such as an ankle sprain or fractures about the ankle or hindfoot. It is very important to elicit a history of diabetes or peripheral vascular disease, which can cause a peripheral neuropathy and mimic some of the symptoms of a tarsal tunnel syndrome.

PHYSICAL EXAMINATION

First, examine the foot in the weight-bearing position, looking for any deformity such as varus or valgus of the hindfoot. Perform gross examination for swelling, color, and temperature. Carry out a detailed neurovascular exam. Check pulses, warmth, and capillary refill. Gross sensory examination is usually not very localizing or helpful. Patients may note some subjective decrease in sensation on the plantar aspect of the foot, but it is difficult to quantify. Bailie and Kelkian (2) reported a significant increase in two-point discrimination (2-PD) of 7 mm in affected feet compared to normal controls. Postoperatively, they noted an improvement of 4 mm in 2-PD. They suggest using the patient's uninvolved foot as the control in unilateral disease because of the wide range of normal values (8–15 mm). Check the range of motion of the ankle, subtalar, and transverse tarsal joints for possible arthrofibrosis from an old injury, or the presence of a tarsal coalition.

Then palpate the entire course of the posterior tibial nerve, starting proximal to the tarsal tunnel and proceeding distally along the medial and lateral plantar nerves. In a patient with a tarsal tunnel syndrome, one can often demonstrate radiation of neuritic symptoms into the plantar aspect of the foot in the distribution of the medial or lateral plantar nerves or both (Tinel's sign). Carefully palpate the tarsal tunnel to identify the presence of any space-occupying lesion such as a ganglion cyst or tumor. Motor function of the intrinsic and extrinsic muscles of the foot rarely reveals weakness. Look for any subtle atrophy of the abductor hallucis or abductor digiti quinti muscles as compared to the opposite foot.

DIAGNOSTIC STUDIES

Electrodiagnosis

Carry out electrodiagnostic studies in all patients to support the diagnosis of tarsal tunnel syndrome. Only when these studies are abnormal, and combined with a history and physical examination consistent with a tarsal tunnel syndrome, can the diagnosis be made. Since Googold et al. (25) have established the electrodiagnostic criteria for tarsal tunnel syndrome, numerous authors have reported on the use of electrodiagnosis for tarsal tunnel syndrome (2,11,16,20,21,25,31,33,41,50,52). As work continues in this area, recommendations for the best method are constantly changing.

Electrodiagnostic tests fall into three broad categories: (a) nerve conduction studies of the medial and lateral plantar nerve, (b) measurement of motor-evoked potentials, and (c) sensory conduction velocity (42). Recent data suggest that the sensory nerve conduction velocity is the most accurate. Galardi et al. (21) found sensory action potential (SAP) to be abnormal in all affected limbs, thereby making it a very sensitive test. This coincides with the findings of Oh et al. (26), who found abnormal SAPs in 90.5% of their patients. Galardi et al. (21) were concerned about the poor specificity of pure sensory potentials. They studied mixed nerve action potentials (NAPs) and found them abnormal in 85.7% of the limbs with tarsal tunnel syndrome, with no abnormal studies in asymptomatic limbs or normal controls, making it very specific. They concluded that both SAPs and mixed NAPs are useful in the diagnosis of tarsal tunnel syndrome. They recommend that the coexistence of abnormal sensory and mixed nerve action potentials is highly sensitive and specific for diagnosis of tarsal tunnel syndrome.

Magnetic Resonance Imaging

Magnetic resonance imaging can accurately depict the contents of the tarsal tunnel and the courses of the terminal branches of the posterior tibial nerve (17). Most studies report that surgical outcome for tarsal tunnel syndrome is best when a definite lesion is identified (11,17,18,51,64). Frey and Kerr (10) noted positive MRI findings in 88% of symptomatic feet studied. They also noted positive MRI findings in 85% of the feet with abnormal electrodiagnostic studies. They concluded that the information provided by MRI could enhance surgical planning by indicating the extent of decompression required. Pfeiffer and Cracchiolo (61) suggest that, unless there is an identifiable lesion on MRI near or within the tarsal tunnel preoperatively, surgical decompression of the posterior tibial nerve should be considered with caution. Again, the diagnosis of tarsal tunnel syndrome is based on clinical and electrodiagnostic data. MRI is a useful adjunct when a space-occupying lesion is suspected.

PREOPERATIVE MANAGEMENT

Nonsurgical treatment depends heavily on the diagnosis and identification of a cause. Nonsteroidal anti-inflammatory medicines or an injection of a corticosteroid preparation can be tried if tenosynovitis is suspected. If a flexible foot deformity is found, an orthotic device can be helpful. If a lesion is found either on examination or on MRI, surgical decompression is indicated. If a patient's symptoms persist after nonsurgical treatment, and you strongly suspect compression or constriction of the posterior tibial nerve within the tarsal tunnel, surgery is also indicated.

OPERATIVE TECHNIQUE

There is no controversy about the surgical technique for decompression of the posterior tibial nerve within the tarsal tunnel. Identify and decompress the distal branches (i.e., the medial and lateral plantar nerves) at the same time.

- Approach the tarsal tunnel through a curved incision starting 10 cm proximal to the tip of the medial malleolus and 2 cm posterior to the medial tibial border. Carry the incision distal to the tip of the medial malleolus, then gently curve it distally and plantarward. Deepen the incision through the subcutaneous tissue to the level of the flexor retinaculum (laciniate ligament).
- Identify the retinaculum proximally. Note the tibialis posterior tendon in its sheath. The flexor digitorum longus tendon and posterior tibial nerve lie directly posterior to it. Open the retinaculum from proximal to distal. As you dissect distally, the retinaculum becomes more thick and taut. Place a curved clamp under the retinaculum, and release it completely.
- Bluntly dissect the posterior tibial nerve from proximal to distal. Note the condition of the nerve as well as any compression along its course. If the normal amount
of perineural fat is present, it should be preserved.

- Trace the medial plantar nerve distally to where it enters into a fibrous tunnel. If the nerve is felt to be compressed at this point, open the tunnel and release the nerve.
- Then trace the lateral plantar nerve distally to where it courses deep to the abductor hallucis muscle. The dorsal portion of the muscle often requires release to decompress the nerve branch. Identify the first branch off the lateral plantar nerve, the nerve to the abductor digiti quinti, as it courses deep to the deep investing fascia encompassing the abductor hallucis muscle. This is discussed in more detail later in this chapter.
- Release the tourniquet to obtain hemostasis. Observe whether the nerve’s normal color returns or if there is a pale area from chronic constriction. Note in the operative report if the nerve appears abnormal, for prognostic purposes. Then close the wound in layers, without repairing the retinaculum. Apply a sterile soft dressing and place a well-padded posterior splint.

GENERAL REHABILITATION AND POSTOPERATIVE PRINCIPLES

Do not allow weight bearing for 3 weeks, then allow a removable walking cast for an additional 3 weeks. During that time, the patient may remove the cast and start early range-of-motion exercises. Physical therapy is rarely indicated. Patients may increase activities as tolerated after 6 weeks.

RESULTS

Overall, superior results are seen when an obvious lesion is identified and treated. If no specific etiology can be identified, approximately 75% of patients obtain relief but 25% obtain little or no relief (42). It is rare for a patient to be more symptomatic following uncomplicated tarsal tunnel release. In 1990, Cimino (11) reviewed 24 articles and compiled the overall treatment results from these reports. Those data are summarized in Table 114.5.

![Table 114.5. Results of Tarsal Tunnel Treatment: Summary of 24 Reports](image)

Since Cimino’s review, Bailie and Kelikian (2) reported 72% patient satisfaction following surgery. They also noted an overall less-satisfied patient group in the presence of a worker’s compensation claim. Pleffer and Cracchiolo (51) reported only 44% patient satisfaction after surgery and cautioned against surgery unless an obvious lesion is identified.

GENERAL PITFALLS AND COMPLICATIONS

Most of the pitfalls associated with tarsal tunnel syndrome are related to misdiagnosis. Tarsal tunnel syndrome is a rare entity. It implies compression of the posterior tibial nerve or its branches within the tarsal tunnel. Pain or neuritis along the course of the posterior tibial nerve is not a tarsal tunnel syndrome. Peripheral neuropathy, often in conjunction with diabetes, can mimic tarsal tunnel syndrome, but surgical decompression will rarely be of benefit. Additional nerve lesions in the same lower extremity can affect the treatment outcome of tarsal tunnel syndrome. These additional lesions, which can occur anywhere along the course of the sciatic, common peroneal, posterior tibial, or plantar nerves, can be detected with electrodiagnostic tests as well as with a thorough history and physical examination (69). As noted, the best results occur when a specific mass or lesion is identified, either clinically or on an MRI scan. When a lesion is not identified, surgical decompression can still be of benefit, but the patient needs to understand that satisfactory outcomes occur only 75% of the time on average, or even less.

Electrodiagnostic studies and the criteria for diagnosing tarsal tunnel syndrome are ever changing. Patients are often referred with an electromyogram and/or nerve conduction velocity study with an interpretation by the examiner of a tarsal tunnel syndrome. The diagnosis is not made on electrodiagnostic studies alone. These studies serve only to support the clinical impression.

Surgical complications have been infrequently reported in the literature. A single case report of posterior tibial tendon dislocation following decompression has been published (37). One series reported an overall 13% complication rate, consisting of a hematoma, suture abscesses, superficial wound infections, and hypertrophic sensitive scars (4). Recurrent symptoms can occur after initial relief. They are believed to be secondary to adhesions or fibrosis around the nerve, rather than the formation of another lesion. An MRI may be quite useful to identify a possible surgical lesion. Revision surgery for tarsal tunnel syndrome is rarely beneficial and should be avoided if possible. This is especially true for the patient who did not obtain any relief from the first surgical decompression.

AUTHOR’S PERSPECTIVE

I believe that tarsal tunnel syndrome is a rare and overdiagnosed condition. If, after a thorough history and physical examination, you feel strongly that the patient’s symptoms are caused by compression of the posterior tibial nerve within the tarsal tunnel, obtain an electrodiagnostic study. Most recent reports indicate that a combination of SAPs and mixed NAPs is a highly sensitive and specific electrophysiologic indication for tarsal tunnel syndrome. Work closely with the person performing these tests and be familiar with their techniques and expertise. If the electrodiagnostic tests are consistent with the diagnosis, and a repeat history and physical examination are unchanged from the first ones, treat the patient for tarsal tunnel syndrome. If an extrinsic cause, such as varus or valgus of the hindfoot, is identified, carry out nonsurgical treatment accordingly. If after 3–6 months the treatment has not provided adequate relief, consider surgical decompression. If a lesion or mass is appreciated on physical examination, or is suspected, obtain an MRI to define the extent of the lesion. If a fracture or tarsal coalition is suspected, obtain a computed tomography scan to delineate the abnormality. Surgery is indicated if an expected lesion is identified. Revision tarsal tunnel surgery has poor results and I try to avoid it.

SURAL NERVE ENTRAPMENT

PATHOPHYSIOLOGY

The sural nerve is most often formed by the medial sural nerve, a branch of the tibial nerve. It may receive branches from the lateral sural nerve or the common peroneal nerve (Fig. 114.11). The sural nerve is accompanied by the short saphenous vein as they course lateral to the Achilles tendon. It passes 1.0–1.5 cm distal to the tip of the lateral malleolus. Readers interested in a detailed description of the anatomy and the many variations of the sural nerve are referred to Sarrafian’s textbook (59).
The sural nerve is well protected throughout its course, being surrounded by subcutaneous tissue, and is not subjected to sharp fascial edges or tight constricting bands. Coert and Dellon (13) identified a potential site of entrapment of the lateral sural nerve as it pierces through the deep vein fascia near the knee. As the knee is extended, the fascia can exert a compressive force on the nerve. Most sural neuro pathies, however, are either related to trauma (e.g., lacerations, fractures, ankle sprains) or external pressure (e.g., ganglia, Baker’s cyst). There are few reports in the literature regarding this entity. In 1974, Pringle et al. (53) reported four cases of sural nerve entrapment. Their report found a fracture at the base of the fifth metatarsal, a recurrent ankle sprain, and ganglion cysts to be underlying causes. Also, external compression of the nerve at different levels has been reported (57).

ASSESSMENT, INDICATIONS, RELATIVE RESULTS

The most reliable feature in making the diagnosis of sural nerve entrapment is a history of neurogenic pain in the distribution of the sural nerve. Often the symptoms occur only with athletic activities. Physical findings are often absent, so the history becomes paramount in making the diagnosis. On occasion one can palpate a mass or cyst, or identify an associated fracture, but more often the history is all there is to go on. Electrodiagnostic testing can be performed to help localize an area of compression if the physical examination is not helpful. Sensory nerve action potentials are reduced in the affected extremity and normal in the contralateral limb. If a mass is suspected, an MRI scan is useful to identify the extent and location of the mass.

PREOPERATIVE MANAGEMENT

Treatment is directed based on the underlying cause. If a history of external compression is identified, the symptoms resolve 1–2 months after removal of the offending cause (57). If the symptoms are secondary to trauma, a combination of casting or rest, nonsteroidal anti-inflammatory medicines, and observation is indicated. If nonsurgical methods fail to resolve the symptoms, consider surgery. A trial injection of a local anesthetic agent around the involved area with temporary resolution of symptoms preoperatively will increase the chance that surgery may help. If a mass or ganglion cyst is noted, surgical excision is indicated.

OPERATIVE TECHNIQUE

- Place the patient either supine or in the lateral position on the operating room table. A tourniquet may be used.
- Make a small incision over the involved area identified preoperatively. Carry out blunt dissection carefully down to the nerve. Excise the mass or release any compression.
- Transpose the nerve if external compression is the problem.
- At closure, cover the nerve with surrounding soft tissue and close the skin with interrupted suture. Apply a compressive dressing.

Postoperatively, the patient may increase activity as tolerated after the incision has healed.

DEEP PERONEAL NERVE ENTRAPMENT

PATHOPHYSIOLOGY

In the distal third of the leg, the deep peroneal nerve courses beneath the extensor hallucis longus muscle. As it approaches the ankle, it is located between the extensor hallucis longus tendon and the tendon of the extensor digitorum longus. It passes beneath the superior and inferior extensor retinacula, then divides into a medial and lateral branch. The medical branch accompanies the dorsalis pedis artery, and it divides into two dorsal branches that supply the first web space (Figs. 114.12, 114.13). Just distal to the inferior retinaculum, the lateral branch penetrates and innervates the extensor digitorum brevis (EDB) muscle. These terminal branches of the peroneal nerve may become compressed beneath the inferior extensor retinaculum. Marinacci (45) called this entrapment the anterior tarsal tunnel syndrome. Since that time, there have been scattered case reports in the literature (1,10,23,35,54), with the largest series being reported by Dellon (14).

ASSESSMENT, INDICATIONS, RELATIVE RESULTS

Most patients reported in the literature have been women. A history of trauma can often be elicited. Shoe straps or tight-fitting boots, such as ski boots, that cross the dorsum of the foot may irritate the nerve and lead to compression of the deep peroneal nerve (Fig. 114.13). Classically, patients complain of a deep ache over the dorsal and plantar aspects of the foot, with paresthesias into the first web space. Symptoms can range from exacerbation with activities and relief with rest, to night pain that awakens the patient. Physical findings include decreased sensation in the first web space, a positive nerve percussion sign (Tinel’s) over the course of the deep peroneal nerve, and atrophy of the EDB muscle. Often, however, only a few—if any—of these signs are present. There are a couple of reasons that atrophy of the EDB may be lacking despite the presence of a true anterior tarsal tunnel syndrome. If the entrapment occurs distal to the take-off of the motor branch, a pure sensory neuropathy occurs. If the motor branch is involved, atrophy and weakness of the EDB may be seen. Another reason is that in 22% of patients the accessory deep peroneal nerve, a branch of the superficial peroneal nerve, innervates the EDB (57,58,43). In these cases, entrapment of the deep peroneal nerve would not manifest as denervation of the EDB muscle.
Electrodiagnostic abnormalities include prolonged distal latencies of the peroneal nerve (Table 114.6) and needle findings described as representing “denervation” changes confined to the EDB muscle. Gessini et al. [73] have suggested that a distal latency of greater than 5 msec confined to the deep peroneal nerve is important in making the diagnosis. Because abnormal needle findings in the EDB muscle have been reported in a high number of normal subjects [1], one must be cautious about using this as the sole criterion for making a diagnosis.

| Table 114.6. Anterior Tarsal Tunnel Syndrome |

A helpful diagnostic maneuver is to inject 3 ml of 1% Xylocaine without epinephrine into the dorsal aspect of the foot proximal to the cuneiform bones. This should provide complete, but temporary, relief of symptoms. This nerve block is recommended prior to surgery in any patient for whom the diagnosis is not clear based on history and physical examination.

PREOPERATIVE MANAGEMENT

Nonoperative management is directed toward the underlying cause. Whatever the treatment, it should be tried for at least 3 months before considering surgery. If shoewear is identified as the problem, alterations can help. Adjusting tight ski boots is possible and would be optimal compared to surgery. Providing relief from straps (e.g., over a bone prominence) should also be tried before surgery. Alteration in athletic or daily activities as well as nonsteroidal anti-inflammatory medications can provide relief of symptoms. If these treatment modalities fail, operative intervention is indicated.

OPERATIVE TECHNIQUE

- Place the patient supine on the operating room table. Administer regional or general anesthesia. Operate with or without a tourniquet.
- Make a dorsal incision over the proximal first metatarsal, then curve it laterally between the junction of the first and second metatarsals with the cuneiforms. Extend the incision proximally to the level of the inferior extensor retinaculum.
- Identify the extensor hallucis brevis tendon crossing the nerve at this point. Release this tendon, identify the deep peroneal nerve, and dissect both proximally and distally until the medial and lateral branches are exposed (Fig. 114.14). Release only a portion of the inferior retinaculum to make sure the nerve is not compressed.
- Examine the nerve. If salvageable, perform a neurolysis. If crushed or not deemed salvageable, resect it. If the nerve is resected, dissect it proximally and bury the nerve end into the muscles of the anterolateral compartment and secure it with 5-0 nylon suture [15]. This prevents traction on the nerve end with ankle motion.
- If there is an underlying exostosis or bone fragment, excise it.
- Close the skin with interrupted sutures and apply a compressive dressing.

SUPERFICIAL PERONEAL NERVE ENTRAPMENT

PATHOPHYSIOLOGY

The superficial peroneal nerve is a branch of the common peroneal nerve. It innervates the peroneus longus and brevis muscles in the lateral compartment of the leg. The nerve is most predictably found about 10.5 cm proximal to the tip of the lateral malleolus as it pierces the fascia in the distal anterolateral leg. Because of its subcutaneous position as it courses between the peroneal muscles and the extensor digitorum longus, it is especially prone to injury at this site. The superficial peroneal nerve then divides into two terminal sensory branches to form the medial dorsal cutaneous and intermediate dorsal cutaneous nerves (Fig. 114.15).
Figure 114.15. Superficial layer of the dorsum of the foot and ankle. 1, Superficial peroneal nerve; 2, intermediate dorsal cutaneous nerve; 3, medial dorsal cutaneous nerve; 4, dorsal cutaneous nerve to fourth web space; 5, dorsal cutaneous nerve to third web space; 6, dorsal cutaneous nerve to second web space with branch to dorsum of big toe; 7, dorsomedial cutaneous nerve to big toe; 8, nerve branch from deep peroneal nerve to first interspace; 9, sural nerve; 10, saphenous nerve; 11, dorsal venous arcades; 12, lesser saphenous vein; 13, greater saphenous vein; 14, dorsal metatarsal veins; 15, stem of inferior extensor retinaculum; 16, superomedial band of inferior extensor retinaculum; 17, inferomedial band of inferior extensor retinaculum.

Patients usually report paresthesias over the dorsum of the foot, sparing the first web space. The symptoms have typically been present for years and are worse with activities such as walking, jogging, or running. Patients also complain of pain over the lateral distal leg and lateral ankle. About 25% of the patients report a prior history of trauma, mostly ankle sprain. Injury to the nerve has also been reported following fibular shaft fractures, or compression by a lipoma (3,40,47,62).

As with all compression syndromes of the foot and ankle, start the physical examination with examination of the back, and look for any sciatic tension signs. Examine the common peroneal nerve around the fibula head for any swelling or a positive Tinel’s sign that reproduces the location and quality of the patient’s complaints. The most common area of entrapment is where the superficial peroneal nerve pierces the deep fascia approximately 10.5 cm proximal to the tip of the fibula. Point tenderness and a positive Tinel’s sign is often elicited at this site. Styf and Morberg (53) described three provocative tests for detection of nerve compression, which are undertaken at rest and then again after exercise. In the first, pressure is applied over the anterior intermuscular septum while the patient actively dorsiflexes the ankle. In the second, the foot is passively planar flexed and inverted at the ankle. The third test is performed by applying passive stretch with inversion, and percussing over the course of the nerve. Pain or paresthesia caused by any of these tests suggests entrapment of the superficial peroneal nerve. According to the authors’ diagnostic criteria, entrapment of the superficial peroneal nerve is diagnosed when sensation over the dorsum of the foot is decreased and there is pain at rest or during exercise, and when at least two of the three provocative tests are positive.

PREOPERATIVE MANAGEMENT

As with the other entrapment or compressive neuropathies, a trial of activity modification, anti-inflammatories, and an ankle strap or orthotic device may prove useful. If this fails, operative management is indicated.

Preoperatively, identify the etiology and site of compression or entrapment. If a mass is present, an MRI scan can help localize it. By examination, identify the area(s) of compression by the provocative tests and map this area out.

OPERATIVE TECHNIQUE

- Place the patient in the supine position under general or regional anesthesia. Use a thigh tourniquet.
- Make a 8 cm incision just dorsal to the previously marked painful sites. Carry the incision bluntly through the subcutaneous tissue and identify the superficial peroneal nerve exiting the deep fascia.
- Incise the roof of the peroneal tunnel longitudinally until the nerve enters the muscle belly of the peroneal longus. Keep the incision close to the anterior intermuscular septum (Fig. 114.16).
- Thoroughly decompress the nerve.
- After the nerve is freed from any surrounding pressure, close the skin with interrupted sutures.

Allow the patient to bear weight in a walking boot the following day.

PLANTAR NERVE ENTRAPMENT

PATHOPHYSIOLOGY

Painful conditions about the heel are common, and the differential diagnosis is extensive. One cause of a painful heel syndrome is an entrapment neuropathy of one of the branches of the tibial nerve (4,5,23). The first branch of the lateral plantar nerve has been implicated as a source of heel pain. It supplies the abductor digiti quinti muscle on the lateral side of the foot. Distal to the laciniate ligament (flexor retinaculum), the tibial nerve divides into four or five branches. There are one or two superficial branches, called the medial calcaneal nerves. The medial and lateral plantar nerves, as well as the nerve to the abductor digiti quinti, then course deep to the abductor hallucis muscle. The nerve to the abductor digiti quinti may be a separate branch of the tibial nerve or arise as a branch of the lateral plantar nerve (Fig. 114.17). It passes beneath the thick, inelastic, deep fascial edge of the abductor hallucis muscle, where it can become compressed. The nerve continues laterally, deep to the origin of the plantar fascia and flexor digitorum brevis muscle, and terminates in the proximal portion of the abductor digiti quinti.

Figure 114.17. A: Nerve to abductor digiti quinti muscle as it migrates under the deep fascia of the abductor hallucis muscle. This nerve is deeper than the more
superficial calcaneal nerve. B: Plantar view of nerve coursing to the abductor digiti quinti muscle.

ASSSESSMENT, INDICATIONS, RELATIVE RESULTS

Patients with painful heel syndrome typically complain of heel pain exacerbated by weight bearing. Pain is worse with the first step in the morning or on arising after a period of rest. The onset is often gradual, and a history of competitive sports is present in 50% of the cases. In contrast to other patients with heel pain who are generally older, heavier, and less active, those with nerve compression as the etiology are younger and more athletic. This patient often has had symptoms for many months or years before seeking medical attention. The pain normally starts medially but can radiate laterally. Rarely does the patient complain of numbness or paresthesias into the foot.

Physical examination reveals tenderness over the origin of the abductor hallucis muscle. Tenderness over the medial tubercle of the calcaneus is a common finding as well. A Tinel’s sign is often lacking, but on occasion one can elicit radiation of pain to the lateral side of the foot. Electrodiagnostic studies can be useful as an adjunct to the history and physical examination for entrapment of the nerve to the abductor digiti quinti (60). However, the exact criteria and best method are yet to be determined.

PREOPERATIVE MANAGEMENT

Even if entrapment of the nerve to the abductor digiti quinti is suspected as a cause of a patient’s symptoms, treat nonoperatively for 6 to 12 months. The treatment is much the same as for heel pain syndrome caused by plantar fasciitis. This includes education, stretching, heel cups, over-the-counter or custom-molded orthoses, nonsteroidal anti-inflammatory medications, and alteration in athletic shoes and/or activity.

OPERATIVE TECHNIQUE

Baxter and coworkers reviewed their experience with the operative results of 69 heels in 53 patients with recalcitrant heel pain who had failed a minimum of 6 months of conservative therapy. Their surgical technique is outlined below (4, 5, 42).

- Place the patient in the supine position on the operating table. Administer anesthesia, typically an ankle block. A tourniquet is not required but can be used.
- Make a 4 cm oblique incision on the medial aspect of the heel over the proximal abductor hallucis muscle. Center the incision over the course of the first branch of the lateral plantar nerve. The incision is oblique and placed distal to the medial calcaneal sensory nerves.
- Divide the superficial fascia of the abductor hallucis muscle with a #15 blade and retract the muscle superiority with a small retractor.
- Remove a section of the deep fascia along the inferior border of the abductor hallucis directly over the area where the nerve is compressed between the taut fascia and the medial border of the quadratus muscle. A small portion of the medial plantar fascia may be removed to facilitate exposure and clearly define the plane between the deep abductor fascia and the plantar fascia (Fig. 114.18).

**Figure 114.18.** A section of deep fascia of the inferior abductor abductor hallucis muscle is removed directly over the area where the nerve is compressed between this taut fascia and the medial border of the quadratus plantae muscle.

- Remove a heel spur, if present, taking care to protect the nerve that runs superiorly with a Freer elevator. Leave intact the abductor hallucis muscle belly and its superficial fascia.
- Do not perform an extensive plantar fascia release unless on direct examination there is evidence of pathology in the entire proximal portion of the plantar fascia.
- Close the wound with interrupted sutures and apply a bulky dressing.

Postoperatively, place patients on crutches, and do not allow weight bearing for 3–4 days. Then begin gradual weight bearing. Dress the wound daily with antibiotic ointment and apply gauze. One week postoperatively, the patient can try to put on an athletic shoe with a soft heel pad. The patient can resume light jogging by 4 weeks, but some symptoms persist for 3 months.

CHAPTER 115

ARTHRODESES OF THE FOOT AND ANKLE

Roger A. Mann and Jeffrey A. Mann

INTRODUCTION

The basic principle of an arthrodesis is to correct a painful, deformed, or unstable joint to produce a painless plantigrade foot. This is achieved by resecting the articular surfaces, correcting malalignment, and then using an appropriate method of internal fixation to provide interfragmental compression at the arthrodesis site. The use of bone graft is usually not necessary in doing an arthrodesis unless a defect is present. Adequate postoperative immobilization is necessary to ensure that fusion occurs.

PRINCIPLES OF TREATMENT

An arthrodesis is a surgical technique by which the articular surfaces of the bones comprising a joint are removed and bone union (fusion) is attempted, thereby effectively eliminating the motion that normally occurs in the joint. Mobility of the adjacent joints should be maintained whenever possible. Mobility of the joints of the foot and ankle aids in shock absorption at the time of initial ground contact and in producing stability within the foot at the time of heel rise and toe off. Shock absorption within the ankle occurs through dorsiflexion and plantar flexion, in the subtalar joint by eversion at the time of initial ground contact, and at the transverse tarsal joint by its flexibility at initial ground contact. Even the tarsometatarsal joints have some motion that helps to absorb stress.

Although a fusion is sometimes necessary to alleviate a patient’s problem, the extent of the fusion should be minimized. If only the subtalar joint is involved, then only the subtalar joint should be fused rather than performing a triple arthrodesis. The motion of the subtalar joint depends on movement within the talonavicular and calcaneocuboid joints (transverse tarsal joint). If the talonavicular joint is arthrodesed, motion of the subtalar joint is essentially eliminated. An isolated calcaneocuboid joint arthrodesis still permits about two thirds of subtalar motion. An arthrodesis of the subtalar joint, however, permits motion to occur within the transverse tarsal joint (abduction-adduction). Although the degree of motion within the midfoot area, namely the intertarsal and tarsometatarsal joints, is minimal, arthrodesis in these joints creates a rigid midfoot and forefoot so that there is little or no accommodation of the forefoot to the ground during stance phase. Therefore, in attempting a fusion of this type, line up the forefoot as anatomically as possible to create a plantigrade forefoot.

The indications for an arthrodesis are to alleviate a painful joint, to correct a deformity, to produce stability, or a combination of these. The pain in the joint is usually caused by arthrosis, whether it be degenerative, traumatic, rheumatoid, or of undetermined etiology. When the articular surfaces are no longer congruent, or the articular cartilage has deteriorated, intractable pain often results. Because the foot is a weight-bearing structure with stress constantly applied to it, the pain may result in considerable disability. Although some of these problems can be managed conservatively with an orthotic device, eventually an arthrodesis is required.

An arthrodesis is often used to correct a deformity of the foot or ankle to produce a plantigrade foot. At times the deformity may cause pain resulting from an abnormal weight-bearing pattern that places too much stress on a localized area of the foot. Sometimes after trauma, such as a severe calcaneal fracture, an explosive-type fracture of the naviculare, or a Lisfranc fracture-dislocation, a significant deformity may result that can be corrected with an arthrodesis.

A neurologic deficit such as peroneal weakness in Charcot-Marie-Tooth disease, a dropfoot secondary to a peroneal nerve palsy, or a deficit following a compartment syndrome or poliomyelitis may produce instability about the foot so that the foot cannot support the body weight. The instability may be produced by rupture of a tendon, such as the posterior tibial or the peroneal tendon. In such cases, a significant degree of instability and possibly a deformity may result that again may cause pain because of instability. In all of these cases, an arthrodesis may be used to realign the architecture of the foot to produce a plantigrade foot that will enable the patient to ambulate with increased stability and little or no pain.

When an arthrodesis about the foot and ankle is contemplated, several factors must be carefully considered. The soft tissue covering the foot and ankle is such that there is often little or no fatty tissue present. Therefore, the surgical approach must be as precise as possible to avoid having to place undue tension on the skin at the time of surgery, for fear that a slough might occur. The skin flaps created must be full thickness with as little undermining as possible. Keep in mind the location of the cutaneous nerves about the foot and ankle. A technically good arthrodesis may not satisfy the patient if a cutaneous nerve is caught up within the scar tissue or sensation is impaired distally as the result of a cut nerve, making it difficult for the patient to wear shoes comfortably. The major mixed nerves running into the foot are susceptible to being cut or stretched, resulting in loss of function.

When considering an arthrodesis, decide whether the arthrodesis should be an in situ fusion or one that requires realignment. An in situ fusion, no change in the overall position of the extremity is made; when realignment is required, the deformed extremity must be carefully examined and compared with the normal side. In this way, the overall alignment of the limb (in regard to the varus-valgus alignment of the hindfoot and forefoot) and the degree of rotation (internal and external) of the extremity are determined. When an arthrodesis is performed, restore normal alignment as much as possible.

Bone preparation for an arthrodesis about the foot and ankle is the same as that for other joints: to ensure the best possible chance for fusion, broad surfaces of cancellous bone must be brought into apposition. When a realignment arthrodesis is being performed, achieving broad bony surfaces is not difficult because a sufficient amount of bone is removed during realignment of the joints. If, however, an isolated talonavicular or calcaneocuboid joint fusion is carried out and too much bone is removed from one side of the foot, a forefoot deformity could result because of shortening of the medial or lateral column. In this situation, adequate bony contact may be impossible without incorporation of some type of bone graft.

Some surgeons prefer to perform an arthrodesis by adding bone graft, obtained either locally or from the iliac crest. Local bone graft may be obtained just above the medial malleolus and from the calcaneus. This is preferable to an iliac crest bone graft. The graft may be in the form of a dowel or a rectangle of bone to be inlaid or placed between the bone surfaces. Regardless of the type of fusion contemplated, the most important factor is careful surgical technique to remove the cartilage and subchondral bone so that there is good cancellous bone contact, which, with good internal fixation, should then proceed to a satisfactory fusion.

Once the bone work has been completed, some type of internal fixation is usually necessary, such as pins, plates, staples, or screws. The type of fixation depends on the surgeon’s preference and the type of fusion. The following sections on each specific fusion discuss our own methods, but there are many ways to carry out an arthrodesis and insert internal fixation. Ours is based on our experience as foot and ankle surgeons.
The preoperative management of an arthritic joint about the foot and ankle involves careful assessment of the patient’s problem. After obtaining a history from the patient regarding the complaint, perform a physical examination to look at the alignment of the entire lower extremity. Assess the range of motion of the ankle, subtalar, transverse tarsal, and metatarsophalangeal joints. Observe the posture of the foot to see if the foot is plantigrade and, if not, the reason for the abnormality. There may be multiple joint ankylosis, as in the rheumatoid patient with involvement of the knee, ankle, subtalar, and transverse tarsal joints. Assess the quality of the skin because adherent skin or multiple scars may make it difficult to expose the arthrodesis site safely. Last, assess the neurovascular status of the foot and, if there are questions about the adequacy of the circulation, do arterial Doppler studies.

The conservative management of an arthritic joint usually requires an ankle-foot orthosis to immobilize a joint or accommodate a deformity. As a general rule, however, most patients with significant arthrosis are not comfortable in the long term with an orthotic device and will usually require fusion.

**PREOPERATIVE PLANNING**

The preoperative planning of an arthodesis is extremely important. Assess the involved joint or joints and decide on the extent of fusion required. Minimize the number of joints to be fused to maintain maximum flexibility of the foot and ankle. Decide whether an in situ fusion will be adequate or if some type of correction of a deformity needs to be achieved to create a plantigrade foot.

Last, inform the patient about the nature of the surgical procedure, including the possibility of failure of the procedure, particularly of a nonunion.

**ANKLE ARTHRODESSES**

An arthodesis of the ankle joint is performed for arthrosis of the joint, malalignment, or both. There are many ways to carry out an arthodesis of the ankle joint; one we describe here is the transfibular approach, which we believe is the most utilitarian type of fusion. Some authors advocate doing an in situ fusion arthroscopically, but this should be attempted only by a very experienced arthroscopist. Most authors who initially touted this method of fusion now utilize a limited approach to the ankle joint rather than carrying it out arthroscopically. The most important factor in carrying out an ankle arthrodesis is the alignment. The alignment of the ankle joint should always be matched to the uninvolved normal side. The planes of alignment include (a) dorsiflexion–plantar flexion, (b) internal and external rotation, (c) varus–valgus, (d) medial–lateral displacement, and (e) anterior–posterior displacement. These five planes must be taken into consideration when carrying out an ankle arthrodesis.

- Approach the ankle joint through a transfibular approach, which starts over the lateral aspect of the fibula approximately 10 cm above the tip of the malleolus and carries distally along the lateral side of the foot toward the base of the fourth metatarsal. Create full-thickness dorsal and plantar flaps in this intermuscular plane down to bone. Continue subperiosteal dissection over the anterior aspect of theibia and ankle joint to the neck of the talus.

---

**SURGICAL TECHNIQUES**

**ANKLE ARTHRODESES**

An arthodesis of the ankle joint is performed for arthrosis of the joint, malalignment, or both. There are many ways to carry out an arthodesis of the ankle joint; one we describe here is the transfibular approach, which we believe is the most utilitarian type of fusion. Some authors advocate doing an in situ fusion arthroscopically, but this should be attempted only by a very experienced arthroscopist. Most authors who initially touted this method of fusion now utilize a limited approach to the ankle joint rather than carrying it out arthroscopically. The most important factor in carrying out an ankle arthrodesis is the alignment. The alignment of the ankle joint should always be matched to the uninvolved normal side. The planes of alignment include (a) dorsiflexion–plantar flexion, (b) internal and external rotation, (c) varus–valgus, (d) medial–lateral displacement, and (e) anterior–posterior displacement. These five planes must be taken into consideration when carrying out an ankle arthrodesis.

- Approach the ankle joint through a transfibular approach, which starts over the lateral aspect of the fibula approximately 10 cm above the tip of the malleolus and carries distally along the lateral side of the foot toward the base of the fourth metatarsal. Create full-thickness dorsal and plantar flaps in this intermuscular plane down to bone. Continue subperiosteal dissection over the anterior aspect of theibia and ankle joint to the neck of the talus.

---

**HINTS AND TRICKS**

- The fibular cut ends approximately 1.5 to 2.0 cm proximal to the level of the ankle joint.

Figure 115.1. Ankle arthrodesis. A: Placement of the incision between the superficial peroneal nerve and the sural nerve. Note that the incision ends near the base of the fourth metatarsal. B: Cuts made in the fibula, distal end of the tibia, and talus. This creates the flat, bony surfaces at the arthrodesis site. The fibular osteotomy is conducted along the lateral aspect of the fibula to free up the distal tibial fragment to prevent fracture of the medial malleolus when this bone fragment is removed. Return now to the lateral wound and remove the distal tibial fragment in its entirety. It is important that this cut be brought all the way across to the lateral aspect of the medial malleolus.

---

**INSERT THE SCREW**

- Insert the screw by first drilling a hole with a 3.2-mm drill bit in the sinus tarsi as obliquely as possible to gain the maximum amount of compression across the arthrodesis.

---

**PLACEMENT OF THE SCREW**

- Place the foot into a plantigrade position, insofar as dorsiflexion–plantar flexion and varus–valgus are concerned.

---

**POSTOPERATIVE CARE**

- If there is some motion, insert a third screw from the tibia, either medially or laterally, into the talus.

---

**INTERNAL FIXATION**

- If it appears that the cut fragment is too thick and a fracture of the medial malleolus may occur, make a second approach along the anterior medial aspect of the joint. Make an anterior medial longitudinal incision over the ankle joint and carry it distally and obliquely around the medial malleolus.

---

**EXTERNAL FIXATION**

- If at this time there is a gap between the talus and the distal tibial cut, the medial malleolus is likely keeping the joint space from collapsing. In this situation, remove the distal 6 to 8 mm of medial malleolus by cutting all soft tissue attachments, avoiding injury to the posterior tibial tendon, artery, and nerve. Once this piece of medial malleolus has been removed, the joint space will readily collapse.

---

**PRESERVE THE MEDIAL MALLEOLUS**

- With the foot held in neutral dorsiflexion–plantar flexion and about 5° of valgus, excise the dome of the talus with a saw cut that parallels the surface of the talus. Excise approximately 3 to 4 mm of talus. Once this has been achieved, there should be a good bony apposition between the two cut surfaces, and the foot should be in a plantigrade position.

---

**PLACE THE MALLEOLOGO人は欠けている**

- Remove the remaining articular cartilage along the lateral side of the distal malleolus and medial side of the talus.

---

**PLACE THE SCREW**

- If the tibia is sclerotic, make multiple drill holes. Place the two broad, flat surfaces of the tibia and talus together so that the anterior cut of the talus matches the anterior aspect of the cut in the tibia. In this way, the normal posterior contour of the heel is achieved.

---

**CHECK FOR REDNESS**

- Check rotation by palpating the patella and rotating the foot into the predetermined degree of external rotation as well as the varus and valgus position of the hindfoot. Use 2.0 0.062-in. K-wires for preliminary fixation of the arthrodesis.
drill bits have been inserted, there is good stabilization of the arthrodesis site.

- Remove the first drill bit, measure and tap the hole, and insert a 6.5-mm long threaded screw. The screw must engage the medial cortex of the tibia to gain maximum interfragmentary compression.
- Next, remove the second drill bit and insert the next screw.

**Postoperative Care**

When closing the wounds, place a small drain and apply a short-leg compression dressing incorporating plaster splints. Approximately 10 days following surgery, remove the dressing. Remove the sutures and apply a short-leg, non-weight-bearing cast for 6 weeks. At 6 weeks, if on radiographs the arthrodesis site appears to be making satisfactory progress. Apply a short-leg weight-bearing fiberglass cast for another 6 weeks. As a general rule, the arthrodesis is solidly healed by 12 to 16 weeks (Fig. 115.2).

*Figure 115.2.* Radiographs demonstrating ankle arthrodesis utilizing the technique described in the text. On the AP view (B), note that the screws engage the medial cortex to maximize interfragmentary compression. It is also important that the threads are past the fusion site.

**SUBTALAR ARTHRODESES**

Arthrodesis of the subtalar joint is used to treat arthrosis of the subtalar joint secondary to trauma, rheumatoid arthritis, or a subtalar coalition (19,22,27,29). Sometimes a subtalar arthrodesis is necessary to treat instability of the subtalar joint secondary to rupture of the posterior tibial or peroneal tendons or because of a marked valgus deformity secondary to collapse of the talonavicular joint as a result of rheumatoid arthritis.

When performing a subtalar arthrodesis for a calcaneal fracture, evaluate whether any lateral impingement is present between the calcaneus and fibula so that it can be corrected at the same time.

As a general rule, we prefer to perform a subtalar fusion without the addition of bone graft from another site, although sometimes when attempting to correct a severe valgus deformity of the subtalar joint, a bone graft may be required to fill the gap created along the lateral aspect of the joint. In the occasional patient with severe collapse of the calcaneus secondary to trauma, we insert a bone block to restore the anatomic relationship between the talus and calcaneus.

- Begin the skin incision at the tip of the fibula and carry it distally just proximal to the base of the fourth metatarsal (Fig. 115.3). The incision should be dorsal to the sural nerve, although a smaller anterior branch may be present that should be looked for and protected. Carry the incision down to the fascia overlying the extensor digitorum brevis muscle. Detach the origin of the muscle from the lateral aspect of the subtalar joint and reflect it distally to the level of the calcaneocuboid joint.

*Figure 115.3.* A: Incision for subtalar fusion; shaded area indicates bone to be resected. B: Correction of varus deformity.

- Visualize the subtalar joint by removing the fat pad from the sinus tarsi and stripping the joint capsule along the lateral side of the posterior facet to delineate the posterior facet and anterior aspect of the subtalar joint.
- Facilitate exposure of the posterior facet by using a lamina spreader in the sinus tarsi to open the joint. Use a sharp curet to methodically remove the articular cartilage from the entire posterior facet and by reaching across the sinus tarsi, the middle facet.
- Remove the lamina spreader and assess the alignment of the subtalar joint. The fusion should place the subtalar joint in 5° to 7° of valgus in relation to the long axis of the lower extremity.
- If in situ fusion is to be achieved, feather the bone with a small osteotome and insert internal fixation. If a varus deformity needs to be corrected, remove a wedge of bone 3 to 5 mm in width from the lateral aspect of the posterior facet to realign the hindfoot. If a valgus deformity is to be corrected, a piece of iliac crest bone used as a strut in the subtalar joint may be necessary.
- When an in situ fusion is done, local bone graft can be acquired by harvesting the anterior process of the calcaneus, avoiding the articular surface of the calcaneocuboid joint. This can be morselized and packed into the sinus tarsi. If more bone graft is required, then we obtain the graft above the medial malleolus.
- Feather the bone surfaces of the posterior and middle facets and sinus tarsi with a 4- or 6-mm osteotome. This elicits a healing response, increases the bony surfaces, and increases the chances of successful fusion.
- For internal fixation, we perform a 7.0-mm full-threaded cannulated screw inserted from the posterior aspect of the calcaneus just off the weight-bearing area to the neck of the talus. We overdrill the calcaneus with a 7.0-mm drill to create a glide hole to achieve intrafragmentary compression between the talus and calcaneus.
- Insert a guide pin from the posterior inferior aspect of the calcaneus about 1 cm above the weight-bearing area utilizing an anterior cruciate guide device to direct the guide pin into the posterior facet of the subtalar joint approximately in the midline and about 3 to 5 mm posterior to the anterior edge of the posterior facet. This ensures that the screw remains within the posterior facet rather than traversing the sinus tarsi.
- Once the guide pin has been placed in the calcaneus, remove the anterior cruciate guide, manipulate the calcaneus into 5° of valgus, and insert the guide pin into the neck of the talus. Use fluoroscopy to ensure proper placement of the guide pin. The guide pin should be entirely within the posterior facet of the subtalar joint and in the neck of the talus. The advantage of this technique is that with only a guide pin in place, the alignment of the subtalar joint can be checked to be certain that it is correct. If the alignment is not satisfactory, back out the guide pin, reposition the calcaneus, and reinsert the guide pin.
- Once the alignment is satisfactory, make a transverse incision on the heel along the pin in the calcaneus. Make this incision large enough to easily seat a washer, achieving excellent interfragmentary compression.
- If by chance there is any rocking or motion at the subtalar joint, insert a 1/8-inch smooth Steinmann pin for additional fixation. This is very rarely needed.
- Check the length of the screw by fluoroscopy, and if it is satisfactory, remove the guide pin.
- Pack bone graft into the sinus tarsi.
- Suture the extensor digitorum brevis back to its origin and close the skin.
- Apply a short-leg compression dressing incorporating plaster splints.
HINTS AND TRICKS

- Under certain circumstances following a calcaneal fracture, when there is lateral impingement of the calcaneus against the fibula, the lateral wall of the calcaneus is removed in line with the lateral aspect of the articular surface of the talus. In this way, the peroneal tendons are decompressed. This bone can be utilized for bone graft if necessary.

Postoperative Care

Ten days following surgery, remove the postoperative cast. Remove sutures and apply a short-leg non-weight-bearing cast, which is kept in place for 6 weeks. At 6 weeks, if satisfactory healing of the arthrodesis is seen on radiographs, permit walking in the short-leg walking cast for another 6 weeks. Solid fusion usually occurs by 10 to 12 weeks (Fig. 115.4).

Figure 115.4. Radiograph demonstrating a subtalar fusion utilizing the technique described in the text.

TALONAVICULAR JOINT FUSION

Talonavicular joint fusion is performed for arthrosis of the talonavicular joint that may be caused by trauma or degenerative or rheumatoid arthritis (11). Subluxation of the talonavicular joint secondary to rheumatoid arthritis or posterior tibial tendon dysfunction is also an indication for an isolated talonavicular fusion (6,15). As a general rule, if the patient is older than 50 years of age, an isolated fusion is probably adequate. If the patient is younger than 50 years old or is very active, the calcaneocuboid joint should be included for increased stability. Careful evaluation is necessary to determine whether an isolated talonavicular fusion will achieve satisfactory realignment of the foot or whether the calcaneocuboid and/or subtalar joints should also be incorporated. If it seems that too much bone will be removed from the medial column when doing the talonavicular fusion, thereby producing an adducted position, always include the calcaneocuboid joint so that a balanced foot will result. Keep in mind that fusion of the talonavicular joint renders the subtalar joint nonfunctional. Therefore, it is essential that the subtalar joint be placed in 5° of valgus when the talonavicular joint is fused; otherwise a nonplantigrade foot will result.

Approach the talonavicular joint medially. Start the incision about 1 cm distal to the tip of the medial malleolus and carry the incision along the midline of the foot to the naviculocuneiform joint (Fig. 115.5). In this area there are no superficial nerves of significant concern. Some surgeons prefer to make a slightly dorsally curved incision to approach the talonavicular joint, which is also satisfactory. When making a slightly dorsally curved incision, avoid injury to the saphenous nerve, which accompanies the saphenous vein.

Figure 115.5. Incision for talonavicular fusion.

- Palpate the talonavicular joint to be certain the proper joint is being exposed, because confusion can arise in this area. Once the talonavicular joint is identified, strip the capsular tissue along its medial aspect and then onto its dorsal and plantar aspects.
- If dorsal spurs are present, remove them. Decortication of the talonavicular joint is sometimes difficult because of limited exposure. It is often helpful to place a large towel clip into the medial aspect of the navicular and pull the foot into a slightly adducted position, which facilitates exposure of the joint.

HINTS AND TRICKS

- In a large person, a 7.0-mm cannulated screw can be utilized.
- Where poor bone stock is present, multiple staples from a power stapilizer can be used.
- Meticulously remove all of the articular cartilage. Once this is achieved, heavily feather the talar head and the navicular.
- Manipulate the foot to assure that there will be adequate bony apposition when the foot is placed into a plantigrade position. If too much adduction will occur without bone grafting, insert bone graft or include the calcaneocuboid joint in the fusion.
- We prefer fixation with two 4.0-mm cannulated screws inserted from the naviculocuneiform joint. Place the foot in a plantigrade position with the subtalar joint in 5° of valgus and the forefoot in neutral abduction–adduction. Correct any forefoot varus by plantarflexing the navicular on the head of the talus.
- Insert a guide pin across the talonavicular joint and a second guide pin just inferior to it. Verify the position on fluoroscopy.
- Insert two 4.0-mm cannulated screws with washers, which produce good interfragmentary compression.
- Close the wound in layers and apply a short-leg compression dressing incorporating plaster splints.

Postoperative Care

Remove the postoperative dressing and sutures at approximately 10 days and place the patient into a short-leg non-weight-bearing cast, which is changed 6 weeks after surgery. If there is radiographic evidence of healing at that time, allow ambulation in a short-leg walking cast for another 8 weeks. As a general rule, fusion occurs by 12 to 16 weeks (Fig. 115.6).
cavus deformity as well as a flat foot deformity. It is not within the scope of this section, however, to discuss all of the various types of triple arthrodeses.

A triple arthrodesis is used to realign the hindfoot for instability secondary to a neurologic deficit, a tendon rupture, arthrosis, or a deformity caused by rheumatoid arthritis. It can be used to correct a subluxation of the hindfoot because subtalar motion depends on rotation of the navicular on the talus and to a lesser degree the calcaneocuboid joint. The advantages of a double arthrodesis over a triple arthrodesis are that the former has decreased morbidity and there is one less joint to fuse.

Approach the talonavicular joint as previously described. Approach the calcaneocuboid joint through a longitudinal incision centered over the calcaneocuboid joint; make this incision cautiously because the sural nerve is in the area. Carefully identify and retract the sural nerve if possible. Deepen the incision to expose the calcaneocuboid joint and expose the joint subperiosteally. Sometimes the lateral aspect of the talonavicular joint can be decorticated through this incision as well.

If the procedure is to be done in situ, the alignment of the foot is not a significant problem, but if there is deformity, the joint surfaces must be realigned. Decorticate and feather the joint surfaces with a 4- or 6-mm osteotome, as previously described.

Before internal fixation, a plantigrade foot must be achieved because there will be no functional subtalar joint motion following the double arthrodeses. Place the subtalar joint in 5° of valgus, place the forefoot in neutral abduction–adduction, and correct any forefoot abnormality, particularly varus, by plantarflexing the navicular on the head of the talus.

Fix the talonavicular joint as described previously with two 4.0-mm cannulated screws or a 7.0-mm cannulated screw, or with multiple staples. We fix the calcaneocuboid joint with two 4.0-mm cannulated screws or multiple staples, depending on the quality of the bone.

After surgery, keep the patient in a short-leg compression dressing incorporating plaster splints.

### Postoperative Care

Change the postoperative dressing at about 10 days, remove sutures, and apply a short-leg, non-weight-bearing cast for 6 weeks. At this point, if there is radiographic evidence of healing, place the patient into a short-leg walking cast for another 6 weeks. Fusion usually occurs by 12 to 16 weeks.

A double arthrodesis is a fusion of the talonavicular and calcaneocuboid joints. It is indicated when there is deformity secondary to rupture of the posterior tibial tendon or after trauma in which the transverse tarsal joints (talonavicular and calcaneocuboid) have been disrupted without involvement of the subtalar joint. It can be used to correct a subluxation of the hindfoot because subtalar motion depends on rotation of the navicular on the talus and to a lesser degree the calcaneocuboid joint. The advantages of a double arthrodesis over a triple arthrodesis are that the former has decreased morbidity and there is one less joint to fuse.

A triple arthrodesis is used to realign the hindfoot for instability secondary to a neurologic deficit, a tendon rupture, arthrosis, or a deformity caused by rheumatoid arthritis or trauma. The triple arthrodesis involves fusion of the subtalar, talonavicular, and calcaneocuboid joints. The fusion may be an in situ arthrodesis, which is relatively simple to achieve; however, when realignment of the foot is required, this procedure can be technically extremely difficult. It can be used to correct a cavus deformity as well as a flat foot deformity. It is not within the scope of this section, however, to discuss all of the various types of triple arthrodeses.

Use two skin incisions to adequately expose the joints to be fused. Expose the subtalar and calcaneocuboid joints through a longitudinal incision starting at the tip of the fibula and carried toward the base of the fourth metatarsal. Expose the talonavicular joint through a longitudinal incision beginning at the tip of the medial malleolus and extended to the area of the naviculocuneiform joint.

Once the joints are exposed, decoricate them as previously described. As a rule, when performing a triple arthrodesis, we prefer to decoricate the surfaces to obtain good bony apposition; others, however, prefer to inlay dowels or rectangular pieces of bone from the iliac crest. Both techniques produce satisfactory results; however, we prefer not to use iliac crest bone graft if possible because of increased morbidity.

If there is malalignment that needs correction, some bone may have to be resected to produce a plantigrade foot. The decorication of the subtalar joint is the same as previously described for subtalar joint fusion. The decorication of the talonavicular and calcaneal joints is the same as for a double arthrodesis.

C: Degenerative arthritis of the talonavicular joint, anteroposterior radiograph. D: Fixation of talonavicular joint using compression screw and staple.

**Figure 115.7.** AP (A) and lateral (B) radiographs following a double arthrodesis utilizing 4.0-mm cannulated screws.

**Figure 115.8.** Triple arthrodesis. A: Dashed line indicates incision; shaded area is bone to be resected. B: Appearance of the joint after preparation of the surfaces. C: An alternative technique involving stabilizing the joints with rectangular bone graft inlays; this may be combined with the procedure shown in Fig. 115.3B.
Once the joint surfaces have been prepared, place the foot into a plantigrade position with the hindfoot in 5° of valgus and the transverse tarsal joint in neutral abduction–adduction and correct any forefoot deformity, particularly forefoot varus, by plantar flexing the navicular on the head of the talus. If a plantigrade foot cannot be achieved, then resect bone as necessary to correct the deformity. Heavily feather and then internally fix the joints.

Fix the subtalar joint with a 7.0-mm cannulated screw, as described previously, and then stabilize the talonavicular joint followed by the calcaneocuboid joint. After surgery, keep the patient in a short-leg walking cast for approximately 10 days, followed by a short-leg, non-weight-bearing cast.

**Postoperative Care**

At 6 weeks, remove the postoperative cast, obtain radiographs, and, if early union is occurring, place the patient into a short-leg walking cast. Fusion usually occurs by 12 to 16 weeks (Fig. 115.9).

![Figure 115.9. Radiographs of a triple arthrodesis. A: Fixation of the triple arthrodesis utilizing screws. B: Triple arthrodesis utilizing staples and screws in a patient whose bone stock was not sufficient to obtain adequate fixation utilizing only screws.](image)

**Complications**

Occasionally, a nonunion occurs following a triple arthrodesis, usually at the talonavicular joint. If symptomatic, it should be surgically repaired. This is most easily accomplished by inlaying or rotating a block of bone within the nonunion site.

Malalignment can occur if the hindfoot is placed into too much varus or valgus or the forefoot is placed into too much adduction, abduction, pronation, or supination. This results in abnormal weight bearing, and it usually cannot be compensated for with an orthotic device or shoe modification, so a revision of the triple arthrodesis may be necessary. The revision is done with the same surgical approach as outlined for the triple arthrodesis. If the forefoot is in too much abduction or adduction, shorten the medial or lateral column of the foot by resecting more bone from the appropriate side to realign the foot. If a pronation or supination deformity of the forefoot also exists, realign by rotation through the transverse tarsal joint. Careful alignment of the forefoot to the hindfoot is needed to obtain a plantigrade foot.

**TARSOMETATARSAL JOINT ARTHRODESES**

Arthrodesis of the tarsometatarsal joint is usually performed for primary arthritis or posttraumatic arthritis. Arthrodeses in the tarsometatarsal area may involve a single joint, such as the first metatarsocuneiform joint, or multiple joints (16). An in situ fusion may be all that is required. If there is deformity, correct it.

If only the tarsometatarsal joints are involved, then the arthrodesis need include only the metatarsal and cuneiform joints. If, however, the cuneiforms have also been disrupted, then a block fusion incorporating the cuneiforms and metatarsals is needed. Sometimes after a Lisfranc fracture dislocation, the fourth and fifth metatarsal cuneiform joints are involved, and thus, fusion of these joints must be included.

The main problems in performing a tarsometatarsal arthrodesis are that there is little soft-tissue coverage, and the nerves over the dorsum of the foot are extremely sensitive to pressure. Even when the nerves are identified during the surgical approach, the pressure from a retractor may cause a neuropraxia, which often will resolve.

There are several techniques for arthrodesis of a tarsometatarsal joint. These may involve decortication of the bony surfaces and internal fixation; others recommend using various types of dowels (17). We prefer to decorticate the bony surfaces, perform a reduction, and insert internal fixation (18,28).

- If only a first metatarsocuneiform arthrodesis is to be done, use a medial approach to expose the first metatarsocuneiform joint. Center the incision over the first metatarsocuneiform joint and carry it down through the subcutaneous tissue to expose the bone. There is no nerve in the way when a direct medial approach is used, but if a dorsal medial approach is used, carefully identify and retract the dorsal medial cutaneous nerve. Once the first metatarsocuneiform joint is identified, reflect the capsule along the dorsal, medial, and plantar aspects.

- Meticulously decorticate the first metatarsocuneiform joint, which is a sinusoidal shape so that sometimes debirding the planar aspect of the joint is difficult. Once this has been achieved, place the joint in the same degree of abduction–adduction and plantarflexion as on the uninvolved foot. Usually the joint will fall into place once all of the soft tissues have been released and the joint surfaces are decorticated. If a deformity is present, some bone may need to be removed to realign the joint, but this is rarely necessary. Then heavily feather the joint surfaces with a 4-mm osteomectome.

- There are several ways to fix the joint, but we prefer to utilize 4.0-mm cannulated screws, one from the metatarsal into the cuneiform and the other from proximally in the cuneiform into the first metatarsal. This pattern of screws gives rather rigid fixation of the joint.

- If multiple metatarsocuneiform joints need to be arthrodesed, or if the fusion mass needs to include the cuneiforms themselves, then two incisions are used. The first incision is the medial incision just described, and the second incision is placed just along the lateral aspect of the second metatarsal. The lateral approach to the second metatarsocuneiform region must be made cautiously because the neurovascular bundle lies just lateral to the extensor hallucis longus tendon. After the skin incision is made and the superficial fascia is opened, take care to expose the cutaneous nerves. We have found it simplest to approach this area by working through a medial incision and stripping the soft tissues over the dorsum of the foot as far as possible. Usually this dissection can be carried along the skeletal plane, thereby passing beneath the neurovascular bundle to about the lateral side of the middle cuneiform. When the lateral incision is deepened to the level of the skeletal plane, most of the soft tissues will have already been elevated, protecting the neurovascular bundle.

- Once the tarsometatarsal and intercuneiform joints that are to be arthrodesed are exposed, they should be meticulously decorticated with a thin rongeur or an osteome. We have found that power tools usually remove too much bone.

- Once all the involved joints have been decorticated, reduce the first metatarsocuneiform joint. Following this, carefully check the alignment of the remainder of the joints to see whether any bone needs to be removed. Usually bone does not need to be removed because most deformities can be corrected by fully mobilizing the tarsometatarsal joints. Feather all of the joints to be arthrodesed with a 4-mm osteomectome.

- Fix the first metatarsocuneiform joint with two crossed 4.0-mm cannulated screws as previously described.

- Next, reduce and fix the second metatarsocuneiform joint, starting the screw distally in the metatarsal and inserting it proximally across the metatarsocuneiform joint into the second cuneiform. If the cuneiform joints are included in the fusion mass, place a transverse screw from medial to lateral across the cuneiforms. If the third metatarsocuneiform joint is to be included, insert an oblique screw from distally in the third metatarsal and proximally into the third cuneiform.

- Occasionally, in a large person or one in whom some instability still seems to be present after the screws have been inserted, place a crossing screw from the first metatarsal into the cuneiform or occasionally a screw from the medial cuneiform into the third metatarsal base. Sometimes arthrodesis is present at the naviculocuneiform joint, which then needs to be incorporated into the fusion.

- As a general rule, fusion of metatarsocuneiform joints 1, 2, and 3 is adequate. If the fourth and fifth metatarsal cuboid joints need to be arthrodesed, then try not to fuse from the cuboid to the lateral cuneiform so that motion can still be present between the medial and lateral arches of the foot. If, however, severe arthrodesis is present in this area, then it must be included in the fusion, but a stiffer foot will result.

- On completion of the arthrodesis, the wounds need to be carefully closed because the skin over the dorsum of the foot is extremely thin and sensitive to pressure.

- After surgery, place the foot into a short-leg compression dressing incorporating plaster splints.

**Postoperative Care**

Change the dressing in 10 days and apply a short-leg non-weight-bearing cast for approximately 1 month. If radiographic union seems to be occurring, use a short-leg walking cast until fusion is complete at 10 to 12 weeks (Fig. 115.10).
GENERAL PRINCIPLES OF POSTOPERATIVE MANAGEMENT FOLLOWING AN ARTHRODESIS

Before applying the dressings, infiltrate the site of the arthrodesis with 0.25% plain bupivacaine (Marcaine). This provides the patient with some initial postoperative analgesia. Once the patient is in the recovery room, have the anesthesiologist do a popliteal block. This provides the patient with anesthesia below the knee that lasts from 18 to 36 hours. Controlling the initial postoperative pain reduces narcotic requirements significantly. If the patient has too much pain the day following surgery, which occurs in about 10% to 15% of cases, do a second popliteal block. By utilizing this type of analgesia, most of our arthrodeses are carried out as outpatient procedures with a minimum amount of patient morbidity.

As a general rule, an arthrodesis results in a fair amount of trauma to the tissues, particularly in the hindfoot and midfoot. Unfortunately, there is not a great deal of soft tissue coverage in this area, so swelling must be carefully controlled with the postoperative dressing. Use a firm compression dressing along with splints for the immediate postoperative period. This firm dressing helps control the initial swelling but also permits expansion, which is important to accommodate the postoperative swelling. Following the initial postoperative period, after the sutures are removed, a firm, well-fitting cast may be applied. The patient should be kept from weight bearing on the foot until union is well under way in the presence of good internal fixation—about 6 weeks.

PITFALLS AND Complications

The complications following an arthrodesis are infection, nonunion, malalignment, skin slough, and nerve entrapment, among others.

Appropriate perioperative antibiotics given when an arthrodesis is performed may help decrease the incidence of infection, but good surgical technique and careful handling of tissues are the most important factors in minimizing the risk of infection. Unfortunately, about 0.5% to 1% of cases become infected following surgery and need to be treated vigorously with debridement and antibiotic therapy.

Nonunion of an arthrodesis may occur at any joint. Minimize the risk by proper preparation of the bone surfaces and adequate internal fixation, using good postoperative immobilization. Sometimes dysvascularity of the bone prevents satisfactory arthrodesis. This may occur at the talonavicular joint if the navicular is avascular secondary to an old crush injury or when an ankle or subtalar arthrodesis is done if the body of the talus has avascular necrosis. Rather than attempting to fuse to a bone that appears avascular, excise the avascular bone and graft into bones that have normal blood supply. If a nonunion occurs and is symptomatic, revision is necessary with excision of the nonunion site and either bone grafting or reestablishing adequate bone apposition along with internal fixation.

A skin slough can be a significant problem. Because there is little soft tissue coverage about the foot and ankle, a skin slough may occur because of excessive pressure from retractors or because of marginal skin from previous surgery or trauma. Too tight a postoperative dressing can compromise skin as well. The best treatment is prevention. When a skin slough occurs, debridement may be necessary, followed by a skin graft or pedicle to close the defect if it is too large. Small marginal sloughs will heal on their own with serial dressing changes.

A nerve entrapment or neuroma can be very bothersome if the patient's shoe puts pressure against the involved area. The patient may then be unhappy in spite of a satisfactory arthrodesis. For persistent pain and disability, excise the neuroma and resect the nerve back to normal soft tissues if possible. Because there is little soft tissue coverage about the foot, it may be necessary to place the end of the nerve into the bone to relieve symptoms.

Malalignment following an arthrodesis can be frustrating for both patient and surgeon. Careful preoperative planning is necessary to prevent malalignment. Carefully assess the alignment of the entire lower extremity before attempting fixation of the arthrodesis site. Take into account the alignment of the foot with the patella because aligning the foot only to the distal tibia may result in mal alignment. Malalignment that cannot be compensated for by the use of an orthosis or shoe modification necessitates a revision of the arthrodesis site.

When performing a triple arthrodesis or other hindfoot procedures, take great care to realign the forefoot to the hindfoot. It is not enough to align the hindfoot with the leg and not take into account the alignment of the forefoot on the hindfoot.

AUTHORS' PERSPECTIVE

An arthrodesis is an excellent procedure to provide pain relief and create a plantigrade foot. There are many pitfalls, unfortunately, along the way to obtaining a satisfactory fusion, but with careful preoperative planning, meticulous surgery, and rigid internal fixation, a satisfactory outcome can usually be achieved. In our experience, the patients who are least satisfied are the ones who have malalignment of the extremity resulting in a nonplantigrade foot. The possibility of nonunion is always present but can usually be avoided by good surgical technique.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; i, basic research article; and +, clinical results/outcome study.

The numbers of cases and problems associated with diabetic foot infections (DFI) have dramatically increased in recent years. The main reason for this increase is the growing diabetic population. For example, there were approximately 6 million diabetics in the United States in 1987 (59), and this number has grown at the rate of 9% per year to 16 million in 1997 (62). Four factors explain this dramatic growth in the number of diabetics.

1. Heredity. The at-risk populations such as Hispanics and Native Americans are increasing.
2. Weight gain. A higher percentage of people are overweight in the United States.
3. Longevity. Improved care for diabetics has decreased the mortality and morbidity rates for the diabetics.
4. Reclassification. The criteria for the diagnosis of diabetes were changed in the mid-1990s, reclassifying many patients who were formerly labeled "glucose intolerant" as diabetic.

Although the increased diabetic population is largely responsible for the elevated rates of problems associated with DFI, other factors play a role. Cases of diabetic ketoacidosis and hypoglycemia are less frequent, and the renal problems, cardiac problems and other comorbidities are better managed. Also, cases of DFI are better handled. These factors result in a reduction in the rate of amputation surgery. Hence, more diabetics are living longer, and with the decrease in amputations, there is an increase in foot problems.

Although the rate of amputation surgery is declining, diabetes is still the leading cause of amputation in the United States. In 1987, 560,000 lower extremity amputations were performed on diabetics (59). Also, diabetics are 40 times more likely than nondiabetics to have an amputation. A diabetic with an amputation has a 30% chance that the other leg will be amputated in 3 years or a 50% chance of this happening within 5 years.

GOALS OF DIABETIC FOOT CARE

The primary goal in the management of DFI is to maintain functional ambulation through the prevention and treatment of neuropathy and infection. It is clear that development of peripheral neuropathy in the diabetic is related to high blood sugar levels (23,33). Frequent blood sugar tests for at-risk groups (e.g., overweight family members) will aid in early diagnosis. Recently, the level of hyperglycemia for the diagnosis of diabetes was lowered from 140 to 126 mg/dl (69), and at-risk group initial screening may be lowered from 40 to 25 years of age. Aggressive management of diabetes with patient education, diet, exercise, and medication yields the best blood sugar control, resulting in decreased complications of neuropathy and vasculopathy.

Many patients are unaware that they have diabetes, which is demonstrated by the fact that almost half (43%) of all diabetics have their first hospital admission or diagnosis of diabetes associated with a foot infection (7,42). Most patients, and many nurses and doctors, are unaware that neuropathy is a main contributing cause of DFI. Ninety percent of these patients have neuropathy that is associated with high blood sugar levels. Eye problems in diabetics (retinopathy) and foot problems (peripheral neuropathy) do not have the same etiology. Peripheral neuropathy is mainly a chemical neuropathy, whereas retinopathy is due to ischemic focal occlusion from plaques in atherosclerotic vessels. Although it was previously believed that proper glucose control would not affect diabetic retinopathy, it has been demonstrated that the diabetic patient under "intensive control" can dramatically reduce the progression of not only neuropathy and nephropathy but also retinopathy (20,23,34).

Therefore, education of the patient, family, and health care team is the key strategy in the prevention of these diabetic-associated problems.

The American Orthopaedic Foot and Ankle Society has published a brochure, "The Diabetic Foot," to help the physician with patient education. One recommendation presented in this publication is that diabetic patients should wear shoes at all times, except in bed, to protect the feet from minor injury. Because DFIs start as ulcers in the insensitive skin, normal or continual pressure on insensitive skin causes the skin to break down. Therefore, diabetics must frequently check their feet to remove wrinkles in socks or foreign objects in shoes and vary pressure on the feet. They must always be cautious to avoid injury and to look for and immediately respond to any signs of infection in their feet. Insensate skin will also break down due to new shoes or a change in the level of use of the foot such as would occur in a new job requiring more walking. One patient of ours, a school teacher, presented with a cellulitic toe ulcer. When we showed him that his shoe had a roofing nail in the sole, he

The American Orthopaedic Foot and Ankle Society has published a brochure, "The Diabetic Foot," to help the physician with patient education. One recommendation presented in this publication is that diabetic patients should wear shoes at all times, except in bed, to protect the feet from minor injury. Because DFIs start as ulcers in the insensitive skin, normal or continual pressure on insensitive skin causes the skin to break down. Therefore, diabetics must frequently check their feet to remove wrinkles in socks or foreign objects in shoes and vary pressure on the feet. They must always be cautious to avoid injury and to look for and immediately respond to any signs of infection in their feet. Insensate skin will also break down due to new shoes or a change in the level of use of the foot such as would occur in a new job requiring more walking. One patient of ours, a school teacher, presented with a cellulitic toe ulcer. When we showed him that his shoe had a roofing nail in the sole, he
said, “We are building a gazebo, but I visited the building site 10 days ago.” He had acquired the nail in his shoe then and had been walking on it since. The cellulitis was bad enough to require admission, intravenous antibiotics, and debridement, followed by a long course of oral antibiotics and wound care, with eventual healing. He returned five years later with a small ulcer in the other foot from another nail. He sheepishly took the nail out of his pocket to show us and commented, “I found this in my shoe shortly after I had been outside.” The second ulcer healed quickly with oral antibiotics. At least he knew to check his shoes and feet, and he knew the signs of infection. Even though his disease had progressed, he had less of a problem with the second infection than with the first.

PATHOPHYSIOLOGY

Peripheral neuropathy is usually present in patients with DFIs (7,49). Although peripheral vascular disease can contribute to the severity of peripheral neuropathy, it is not the primary factor. Distal polyneuropathy is present in approximately 60% of diabetics and can be seen in any age group regardless of whether they require insulin or not (23). Nerve death in the diabetic is a result of metabolic, vascular, and histologic changes.

METABOLIC MECHANISMS OF PERIPHERAL NEUROPATHY

In the diabetic, nerves undergo metabolic changes due to a build-up of sorbitol and fructose, and a decrease of myo-inositol and sodium-potassium-adenosine triphosphatase. These changes occur when increased tissue glucose is metabolized by an alternate pathway as a result of the lack of insulin, leading to decreased nerve cell function and disruption of the membrane-associated sodium pump. This factor, in turn, causes a reduction in the ability of the nerve cell to maintain a normal polarized state, and leads to demyelination, nerve injury, and eventually, nerve death (23). Loss of large sensory fiber and motor nerves causes a decrease in light touch sensation and proprioception, as well as ataxia and weakness. Loss of small sensory fibers causes a decrease in pain and temperature sensation. With decreased sensation, injuries may go unnoticed and repeated insults to the soft tissue and bone can occur (9). Also, loss of protective sensation in the joints often results in excessive forces applied to ligaments, cartilage, and bone, leading to joint erosions, dislocations, fractures, and Charcot's joint (common eponym for neuroarthropathy) development and necrosis (25,32). Neurovascular dysfunction and autonomic failure may also play roles in the development of the Charcot’s joint (8,31).

VASCULAR DISEASE

Vascular Etiology

Blood vessels in the diabetic are subject to accelerated atherosclerosis, and blood is characterized by increased viscosity, clotting, and thrombosis formation (18,65). This causes nerve death, ischemia, and embolization.

Histologic Changes

Histologic changes include paranoid and segmental demyelination in peripheral nerves, connective tissue build-up, and capillary basement membrane hypertrophy with capillary closure, resulting in the death of both large and small myelinated nerve fibers (25,32,33 and 34).

Pathophysiology of Vascular Disease

The concept that diabetic ischemia is due to small vessel disease has been challenged. It appears that there is minimal collateral vessel formation in the foot due to the rapid onset of diabetic arteriosclerosis and lack of angiogenesis (18,40). Although neuropathy is the cause of most ulcerations, vascular disease, either alone or superimposed on neuropathy, can cause DFIs (51).

Susceptibility

Diabetics are more susceptible to and have more severe arteriosclerosis than nondiabetics. Bilaterality is more often an expression of more aggressive disease progression. Calcification in diabetic arteries is diffuse and found in the media layer. In contrast, nondiabetics suffering from arteriosclerosis have a patchy distribution of plaques in the intimal layer of the diseased artery (40,53). Calcified small arteries of the foot are commonly seen on radiographs of diabetics suffering from this vascular process.

Distribution

Although diabetics get proximal occlusive disease in the iliac and femoral vessels requiring endarterectomies and proximal bypass, this disease differs from that seen in nondiabetics because diabetics tend to have a more distal distribution of disease. More distal vessel disease in the diabetic is thought to occur because the rapid progression overcomes the rate of distal collateral revascularization. Frequently, this disease has diffuse involvement of all three vessels below the trifurcation and may require a bypass that extends far more distally than that seen in nondiabetics (7).

Risk Factors

The major risk factors for development of arteriosclerosis in nondiabetics are cigarette smoking, lipoprotein abnormalities, and high blood pressure. Diabetics seem to be at greater risk for these factors, and blood pressure, triglycerides, and cholesterol are more frequently elevated and difficult to control in these patients (60).

METABOLIC CONTROL AND NUTRITION

Multiple studies have shown a correlation between poor wound healing and poor nutrition. Therefore, it is imperative that the diabetic patient learn to monitor blood sugars closely with visits to the endocrinologist, diabetologist, internist, and nutritionist. When an infection is present, blood sugar levels are more difficult to control, and may require several days or weeks to stabilize after the infection is controlled. A well-kept patient diary that records date, time, blood sugar levels, food, and medication is a useful tool.

LIMITED JOINT MOBILITY SYNDROME

Limited joint mobility occurs in diabetics as the foot loses its sensation, proprioception, and intrinsic muscle function. Sensation and intrinsic muscle causes an “extrinsic plus” wide-based gait for balance that progresses to claw toes, midfoot valgus, and calcanealequinovalgus with decreased ankle and subtalar motion. Thus, a flat, stiff, insensitive foot is more prone to injury, further breakdown, decreased mobility, and ulcer formation.

PATHOPHYSIOLOGY OF INFECTIONS IN DIABETICS

Immunology

Diabetics have a poor response to infection. Decreased phagocytosis of bacteria and impaired cell-mediated immunity are noted and are worse when the serum glucose is poorly managed. Also, many antibiotics are ineffective in the resulting hypoxic, acidic environment and may be subtherapeutic in the ischemic tissue of diabetics. Blood flow is further decreased in the swollen, infected tissue seen in cellullitis, ulcers, abscesses, osteomyelitis, gangrene, and Charcot's joints. These complications often produce large dead spaces and necrotic tissue, making the local host response and antibiotic penetration even less effective.

Bacteriology

DFIs are polymicrobial and usually involve both aerobic and anaerobic species (63,64) (Table 116.1). Skin flora can cause deep infections in diabetics, occasionally making it difficult to determine the correlation between cultures taken from superficial ulcers or sinus tracts and the true pathogens causing deep infection (66). Tolarized state, the most meaningful cultures are those that are taken in the operating room from deep tissue underneath the ulcers or open wounds. Many of the acute soft tissue infections are caused by streptococci or Staphylococcus aureus, which may be found as the single pathogenic species (51). With an increase in the chronicity of the infection, or in the face of partial antibiotic treatment, polymicrobial infections are found in greater frequency. Infections may include Pseudomonas and anaerobic organisms, although it is uncommon to see a monomicrobial anaerobic infection (66).
Factors that predispose diabetics for foot infections include patient noncompliance and poor visual acuity, making daily foot inspections unreliable. Patients with PREDISPOSING FACTORS

PREVENTIVE STRATEGIES

PRINCIPLES OF FOOT CARE AND PREVENTION

THE FOOT CARE TEAM

The family physician, internist, orthopedic surgeon, vascular surgeon, plastic surgeon, nutritionist, diabetic nurse, and social worker need to work with the patient and the patient's family. Regular, urgent, and emergent clinics that the diabetic patient can easily access will prevent minimal problems from becoming major problems. The diabetic wound care nurse or physician's assistant plays a vital role as a part of the care team. Special training, either with a skilled local foot care team or at national courses, can give the nurse or physician's assistant the skills to organize a wound care clinic. This clinic should be open 5 days a week for dressing care, and a member of the foot care team must be readily available to answer telephone inquiries from patients and for referrals. Education of local emergency rooms and primary care clinics regarding preventive care and the decision of when to refer is important. The most important members of this team are the patient and family because they must become knowledgeable and involved. If they are not or cannot be involved, then the prognosis of the patient is typically poor and they will require more care by the doctors and nurses in the clinic or hospital.

The treatment of DFIs is extremely important. Eighty percent of amputations and 20% of hospital admissions each year are due to DFIs (60). In a poorly treated foot ulcer, osteomyelitis increases the risk of amputation (6). A good treatment plan must address the underlying cause of the skin breakdown or infection and not just simply treat the ulcer itself.

TEAM EDUCATION AND ASSESSMENT

We have found it helpful to teach the patient, family, and health care team the most common causes of (and terms for) infection and pathology in the diabetic foot. The team, which consists of the patient, family, doctors, nurses, and assistants, must be able to classify the infection and respond to it appropriately: "Is it more red?" (i.e., cellulitis); "Is there a skin sore?" (i.e., ulcer); "Is there a deep infection?" (i.e., abscess or bone infection); "Is there dead tissue?" (i.e., gangrene); "Is it getting better or worse?" (i.e., do we continue with this treatment or go to the clinic for a check-up or to the emergency room for admission?).

We have looked at diabetic infections in 1,752 cases over a 20-year period and have concluded that a simple, common classification system (Table 116.2) aids in consistent categorization and treatment for the best outcome (7,10,11). The simplicity of the classification also facilitates ease of communication between the team and the patient. The best way to think about the type of infection in order of increasing severity and stage is cellulitis, ulcer, abscess, osteomyelitis, and gangrene. One or all of these infection grades can be present, but typically one predominates and the more severe type (i.e., the higher stages) determines treatment. Furthermore, the presence of neuropathy and ischemia make the treatment more involved.

Table 116.2. The Common Types of Diabetic Foot Infections

patient's sight is poor and toes are insensitive. Usually, a nurse or a physician's assistant can provide nail care in the office.

Footwear

Most commercial insurance companies and most managed care plans now pay for extra-depth diabetic shoes. If the patient's insurance company does not cover the cost of these special shoes, send a letter of medical necessity or contact the insurance company with the recommendation that in order to try to prevent expensive surgery or greater disability, the patient needs extra-depth diabetic shoes. Many patients can be managed in the more "fashionably" acceptable jogging or walking shoes. Deformities such as ingrown toenails, claw toes, bunions, and hyperkeratotic areas can be managed with orthotics or shoewear modifications.

PRINCIPLES OF DIAGNOSIS

PREDISPOSING FACTORS

Factors that predispose diabetics for foot infections include patient noncompliance and poor visual acuity, making daily foot inspections unreliable. Patients with
peripheral neuropathy often have delays in diagnosis of infection owing to a failure to sense tissue damage. Also, autonomic dysfunction leads to anhidrosis and a loss of skin temperature regulation, which can result in dry, scaly, easy-cracking skin contributing to ulcer formation. These cracks and ulcers provide a portal for bacterial invasion that leads to infection. Poorly controlled diabetics have these problems in greater frequency (27). When ischemia or malnutrition is present, infection is also more likely to develop.

PHYSICAL EXAMINATION

The focused orthopaedic examination of a DFU should begin with the evaluation of both lower extremities from the knee down. Owing to peripheral neuropathy, diabetics with infection may not have pain as a primary complaint. The patient and family will note fever, chills, and recent hyperglycemia despite a normal dose of insulin. On physical examination, look for erythema, swelling, induration, or fluctuance, and probe ulcers for depth and the presence of an abscess or exposed bone.

Laboratory studies may show an elevated white blood cell (WBC) count with an increase in polymorphonuclear cells and elevated erythrocyte sedimentation rate, C-reactive protein, or glycosylated hemoglobin.

NEUROLOGIC EXAMINATION

Neuropathy assessment includes evaluation of sensory, autonomic, and motor functions. Although diabetics may have numbness, they may still feel pain. The so-called “stocking-glove” description of the sensory deficit distribution is not accurate. Although peripheral neuropathy is usually more severe distally, the proximal border of the neuropathic area is not, typically, a perfect cross section of the affected limb. The border is typically more distal directly over the major sensory nerves for evaluation of touch and more proximal farther from the major nerves for evaluation of painful stimuli. Some patients complain of severe paresthesia (spontaneous pain or burning) and dyesthesia (contact pain), which is thought to be a result of spontaneous depolarizations of injured or regenerating nerves (33). Light touch, the pinprick, monofilament discrimination, and the Semmes-Weinstein monofilament can be used to document the sensory deficit. About 10% of patients who have already had ulceration still meet the supposed threshold criterion of feeling the 5.07% Semmes-Weinstein monofilament (7). The pinwheel test allows rapid cutaneous sensory mapping of fine point and pain perception. Clean the pinwheel well with alcohol between patients or use disposable pinwheels. Autonomic deficits present as dry, stiff skin that easily cracks to a loss of skin temperature regulation, abnormal sweating, and arteriovenous shunting (1,27). Clawing, pes planus, and equinus contracture occur from motor derervation of the intrinsices and compensation by the extrinsics. When combined with decreased sensation, the likelihood of ulceration increases dramatically.

VASCULAR EXAMINATION

Patients with good capillary refill do not require additional diagnostic screening. Patients without pulses and good capillary refill may benefit from vascular consultation and noninvasive vascular studies. Transcutaneous oxygen measurements, or angiograms. Vascularopathy can be demonstrated by blanching normal skin and releasing the pressure. Normal blood flow results in capillary refill in less than 2 seconds. A mild decrease in the blood flow requires 7 seconds, moderate flow takes up to 13 seconds, and severe impairment greater than 13 seconds. Assess the temperature of the skin with the back of one’s fingers. Other signs of vascular insufficiency can be observed by skin changes that include loss of hair and smooth or edematous skin.

Wagner has used ankle brachial Doppler pressure ratios of less than 0.45 to indicate the potential for poor wound healing (10,54,69). For Doppler pressures, request toe pressures and pulse-volume recordings (PVR) at different locations along the limb. The PVR is normally triphasic, but when the vessel loses compliance, the waveform becomes monophasic or biphasic (7). Toe pressures less than 40 mm Hg are unlikely to result in healing of ulcers and are at a higher risk for requiring reconstructive procedures (2). We recommend the use of transcutaneous oxygen measurement (TcPO\textsubscript{2}) for evaluating vascularity, healing potential, and soft-tissue viability (3,11,29). Values of TcPO\textsubscript{2} lower than 20 mm Hg often result in local surgical failure unless a vascular bypass is performed (13,14,70). Other useful studies are angiography or xenon clearance studies, but these procedures are more expensive and invasive.

IMAGING

The clinical presentation and findings on physical examination determine the need for imaging studies. Imaging studies are often overused. Plain radiographs suffice in the vast majority of DFU cases. In all patients presenting with DFU, high-quality radiographs of the feet include anteroposterior (AP), lateral, and oblique views. Look for loss of soft-tissue planes, luencies indicating gas, foreign bodies that may have precipitated the infection, and bony changes such as erosion and periostial new bone formation that may indicate osteomyelitis. The osseous radiographic changes of neuroarthropathy can simulate osteomyelitis and the differential diagnosis can sometimes be difficult. Lytic changes in bone without overlying skin ulceration is usually not due to osteomyelitis but rather due to neuroarthropathy. Radionuclide scans, computed tomographic (CT) imaging, and magnetic resonance imaging (MRI) may be necessary to differentiate between osteomyelitis and Charcot’s arthropathy, abscess, cellulitis, or early osteomyelitis (19,30,50,55,68). Although these studies are useful in certain instances, a sterile aspiration or biopsy in clinic or on the hospital floor is an easy, rapid, and painless procedure, because the patient has no sensation in the involved area.

CLASSIFICATION AND TREATMENT OF INFECTIONS

Wagner’s classification system for foot infection is quite explanatory and an excellent teaching tool for physicians and nurses; however, because it is complex it can make taking an accurate history and understanding by patients problematic. A commonly used classification that is simple is (in order of increasing severity and stage) cellulitis, ulcer, abscess, osteomyelitis, and gangrene.

CELLULITIS

Cellulitis can range from mild redness around a callus or ulcer to full foot or leg involvement, with swelling and lymphedema. Underlying abscess, osteomyelitis, gas gangrene, or necrotizing fasciitis that can cause sepsis and death should be ruled out by examination and radiographs. Most mild cellulitis around a callus or ulcer can be managed on an outpatient basis with local skin care and oral antibiotics (Fig. 116.1). Mark the border of the red cellulitic skin with a permanent pen to establish a baseline before treatment is started. If the cellulitis worsens (extends 2 to 3 cm past the baseline) after 24 to 48 hours of oral antibiotics, the patient should be re-evaluated and treated with different oral antibiotics or hospital admission and intravenous antibiotics.

![Figure 116.1](image)

**Figure 116.1.** A: Latino man, 52 years of age, who had non-insulin-dependent diabetes mellitus (NIDDM) for 10 years and was employed as head of housekeeping at the hospital. Admitted to the hospital with cellulitis and diabetic ulcer on the plantar aspect of left great toe. The TcPO\textsubscript{2} was 38 mm Hg at the base of toe. The patient was discharged after 3 days of intravenous (IV) antibiotics [cephalexin (Keflex) and gentamicin], local wound care, and oral antibiotics (Keflex for 2 weeks); the wound healed at 2 months. B: Similar ulcer 3 years later treated without hospital admission, oral antibiotics for 2 weeks, and local wound care. Patient still works as chief of housekeeping 10 years later.

**ULCERS**

It is imperative to determine whether or not an ulcer is infected before beginning wound care. Clinicians should diagnose ulcer infection by looking for draining, depth, erythema, and cellulitis surrounding the wound; if infection is suspected, take wound cultures. Swab cultures from the surface of an ulcer or from sinus drainage have been shown to be poor indicators of the bacterial species below (54). Therefore, clinicians should curet and culture an ulcer from the base for aerobic and anaerobic organisms. Start with empirical antibiotics if infection is suspected, and modify them, if necessary, when the culture results and antibiotic sensitivities are available. The
bacterial species seen in DFIs are often multiple and range from streptococcus or staphylococcus species (the two most common) to gram-negative organisms and anaerobic organisms (Table 116.1). Bacterial infections usually can be treated with empiric oral antibiotics. We usually begin with first-generation cephalosporins and modify treatment based on the response to treatment, antibiotic sensitivities, and cultures. Quinolones may be added for gram-negative coverage and penicillin-VK for clostridial infections (Table 116.3). If the infection is arrested after 2 to 4 weeks of treatment, the antibiotic may be stopped or the dose decreased. In patients with advanced cellulitis, gas gangrene, or sepsis, treatment usually requires hospital admission, intravenous antibiotics, urgent surgical debridement, deep tissue cultures, and an infectious disease consultation.

Table 116.3. Antibiotic Selection

In general, most ulcers can be treated on an outpatient basis with local wound care in conjunction with redistribution of pressure with total contact casts, orthotics, or diabetic shoes. The evolution of wound management and wound care products has created the need for standardized pathways for wound management. Accurately record the size of the ulcer in centimeters with an anatomic sketch in the patient's chart. An alternative method is to trace the ulcer on a glove or ziplock bag, then separate and dispose the side of the glove or bag that touched the ulcer and tape the tracing in the chart. Digital photographic prints of the wound are the easiest, most accurate means of documentation. Make note of the size and color of the wound bed, and look closely at the wound margins to identify sinus tracts, undermining or rimming. Describe the characteristics of the exudate by including the type, amount, color, consistency, odor, and the adherence to the wound base. These characteristics must receive ongoing assessment so that an appropriate dressing can be used that is based on the healing stage of the wound. The primary function of a wound dressing is to promote the moist healing environment necessary for tissue repair (72). The functions and indications of the most commonly used dressing materials are listed in Table 116.4. Ulcers with significant drainage require gauze dressings with frequent changes.

Table 116.4. Characteristics of Some Available Wound Care Dressing Materials

After healing, further ulceration can be prevented by using custom-molded, extra-depth, diabetic shoes. Deeper ulcers with hyperkeratotic edges or necrosis can be debrided in the clinic and successfully treated with the application of a total contact cast. Treatment with intravenous antibiotics based on a swab culture, or preferably, a deep culture, is helpful if significant cellulitis is present.

Total Contact Cast Technique

The goal of total contact casting is the relief of pressure by distributing stresses over a large surface area.

- Apply a light dressing to the wound and hold it in place with a stockinette.
- Pad all bony prominences for protection while in the cast.
- Overlap cast padding only one-half width of the roll.
- Apply a layer of plaster, which is then overwrapped with fiberglass.
- Use a cast shoe.
- Excessive padding will allow movement in the cast and cause skin irritation or ulceration.
- The cast can be bivalved so dressing changes are easier and the cast will last longer.

Initially, casts are changed weekly to evaluate the skin and the wound. As the situation stabilizes, the cast may be changed less often.

ABSCESS AND OSTEOMYELITIS

Treat abscesses and osteomyelitis with thorough debridement to remove all necrotic, infected tissue, followed by reconstruction (Fig. 116.2C, Fig. 116.2D and Fig. 116.2E). Surgery for diabetic abscess and osteomyelitis is more difficult than that for a nondiabetic because of the poor blood supply and insensitive tissue. Toe amputations, ray resections, midfoot amputations, Syme's amputations, muscle flaps, or distal below-the-knee amputations (BKAs) require good blood flow to heal and adequate protective sensation to stay healed. If the area being treated is insensitive, it allows more aggressive debridement with less general anesthesia, which is safer owing to the multiple system dysfunction (renal, cardiac, pulmonary) in the diabetic. Some anesthesiologists may be unfamiliar with diabetes-associated numbness and require guidance on the amount of analgesia to use during procedures. We test for lack of sensation at the incision site by squeezing with toothed tissue pick-ups before administration of anesthesia. Most distal debridement and amputation can be performed with a small amount of local or intravenous analgesia. The anesthesiologist must be present to monitor cardiac, pulmonary, and renal function. Amputation for the treatment of osteomyelitis is commonly used to remove a chronic nidus of infection and to get to the level of protective sensation for prosthetic wear. Antibiotic treatment for deep abscesses and osteomyelitis is based on cultures and antibiotic sensitivities. Only 2 weeks of antibiotics may be required if the infected bone and soft tissue are removed and good bleeding soft tissue is left. Up to 6 weeks may be required if there is osteomyelitis. Hyperbaric oxygen helps the patient with marginal oxygen levels to heal.
**Figure 116.2.** A: White man, 37 years of age, who has NIDDM and works as welder. He has five children but no insurance. He presented with an ulcer on his toe. B: He had no osteomyelitis. He was not able to perform wound care or use total contact cast because of work. The ulcer progressed to osteomyelitis of the first metatarsophalangeal joint (C) and plantar abscess (D). He was treated with amputation of the toes and debridement of midfoot, IV antibiotics for 3 weeks, and second-stage closure with skin graft at 2 weeks (E). He still works 10 years later with same foot.

**GANGRENE**

Gangrene or tissue necrosis can present as dry, wet, or gas gangrene, or necrotizing fasciitis. Although all gangrenous tissue will eventually be removed, dry gangrene can be managed on an outpatient basis with local wound care for long periods until the odor, pain, or local infection requires surgical removal. Outpatient management for dry gangrene requires that the patient, family, or local care provider watch for signs of sepsis or gas gangrene. Although dry gangrene usually is painless, some patients have good sensation, and in this patient subset, the acid from the dead tissue can cause severe pain that is relieved only with amputation (Fig. 116.3). Outpatient management for forefoot gangrene can occasionally result in “auto-amputation,” in which the necrotic tissue breaks off spontaneously.

**Figure 116.3.** White woman, 63 years of age, who had NIDDM for 3 years. She had normal sensation and a very painful gangrenous toe. TcPO\(_2\) at foot of 12 mm Hg; at ankle, 21 mm Hg; at proximal tibia, 41 mm Hg. Treated with BKA.

The need for and level of amputation is determined by tissue viability and protective sensation (Fig. 116.4). We use TcPO\(_2\) greater than 40 mm Hg as an indication of good perfusion and potential for healing. A patient with a TcPO\(_2\) of less than 40 mm Hg has an increased failure rate, and healing can be helped with hyperbaric oxygen (52). If the patient refuses a higher amputation level or if the patient is healthy, we use the lowest amputation level that will help with ambulation and prescribe adjunctive hyperbaric oxygen therapy (Fig. 116.5). If the patient is ill or not able to use the lower amputation level for a prosthesis or amputation and has a TcPO\(_2\) of less than 40 mm Hg, we perform a higher amputation. To assess the patient’s healing potential intraoperatively, we use William Wagner’s (69) tourniquet technique. When a tourniquet above an amputation site is deflated and poor bleeding results after as much as 5 minutes, wound healing is unlikely. If bleeding begins 3 minutes after deflation, there is an 80% healing rate, and at 2 minutes or less, a 100% healing rate occurs (69) (Fig. 116.9D).

**Figure 116.4.** White man, 40 years of age, who had insulin-dependent diabetes mellitus (IDDM) for 5 years. He had protective sensation at ankle and good blood flow. He was treated with amputation of all toes.

**Figure 116.5.** A,B: White man, 51 years of age, who had IDDM for 7 years. The TcPO\(_2\) at BKA site was 29 mm Hg, indicating gas gangrene. The patient was treated with BKA, hyperbaric oxygen treatment, and IV antibiotics.

**Figure 116.9.** A,B: White man, 46 years of age, had IDDM for 8 years and a Charcot midfoot for 6 months. C: The deformity progressed and he developed a plantar ulcer. The TcPO\(_2\) at the foot was 11 mm Hg; at the ankle, 21 mm Hg; at the BKA site, 39 mm Hg. There was pain sensation in the proximal anterior tibia and posterior midcalf. A radiograph showed gas in the tissue. The patient was febrile and felt ill. He was admitted to the hospital and placed on penicillin, clindamycin, and ciprofloxacin. Cultures showed Staphylococcus, Streptococcus, Pseudomonas, and Diptheroids. D: Emergent guillotine amputation was performed; there was minimal
Neuropathic arthropathy is accelerated osteoarthritis that causes hypermobility of the joint. Typically, joint fragmentation and fractures occur with destruction of the bone. This may be due to autonomic neuropathy and can contribute to the bone and joint destruction that sometimes occurs despite adequate immobilization and rest (21). Microtrauma to have additive effects on bone and joint destruction (21). Charcot’s joint, the common eponym for neuropathic arthropathy, was coined from the description given in 1868 by J. M. Charcot for a patient with syphilitic joint disease.

**Neuropathic Arthropathy**

Neuropathic arthropathy is joint destruction caused by a lack of protective sensation. The incidence of neuroarthropathy in diabetics ranges from 1% to 2.5% (20). Revascularization can heal ulcerations and allow more distal foot reconstructions or amputation (20). For vascular insufficiency, consider vascular surgery for possible reconstruction. This procedure may range from a single vessel angioplasty to multiple by-pass arterial procedures. In the diabetic vessel, bypass operations are more distal owing to the higher number of diseased arteries below the trifurcation of the popliteal artery (40).

**Vascular reconstruction**

If the infection is not too severe and bleeding is adequate, all lower extremity wounds should be closed. If the degree of infection is too severe (i.e., purulence, cellulitis, or edema), then perform a staged debridment and closure, returning the patient to the operating room in a few days for repeat debridement or wound closure, or both. The surgeon must debride or amputate to a level on the limb that produces sufficient bleeding indicative of adequate circulation for healing.

**Role of Amputation**

Amputation can be lifesaving surgery if sepsis, gas gangrene, or necrotizing fasciitis is present (Fig. 116.6). It can cause a great deal of stress for patients, so they may need time and counseling before making a decision about an amputation. Of the “stressful events of life” amputation is second only to loss of a loved family member. Patients frequently go through the “stages of death and dying” of denial, anger, negotiation, depression, and acceptance. Some patients refuse to have an amputation for religious reasons or request that the amputated part be stored for the time of burial. We describe amputation to patients as a type of reconstructive surgery that is necessary to remove infected or dead tissue so that the patient’s health and function may improve. Most patients understand this and work very hard to rehabilitate. The design of prosthetic devices continues to improve, thereby increasing the percentage of patients that have a functional outcome. See Chapter 120 and Chapter 122 on amputation and prosthetics.

**Figure 116.6** Black man, 63 years of age, who had a foot with wet gangrene. The TcPO2 at the BKA site was 21 mm Hg. The patient was treated with BKA, hyperbaric oxygen treatment, and IV antibiotics.

**Principles of Foot Reconstruction**

Realignment and restoration of normal foot mechanics with attention to nerve and vascular function are the main principles of foot reconstruction. After the infected, dead tissue is removed, wound closure with a good weight-bearing stump is essential. Do not leave bony prominences or less than five toes or metatarsals because this produces an unbalanced foot that almost guarantees further surgery in the next year. It is also of no value to perform inadequate debridement or close ischemic skin or muscle.

**Neuropathy Control**

Good glucose control and attempting to maintain HbA1c levels at less than 8% help prevent progression of neuropathy (20). Analgesics and other pharmaceuticals [e.g., amitriptyline (Elavil) 25 to 100 mg at bedtime for sleep, or fluphenazine (Prolixin)] can be helpful in controlling the paresthesias and dysesthesia (1,42,65).

**Orthotics and Special Shoes**

Orthotics should be accommodating but not rigid, with adequate padding to relieve overloaded bones and tissue. Soft Plastazote is better than Petité to avoid shear stress and give a firm underlayer of support. A wide toe box with extra-depth shoes is necessary to provide room for toe deformities. Shoes should fit well when purchased and should not be expected to stretch out with wear.

**Treatment of Deformity**

Surgical treatment of the underlying deformity is often necessary to heal the ulcers or prevent recurrence. With good blood supply, an osteotomy may relieve the pressure of a bony prominence. Balancing of muscle forces such as percutaneous tendoachilles lengthening for tight heel cords, as well as procedures for intrinsic minus clawing can relieve excessive pressure on the metatarsal heads. Plastic surgery consultation may be needed when soft-tissue coverage is needed (46). See Chapter 112, Chapter 113, Chapter 114, Chapter 115 and Chapter 118 for details on foot reconstruction.

**Vascular Management**

**Medical Management**

Studies have shown that pentoxifylline is effective in diabetic patients with chronic ulcerations that do not heal despite other treatment options. Pentoxifylline and its metabolites decrease the viscosity of blood, therefore improving its flow properties. It improves tissue oxygenation. In addition, pentoxifylline 800 mg/day was shown to improve walking distance, paresthesia, skin temperature, and subjective overall response (12).

**Vascular Reconstructive Surgery**

For vascular insufficiency, consider vascular surgery for possible reconstruction. This procedure may range from a single vessel angioplasty to multiple by-pass arterial procedures. In the diabetic vessel, bypass operations are more distal owing to the higher number of diseased arteries below the trifurcation of the popliteal artery (40). Revascularization can heal ulcerations and allow more distal foot reconstructions or amputation (20).

**Neuropathic Arthropathy**

Neuropathic arthropathy is joint destruction caused by a lack of protective sensation. The incidence of neuroarthropathy in diabetics ranges from 1% to 2.5% (27). Charcot’s joint, the common eponym for neuropathic arthropathy, was coined from the description given in 1868 by J. M. Charcot for a patient with syphilitic joint destruction (41). Treatment is directed toward preventing progression and the sequelae of infection and amputation. See Chapter 124 for more details.

**Pathophysiology**

Diabetes is the most common cause of neuropathic arthropathy. It is believed to be caused by a loss of protective sensation about joints, allowing repetitive microtrauma to have additive effects on bone and joint destruction (23). The inflammatory changes of erythema and increased blood flow seen in Charcot’s arthropathy may be due to autonomic neuropathy and can contribute to the bone and joint destruction that sometimes occurs despite adequate immobilization and rest (43). Neuropathic arthropathy is accelerated osteoarthritis that causes hypermobility of the joint. Typically, joint fragmentation and fractures occur with destruction of the bone.
Articular cartilage and bone, with accompanying synovitis and pannus formation (9).

Other diseases that can cause neuropathic arthropathy are syphilis, syringomyelia, alcoholism, stroke, congenital insensitivity to pain, spinal cord or peripheral nerve injury, and spina bifida (35). Patients with these diseases, however, usually do not have the severe vascular and immunologic changes that diabetics experience. Other severe problems might also be present (e.g., alcoholism, malnutrition, cord injury, and total paralysis), but the neuropathic arthropathy can be managed much like that for diabetics.

PRESENTATION

Patients frequently complain of foot swelling, redness, and numbness. A recent increase in shoe size may also be reported. Pain is not typically a chief complaint, and when it is present, it is usually less than expected. Neuroarthropathy is commonly found in middle-aged diabetics with a history of poor glucose control. Fever, chills, nausea, and malaise are generally absent, but may be present with an infected Charcot joint. Capillary refill can be assessed with a blanch test or foot elevation, or both, and is typically normal in the Charcot foot. If the foot remains red and warm with elevation, infection may be present.

Laboratory Tests

Without infection, the complete blood count is normal, but the erythrocyte sedimentation rate and glycosylated hemoglobin are usually elevated. Also, TcPO₂ is usually normal.

Radiographs

Radiographs correspond to the stage of neuropathic arthropathy (15, 16, 26, 36, 41, 71) (Table 116.5). Eichenholtz staging refers to the individual fracture’s healing (Table 116.6). In the preneuropathic arthropathy stage, joints at risk for progression or deformities (e.g., hallux valgus or claw toes) can be seen, and muscular imbalances (e.g., tight heelcord and clawing) can be identified. Radiographs of patients with early neuropathic arthropathy show joint widening and stress fractures. In progressive and late stages, further destruction and multiple joint involvement are seen.

Table 116.6. Eichenholtz Staging of Neuropathic Arthropathy

Changes seen in the forefoot are dorsal dislocation of the toes, metatarsophalangeal joint destruction, and metatarsal stress fractures (6, 17, 43). In the midfoot, the arch becomes flattened, the distal segments dislocate dorsally, and fragments of the cuneiform or cuboid become prominent in the sole and can cause ulcers (48). The hindfoot is disrupted as the calcaneus or talus dislocate, allowing the talus or malleolus to become prominent and cause ulcers (65). Occasionally, entire bones, especially the talus, cuneiform, or cuboid, are crushed in situ.

The most common location for Charcot's arthropathy is Lisfranc's joint (Fig. 116.7). This can account for 70% of cases, whereas the forefoot and hindfoot each account for 15% (Fig. 116.8). Recurrence of the neuroarthropathic process is rare and is most commonly seen in renal transplant patients. Bilateral involvement has been seen in 35% of patients with diabetic Charcot's process (38).

Figure 116.7. A.B: Black man, 55 years of age, who worked in hospital as a radiology technician. He had IDDM for 12 years before he noticed both feet swelling for 2 years before presentation. At presentation, he had minimal pain and was placed in extra-depth diabetic shoes for bilateral, midfoot, early Charcot's joints. The condition continued to progress on the right side, so he underwent bilateral midfoot and hindfoot fusions 2 years later. Six years later, the deformities have stabilized (C–G) and the patient is disabled.
TREATMENT OF CHARCOT FOOT

Imaging

Bone scans, CT, and MRI help differentiate early Charcot's joint changes from infection. A technetium bone scan will show increased uptake in neuropathic arthropathy but is not needed if infection is either obvious or not suspected (26,47). Gallium and indium scans can be helpful in diagnosing and defining the extent of infection. Arteriography is frequently used to determine if and where vascular bypass is indicated (37,44,45,67). Although an 111-indium WBC scan is preferable to MRI to rule out osteomyelitis, it is usually negative in patients with neuropathic arthropathy, although false-positive readings may occur. MRI is sensitive in showing the extent of infection that might be superimposed on Charcot's changes (30,50). If the 111-indium WBC scan is positive, biopsy confirmation is recommended (30).

Orthotics and Special Shoes

It is imperative that patients with neuropathic arthropathy have custom-molded orthotics that accommodate the deformity and resist its progression. Rigid orthotics should be avoided because they will cause ulcers. Wide toe box, extra-depth shoes provide room for the abnormal forefoot. Rocker bottom soles decrease midfoot stresses (27). High-top, ankle-lace-up shoes attached to molded lower leg braces resist ankle deformity.

Total Contact Casting and Bracing

Total contact casting is useful for treating ulcers and to prevent deformity progression until consolidation occurs. Patellar tendon-bearing casts unload the foot and ankle (61). During phases of swelling, frequent cast changes are needed to prevent pressure ulcers caused by the cast. Likewise, bracing can be helpful both during and after progression of a deformity by placing the foot into optimal alignment and position and supporting it. This can be provided by a fairly restrictive orthosis such as a customized ankle-foot orthosis that is well padded to accommodate any structural abnormality.

Operative Treatment

Treatment depends on soft-tissue viability and infection. For ischemia, vascular repair might be indicated, but most Charcot's joints have good to excellent blood flow (37,44,45,58,67). Infection is usually obvious with an ulcer, and drainage can be easily established with a sterile aspiration of the insensate foot in the clinic (Fig. 116.9). Infection in the Charcot joint is treated much the same way as DFIs outlined earlier. Establish the extent of infection—cellulitis, ulcer, abscess, osteomyelitis, and gangrene—and treat with culture and sensitivity-directed antibiotics, debridement, and reconstruction. Infection in the Charcot joint usually means there is an excellent blood supply (but not always!) so antibiotic delivery and the host's ability to fight the infection are good, but the bone and joint involvement is more severe, so the debridement and reconstruction are more difficult. Usually, an infected Charcot joint will need to be "staged." In the first stage, identify the bacteria with sterile deep cultures and debride all infection and dead bone. In the second stage, reconstruct remaining tissue, usually with fusions (Fig. 116.7) or amputate if reconstruction is not possible owing to the patient's health and the local conditions.

Osteotomy or Osteotomy

A cheilectomy, or "bumpectomy," to remove protruding bones can treat or prevent ulceration (8). Realignment osteotomies and fusions after the hyperemic or osteopenic phase is over require extended immobilization (up to 1 year), but even a pseudoarthrosis may improve function, relieve pressure, and treat ulcers (4,24,48,57).

Correction of Muscle Imbalance

Muscle imbalance due to an intrinsic minus foot with claw toes, flat foot, and valgus heel and calcaneal equinus can be corrected somewhat with a percutaneously lengthening of a tight heelcord.

Amputation

Owing to the severity of many of these cases, especially those involving deep infections, amputation is often the most reasonable surgery.

AUTHORS' PERSPECTIVE

DFIs and Charcot joints are increasing and can be treated in a straightforward way. Excellent treatment of the diabetic foot is gratifying for the surgeon and for the patient. A balanced foot care team with individuals with varied skills and roles is key. The team consisting of the patient, family, doctors, nurses, and clinical assistants needs to be educated about foot problems and be able to work together to provide the best care for these patients. Looking at the infection in common terms (cellulitis, ulcer, abscess, osteomyelitis, gangrene), with an understanding of neuropathy (pain or protective level for prosthesis and Charcot joint) and vasculopathy (level of blood supply but not always!), the surgeon will be able to weigh the possible ways to treat and reconstruct the foot and ankle.

SUGGESTED READINGS

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Rheumatoid arthritis is a systemic disease that affects up to 2% of the general population in the United States (73,77). Women are affected more frequently than men, with a peak onset noted in the third to fifth decade. Rheumatoid arthritis affects both small and large joints in the upper and lower extremities. Although its onset is typically insidious, an acute presentation is not uncommon. Chronic inflammatory changes of rheumatoid arthritis can cause significant disability of the foot. Initial involvement of the feet is noted in 16% of patients with acute manifestations of rheumatoid arthritis; however, the incidence of chronic foot deformities in patients with longstanding rheumatoid arthritis may approach 90% (65,69). In chronic rheumatoid arthritis, symmetric involvement is frequently reported, although early involvement may be asymmetric. Because of chronic inflammatory synovitis, the metatarsophalangeal joints become distended. This eventually leads to the loss of integrity of both the collateral ligaments of the metatarsophalangeal (MTP) joints and the supporting capsular structures, which sets the stage for progressive deformity due to loss of stability.

**PATHOPHYSIOLOGY**

Progressive destructive articular changes are characterized by erosion of the metatarsal heads with cystic degeneration. As a patient continues to ambulate in the presence of incompetent ligamentous and capsular structures, subluxation and eventual dislocation can occur at the MTP joints (17). In the presence of an active synovitis, the intrinsic muscles are overpowered by the extrinsic flexor and extensor muscles, and clawing of the interphalangeal (IP) joints and dislocation of the MTP joints can occur (Fig. 117.1). This clawing leads to a distal displacement of the plantar fat pad and the formation of intractable plantar keratoses beneath prominent metatarsal heads (Fig. 117.2). Marked rigidity of the foot due to ankylosis of the ankle, hindfoot, or midfoot makes the foot less supple, which compounds forefoot symptoms.

**Figure 117.1.** A: Rheumatoid arthritis with dislocated third metatarsophalangeal joint and chondrolysis of remaining lesser MTP joints. B: Seven years later, severe hallux valgus with dislocation of the second, third, fourth, and fifth MTP joints has occurred.

**Figure 117.2.** A: Normal anatomy of the lesser toe. B: Pathophysiology of lesser toe deformity in rheumatoid arthritis. (From Coughlin M. The Rheumatoid Foot. Pathophysiology and Treatment of Arthritic Manifestations. Postgrad Med 1984;75:207, with permission.)
Stages of Rheumatoid Arthritis

Typically, the initial complaints of patients with inflammatory arthritis are ill-defined metatarsalgia and forefoot pain. These complaints are often associated with synovitis and concomitant intra-articular effusions that impair ambulation. Although ill-defined metatarsalgia may be misdiagnosed as an interdigital neuroma (80), in time chronic synovitis may make a diagnosis of rheumatoid arthritis more obvious. In the presence of forefoot problems, as time passes synovitis usually develops. Findings include nonspecific forefoot edema, swelling, tenderness to palpation, and impaired ambulation. In time, a hallux valgus deformity, subluxation or dislocation of the lesser MTP joints, and fixed hammer-toe or claw-toe deformities may develop (Fig. 117.4). Wagner (84) reported on 8,000 clinic visits to Rancho Los Amigos Hospital by patients with arthritis; in this group, 90 ankle arthrodeses were performed. Only three ankle arthrodeses were performed for patients with rheumatoid arthritis. Thus, a very small percentage of patients had rheumatoid arthritis of the ankle and progressed to surgery.

HISTORY, PHYSICAL EXAMINATION, AND RADIOGRAPHIC EXAMINATION

The radiographic findings of rheumatoid arthritis are typical of synovial inflammatory diseases associated with hyperemia, periarticular osteopenosis, and soft-tissue swelling. In time, marginal cortical erosions may develop that then progress to central erosions, joint-space narrowing, and eventual joint subluxation and dislocation as destruction of the articular cartilage develops. Rheumatoid arthritis tends to involve the first, fourth, and fifth metatarsal joints early on (32), specifically the medial aspect of the first, second, third, and fourth metatarsals and the lateral aspect of the fifth metatarsal. The IP joints of the toes are typically not involved except for the hallux. Hindfoot and midfoot deformities include midfoot collapse, pes planus, and subtalar sclerosis. Look for involvement of the knee and hip joints, because in general, involvement of these joints requires total joint arthroplasty before reconstructive foot surgery (20).
Stage 1Discomfort, synovitis without significant joint-space narrowing; no bony deformity
Stage 2Minimal erosive articular changes; early involvement without fixed deformity
Stage 3No significant joint erosion; soft-tissue deformity
Stage 4Severe hallux valgus, lesser MTP-joint dislocation with fixed hammer-toe or claw-toe deformities, articular destruction, pes plano valgus, hindfoot arthritis

PRINCIPLES OF TREATMENT

The principles of nonoperative treatment involve maintaining a good gait pattern and independent ambulation, or restoring adequate gait by minimizing inflammation, reducing pain, and supporting inflamed joints. In the presence of fixed deformity, surgical correction may be necessary, with arthrodeses and occasional excisional arthroplasty being the preferred treatments.

Use rest and limited weight bearing to relieve the swollen and inflamed joints of an acute rheumatoid flare-up. Application of a cast may be necessary. Roomy footwear, padding, and prefabricated or custom longitudinal arch supports may be efficacious. An important aspect of nonsurgical care involves proper shoes and the modification of shoes. A metatarsal pad placed proximal to an area of plantar keratoses may diminish tenderness and relieve discomfort associated with increased pressure. Many patients with early rheumatoid foot deformities can be adequately treated with a soft-soled and broad-toed shoe (89). An in-depth shoe with a custom-molded, a viscoelastic, or a soft insole may help to accommodate progressive deformities. Working with a podiatrist with skill in the use of specialized orthopaedic appliances helps to maintain function and prevent deformities. Orthotic devices help redistribute plantar weight-bearing forces, which may decrease discomfort associated with pressure areas, and support unstable joints. Shoes with low heels, increased depth, and soft leather uppers may be used to accommodate hammer-toe and claw-toe deformities. A soft-soled rocker-bottom shoe is helpful in the treatment of not only metatarsalgia but hindfoot deformities.

Instruct patients in appropriate foot care and show them how to look for potential breakdown areas in their skin. Patients with hindfoot and midfoot discomfort with minimal or no deformity can be adequately treated with a custom arch support or a polypropylene ankle or foot orthosis. As deformities increase, custom bracing may alleviate discomfort and provide support. A molded leather ankle lacer with steel stays can be used inside a shoe and provides significant hindfoot and ankle support. With progressive deformity or deformity associated with unremitting pain refractory to conservative treatment, surgical intervention for forefoot, midfoot, or hindfoot dysfunctions may be indicated.

The objective with conservative care or with surgery is to maintain or attain a plantigrade foot. The clinical course of a patient’s rheumatoid arthritis determines the treatment program. Direct treatment toward correction of deformity, restoration of function, and pain relief. Pharmacologic treatment is an essential part of controlling the disease process, and involvement of a rheumatologist for medical management is most important. Rheumatologists often prescribe salicylates, nonsteroidal anti-inflammatory medications, gold salts, antimalarials, and immunosuppressive agents for the treatment of inflammatory arthritides, with the goals being reduction of inflammation and relief of pain. An occasional intra-articular corticosteroid injection may be helpful, but oral steroid therapy is employed less commonly because of the deleterious side effects associated with chronic use (24). I recommend that methotrexate be discontinued 1 week before and 1 week after surgery to avoid the diminished wound-healing capacity often associated with it. See Chapter 99 for more details on medical management. Cover patients who had previous total joint arthroplasty with perioperative antibiotics at the time of foot and ankle surgery.

Physical therapy on occasion may be helpful in treating forefoot and hindfoot deformities associated with rheumatoid arthritis. Stretching exercises for contracted Achilles tendon, manipulation of ankle and hindfoot joints to maintain or restore range of motion, muscle-strengthening exercises to assist in maintaining ambulatory capacity, and the use of ambulatory aids such as crutches, walkers, and canes may help in maintaining ambulation. With upper extremity involvement, platform or stairs may be necessary. Reduced ambulation during acute flare-ups, and stretching and exercises for involved joints are important elements of a physical therapy regimen to help maintain function in the patient with progressive rheumatoid arthritis.

PREOPERATIVE MANAGEMENT AND PLANNING

Whereas medical management is critically important throughout the progression of the rheumatoid disease process, surgical intervention depends on the progression of the disease process and its severity. Individualize the timing of specific surgical procedures for each patient. Although sometimes conservative management provides relief of pain, making surgical intervention unnecessary, a synovectomy may be indicated to slow the progression of the inflammatory process. With increasing deformity, the ultimate goal is to prevent the loss of capacity to ambulate that may occur with progression of the arthritis. Surgical intervention may be interspersed with long periods of conservative care. In general, proximal joint surgery (total hip and knee arthroplasty) should precede foot and ankle surgery. Hindfoot surgery typically precedes forefoot surgery (22). The rationale for hindfoot surgery preceding forefoot surgery is that with a progressive pes planus deformity, a recurrent forefoot deformity may occur. I prefer to operate on one foot at a time, because the magnitude of surgery may diminish ambulatory capacity in the postoperative period.

SURGICAL TECHNIQUES

LESSER METATARSOPHALANGEAL JOINT SYNOVECTOMY

Synovectomy of the lesser MTP joints is indicated for the treatment of painful joints early in the disease process, before significant deformity has occurred (23,11,24). This procedure is contraindicated in the presence of MTP joint subluxation or dislocation, or with the formation of intractable plantar keratoses; in these cases, it achieves limited gains. Excision of hypertrophic synovial tissue may slow or arrest the degenerative process, decrease distention of MTP joints, and reduce the soft-tissue deformation that would lead in time to subluxation and dislocation. Success of surgery depends on the length of remission, but a patient should be informed that a synovectomy may provide only temporary relief. Nonetheless, it helps to maintain function of the lesser MTP joints and toes.

- Center a dorsal longitudinal incision over the involved MTP joint. With multiple joint synovectomies, use a second and/or fourth interspace incision to expose adjacent joints.
- Using the extensor tendon as a guide, carry the dissection down through the extensor hood and incise the capsule, exposing the MTP joint.
- Resect proliferative synovial tissue on the medial and dorsolateral aspects, taking care to remove any synovium beneath the collateral ligaments. Carry the resection as far as in the plantar direction as possible.
- Close the joint capsule with absorbable sutures, and approximate the skin with interrupted sutures.
- Carry out a synovectomy of the first MTP joint through a dorsal longitudinal incision centered over it, using a technique similar to that described for the lesser MTP joints.

Postoperative Care

Apply a gauze-and-tape compression dressing at surgery, and change it weekly for 6 weeks. Initiate active and passive MTP range-of-motion exercises 3 weeks after surgery.

Results and Complications

Metatarsophalangeal joint synovectomy may diminish symptoms of metatarsalgia and reduce progression of deformity. Aho (2) and others (24,74,90) have reported good pain relief following synovectomy. Major complications include injury to the dorsal cutaneous nerve of the lesser toes. Take care to avoid injury to adjacent sensory nerves. In time, recurrence of synovial hypertrophy may lead to symptoms and require further surgery.

TREATMENT OF HAMMER-TOE DEFORMITIES

With time, chronic rheumatoid arthritis may lead to hammer-toe and claw-toe deformities that occur in association with MTP subluxation and dislocation. Whereas a mild deformity may be treated with passive manipulation and intramedullary Kirschner wire (K-wire) fixation (closed osteoclasis) (14,23,49,70), more severe deformities need a proximal phalanxectomy and osteotomy to achieve realignment with bony decompression (22,23,43,49,95).

- Center an elliptical incision over the dorsal proximal interphalangeal (PIP) joint of the lesser toe (Fig. 117.6). Excise the dorsal callus, extensor tendon, and joint capsule, exposing the PIP joint.
Further involvement of the remaining MTP joints. Arthroplasty be performed when two MTP joints required resection. I support this procedure because it frequently eliminates the need for later additional surgery with recommended that an entire forefoot arthroplasty be performed if three joints were involved. Marmor (the fifth MTP joint, perform an arthroplasty of the fifth MTP joint as well. Whereas Thomas (involving the other MTP joints. Rarely is the first MTP joint spared when the other lesser metatarsal joints are involved. When the entire forefoot is involved except for On occasion, only one or two MTP joints are involved, and a decision must be made as to whether an entire forefoot arthroplasty should be performed. If one or two joints are involved, an arthroplasty may be performed on only these joints. However, alert the patient that the disease process will likely progress in time, eventually involving other MTP joints. Rarely is the first MTP joint spared when the other lesser metatarsal joints are involved. When the entire forefoot is involved except for the fifth MTP joint, perform an arthroplasty of the fifth MTP joint as well. Whereas Thomas (85) recommended surgical resection for a single involved MTP joint, he recommended that an entire forefoot arthroplasty be performed if three joints were involved. Marmor (52) and others (9,126,72) recommended that an entire forefoot arthroplasty be performed when two MTP joints required resection. I support this procedure because it frequently eliminates the need for later additional surgery with further involvement of the remaining MTP joints.

- Sever the collateral ligaments on the medial and lateral aspects, allowing the condyles to be delivered into the wound. Take care to avoid injury to the adjacent neurovascular bundles.
- Resect the condyles of the proximal phalanx in the supracondylar region, and smooth them with a rongeur. As the toe is brought into correct alignment, if there appears to be any remaining tension at the PIP joint, ressect more bone. You may ressect the articular surface of the base of the middle phalanx with a rongeur to achieve arthrodesis, but this is optional.
- To stabilize the arthroplasty, introduce a 0.045 K-wire at the PIP joint, and drive it distally to exit the tip of the toe. With the toe aligned, drive the pin in a retrograde fashion, stabilizing the repair.
- If MTP joint arthroplasty is also done, advance the pin into the metatarsal shaft, stabilizing the arthroplasty site. Although the use of an intramedullary K-wire to stabilize the PIP arthroplasty site is a matter of preference, internal fixation appears to improve the cosmetic result by achieving and maintaining alignment postoperatively (83,85,95).

Postoperative Care
Apply a gauze-and-tape dressing, and change it each 7–10 days. Remove sutures and K-wires 3 weeks after surgery, and support the toes with a gauze-and-tape dressing for 3 more weeks. Discontinue dressings 6 weeks after surgery. Avoid constrictive shoe wear for at least 3 months following surgery.

Results and Complications
Although no long-term results of hammer-toe repairs in patients with rheumatoid arthritis have been reported, the goal of treatment is to achieve and maintain adequate alignment of the lesser toes. The major complication following surgery is recurrence of deformity, which in time may lead to hyperextension of the MTP joint. Recurrent deformity may be due to a lack of initial correction or to true recurrence. Other complications include prolonged swelling, which usually subsides in time; mlooding of the toe to the shape of the adjacent toes; and, on occasion, a painful arthroplasty site, for which injection with corticosteroids often gives lasting relief.

TREATMENT OF THE LATERAL RHEUMATOID FOREFOOT
A forefoot arthroplasty is indicated for progressive rheumatoid arthritis associated with hallux valgus, metatarsalgia, and subluxation/dislocation of the lesser MTP joints. The choices of techniques include a Hoffman procedure (metatarsal head excision) (Fig. 117.7A) (38), a Fowler procedure (resection of the base of the proximal phalanx with beveling of the plantar metatarsal surface) (Fig. 117.7B) (30), and a Clayton procedure (partial proximal phalangectomy combined with metatarsal head resection) (Fig. 117.7C) (13,14 and 15). The choice of operative incisions depends on your preference. A transverse plantar incision, an elliptical plantar incision with resection of redundant skin and soft tissue, a transverse dorsal incision, and multiple longitudinal dorsal incisions are all alternatives (Fig. 117.8). I prefer three longitudinal dorsal incisions, with the medial incision centered over the first MTP joint and the two lateral incisions located over the second and fourth intermetatarsal spaces.

On occasion, only one or two MTP joints are involved, and a decision must be made as to whether an entire forefoot arthroplasty should be performed. If one or two joints are involved, an arthroplasty may be performed on only these joints. However, alert the patient that the disease process will likely progress in time, eventually involving other MTP joints. Rarely is the first MTP joint spared when the other lesser metatarsal joints are involved. When the entire forefoot is involved except for the fifth MTP joint, perform an arthroplasty of the fifth MTP joint as well. Whereas Thomas (85) recommended surgical resection for a single involved MTP joint, he recommended that an entire forefoot arthroplasty be performed if three joints were involved. Marmor (52) and others (9,126,72) recommended that an entire forefoot arthroplasty be performed when two MTP joints required resection. I support this procedure because it frequently eliminates the need for later additional surgery with further involvement of the remaining MTP joints.

- Through two longitudinal dorsal incisions centered in the second and fourth interspaces, expose the lesser MTP joints (Fig. 117.8). Commence the incisions at the webspace and extend them proximally 3 cm.
- With the skin flaps slightly undermined, dissect obliquely to each side to expose the adjacent MTP joints.
- Identify the extensor tendons, but leave them intact except in the presence of significant contracture.
- Identify the bases of the proximal phalanges by tracing the insertion of the long extensor tendon. Take care to protect the neurovascular bundles.
- With sharp dissection, incise the capsule and expose the metatarsal neck and head circumferentially. Plantar flexion of the phalanx often delivers the metatarsal head dorsally.
- Resect redundant synovium.
- With a bone-cutting rongeur, transect the metatarsal in the metaphyseal region. The amount of bone resection depends on the shortening that has occurred with the dislocation.
- Grasp and remove the metatarsal head. Removal of the entire metatarsal head in one piece avoids leaving remnants of bone, which may later lead to recurrent deformities.
- Bevel the plantar aspect of the metatarsal shaft to reduce any prominence. Resect any synovial cysts or bursa as well.
- I prefer to preserve the concave surface of the proximal phalanx (avoiding a partial proximal phalangectomy), because I believe the base of the proximal phalanx affords significant stability to the pseudoarticular contact at the MTP joint. With decompression of the MTP joint, I have found that in time the fat pad routinely realigns, thereby eliminating the need for resection of the plantar skin (Fig. 117.9A). It is important that the excisional arthroplasty of the lesser MTP joints achieve decompression of the MTP joint; usually a space of 1 cm between the resected metatarsal surface and the base of the proximal phalanx is sufficient.

**Figure 117.9.** Metatarsal head resection. **A:** Excision of the four lesser metatarsal heads through two longitudinal intermetatarsal incisions. **B:** Introduction of the index fingertip into the resection site. **C:** Stabilization of the digits with intramedullary K-wires. **D:** Second and third metatarsals of equal length, and fourth and fifth metatarsals progressively slightly shorter.

- With longitudinal tension on the toe, insert the tip of your index finger into the resection arthroplasty site and gauge the adequate amount of resection (Fig. 117.9D). There should be room for the tip of your finger to be placed comfortably in this interval. It is important to resect the metatarsal heads and metaphysis symmetrically. I prefer that the first and second metatarsals be of equal length, with the third, fourth, and fifth metatarsals being progressively shortened from medial to lateral. This helps to avoid an abnormally long metatarsal with consequent development of intractable plantar keratoses.
- Following metatarsal head resection, correct hammer-toe deformities with a closed osteoclasis or an open hammer-toe repair (see Chapter 113). Introduce an 0.045 K-wire at the PIP joint and drive it in a distal direction to exit the tip of the toe (Fig. 117.9C). Advance it proximally into the metatarsal diaphyses and metaphyses.
- Embed the K-wire in the proximal metatarsal base to give stability to the arthroplasty site. Bend the pin at the tip of the toe to prevent proximal migration.
- Approximate the arthroplasty sites with the skin closure (Fig. 117.9D).

**Postoperative Care**

Apply a gauze-and-tape compression dressing at surgery. Change it weekly for approximately 6 weeks. Remove K-wires and sutures 3 weeks after surgery. Allow the patient to ambulate in a wooden-soled postoperative shoe. Immediately after surgery, observe the circulatory status of the toes. With severe deformities, vascular compromise may develop, necessitating removal of the K-wires.

**Results and Complications**

In general, the results of lesser MTP joint arthroplasty are gratifying (Fig. 117.10). Mann and Thompson (66) showed 89% good and excellent results at final follow-up. Of 1,874 cases reported in many series using various surgical techniques, an overall satisfaction rate of 81% has been reported (4.5.9-13, 16, 26, 30, 35, 44, 55, 58, 60, 62, 63, 66, 68, 79, 80, 91, 92-95).

**Figure 117.10.** A: Preoperative radiograph demonstrating hallux valgus and dislocation of lesser metatarsophalangeal joints. B, C: Radiographs taken after MTP fusion and lesser MTP joint arthroplasty.

Reports on partial proximal phalangectomy show a satisfaction rate of 65% (180 of 278 cases) (16, 26, 68, 79). Partial proximal phalangectomy with combined beveling of the metatarsal head (4.5.9-17, 30, 35, 48, 55, 57, 59, 60, 62, 63, 70). Metatarsal head excision (Hoffman procedure) has achieved the highest published success rate—89% good and excellent results (748 of 843 cases) (4.5.9, 24, 26, 33, 37, 38, 44, 49, 56, 66, 80, 85, 91, 92-95). I prefer metatarsal head resection to achieve decompression of the MTP joint. The most common complication following forefoot arthroplasty is recurrence of intractable planar keratoses or recurrent pain due to inadequate resection. Clayton (13, 14) reported a 10% reoperation rate resulting from inadequate resection of the lesser metatarsal heads. Thus, adequate decompression at the MTP joint is extremely important to avoid recurrent deformity. While chronic swelling of the forefoot postoperatively is a frequent complaint, it usually subsides with time. On the other hand, isolated resection of one or two metatarsal heads should be avoided, as intractable plantar keratoses often develop beneath the remaining metatarsal heads. I believe that revision surgery for the rheumatoid forefoot becomes necessary most frequently for the following reasons: (a) irregular lesser metatarsal head resection, (b) limited surgery with resection of only one or two metatarsal heads, (c) bony regrowth in the area of the lesser metatarsal head resection, and (d) recurrent deformity following development of hindfoot or ankle joint problems.

Use careful and meticulous surgical technique, with special attention to the resection of the metatarsal heads in a line in which the first and second metatarsals are of equal length and the third, fourth, and fifth are progressively shorter, to help avoid recurrent plantar keratoses. Likewise, meticulous debridement in the area of the metatarsal head resection is necessary because complete removal of all bone fragments will minimize bony regrowth. All four lesser metatarsal heads should be resected; Avoid limited surgery in which only one or two metatarsal heads are resected. Likewise, in the presence of hindfoot or ankle joint dysfunction, treat these problems first. Reserve surgery to correct rheumatoid forefoot deformities for patients with significant pain and disability, because this is truly a salvage procedure, and after surgery the lesser toes will have little active function.

**TREATMENT OF THE FIRST METATARSOPHALANGEAL JOINT**

Although in the past, resection arthroplasty of the first MTP joint was recommended concomitantly with forefoot reconstruction (4, 5, 7, 30, 35, 50, 62), McGarvey and Johnson (63) and others (35, 67) have found that Keller resection arthroplasty for the rheumatoid forefoot frequently fails. McGarvey and Johnson (63) reported a 57% level of dissatisfaction after Keller arthroplasty combined with lesser MTP forefoot arthroplasty. They noted recurrent hallux valgus in 53% and forefoot instability in...
reported significant reduction in the 1–2 intermetatarsal angle following fusion. Mann and Katcherian (31) reported that 71% of resection arthroplasties of the first MTP joint were unsatisfactory. Likewise, silastic implant arthroplasty of the first MTP joint has been recommended as an alternative treatment (23,41). However, silastic implants have been fraught with both long- and short-term complications, including implant fracture, synovitis, recurrent osteolysis, and recurrent pain (81). First-MTP-joint arthrodesis is recommended for the stability that it affords the first ray (17,26,53,57,58,60,67,75). A resection arthroplasty of the lesser MTP joints affords little lateral stability to the hallux, allowing lateral displacement. With an arthrodesis, the first ray bears increased pressure, and a permanently stable construct is created. Henry and Waugh (36) observed improved weight-bearing function of the great toe following first-MTP arthrodesis, and Watson (92) concluded that arthrodesis was the treatment of choice for correction of a forefoot deformity (Fig. 117.11).

Figure 117.11. Arthrodesis of the first metatarsophalangeal joint. A: Dorsal incision exposing the MTP joint of the hallux. B: Resection of the MTP articular surfaces. C: AP (D) and lateral (E) radiographs demonstrating compression-plate fixation of the first MTP joint arthroplasty. The excisional arthroplasty of the lesser MTP joints has been stabilized with K-wires. To a large extent, the postoperative alignment and stability of the great toe determine the ultimate level of patient satisfaction. Fitzgerald (28) noted a high correlation between degenerative IP joint arthritis and the magnitude of MTP deformity, and he recommended arthrodesis for 20° of valgus or more. Recommendations for valgus alignment vary from 15° to 30°, and whereas a straight position (minimal valgus or slight varus) may lead to pain along the medial border of the hallux as it strikes the toe box, excessive valgus is often poorly tolerated as well. I usually recommend arthrodesis in 15° to 20° of valgus because it tends to attain a more acceptable first-ray alignment in relationship to the lesser metatarsals. Recommendations for dorsiflexion (in relationship to the planter surface of the foot) vary from 10° to 30°, with 20° being the average recommendation. Women designing to wear heel-less shoes may desire increased dorsiflexion. Minimal dorsiflexion (less than 10°) may leave the patient with a complaint of pressure at the tip of the toe with ambulation, and dorsiflexion greater than 40° may lead to increased pressure beneath the first metatarsal head. In measuring the dorsiflexion at the fusion site, take into account the average plantar inclination of the first metatarsal, which is 15°. Combined with dorsiflexion of the phalanx of 5° to 15°, this translates into 20° to 30° of dorsal angulation at the arthrodesis site.

Correct rotation of the great toe is important. Place the toe in neutral rotation when arthrodesed. Excessive pronation may lead to pressure on the medial border of the toenail, causing an ingrown toenail.

An increased metatarsal angle between the first and second is not a contraindication for MTP arthrodesis. Harrison and Harvey (34) and others (54,58,64,67) have reported significant reduction in the 1–2 metatarsal angle following fusion. Mann and Katcherian (58) and Humbert et al. (39) have noted an average decrease in the 1–2 metatarsal angle of approximately 6° following arthrodesis. Thus, a first-metatarsal osteotomy is rarely indicated after MTP fusion.

To an extent, the postoperative alignment and stability of the great toe determine the ultimate level of patient satisfaction. Fitzgerald (28) noted a high correlation between degenerative IP joint arthritis and the magnitude of MTP deformity, and he recommended arthrodesis for 20° of valgus or more. Recommendations for dorsiflexion range from 10° to 30°, and whereas a straight position (minimal valgus or slight varus) may lead to pain along the medial border of the hallux as it strikes the toe box, excessive valgus is often poorly tolerated as well. I usually recommend arthrodesis in 15° to 20° of valgus because it tends to attain a more acceptable first-ray alignment in relationship to the lesser metatarsals. Recommendations for dorsiflexion (in relationship to the plantar surface of the foot) vary from 10° to 30°, with 20° being the average recommendation. Women designing to wear heel-less shoes may desire increased dorsiflexion. Minimal dorsiflexion (less than 10°) may leave the patient with a complaint of pressure at the tip of the toe with ambulation, and dorsiflexion greater than 40° may lead to increased pressure beneath the first metatarsal head. In measuring the dorsiflexion at the fusion site, take into account the average plantar inclination of the first metatarsal, which is 15°. Combined with dorsiflexion of the phalanx of 5° to 15°, this translates into 20° to 30° of dorsal angulation at the arthrodesis site.

Correct rotation of the great toe is important. Place the toe in neutral rotation when arthrodesed. Excessive pronation may lead to pressure on the medial border of the toenail, causing an ingrown toenail.

An increased metatarsal angle between the first and second is not a contraindication for MTP arthrodesis. Harrison and Harvey (34) and others (54,58,64,67) have reported significant reduction in the 1–2 metatarsal angle following fusion. Mann and Katcherian (58) and Humbert et al. (39) have noted an average decrease in the 1–2 metatarsal angle of approximately 6° following arthrodesis. Thus, a first-metatarsal osteotomy is rarely indicated after MTP fusion.

For an MTP arthrodesis, exsanguinate the foot and use a tourniquet.
- Center a 5 cm dorsal longitudinal incision over the first MTP joint and protect the adjacent neurovascular bundles. They are often ill defined in the presence of chronic soft-tissue inflammation or where previous surgery has been performed.
- Deepen the dissection along the medial aspect of the extensor hallucis longus tendon to the MTP joint (Fig. 117.11A). Enhance the exposure with a self-retaining retractor.
- Release the collateral ligaments and the adductor hallucis. Release the medial and lateral capsules, and resect the proliferative synovial tissue.
- Initially, soft-tissue release adequately decompresses the joint. The amount of bony resection depends on the shortening achieved with the lateral MTP joint arthroplasties.
- Use transverse osteotomies to resect the articular surfaces of the base of the proximal phalanx and the metatarsal head (Fig. 117.11B). Make these cuts with a small oscillating saw or osteotome. The first ray at the conclusion of surgery should not be significantly longer than the adjacent second ray. Usually, if the lateral forefoot arthroplasties have been performed before first-ray surgery, appropriate postoperative length is achieved. Frequently, you must resect additional bone to shorten the first ray. More bone is usually removed from the distal metatarsal than from the proximal phalanx.
- Resect the medial eminence of the metatarsal.
- The angle of the osteotomy of the articular surface of the proximal phalanx and first metatarsal determines the position of fusion. Valgus of 10° to 20° and dorsiflexion of 15° to 25° are most common. Usually, women prefer more MTP dorsiflexion than men. Determining the valgus position of the arthrodesis site can be difficult.
- Once the MTP joint has been decompressed, ascertain the flexibility of the metatarsocuneiform joint by compressing the transverse metatarsal joint. With adequate flexibility, fixation in 10° to 20° of valgus is appropriate (Fig. 117.11C, Fig. 117.11D and Fig. 117.11E).

An alternative to preparing flat arthrodesis surfaces is to create curved, cup-shaped surfaces. I have designed canulated reamers (18,19 and 20) that prepare the phalangeal and metatarsal surfaces so that rotation, valgus, and dorsiflexion/plantar flexion can be varied independently without changing other alignment factors.
- First, employ a barrel-shaped reamer to shape the metatarsal metaphysis into a cylinder (Fig. 117.12A). Then use a cup-shaped reamer to create a convex metatarsal surface (Fig. 117.12B). Ream the base of the phalanx to create a concentric concave surface (Fig. 117.12C).

- Fixation is possible with crossed K-wires, compression screws, and multiple intramedullary Steinmann pins. Application of a Vitallium mini-fragment plate dorsally gives increased strength of fixation (Fig. 117.12D) (21). In younger patients who do not have significant osteoporosis, fix the arthrodesis site with a small Vitallium compression plate. Other methods may be necessary in older patients with osteoporotic bone.
- Once the MTP joint has been placed in the appropriate amount of valgus and dorsiflexion, stabilize the fusion site with an 0.062 K-wire. Introduce it from a plantar/medial direction and drive it proximally across the MTP joint. It may be used temporarily during the plate application, or it may be left in place for 3–4 weeks to augment fixation.
- Alternatively, replace the K-wire with a cross-compression screw. In using the dorsal six-hole mini-compression plate (Fig. 117.12D), bend it to 10° to 20° of dorsiflexion and fix it dorsally with six bicortical screws.
- Take bimodal radiographs to ensure that the IP joint has not been violated.
Approximate the wound with interrupted subcutaneous and skin sutures.

Postoperative Care

Apply a gauze-and-tape compression dressing at surgery, and change it weekly. Permit the patient to ambulate in a wooden-soled postoperative shoe, initially bearing weight on the heel and the outer aspect of the foot. A below-knee walking cast is an alternative. Discontinue dressings or casting 8–12 weeks after surgery, when there is radiographic evidence of successful arthrodesis.

Alternative Method of Fixation

On occasion, either after a failed resection arthroplasty or in the presence of significant osteoporosis, intramedullary fixation may be necessary to stabilize an arthrodesis site. Use two double-pointed, threaded½-inch Steinmann pins for fixation (Fig. 117.13).

Figure 117.13. Intramedullary fixation of first-MTP-joint arthrodesis. A: Introduction of double-pointed threaded Steinmann pins. B: Radiograph showing the pins stabilizing the MTP joint.

- After preparing the MTP joint surfaces, center a threaded Steinmann pin on the base of the proximal phalanx and drive it distally across the IP joint through the distal phalanx and out through the tip of the toe (Fig. 117.13A).
- Attach a drill to the distal end of the pin, and pull this pin, under power, farther distally until its proximal tip is flush with the prepared phalangeal surface. Use a pin cutter to remove 4 inches of the distal aspect of the pin so that it will not interfere when a second pin is drilled distally.
- Center a second double-pointed, threaded Steinmann pin just to the medial side of the first pin, and drive it in a similar fashion across the IP joint and out the tip of the toe.
- Attach the drill to the distal end of the second pin, and pull this pin distally until its proximal point is flush with the prepared phalangeal surface.
- Position the toe in the desired amount of rotation, valgus, and dorsiflexion. With axial compression pressure on the phalanx across the joint, drive the longest pin in a retrograde fashion across the MTP joint and into the metatarsal shaft. After it penetrates the proximal metatarsal plantar medial cortex, further advancement is not necessary. Use a pin cutter to sever the pin, leaving ½ to ¼ inch extending beyond the tip of the toe for ease of removal after successful fusion occurs (Fig. 117.13B).
- Attach the power drill to the first pin that was placed, and drive it proximally in a similar manner.
- Following placement, cut the pin with ½ inch protruding beyond the tip of the toe.
- Carry out the subcutaneous and skin closures as previously described. Apply a compression dressing.

Twelve to 16 weeks after surgery, when the arthrodesis is solidly healed, remove the pins under a digital nerve block in an office setting. Oral analgesics are helpful as well. Use a pin remover or power drill to remove the Steinmann pins.

Results and Complications

A review of the literature reveals an overall fusion rate of 91% (1,394 of 1,536 arthrodeses; range, 77% to 100%) (6, 8, 12, 19, 21, 22, 29, 31, 34, 36, 39, 40, 42, 56, 60, 64, 75, 76, 78, 83, 86, 87, 96, 97 and 98). Mann and Thompson (60) reported on MTP arthrodesis in 18 feet with an average 4-year follow-up. Their results were classified as good or excellent in 16 of 18. Seventeen of 18 went on to successful arthrodesis. Degenerative arthritis of the IP joint was noted radiographically but was not believed to be clinically significant (Fig. 117.14). A 92% fusion rate (1,074 of 1,164) with the use of conical reamers has been reported (8, 19, 21, 29, 40, 42, 61, 64, 75, 76, 82, 96, 98). Coughlin and Abdo (21) reported on 47 patients (58 feet) who were evaluated after first-MTP-joint fusion. Twenty-eight patients had rheumatoid arthritis. A 98% fusion rate was achieved. The average correction of the 1–2 intermetatarsal angle was to 9.5° and the hallux valgus angle was corrected to 17.1°.

Figure 117.14. Degenerative arthritis of the interphalangeal joint associated with first-MTP-joint arthrodesis in minimal valgus.

Complications after arthrodesis are uncommon and include nonunion and malunion. Unsuccessful arthrodesis does not necessarily lead to a painful pseudoarthrosis, and McKeever (64) noted that a nonunion may still give an acceptable result (Fig. 117.15). Results tend to vary depending on the method of internal fixation and operative technique utilized. The highest rate of nonunion (23%) (31) follows crossed K-wire fixation. Malunion in any plane—whether rotation, varus/valgus, or dorsiflexion/plantar flexion—is poorly tolerated. IP joint arthritis may develop following MTP fusion and has been reported to vary from 6% to 60% (6, 12, 21, 22, 36, 67, 76). Coughlin and Abdo (21) reported a 10% incidence of progressive IP joint arthritis, but only 2% were symptomatic.
Relative contraindications to MTP arthrodesis include degenerative arthritis of the IP joint and bony insufficiency due to previous excisional arthroplasty or severe osteoporosis. Arthrodesis in these situations can be more difficult to achieve.

EXCISIONAL ARTHROPLASTY

Although I do not favor excisional arthroplasty, others do prefer this technique, which Keller described in 1904 (46). In an older patient who may have difficulty with the compliance required for MTP arthrodesis or in the presence of recurrent infection or atrophic skin, excisional arthroplasty may be a simple and expeditious procedure. Resection of the base of the proximal phalanx detaches both the intrinsic muscle insertions and the plantar aponeurosis. Although this salvage procedure allows correction of the deformity by decompression of the MTP joint, it shortens the toe and impairs strength and control of the hallux. Preoperative counseling is important to ensure that the patient is aware of these factors.

- Deepen a longitudinal incision on the dorsomedial aspect of the first MTP joint along the medial aspect of the extensor hallucis longus tendon. Take care to protect the dorsal and plantar neurovascular bundles.
- Incise the MTP joint capsule, and expose the base of the proximal phalanx.
- Elevate the capsule off the medial eminence, and resect the medial eminence.
- Dislocate the base of the proximal phalanx. With a power saw, resect approximately one third of the proximal phalanx (Fig. 117.16). Excessive resection may lead to a weakened or flail toe or a cock-up deformity (22).

Postoperative Care

Apply a gauze-and-tape compression dressing at surgery, and change it weekly for approximately 6 weeks. Remove sutures and the intramedullary K-wire 3 weeks after surgery.

**Results and Complications**

Shortening of the hallux, loss of power, and lateral metatarsalgia are major complaints following excisional arthroplasty. Henry and Waugh (36) reported lateral metatarsalgia following the Keller procedure and advocated MTP fusion. You may note a recurrence of hallux valgus after excisional arthroplasty, especially with progression of the inflammatory process (Fig. 117.17A). A cock-up or claw-toe deformity of the hallux, with detachment of the intrinsic muscle insertion on the base of the proximal phalanx, has also been reported as a postoperative result of excisional arthroplasty (Fig. 117.17B) (22).

**Repair of the Rheumatoid Hindfoot**

Involvement of the hindfoot in chronic rheumatoid arthritis is not uncommon. Vainio (89) reported that 72% of women and 59% of men with chronic rheumatoid arthritis had involvement of the subtalar (Fig. 117.18A) and midtarsal joints. Clayton and Gianone (15) noted a tenfold incidence of forefoot involvement in relationship to the hindfoot.
The typical findings with chronic rheumatoid arthritis are midfoot and hindfoot pain, swelling, flattening of the longitudinal arch, and progressive valgus of the hindfoot. Again, conservative care includes proper footwear, rest to relieve swollen and inflamed joints from the stresses of weight bearing, padding, and longitudinal arch supports. When progressive deformity occurs or unremitting pain is refractory to conservative treatment, surgery of the hindfoot may be necessary.

Prior to surgery, evaluate the vascular supply of the foot. Rheumatoid vasculitis, while uncommon, may present an increased risk to wound healing. Recognition of the degree of involvement of other joints necessitates planning various lower-extremity operations. With isolated forefoot involvement, occasionally a repair of the rheumatoid forefoot will precede total hip and knee arthroplasty to improve ambulatory capacity after surgery. Therefore, if the hindfoot is mobile and relatively uninvolved, forefoot reconstruction usually proceeds first. When the midfoot and hindfoot are significantly involved with rheumatoid arthritis, you may delay surgical intervention so that total knee and total hip arthroplasty may be performed first. Then align the hindfoot with respect to the overall axial alignment of the lower extremity. If both forefoot and hindfoot are involved, the hindfoot reconstruction should precede the forefoot reconstruction.

The involvement of specific joints and the deformities that are present help in decision making. When an isolated talonavicular joint is involved (Fig. 117.18A), arthrodesis of this joint may give good results. Early talonavicular fusion may arrest the progression of insidious pes planus and eliminate a later need for more extensive hindfoot correction (Fig. 117.13). Involvement of the metatarsocuneiform joint also may be treated with isolated arthrodesis of the Lisfranc joint.

When the talonavicular and calcaneocuboid joints are relatively uninvolved, and when the valgus deformity of the hindfoot can be passively corrected, subtalar fusion may be indicated. In this situation, where valgus is usually not excessive, an in situ fusion with an iliac crest graft can be performed without significant alteration of the transverse tarsal joint. The development of a valgus deformity of the hindfoot can occur because of various pathologic conditions. It may be associated with erosion of the lateral subtalar joint, hindfoot ligamentous laxity, or both. It may also be associated with a valgus deformity of the ankle. When a unilateral valgus deformity occurs suddenly, suspect a rupture of the posterior tibial tendon. Whether a soft-tissue reconstruction or hindfoot arthrodesis is preferable depends on the condition of other hindfoot joints and the severity of the deformity. See Chapter 118 for a discussion of the treatment of rupture of the posterior tibial tendon, and Chapter 115 for a description of hindfoot arthrodesis.

With progressive involvement of the transverse tarsal joint or with more severe and irreducible valgus of the hindfoot, perform a triple arthrodesis, not only to stabilize the hindfoot but also to correct the deformity (Fig. 117.19). In the patient with hindfoot involvement and a rigid forefoot (Fig. 117.20A), the objective is to obtain a plantigrade foot. Therefore, a triple arthrodesis is usually necessary (Fig. 117.20B). However, after completion of the subtalar component of this fusion, you must pronate the forefoot or a plantigrade foot will not be obtained. This correction is achieved at the transverse tarsal joint.

If a severe valgus deformity is present with a supple forefoot, a subtalar fusion may be feasible, but in all probability a bone graft to realign the excessive valgus deformity will be necessary. The objective is to obtain heel valgus of 5° at the completion of the arthrodesis. Failure to perform a bone graft with a severe valgus deformity may lead to a recurrence of valgus.

Uncommonly, the ankle joint is involved in severe rheumatoid arthritis. When progressive hindfoot valgus has occurred, hindfoot stabilization is often indicated. The choice between subtalar and triple arthrodesis depends on several factors, including the severity of joint involvement, the degree of joint deformity, and the ankle involvement. Nonetheless, attention to the ankle joint is necessary, since subtalar or triple arthrodesis with concurrent ankle disease may eventually progress to a pantalar arthrodesis.

Wagner (84) noted that ankle fusion is rarely indicated in rheumatoid arthritis. When significant degeneration has occurred, surgical intervention may be necessary (Fig. 117.21). Whereas long-term evaluation of total ankle arthroplasty has revealed suboptimal results (47,69,98,99), newer uncemented components have yielded encouraging results (Fig. 117.22) (48). Ankle arthrodesis also may be an alternative for the treatment of end-stage ankle arthritis refractory to conservative care. On the rare occasion that subtalar and ankle joints are involved, perform pantalar arthrodesis. However, even with significant chondrolysis of the ankle joint, surprisingly...
good function may be retained.

Figure 117.21. AP (A) and lateral (B) radiographs demonstrating ankle arthrodesis in a rheumatoid patient following spontaneous subtalar arthrodesis at an early age.

The techniques for talonavicular, subtalar, triple, and ankle arthrodeses are described in Chapter 115. The use of autogenous iliac crest graft depends on the deformity and the fusion that is attempted. If correction is desired, bone grafting may be necessary. Occasionally, a bone mill is used in the preparation of bone. This graft is then placed in the realigned subtalar joint, which is then stabilized with internal fixation.

ACHILLES TENDINOSIS AND RUPTURE

PATHOPHYSIOLOGY

The gastrocnemius muscle and the soleus muscles combine in the posterior compartment of the leg to produce a common tendon, the Achilles tendon, which inserts into the posterior tuberosity of the calcaneus. The tendon does not have an accompanying synovial sheath, but it is surrounded by a pannus of fibrous covering that is derived from the crural fascia. During steady-state walking, the primary function of the gastrosoleus muscle group is to decelerate the tibia as it passes over the foot. This is accomplished with eccentric muscle contraction. Toe-off is a passive event during steady-state walking and an active event during steady-state running or acceleration.

Using pathologic criteria, the classification of Achilles tendon dysfunction is best divided into paratenonitis, tendinosis, and partial or complete rupture. Paratenonitis is defined by inflammation of the tissues surrounding, but not including, the Achilles tendon. Paratenonitis is commonly attributed to athletic training errors, such as ineffective stretching or warm-up and overuse. Mechanical factors, such as excessive foot pronation or a tight Achilles tendon, have also been implicated. Tendinosis is defined by degenerative changes within the substance of a tendon; these changes are probably age related and may represent a precursor to partial tears. Histologic examination of chronic Achilles tendinosis reveals abnormal fibrous structure, focal hypercellularity, and vascular proliferation. Curiously, inflammatory cells are not found. Angiographic and microangiographic examinations reveal a paucity of vasculature in the segment of tendon between 2 and 6 cm proximal to the insertion. Clinical findings suggest that this same area is susceptible to tendinosis and rupture.

PRINCIPLES OF TREATMENT

The goal of treating Achilles tendinosis is to alleviate pain, prevent further degeneration, and preserve function. The goal of treating Achilles tendon ruptures is to restore the functional integrity to the gastrosoleus complex. For both conditions, surgical and nonsurgical methods are used in an effort to maximize outcome.

ASSESSMENT

The patient with Achilles tendinosis presents with pain over the Achilles tendon that is aggravated by activity. Physical examination begins with gait analysis; moderate to severe tendinosis produces an antalgic pattern. Examine the patient in the standing position to evaluate swelling or fullness related to the Achilles tendon. Assess calf atrophy by comparison with the contralateral extremity. Have the patient perform a repeated single-heel rise test. This is accomplished by having the patient stand at a nearby wall using hands for balance. The patient lifts the unaffected extremity while performing repeated single-heel rises on the affected extremity. The test is positive if the patient is unable to perform the maneuver owing to pain or if the maneuver causes pain at the Achilles tendon. Then seat the patient and palpate the posterior leg to assess swelling and tenderness. Nodular or fusiform swelling typically accompanies tendinosis.

Diagnostic imaging for the patient with Achilles tendinosis begins with a lateral radiographic view of the distal leg and hind foot. Look for intratendinous calcification associated with tendinosis and check the topography of the posterior superior calcaneus. The presence of a hyperconvex superior tuberosity of the calcaneus may be associated with distal tendinosis. Although it is not required for evaluation of Achilles tendinosis or rupture, magnetic resonance imaging (MRI) is probably the most useful imaging modality. On a T2-image sequence, tendinosis shows increased signal activity within the tendon as well as localized thickening, cystic changes, and even partial tears.

Rupture of the Achilles tendon may occur without antecedent symptoms or may follow a period of pain associated with Achilles tendinosis. Rupture is associated with the acute onset of pain over the Achilles tendon and the loss of plantar flexion power, either subtle or overt. Occasionally, the patient recalls sensing or hearing a "pop" at the time of rupture. Examination of the standing patient may reveal subtle to massive swelling along the posterior leg. With the patient in a prone position, perform a Thompson's test by squeezing the calf at midsubstance and looking for the absence of foot plantarflexion. When foot plantarflexion is not observed, the test is considered positive and the diagnosis of ruptured Achilles tendon is established. Palpation of the Achilles tendon itself may reveal a defect. Failure to find this defect, however, does not rule out tendon disruption.

Complete tears of the Achilles tendon are easily identified on MRI, but the diagnosis is usually obvious on clinical examination as well. MRI is not required for the routine evaluation of Achilles tendon ruptures.

CLASSIFICATION
Achilles tendinosis consists of a spectrum of injuries ranging from small focal areas of degeneration associated with mild pain and minimal dysfunction through significant areas of degeneration and partial tearing associated with significant discomfort and loss of function. Furthermore, tendinosis can be classified with an anatomic system based on the location of the degeneration relative to the insertion. Noninsertional tendinosis includes degenerative changes of the Achilles tendon between the musculotendinous junction to a point proximal to the insertion. Insertional tendinosis is limited to degeneration at the Achilles tendon insertion. This entity tends to be more focal, but similar treatment principles apply.

Achilles tendon ruptures may occur de novo through a section of healthy tendon or through a section of tendinosis. Lacerations, ruptures through previously healed tendon disruptions, and chronic ruptures are recognized as distinct entities.

PREOPERATIVE MANAGEMENT

Treat Achilles tendinosis initially with rest, application of ice, and nonsteroidal anti-inflammatory medication. Patients with moderate to severe symptoms require immobilization with a weight-bearing cast or removable cast boot. Once the pain, swelling, and tenderness have resolved, institute a rehabilitation program. Place emphasis on stretching the gastrosoleus motor complex. Also correct training errors related to intensity or frequency of activity.

Patients with acute, complete Achilles tendon rupture may be treated by surgical or nonsurgical methods. The ideal treatment of the acute, complete Achilles tendon rupture remains controversial. Nonsurgical methods have the advantage of avoiding wound complications, but they appear to have a higher rerupture rate (14,29).

Patients treated with surgical primary repair have a significantly lower rerupture rate and a higher degree of satisfaction; unfortunately, they are also prone to surgical complications such as deep infection, fistula, and skin or tendon necrosis (14,29).

For nonsurgical treatment of acute, complete Achilles tendon ruptures, use a non-weight-bearing equinus cast for 6 weeks, followed by a weight-bearing cast boot for a second 6-week period, then place a silicone heel wedge in the cast boot and subsequent shoewear. On the resolution of local warmth and swelling, begin a motion and strengthening program. Surgical treatment consists of primary repair of the Achilles tendon. Achilles tendinosis that is recalcitrant to a prolonged course of immobilization and conservative management requires surgical debridement and possible reconstruction. Although it is not required, an MRI may be obtained in order to better delineate the extent of tendon degeneration.

OPERATIVE TECHNIQUES

Debridement of Achilles Tendinosis

- Using general or regional anesthesia and a proximal thigh tourniquet, make a longitudinal incision parallel to and 1.5 cm anterior to the medial border of the Achilles tendon. Because the wound is prone to marginal necrosis and breakdown, exercise caution when handling soft tissues. By sharp dissection, expose the Achilles paratenon and incise it longitudinally, allowing complete inspection of the tendon.
- Degenerative changes are suggested by changes in local color, swelling, localized tissue edema, cystic changes, and partial tears. Sharply excise all degenerative sections. If the functional integrity of the tendon is compromised, perform a reconstructive procedure. If, however, the remaining tendon remains functionally competent, carefully repair the subcutaneous tissue with interrupted absorbable sutures and close the skin with nylon or skin clips.
- Apply a large, bulky, compression dressing with the foot in a neutral position.
- Postoperative management: Ten days after surgery, remove the sutures, place the leg in a removable cast, and begin a range-of-motion and strengthening program. After local swelling and warmth have resolved, gradually resume athletic activity.

Debridement of Achilles Tendinosis and Reconstruction with Transfer of the Flexor Hallucis Longus Tendon

If systematic debridement of the Achilles tendon results in the loss of functional integrity, it must be reconstructed. The flexor hallucis longus (FHL) tendon transfer provides not only additional collagen but also an additional motor unit.

- Make an incision on the medial aspect of the forefoot from the navicular to the metatarsal head. Identify the abductor hallucis muscle and release its fascia longitudinally from the first metatarsal. Retract the muscle to visualize the planatar nerves as well as the FHL and flexor digitorum longus (FDL) tendons.
- Carefully release the flexor knot of Henry as well as all fascial connections between the FHL and FDL tendons. Tenodese the distal FHL tendon with a #2 nonabsorbable suture. Then divide it just proximal to the tenodesis.
- Then make an incision along the medial aspect of the Achilles tendon from the calcaneus for as proximal as necessary. Identify the FHL muscle and its tendon. Pull it into the proximal wound. Using a quarter-inch drill, make a tunnel through the superior tuberosity of the calcaneus, smoothing its edges (Fig. 118.1). Then pass the FHL tendon through the tunnel. With the foot in a plantarflexed position, carefully adjust the tension in an effort to approximate that of the contralateral Achilles tendon. Then suture the FHL tendon to itself and to the adjacent Achilles tendon with nonabsorbable suture.
- Typically, the remaining section of FHL tendon is woven across the Achilles tendon defect.

Figure 118.1. Debridement and reconstruction of the Achilles tendon with the FHL tendon. A: The shaded area represents the area of tendinosis and debridement. B: Reconstruction with the FHL tendon. See text for details.

- If further reinforcement is required, perform a plantaris tendon weave, a turn-down of the central one third of the Achilles tendon, or a V-Y advancement of the musculotendinous junction.
- Close the subcutaneous tissue with interrupted absorbable sutures and close the skin with nylon or skin clips.
- Apply a large bulky compression dressing with the foot in a plantarflexed position.
- Postoperative management: Ten days after surgery, remove the sutures and apply another plantarflexed cast. Between 2 and 4 weeks after surgery, gradually bring the foot up to a plantigrade position and continue in a cast. At 5 weeks after surgery, use a removable cast boot so that range-of-motion and strengthening exercises can be instituted. At 12 weeks, discontinue immobilization. After local swelling and warmth have resolved, gradually resume athletic activity.

Achilles Tendon Turn-Down Flap

The reconstruction of the Achilles tendon with a turn-down flap is shown in Figure 118.2.
With the patient in the prone position, make a longitudinal incision from the midportion of the calf in the midline, extending distally to the posteromedial heel. Expose the posterior calcaneus and Achilles tendon, and excise the scar in the defect.

- Using a 4.5 mm drill, make a transverse tunnel in the calcaneal tuberosity, and enlarge it as needed using curets.
- Divide the lateral half of the Achilles tendon transversely at the proximal musculotendinous junction, just up to the lateral edge. Leave the lateral edge intact as a cuff. Split the proximal tendon longitudinally both laterally and in the midline. In the midline, turn the tendon down, stopping 1 inch proximal to the site of rupture. Separate this segment from the underlying muscle with a pair of scissors.
- Insert several stay stitches of 0 absorbable suture at the pivot point to prevent distal tearing.
- Form a tube of the now-distal tendon by sewing its medial and lateral sides together with a running 0 absorbable suture. Weave a #1 nonabsorbable suture through the end of the graft, and pass the suture through the calcaneal tunnel. Place the ankle in 20° of plantarflexion and tension the graft. Sew it back to itself with the nonabsorbable suture. Use multiple stitches of 0 absorbable suture to augment this repair and to secure the graft to the calcaneal periosteum at the medial and lateral ends of the tunnel.
- Divide the plantaris tendon proximally, leaving its calcaneal insertion intact, and fan it out as a covering for the reconstruction.
- Proximally repair the remaining medial half of the tendon to the remaining lateral cuff with interrupted 0 absorbable sutures.
- Close the subcutaneous tissue and skin of both wounds in layers. Apply a short-leg posterior splint with the ankle in 20° of plantarflexion.

**Postoperative management:** Remove the skin sutures at one week and apply a short-leg non-weight-bearing cast, with the ankle in 20° plantarflexion, which is worn for 5 weeks. Then apply a removable orthosis with the ankle at neutral for 4 to 8 more weeks. Allow active ankle exercises for motion without resistance during this time. Begin passive motion and soft-tissue mobilization between 8 and 10 weeks after surgery. Swimming and cycling can begin 4 months after surgery, followed by plantarflexion-resistive exercises. A permanent loss of power must be expected, but running and jumping are possible. Return to sports requires a minimum of 12 months recovery.

**Repair of an Acute, Complete Achilles Tendon Rupture**

- Using general or regional anesthesia and a proximal thigh tourniquet, make a longitudinal incision parallel to and 1.5 cm anterior to the medial border of the Achilles tendon. Because these wounds are prone to marginal necrosis and breakdown, exercise caution when handling soft tissues.
- Sharply dissect directly to the Achilles paratenon. Incise the paratenon longitudinally, allowing complete inspection of the tendon rupture. Debride the rupture site of hematoma.
- Approximate the tendon ends and do a primary repair with a core suture of #3 nonabsorbable braided suture (**Fig. 118.3**). Follow with a circumferential peripheral tendon repair with braided nonabsorbable suture. Weave the plantaris across the repair site and secure it with 2-0 braided nonabsorbable sutures.

**Figure 118.3.** Primary repair of an acute Achilles tendon rupture with a core suture. **A:** Insertion of sutures. **B:** Completed repair.

- Carefully repair the subcutaneous tissue with multiple absorbable sutures and close the skin with fine nylon or skin clips.
- Apply a large, bulky compression dressing with the foot in a plantarflexed position.
- Postoperative management: Remove the sutures 10 days after surgery and apply a non-weight-bearing cast, with the foot in a plantarflexed position. Over the next 4 weeks, gradually bring the position of the foot to a plantigrade position. At the 4-week postoperative visit, apply a removable cast boot and begin range-of-motion and low-resistance exercises. At the 8-week postoperative visit, begin weight bearing. At 12 weeks after surgery, immobilization can be discontinued. Gradually resume athletic activity once local warmth and swelling have resolved.
- Delay postsurgical stretching of the Achilles tendon until local swelling, warmth, and tenderness have resolved. Early and aggressive stretching may result in lengthening of the gastrosoleus complex with concomitant loss of power. Once local conditions permit, warm-up and stretching of the entire lower extremity remain important tools in the enhancement of performance and reduction of repeat injury.

**COMPLICATIONS**

Rerupture is a complication of Achilles tendon rupture treated with either surgical or nonsurgical intervention. The rerupture rate appears to be higher in those patients treated with cast immobilization alone (14,29), particularly in those treated with less than 8 weeks of immobilization (19).

Skin slough and wound infection are serious complications because of the subcutaneous position of the tendon. Surgical technique requires preservation of full-thickness skin flaps, gentle soft-tissue handling, and tension-free closure. Before immobilization of the foot at surgery, verify the viability of the skin overlying the Achilles tendon, with the foot in the proposed position of immobilization.

**CONCLUSIONS**

With regard to the controversy surrounding acute, complete Achilles tendon ruptures, we prefer early, primary repair for healthy, active individuals. We believe that this treatment modality allows a faster and more complete recovery.

**POSTERIOR TIBIAL TENDON DYSFUNCTION**

**PATHOPHYSIOLOGY**

From the deep posterior compartment of the leg, the posterior tibial muscle forms a tendon that courses behind the medial malleolus, turns anteriorly, and inserts directly into the navicular tuberosity. The tendon is surrounded by a synovial sheath. The position of the tendon relative to the ankle and subtalar joint axes of rotation defines its function as an invertor and plantarflexor of the foot (**Fig. 118.4**). Insufficiency of the posterior tibial tendon (PTT) results in the production of an asymmetric flatfoot identified by heel valgus, midfoot collapse and abduction, and forefoot pronation. Insufficiency may be related to acute or chronic tenosynovitis or partial or complete rupture. It is unknown why the PTT is predisposed to injury, but it may be related to a zone of relative hypovascularity within the tendon located behind and distal to the medial malleolus (11). PTT dysfunction occurs more frequently in patients with diabetes, hypertension, and obesity compared with the general population (13).
PRINCIPLES OF TREATMENT

The loss of PTT function results in significant impairment to the lower extremity. The primary goal of treatment is to re-establish the function of the PTT, when possible. For patients with advanced disease, the substitution or addition of the FDL tendon may be required. The most advanced stages of dysfunction are not amenable to soft-tissue reconstruction and require identification and treatment of fixed deformities.

ASSESSMENT

Begin the physical examination with gait analysis. When viewed from behind, the patient with PTT dysfunction may have decreased heel inversion between flatfoot and toe-off, and in advanced cases, an antalgic gait may be noted. Examination of the standing patient may reveal varying degrees of swelling over the course of the PTT, as well as heel valgus, midfoot collapse, and abduction. Ask the patient to perform a repeated single-heel rise test. This is accomplished by having the patient stand at a nearby wall, using the hands for balance. The patient lifts the unaffected extremity while performing repeated single-heel rises on the affected extremity. Patients with tenosynovitis, mild degenerative changes are able to perform the maneuver with evidence of gait and heel inversion, but this is typically a painful maneuver. In advanced stages, heel height and heel inversion decrease. Finally, patients with complete dysfunction of the PTT are unable to perform the maneuver. Then seat the patient and palpate the posterior leg to assess swelling over the PTT and associated tenderness. Tenderness at the sinus tarsi may indicate lateral impingement in advanced cases. Early findings include supple motion at the ankle, hindfoot, midfoot, and forefoot. With progression of the disorder, subtalar motion becomes limited and the heel eventually becomes fixed in a valgus position, midfoot abduction increases with a concomitant decrease in midfoot adduction, and forefoot motion becomes fixed, which paradoxically produces fixed forefoot varus when the heel is held in a neutral position. In the most advanced cases, Achilles contracture produces equinus deformity, which is most easily appreciated when ankle motion is evaluated with the heel held in a neutral position. Manual motor testing reveals loss of function varying from slight weakness associated with tenosynovitis to complete loss of function associated with chronic tenosynovitis or complete rupture.

Begin the radiographic examination with weight-bearing views of the foot and ankle. Valgus tilt of the ankle mortise increases the amount of chronic stress across the posterior tibial tendon. Loss of ankle joint height, especially at the lateral joint line, is a risk factor for rapidly progressive arthritis after hindfoot fusion. An enlarged or accessory tarsal navicular is a predisposition to PTT dysfunction. Assess foot alignment, with particular attention to midfoot collapse on the lateral view and midfoot abduction on the anteroposterior view. Advanced imaging of the PTT is best accomplished with MRI. The tendon is normally round to oval in shape with a low, homogenous signal. Tenosynovitis is easily identified by increased fluid surrounding the tendon. Degeneration and partial and complete tears are identified on the T2 sequence by thickening, increased signal activity, and cystic changes.

CLASSIFICATION

PTT dysfunction can arbitrarily be divided into synovitis; tendinosis manifested by partial or complete tears, leading to loss of the functional integrity; tendinosis with supple hind foot valgus; and tendinosis associated with fixed deformity of the subtalar and transverse tarsal joints.

PREOPERATIVE MANAGEMENT

Preoperative management

Treat patients with posterior tibial tenosynovitis with reduction or modification in activity. For advanced or recalcitrant symptoms, immobilize the leg in a short-leg walking cast or removable cast boot. For risk factors such as excessive pronation, use orthotic devices.

Treat patients with tendinosis in a fashion similar to that discussed earlier. Immobilization for 6 to 8 weeks may be required. Occasionally, symptoms recur immediately on discontinuation of treatment. For patients unwilling to pursue surgical treatment, a custom ankle-foot orthosis is indicated.

For patients with a completely dysfunctional tendon, nonoperative treatment is predicated on the presence of hindfoot and forefoot deformity. Patients with mild to moderate deformity may be treated in a custom ankle-foot orthosis. Patients with severe deformity require more extensive bracing with a double upright brace and medial T-strap.

Evaluate patients with tenosynovitis and early tendinosis with MRI to evaluate the extent of tendon degeneration. Patients with advanced tendinosis with loss of PTT function do not require evaluation by MRI. The presence of hindfoot valgus, supple or fixed, along with the presence of any fixed deformity including Achilles tendon contracture, must be appreciated before surgical intervention.

OPERATIVE TECHNIQUES

Debridement

Debridement and Reconstruction with FDL Tendon Transfer

Patients with posterior tibial tendinosis who fail conservative management require surgical intervention in a timely manner in order to reduce the risk of permanent structural changes.

- Using general or regional anesthetic and a proximal tourniquet, make a linear incision over the course of the PTT from the tip of the medial malleolus to the navicular. Sharply dissect down to the tendon sheath, which is longitudinally divided throughout the length of the surgical wound.
- Synovitis is manifested by the presence of an effusion, synovial proliferation, and increased vascular activity. Systematically excise the synovium.
- Occasionally, proximal exposure of the PTT is required. Extend the skin incision proximally over the course of the PTT. Leave a 1 cm section of PTT sheath and flexor retinaculum intact at the medial malleolus. Once the tendon is completely exposed, carefully inspect it. The treatment of tendon tears is discussed later.
- On completion of the procedure, loosely close the tendon sheath, followed by subcutaneous tissue closure with interrupted absorbable suture and skin closure with nylon or skin clips. Imobilize the foot and ankle in a neutral position.
- Postoperative management: Remove sutures or skin clips 10 days after surgery and apply a removable cast. Begin range-of-motion exercises and allow weight bearing as tolerated. At 4 weeks after surgery, begin a strengthening program. Permit a gradual return to activities once local swelling and warmth resolve.

Debridement and Reconstruction with FDL Tendon Transfer

Patients with posterior tibial tendinosis who fail conservative management require surgical intervention in a timely manner in order to reduce the risk of permanent structural changes.

- Expose the PTT sheath and debride as previously described. Using sharp resection, completely remove the degenerative portions of the tendon, which are indicated by color changes, thickening, loss of tendon consistency, cystic changes, and partial tears. If necessary, debride the entire tendon from the navicular to a point proximal to the degenerative changes.
- On completion of tendon debridement, inspect the deltoid and spring ligaments. Reconstruct excessive laxity in the spring ligament by excision and imbrication of redundant tissue.
- Harvest the FDL tendon by extending the incision to the medial forefoot. Identify the abductor hallucis muscle and release its fascia longitudinally from the first metatarsal. Plantar retraction of the muscle allows visualization of the plantar nerves as well as the FHL and FDL tendons. Carefully release the flexor knot of...
Perhaps because of the intrinsic lack of bony stability, the PTs have a propensity to dislocate out of the peroneal groove to a position anterior to the lateral malleolus.

The peroneal tendons (PTs) share a common synovial sheath on the posterolateral vincula (3). The peroneus brevis tendon remains anterior to the peroneus longus tendon. The tendons are retained behind the lateral malleolus by the superior peroneal retinaculum. The peroneus brevis and longus muscles originate from the lateral compartment of the leg. Distally, they form individual tendons, which pass behind the lateral malleolus to turn anteriorly toward their respective insertions at the base of the fifth metatarsal and the base of the first metatarsal.

The peroneus brevis and longus muscles function as plantar flexors and evertors of the foot (3). The peroneus brevis tendon is deepened by a fibrocartilaginous ridge, a structure that originates from the periosteum on the posterolateral ridge of the fibula (3). The position of the tendons relative to the axis of rotation of the ankle and subtalar joints determine their function as plantar flexors and evertors of the foot (Fig. 118.4).

Debride and reconstruct the posterior tibial tendon as previously described. Apply a bulky dressing and splint the foot and ankle in a plantar flexed and inverted position. At 4 weeks, place the foot in the neutral position and apply a removable cast boot. At 6 weeks after surgery, start range-of-motion exercises for the foot and ankle, and allow weight bearing to tolerance with the cast boot. Institute a strengthening program with an elastic band after 8 weeks. Activities are gradually resumed once local warmth and swelling are resolved.

**Subtalar Arthrodesis**

PTT dysfunction associated with fixed hindfoot deformity is not amenable to soft-tissue reconstruction. When the deformity is limited to the subtalar joint, and the remainder of the foot remains supple (i.e., the absence of fixed forefoot varus), then treatment with an isolated subtalar arthrodesis is possible. The surgical technique for hindfoot arthrodesis is described in Chapter 115. Take care to produce a neutral heel and plantigrade foot before the placement of internal fixation.

**Double and Triple Arthrodesis**

Advanced PTT dysfunction associated with hindfoot valgus will eventually produce fixed forefoot deformities, namely, forefoot varus. The correction of the subtalar deformity alone will not produce a plantigrade foot. Fixed forefoot deformity is best addressed with a double or triple arthrodesis. The triple arthrodesis increases the likelihood of talonavicular fusion and is used in patients at risk for nonunion (e.g., those who smoke or who have diabetes, rheumatoid arthritis, or excessive bone loss).

On completion of the arthrodesis, final assessment of foot position allows a true evaluation of Achilles tendon contracture. Occasionally, a triple hemisection, gastrocnemius recession, or an open Achilles tendon lengthening is necessary. Failure to identify Achilles tendon contracture results in inordinate stress across the transverse tarsal arthrodesis and increases the likelihood of talonavicular malunion and nonunion.

**GENERAL REHABILITATION**

Patients who have been successfully managed with nonsurgical methods as well as those managed with soft-tissue reconstruction are placed on programs designed to maintain motion of the foot and ankle, and to increase strength of the posterior tibial muscle or the transferred FDL muscle. Orthotics designed to resist excessive pronation and hindfoot valgus are also described as needed.

**COMPLICATIONS**

Care must be taken not to allow the patient with early posterior tibial tendon dysfunction, synovitis, or mild tenosynovitis to progress to a more advanced stage requiring more invasive and more morbidity intervention.

**PERONEAL TENDON SUBLUXATION, DISLOCATION, AND LONGITUDINAL RUPTURE**

**PATHOPHYSIOLOGY**

The peroneus brevis and longus muscles originate from the lateral compartment of the leg. Distally, they form individual tendons, which pass behind the lateral malleolus to turn anteriorly toward their respective insertions at the base of the fifth metatarsal and the base of the first metatarsal. At the lateral malleolus, the peroneus brevis tendon remains anterior to the peroneus longus tendon. The tendons are retained behind the lateral malleolus by the superior peroneal retinaculum (3). A structure that originates from the periosteum on the posterolateral ridge of the fibula (5). The peroneal groove or retrocalcaneal sulcus is a shallow bony groove (9) that is deepened by a fibrocartilaginous ridge (Fig. 118.5). The position of the tendons relative to the axis of rotation of the ankle and subtalar joints determine their function as plantar flexors and evertors of the foot (Fig. 118.4).

Figure 118.5. Anatomic relationships at the lateral aspect of the ankle. Note on the cross section that the peroneal groove is supplemented by a fibrocartilaginous ridge.

The peroneal tendons (PTs) share a common synovial sheath (35) that bifurcates above and below the lateral malleolus. The tendons receive vascular supply through a posterior lateral vincula (37). Unlike the Achilles and posterior tibial tendons, the PTs do not have a demonstrable zone of hypovascularity.

Perhaps because of the intrinsic lack of bony stability, the PTs have a propensity to dislocate out of the peroneal groove to a position anterior to the lateral malleolus.
The injury occurs as a result of sudden, forceful, passive dorsiflexion of the inverted foot with reflex contraction of the PTs (8, 17, 27, 39). An association with chronic lateral ankle instability has also been reported (12). Dislocation of the peroneal tendons out of the peroneal groove is associated with a variety of underlying pathoanatomic findings, including a tear of the superior peroneal retinaculum, elevation of the superior retinaculum off the lateral border of the fibula with concomitant dissection of the tendon beneath the lateral fibular periosteum, and fracture of the posterolateral margin of the fibula.

Chronic subluxation of the peroneus brevis tendon onto the posterolateral border of the fibula may occur as a clinical or subclinical entity. This condition has been implicated as a major causative factor in the development of longitudinal tears of the peroneus brevis tendon (17, 36). Anatomic factors associated with longitudinal tears of the peroneus brevis tendon include laxity of the superior peroneal retinaculum, compression of the peroneus brevis tendon by the overlying peroneus longus tendon (17, 32, 36), the presence of peroneal musculature at the peroneal groove, and finally, the presence of an anomalous peroneal muscle such as the peroneus quartus muscle (36). A longitudinal tear of the peroneal tendons has also been described after acute and chronic lateral ankle inversion injury (3, 33).

**PRINCIPLES OF TREATMENT**
