Chapter References

Surgery injures tissues. Proper planning and thorough understanding of the surgical exposure, however, can minimize tissue injury and expedite the procedure. Proper exposure protects the important neurovascular structures by providing direct observation or enabling total avoidance. The surgical exposures described in this chapter allow excellent exposure of the upper extremities.

Hemostasis is mandatory. Because most procedures in the upper extremity are done under tourniquet control, a cut vessel requires immediate coagulation or ligation. Otherwise, it retracts, goes into spasm, and may later start bleeding. Never purposely cut a cutaneous nerve. Every severed nerve forms a neuroma, and every neuroma can become exquisitely tender. Always strive for a cosmetically acceptable scar using, if possible, subcuticular sutures with Steri-strips.

SHOULDER

STERNOCLAVICULAR APPROACH

Exposure of the sternoclavicular joint (SC) is rarely necessary. Infection, arthritis, or posterior dislocation of this joint may necessitate an open procedure.

- Make an incision along the medial 4 cm of the clavicle and curve it gently, inferiorly over the SC joint. This joint is at a 45° inclination, so incise the capsule from superior medial to inferior lateral.
- If resecting the medial clavicle, remove 1.5 cm of bone, staying medial to the costoclavicular ligament.
- For a posterior dislocation, release of the sternocleidomastoid muscle origin superiorly may improve the exposure. Be very careful of the vital structures posterior to the SC joint (i.e., right innominate artery, left common carotid artery, subclavian vein, and lung tissue).

ACROMIOCLAVICULAR APPROACH

Exposure of the acromioclavicular joint (AC) may be necessary for arthritis, dislocation, or intra-articular fracture.

- Make a 6–7 cm, anterior to posterior saber incision just medial to the AC joint. Incise the trapezius and deltoid fascia, and elevate off the clavicle as needed.
- Cut the capsule perpendicular to the joint and reflect it anteriorly and posteriorly to expose the joint. It is important to reattach this capsule to close the space created if the distal clavicle has been resected.
- If repair or reconstruction of the coracoclavicular ligaments is required, extend the exposure inferiorly to expose the coracoid process. This is best done by splitting the deltoid or utilizing the deltopectoral interval (Fig. 1.1).

Figure 1.1. Exposure of the acromioclavicular joint and coracoid process.

HENRY'S ANTERIOR APPROACH

Henry's anterior approach (3) is used to treat recurrent anterior shoulder dislocations, fractures of the proximal humerus, rotator cuff repairs or reconstructions, and anterior shoulder arthroscopies and arthroplasties (Fig. 1.2).
The lateral deltoid splitting exposure is used for limited exposure of the rotator cuff and subacromial bursa. Henry’s anterior strap approach is useful for exposing the rotator cuff.

In the proximal wound, incise the clavicle and subcutaneous tissue to the deltoid. Incise the deltoid, starting proximally to the tip of the coracoid. This approach is identical to Henry’s anterior approach, with the exception of the limited skin incision needed.

Position the patient in a semi-sitting position (40° off the horizontal) with a rolled towel under the ipsilateral scapula. The shoulder should be freely mobile. A Mayo stand, padded with a pillow, next to the operating room table facilitates resting the shoulder in abduction and external rotation. Drape the arm free. Overwrap the stockinet on the hand and forearm to facilitate control of the arm.

Locate the deltopectoral groove. In an obese patient, this groove is located by internal and external rotation of the shoulder. Start the incision at the clavicle just lateral to the coracoid, and extend it distally along the deltopectoral groove to the deltoid insertion for approximately 15 cm.

Develop skin flaps to expose the deep fascia. Open the fascia over the deltopectoral groove with blunt scissors, looking for the cephalic vein. This vein serves as an important landmark for identifying the avascular interval between the deltoid and pectoralis major muscles. Bluntly develop this interval, and retract the deltoid laterally and the pectoralis major medially. The vein can be ligated or retracted with the deltoid.

In the proximal wound, incise the clavpectoral fascia arising over the coracoacromial ligament, and identify and coagulate the underlying acromial branch of the thoracoacromial artery. The anterior circumflex vessels lie in the middle of the wound, just superior to the pectoralis major muscle; they may need to be isolated, clamped, and coagulated.

Retracting the coracobrachialis and short head of the biceps medially with a broad retractor protects the axillary neurovascular bundle. Detachment of the anterior deltoid muscle from the clavicle should be avoided if at all possible, because it usually weakens the anterior deltoid. If detachment is necessary, carefully elevate a flap of tendon superiorly and inferiorly off the clavicle for resurfacing the deltoid, or detach the deltoid by removing a small wafer of bone and reattaching it with drill holes later. For extensive proximal humerus procedures, detach the deltoid insertion off its tuberosity distally and reflect the deltoid superiorly. This provides excellent exposure. Repair of the deltoid is simplified by suturing it to the origin of the brachialis with interrupted figure-eight sutures.

If better exposure of the rotator cuff is necessary, resection of the coracoacromial ligament and an anterior acromioplasty as described by Neer facilitates exposure. The anterior joint capsule can be exposed by releasing the subscapularis tendon. This is facilitated by passing a curved hemostat from distal to proximal in the interval between the tendon and the anterior joint capsule, exiting between the subscapularis and the supraspinatus. Because the tendon and capsule blend together near the humeral insertion of the tendon, cut it 2.5 cm medial to its humeral insertion. After the tendon is released, tag it with a nonabsorbable suture to ensure easy identification when it is reattached.

If exposure of the axillary neurovascular structures is necessary, incise and reflect medially the humeral insertion of the pectoralis major. Identify the loose fascia overlying the short head of the biceps and coracobrachialis. Incise this fascia medially over the coracobrachialis muscle 3.5 cm distal to the coracoid to avoid cutting its innervation from the musculocutaneous nerve. Develop the interval medially to the biceps and coracobrachialis muscles, and reflect these muscles laterally to expose the neurovascular bundle.

Wider exposure is possible if the muscle origins from the coracoid are transected. If more proximal exposure is needed, it may be necessary to transect the origin of the pectoralis minor muscle. A more comprehensive exposure for total shoulder arthroplasties is described in the article by Neer et al. In such cases, release the origins of the coracobrachialis and the short head of the biceps from the tip of the coracoid, leaving a cuff on the tip of the coracoid for repair. Leave the pectoralis minor intact. Retraction medially must be gentle to avoid injury to the musculocutaneous nerve.

**LESLEY AND RYAN’S ANTERIOR AXILLARY APPROACH**

Leslie and Ryan’s anterior axillary approach (Fig. 1.3) is useful for exposing the anterior shoulder for recurrent shoulder dislocations if a more cosmetically acceptable scar is desired. The exposure, however, may be restricted in a patient with well-developed musculature.

With the patient’s arm at his side, identify the superior aspect of the anterior axillary fold. From this point, make an incision 7 cm inferiorly into the axilla. Because the skin and subcutaneous tissue are quite mobile in this area, extensive undermining above the deep fascia is possible for exposure of the deltopectoral groove.

The rest of the surgical exposure is as described previously in the section on Henry’s Anterior Approach. Exposure can be facilitated by extending the skin incision proximally to the tip of the coracoid. This approach is identical to Henry’s anterior approach, with the exception of the limited skin incision.

**HENRY’S ANTERIOR STRAP APPROACH**

Henry’s anterior strap approach is useful for exposing the rotator cuff.

Start the incision over the acromioclavicular joint, and extend it 8 cm inferiorly along the anterior deltoid, just lateral to the deltopectoral groove. After mobilizing skin flaps, identify the clavicular attachment of the deltoid. Detach only as much of the deltoid as necessary for exposure, using the technique as described under Henry’s Anterior Approach.

Incise the underlying subacromial bursa to expose the rotator cuff. Internal and external rotation of the shoulder help to further visualize the anterior and posterior portions of the cuff.

**LATERAL DELTOID SPLITTING EXPOSURE**

The lateral deltoid splitting exposure is used for limited exposure of the rotator cuff and subacromial bursa (Fig. 1.4).
**Lateral Deltoid Splitting Exposure**

- Make a transverse incision approximately 6 cm long, starting 2.5 cm inferior to the lateral tip of the acromion. This gives a more cosmetic scar than a vertical incision.
- Undermine the skin flaps, and bluntly incise the deltoid muscle parallel to its fibers from the tip of the acromion superiorly to 4 cm inferiorly. Branches of the axillary nerve course transversely, approximately 5 cm inferior to the tip of the acromion; avoid cutting them.
- Expose the subacromial bursa in the floor of this exposure. Incise the bursa and expose the underlying rotator cuff. Rotation and abduction of the shoulder exposes most of the rotator cuff in the operative field. Additional exposure of the rotator cuff is facilitated by detaching the lateral one third of the deltoid from the acromion and performing an anterior acromioplasty. Refer to Henry’s Anterior Approach for a complete description.

**Posterior Exposure**

Exposure of the posterior shoulder joint may be necessary for posterior shoulder instability, dislocation, glenoid osteotomy, or soft tissue tumor. Two posterior surgical exposures may be used. The posterior inverted U approach described by Abbott and Lucas (1) detaches the deltoid from the scapular spine, and the other exposure splits the deltoid parallel to its fibers.

**Abbott and Lucas Inverted U Approach**

The posterior inverted U approach (Fig. 1.5) is based on the relatively avascular plane between the posterior and middle heads of the deltoid muscle.

**Deltoid Splitting Approach**

The deltoid splitting approach (Fig. 1.6) theoretically prevents possible weakening of the deltoid.

**Figure 1.4.** Lateral deltoid splitting exposure.

**Figure 1.5.** Abbott and Lucas inverted U approach.

**Figure 1.6.** Posterior exposure.
HUMERUS

HENRY’S ANTEROLATERAL EXPOSURE

- Identify the interval between the biceps and the brachialis by grasping and moving the mobile biceps muscle medially (Fig. 1.7). Incise the skin just lateral to the border of the biceps 8 cm proximal to the elbow flexion crease, and continue distally, crossing the elbow flexion crease if needed. This exposure is extensile and can be carried to the shoulder as needed using the deltopectoral interval.

Figure 1.7. Henry's anterolateral exposure.

- While protecting the cephalic vein, retract the biceps medially to expose the brachialis covering the distal anterior one half of the humerus. The shaft of the humerus is exposed by blunt dissection through the brachialis muscle in an oblique direction from proximal lateral to distal anterior. Do not sever the cutaneous branches of the musculocutaneous nerve crossing over the brachialis muscle distally. The radial nerve can be identified, if necessary, by splitting the brachialis muscle 1 cm distal and posterolateral to the deltoid insertion. Otherwise, the radial nerve is protected by the brachialis muscle reflected laterally.

- Wider exposure of the humerus can be achieved by flexing the elbow, which relaxes these muscles. If more proximal exposure is needed, refer to Henry’s anterior shoulder approach described previously. If more distal exposure is required, refer to Henry's anterior elbow exposure described later in this chapter.

- In nonunions, full exposure of the radial nerve may be necessary before safe exposure of the bone is possible. In this case, undermine the skin anteriorly and posteriorly over the distal arm. Identify the interval between the brachialis and brachioradialis. This interval can be difficult to find. The fibers of the two muscles have slightly different degrees of coarseness and different directions, which the surgeon can detect visually. Split bluntly into the most distal portion of this interval; a Metzenbaum scissors is useful. Approximately 1–2.5 cm deep into the interval, identify the radial nerve and follow it proximally into the spiral groove or until you are proximal to the fracture and the nerve is freed from all scar tissue and callus.

HENRY’S POSTERIOR EXPOSURE

- To perform Henry’s posterior exposure (Fig. 1.8, Fig. 1.9), place the patient prone on the operating table with the upper extremity on an arm board or on a padded gynecologic knee support. The lateral decubitus position with the arm supported on bolsters also works well. Identify the long head of the triceps, which is mobile and posteromedial. Using this as a landmark, make an incision (Fig. 1.8) 3 cm inferior to the acromion, extending distally along the lateral edge of this muscle to the olecranon if necessary. Develop the skin and subcutaneous flaps to expose the long and lateral heads of the triceps.

Figure 1.8. Henry's posterior exposure (posterior and lateral heads of triceps exposure).

- Digitally develop the proximal interval between these two heads of the triceps. Lift the seam from the underlying tissue and split it distally. The distal one half of this seam requires sharp dissection along the septum between the long and the lateral heads. Splitting the seam (Fig. 1.9) exposes the deep head of the triceps, with the neurovascular bundles located proximally. Notice the relation of the radial nerve and its branches to the three heads of the triceps. While protecting the median nerve, ulnar nerve, and brachial artery medially, and the radial nerve and profunda artery laterally, the deep head of the triceps can be safely split to expose the posterior shaft of the humerus (Fig. 1.10). Confirm that branches of the radial nerve are identified and protected before splitting the deep head. The radial nerve may be further visualized distally by splitting the lateral intermuscular septum. To expose the radial nerve more proximally requires incising the tendinous insertion of the teres major and latissimus dorsi.

Figure 1.9. Henry's posterior exposure (deep head of triceps exposure).

Figure 1.10. Henry's posterior humeral shaft exposure.
MEDIAL EXPOSURE

The medial approach is used to explore the median and ulnar nerves and brachial artery (Fig. 1.11).

Figure 1.11. Medial exposure.

- Identify the medial border of the mobile biceps muscle. Start the incision proximally from the anterior axillary fold to the level of the elbow flexion crease distally, following the border of the biceps. If more distal exposure is needed, refer to the anteromedial elbow exposure. Protect the branches of the median antebrachial cutaneous nerve in the subcutaneous tissue.
- Starting proximally, incise the deep fascia to expose the brachial artery, the basilic vein, and the median and ulnar nerves. The artery, vein, and median nerve course distally, staying anterior to the median antecubital septum to enter the antebrachial fossa. The ulnar nerve penetrates the intermuscular septum at the midpoint of the upper arm, entering the posterior compartment of the upper arm. To expose the ulnar nerve distally, incise this septum.

ELBOW

LATERAL EXPOSURE

The lateral exposure is useful for exposing the radial head and elbow joint for removal of loose bodies and synovectomy (Fig. 1.12).

Figure 1.12. Lateral exposure.

- Pronate the forearm and flex the elbow 90° on an arm board. Identify the lateral epicondylar ridge and the radial head by rotating the forearm. Make a gentle curvilinear incision along the lateral epicondylar ridge 3–4 cm proximal to the joint line and extending 3–4 cm distal to the joint along the interval between the extensor carpi ulnaris and the anconeus overlying the radial head.
- Proximally, reflect the triceps posteriorly. Reflect the extensor carpi radialis longus and the brachioradialis anteriorly. This dissection can be subperiosteal, or a wafer of bone may be taken with the extensor carpi radialis longus origin.
- The radial nerve passes anteriorly between the brachialis and the brachioradialis and therefore is protected with this proximal exposure. Distally, sharply incise the interval between the extensor carpi ulnaris and anconeus to expose the underlying joint capsule. Incise the joint capsule from the lateral epicondyle to the annular ligament of the radial head. Do not extend the incision distal to the annular ligament, because this can sever the posterior interosseous nerve, which crosses anterolaterally across the radial neck through the supinator muscle. Pronation of the forearm helps to place this nerve anterior to the operative field. A smaller incision may be used if only the radial head is to be exposed. Wider exposure for synovectomy or other procedures is accomplished by detaching the common extensor origin and the joint capsule from the humerus.

HENRY’S ANTEROLATERAL EXPOSURE

Henry’s anterolateral exposure is useful for exposing the radial nerve and the arch of Frohse, lesions of the proximal radius, and the radial tuberosity for bicipital tendon ruptures (Fig. 1.13) (2).

Figure 1.13. Henry’s anterolateral exposure.

- Position the arm with the elbow extended and the forearm supinated. Start the incision along the lateral border of the biceps proximally, cross the elbow flexion crease in a curvilinear fashion, and extend the incision distally along the medial border of the brachioradialis. The length of the incision depends on the operative needs. If exposure of the anterior distal humerus is needed, refer to Henry’s anterolateral humeral surgical exposure described previously.
- Identify and preserve the lateral cutaneous nerve of the forearm proximally in the interval between the biceps and brachialis muscles. Identify the biceps tendon and the lacertus fibrosis.
- For better exposure, incise the lacertus fibrosis, flex the elbow, and pronate the forearm. Bluntly develop the interval between the brachioradialis laterally and the
The medial intermuscular septum must be incised to prevent proximal tethering of the transposed nerve. The fascia over the flexor carpi ulnaris must be incised to prevent distal tethering of the nerve. Pass a 0.6 cm Penrose drain around the nerve for retraction. The thick ligament over the ulnar groove must be incised. The ulnar muscular branches of the flexor carpi ulnaris may need to be exposed to facilitate the transfer.

MEDIAL EXPOSURE

Use the medial exposure to expose the ulnar nerve or medial elbow joint (Fig. 1.14).

- Place the elbow on an arm board with the shoulder externally rotated and the elbow flexed 90°. Identify the medial epicondyly. Start the incision approximately 4 cm proximal to the epicondyly, and extend the incision 4 cm distally along the flexor carpi ulnaris.
- Bluntly dissect the subcutaneous tissue and identify the branches of the medial antebrachial cutaneous nerves.
- After these nerves are protected and the deep fascia over the flexor-pronator muscles is exposed, palpate for the ulnar nerve proximal to the ulnar groove.
- Expose this nerve by incising its overlying fascia.
- If the nerve is to be transposed anteriorly, several principles apply:
  1. The medial intermuscular septum must be incised to prevent proximal tethering of the transposed nerve.
  2. The thick ligament over the ulnar groove must be incised.
  3. The fascia over the flexor carpi ulnaris must be incised to prevent distal tethering of the nerve.
  4. The ulnar muscular branches of the flexor carpi ulnaris may need to be exposed to facilitate the transfer.
  5. Pass a 0.6 cm Penrose drain around the nerve for retraction.
  6. Protect the accompanying small vessels to the ulnar nerve, if at all possible, to prevent ischemic damage to the nerve.
- To expose the medial aspect of the elbow joint, define the interval between the brachialis and pronator teres anteriorly and protect the ulnar nerve posteriorly. Osteotomize the medial epicondyly with its attached flexor pronator muscles and retract it distally. Be careful not to retract it too vigorously, to prevent median nerve injury. The joint capsule and medial collateral ligament complex can be incised to expose the joint. The osteotomized bone may be reattached with sutures or preferably with a 3–4 mm A-O cancellous screw through a hole drilled before the osteotomy. During closure, do not suture the deep fascia of the forearm, to prevent an iatrogenic compartment syndrome.

ANTEROMEDIAL EXPOSURE

The anteromedial exposure is useful for exposing the brachial artery, median nerve, and bicipital tendon (Fig. 1.15).

- Place the arm with the elbow extended and the forearm supinated. Start the incision proximally along the medial border of the biceps, zigzag along the elbow flexion crease, and extend it distally along the pronator teres. The length of the incision depends on the operative needs. If more proximal exposure is needed, refer to the medial humeral exposure.
- Identify the basilic vein and branches of the medial antebrachial cutaneous nerve in the subcutaneous tissue. Incise the deep fascia proximally to expose the median nerve and brachial artery.
- Trace these structures distally to the level of the elbow flexion crease, where they dive under the lacertus fibrosis. While protecting these structures, incise this fibrotic band.
- Bluntly develop the interval between the brachioradialis and the pronator teres to expose the radial and ulnar arteries and the median nerve. If more distal exposure of these nerves is needed, refer to McConnell’s exposure of the median and ulnar nerves of the forearm described later in this chapter.

BRYAN AND MORREY’S POSTEROLATERAL EXPOSURE

The posterolateral exposure of Bryan and Morrey (6) is useful for previous elbow dislocations, arthroplasty, and repair of comminuted interarticular fracture of the distal humerus. It avoids an olecranon osteotomy by preserving the continuity of the triceps mechanism.

- Position the patient in a supine position with a rolled towel under the scapula. A sterile tourniquet may be utilized. Make a posterior incision lateral to the olecranon 9 cm proximal to the olecranon tip, extending it 9 cm distal to the tip.
- Create a triceps and ulnar periosteal flap in continuity by incising the lateral border of the triceps and extending it distally 6 cm along the ulnar shaft.
- By careful subperiosteal dissection, reflect the triceps tendon and its periosteal attachment in continuity toward the lateral side, preserving the ulnar collateral ligament.
- The radial head can be exposed by including the anconeus in the subperiosteal dissection. The ulnar nerve is protected by the soft tissues. Exposure and transfer is usually not necessary unless it is at risk. Now the entire posterior elbow joint is exposed (Fig. 1.16). Further exposure for arthroplasty can be obtained by releasing the joint capsule.
CHAPMAN’S COMPREHENSIVE POSTERIOR APPROACH

The Chapman comprehensive posterior approach was developed for the open reduction and internal fixation of intraarticular fractures of the distal humerus. It has also proven useful for reconstructive surgery, including complete posterior and anterior release for arthrofibrosis of the elbow. It avoids olecranon osteotomy with its potential complications and provides better exposure.

- Position the patient in the lateral decubitus position with the operated elbow supported on a well-padded gynecologic knee support and flexed to 90°. Be certain that the forearm is not obstructed, as further flexion to 110° is necessary for full exposure of the articular surface.
- Make a longitudinal midline posterior incision as long as necessary, staying slightly to one side of the olecranon; full exposure requires an incision at least 20 cm in length. Incise directly down to the deep fascia. Creation of flaps is not necessary unless transfer of the ulnar nerve is planned.
- If transfer of the ulnar nerve is necessary, do it now, placing the nerve in a subcutaneous tunnel.
- Split the triceps muscle in the midline, beginning proximally and extending distally to the olecranon. Split the joint capsule as well.
- Elevate the extensor and flexor forearm muscles off the shaft of the proximal ulna with a sharp elevator, beginning about 4 cm distally and working proximally to the tip of the olecranon.
- Using a #15 blade, reflect the triceps insertion, medially and laterally, off the olecranon in continuity with the forearm muscles, maintaining the integrity of the retinaculum and periosteum. Take the joint capsule in continuity with these flaps (Fig. 1.17).

Closure of a single layer of capsule, muscle, and fascia, using interrupted figure-eight sutures, allows early mobilization of the elbow joint.

POSTERIOR TRANSOLECRANON EXPOSURE

The posterior transolecranon exposure is excellent for exposing a comminuted intra-articular distal humeral fracture (Fig. 1.18), although it does have the disadvantage of the olecranon osteotomy.

- Place the patient supine with her arm across her chest. The skin incision is the same as that previously described for the posterolateral approach to the elbow. Incise the deep fascia to expose the triceps tendon and proximal olecranon. Identify and protect the ulnar nerve medially.
- Make a 1 cm linear incision through the triceps tendon to expose the tip of the olecranon. Predrill and tap the olecranon for two fixation screws. Expose the medial and lateral borders of the proximal 3 cm of the olecranon, protecting the ulnar nerve. Before cutting the olecranon with a small oscillating saw, score the bone at the proposed osteotomy site to ensure proper alignment during reattachment. Cut the bone 2 cm from its tip. Use either a transverse osteotomy, as illustrated, or a chevron osteotomy, which may help with a more accurate reattachment. Use an osteotome to cut the subchondral bone.
- Reflect the triceps proximally with its attached olecranon. Release the remaining medial and lateral soft-tissue attachments as necessary to facilitate proper exposure of the distal intra-articular humerus.
- Perform closure by realigning the olecranon fragment and securing it with two cancellous lag screws and washers. An alternative method is to add a tension band wire.

HENRY’S POSTERIOR INTEROSSEOUS NERVE EXPOSURE

- With the forearm pronated, palpate the posterior border of the mobile wad to identify the interval between the extensor carpi radialis brevis and the extensor digitorum communis (Fig. 1.19). Start an incision proximally, at the radiocapitellar joint line, and extend it 6 cm distally along this interval.
Figure 1.19. Henry's posterior interosseous nerve exposure.

- Develop skin flaps and incise the deep fascia. Distally, the interval between these muscles is easily separated and, once identified, can be split with scissors from distal to proximal to expose the underlying supinator muscle. Avoid cutting into the supinator muscle during this step.
- Bluntly dissect along the muscle fibers of the supinator 3 cm distal to the radial head to expose the posterior interosseous nerve. Rotation of the forearm at this time facilitates locating this nerve.
- If exposure of the proximal radius is needed, incorporate this incision with the lateral exposure of the elbow (Fig. 1.12). After the posterior interosseous nerve is safely identified, the supinator muscle can be reflected from the ulna to expose the proximal radius.

FOREARM

ANTERIOR EXPOSURE OF THE DISTAL TWO THIRDS OF THE RADIUS

To expose the proximal one third of the radius, refer to Henry's anterolateral elbow exposure described previously and to Thompson's approach described later in this chapter. In its distal third, the anterior radius is flat and can accommodate a plate better than the convex posterior surface (Fig. 1.20).

Figure 1.20. Anterior exposure of the distal two thirds of radius.

- With the forearm supinated, start a curvilinear incision 4–5 cm distal to the elbow flexion crease along the medial border of the brachioradialis muscle, and extend it inferiorly toward the radial styloid. The length of the incision depends on the exposure needed.
- Incise the deep fascia, and distally develop the interval between the brachioradialis and the flexor carpi radialis to expose the medial border of the radius. Protect the radial artery, which runs in this interval, and ligate its branches if needed.
- The superficial cutaneous branch of the radial nerve travels under the brachioradialis muscle in the proximal two thirds of the forearm and must be identified and protected. Expose the radius distally by reflecting the pronator quadratus and the flexor pollicis longus subperiosteally.
- For more proximal exposure subperiosteally, dissect the flexor digitorum sublimis and pronator teres off the radius. Forearm pronation facilitates proximal exposure of the pronator teres attachment.

ULNAR SHAFT EXPOSURE

- The ulnar shaft approach is facilitated by flexing the elbow and laying the arm across the patient's chest (Fig. 1.21). Identify the subcutaneous border of the ulna by palpation. Make a skin incision just volar to this border. The length of the incision depends on the surgical needs.

Figure 1.21. Ulnar shaft exposure.

- Incise the deep fascia, and distally expose the ulnar shaft by incising the periosteum between the flexor carpi ulnaris and the extensor carpi ulnaris.
- Subperiosteally, reflect the flexor carpi ulnaris or extensor carpi ulnaris for volar or dorsal exposure, respectively. To expose the shaft proximally, continue the subperiosteal dissection between the flexor carpi ulnaris medially and the anconeus laterally.
- Identify and protect the ulnar nerve if the proximal ulna (olecranon) is exposed. In the distal exposure, the ulnar nerve is safely protected if the flexor carpi ulnaris is subperiosteally reflected.

POSTERIOR EXPOSURE OF THE RADIUS

To expose the proximal one third of the posterior radius, refer to Henry's exposure of the posterior interosseous nerve described previously and to Thompson's extended exposure described later in this section (Fig. 1.22).
With the forearm pronated, palpate for the posterior border of the mobile wad to identify the interval between the extensor carpi radialis brevis and the extensor digitorum communis. Proximally start a curvilinear incision in this interval 5 cm distal to the radiocapitellar joint, and extend it distally to the wrist joint midway between the radial styloid and Lister's tubercle. The length of the incision depends on the surgical needs.

Incise the deep fascia, and proximally identify and develop the muscle interval between the extensor carpi radialis brevis and the extensor digitorum communis to expose the radial shaft. In the middle one third of this exposure, the abductor pollicis longus and the extensor pollicis brevis cross the radial shaft obliquely toward the distal radial border of the radius. These muscles are left intact but mobilized so they can be retracted proximally and distally as needed.

To expose the distal radius, dissect between the extensor carpi radialis brevis and the extensor pollicis longus. The posterior interosseous nerve is not encountered with this approach if the supinator muscle is not exposed and the radial shaft is approached as described. For more proximal dissection, it is essential to identify and protect the posterior interosseous nerve.

In 1918, Thompson (10) described extensions of this exposure, including exposure of the entire radius and exposure of the posterior interosseous nerve if needed. Follow the line of separation between the extensor digitorum communis and the extensor carpi radialis brevis muscles up to the lateral epicondyle of the humerus if needed. This fully exposes the supinator muscle. Detaching the origins of these muscles from the lateral epicondyle allows even wider exposure. By supinating the radius, the junction of the supinator origin and the biceps tendon can be visualized.

Carefully dissect the supinator off the radius, staying against bone. Expose only as much radius as necessary. Avoid over-retraction, because a stretch injury to the posterior interosseous nerve can result, particularly where it is tethered by the motor branches to the extensor digitorum communis. To expose the posterior interosseous nerve, identify it proximal to the supinator, and trace it into the body of the supinator.

### McConnell’s Median and Ulnar Nerve Exposure

Place the forearm supinated on an arm board. Proximally, start the incision near the medial epicondyle and extend it distally in a lazy-$S$ fashion to the radial border of the pisiform (2) (Fig. 1.23). The length of the incision depends on the surgical needs. Protect the medial antebrachial cutaneous nerves in the proximal forearm.

Distally, expose the ulnar artery and nerve by incising the deep fascia along the radial border of the flexor carpi ulnaris. Retracting the flexor carpi ulnaris ulnarily and the flexor digitorum sublimis radially allows the ulnar artery and nerve to be visualized and followed proximally. Flexion of the wrist helps to relax these tendons.

The artery and nerve run parallel until the proximal one third of the forearm, where the artery courses toward the antecubital fossa and the ulnar nerve continues under the flexor carpi ulnaris to the ulnar groove. Protect the branches of the ulnar nerve innervating the flexor carpi ulnaris and part of the flexor digitorum profundus in the proximal forearm.

Distally, identify the median nerve as the flexor digitorum sublimis is reflected radially. Follow the median nerve proximally as it lies between the sublimis and profundus muscles. Halfway up the forearm, the median nerve is bound to the intermediate tendinous portion of the sublimis muscle. Because the nerve is on the radial side of this juncture, incising along its ulnar border further exposes the nerve.

To expose the median nerve more proximally, identify and develop the interval between the pronator teres and the flexor carpi radialis. Just inferior and deep to the pronator teres lies the median nerve. Sometimes the arch of the sublimis covers the nerve at this level, but dissecting through this portion of the sublimis exposes the nerve.

SURGICAL APPROACHES TO THE ACETABULUM AND PELVIS

J. M. Matta

CHAPTER 2

APPROACHES TO THE ACETABULUM

Fracture classification as well as specific fracture pattern determine the surgical approach to the acetabulum. The vast majority of fractures can be reduced and fixed through a single surgical approach.

The important preoperative question is whether or not the fracture can be reduced through the chosen approach. Fixation is less of a determining factor inasmuch as all three approaches—ilioinguinal (II), Kocher-Langenbeck (KL), and extended iliofemoral (EIF)—give access for fixation of both the anterior and posterior columns. I prefer to operate on the Tasserit (Judet) surgical table, placing patients prone for the KL, supine for the II, and lateral for the EIF approaches. If the surgeon chooses to operate on a standard table, particularly without traction, the reduction can usually also be performed. In that case, however, the need for either two approaches or the EIF may arise more often, and my recommendations for surgical approach (Table 2.1) may not apply. The KL and II approaches are preferable to the EIF approach because the EIF involves more muscle stripping from the outside of the bone. As a result, the period of rehabilitation is longer and the incidence of heterotopic ossification is higher. If the reduction and fixation are not judged to be possible through either the KL or II alone, however, choose the EIF.

Table 2.1. Acetabulum Fractures: Indications for the Various Operative Approaches

In some instances, the surgeon may initially choose the KL or II approaches, but during surgery he may find that completion of the reduction is impossible. In these cases, complete the reduction and fixation for the exposed column of the acetabulum, taking care not to place fixation into unreduced fracture lines. Close the wound and turn the patient from prone to supine or vice versa to perform a subsequent II or KL approach.

I do not advocate placing the patient in the so-called floppy lateral position to perform simultaneous II and KL approaches. Dispensing with the Tasserit table and placing the patient in the floppy position limits the effectiveness of either the II or KL approach and makes the need for a second approach more likely. With the patient in the floppy position, it is also difficult to maintain adhesion of surgical drapes, and sterility is thereby compromised. Second surgical approaches should rarely be needed if the surgeon does appropriate preoperative planning (3, 4).

In exceptional cases, for example certain T-shaped fractures, it may be desirable to plan for the KL and II surgical approaches to be performed successively in preference to the EIF. First, position the patient prone, then supine, or vice versa.

OPERATIVE TECHNIQUES

Ilioinguinal (II) Approach

After finding existing approaches to the anterior acetabulum to be inadequate, Emile Letournel (2) returned to the historic Paris anatomy institute, the Fer à Moulin, where he developed the II approach. The innovation of the approach was that in opening the inguinal canal at its roof and floor for access to the pelvis, it would nonetheless be possible to obtain a sound repair of the soft tissues at the completion of the procedure. This elegant approach remains the standard for access to the anterior column and internal aspects of the innominate bone. Through this approach, the interior of the joint can be visualized through displaced fracture lines (intraoperative visualization with the image intensifier can be helpful as well), but it is not visible after completion of the reduction. The reduction is inferred by the reduction of the inner aspect of the innominate bone.

- Place a Foley catheter in the bladder before positioning the patient.
- Position the patient supine, usually on a fracture table—the Tasserit (Judet) table is preferable. Support the pelvis with a narrow sacral support to facilitate the necessary access around the iliac crest; a broad flat table top inhibits access. Place the hip in about 20° of flexion to relax the iliopsoas and facilitate access to the internal iliac fossa and true pelvis.
- Start the incision in the midline of the abdomen, 2 cm proximal to the symphysis pubis. Direct the incision laterally toward the anterior superior iliac spine, and follow the iliac crest about two thirds of the way posteriorly to or beyond the most lateral convexity of the crest (Fig. 2.1).

Figure 2.1. Skin incision for the II approach.
Sharply incise the periosteum over the iliac crest, and release the attachment of the abdominal muscles and the iliacus from the iliac crest. Using a periosteal elevator, expose the internal iliac fossa as far posteriorly and medially as the anterior SI joint and the pelvic brim. Be careful to avoid injuring the internal femoral cutaneous nerve to the thigh (discussed below).

The first abdominal layer encountered is the aponeurosis of the external oblique and the external rectus abdominis sheath in the most medial portion of the incision. Incise this layer in line with the skin incision.

Reflect the aponeurosis of the external oblique and the external rectus sheath distally as a single layer; the inguinal canal is thereby unroofed (Fig. 2.2).

Identify the ilioinguinal nerve and spermatic cord or round ligament. Pass a finger bluntly around the spermatic cord, and pass a Penrose drain around the spermatic cord and ilioinguinal nerve together.

Medial to this split, transect the conjoined tendon of the internal oblique and transverse abdominis and a portion of the rectus tendon near the body of the pubis (Fig. 2.3). The medial portion of this dissection gives access to the retropubic space of Retzius.

Perform the incision along the inguinal ligament, with care to avoid injuring the structures immediately underlying it, which include the external iliac vessels and their accompanying lymphatics, the femoral nerve, and the lateral cutaneous nerve of the thigh.

Beneath the inguinal ligament lie two lacunae that contain the structures passing under it. Laterally is the lacuna musculorum, and medially is the lacuna vasorum (Fig. 2.4). The two lacunae are separated by the iliopectineal fascia, which runs obliquely from the anterior iliac crest to the pectineal eminence and the pelvic brim. The iliopsoas and the femoral and lateral cutaneous nerves of the thigh are found in the lacuna musculorum. The femoral vessels and their surrounding lymphatics are found in the lacuna vasorum. The lateral cutaneous nerve of the thigh is found at a variable distance from the anterior superior spine, from just adjacent to it to 3 cm medially. It is usually found immediately after incision along the inguinal ligament. The femoral nerve is more posterior and medial within the iliopsoas sheath and intimately is associated with the iliopsoas muscle.

Incise the iliopectineal fascia, which divides the false pelvis from the true pelvis and its quadrilateral surface. Incise it at the level of the inguinal ligament in a posterior and medial direction to the pectineal eminence, and then detach it proximally from the pelvic brim. Before dividing this fascia, fully isolate it by carefully dissecting the external iliac or femoral vessels with the surrounding lymphatics off the medial aspect of the fascia. Dissect the iliopsoas and femoral nerve off the lateral aspect. retract these structures medially and laterally away from the fascia, and sharply incise the fascia to the pectineal eminence. Cut the fascia proximally along the pelvic brim in a proximal and posterior direction until the anterior SI joint is palpable (Fig. 2.5A, Fig. 2.5B and Fig. 2.5C). The fascia attachment may be combined at the pectineal eminence with the psoas minor tendon attachment. If the psoas minor tendon attachment is present, it appears as a very dense section of the fascia and should be transected.

Pass a second Penrose drain around the iliopsoas and femoral nerve together. Passing a finger posteriorly to the external iliac vessels into the retropubic space medially, check for the possibilities of a retropubic anastomosis or anomalous origin to the obturator artery (corona mortis) from the external iliac. If this anomalous artery is present, it should be palpable on the posterior aspect of the superior pubic ramus. Visualize this area to check for the anastomosis. If present, sacrifice this anastomosis by cauterizing it or ligating it. Place a Penrose drain around the iliac vessels and their surrounding lymphatics as a unit. Do not
dissect the vessels individually. Individual dissection injures the lymphatics and produces postoperative lymphedema of the extremity.

Further expose the bone and the fracture lines by periosteal elevation along the superior pubis ramus and pelvic brim. Use a periosteal elevator over the pelvic brim to clear the obturator internus muscle from the quadrilateral surface, and approach the posterior column. In doing so, approach the sciatic notch carefully, because it is easy to injure the superior gluteal vessels or branches of the internal iliac vein. The obturator nerve can easily be seen as it runs parallel and medial to the quadrilateral surface and enters the obturator canal at the superolateral aspect of the obturator foramen. The exposure is now complete. Perform the operation through the various windows surrounded by the structures crossing the inguinal ligament.

The first window (Fig. 2.6) gives access to the internal iliac fossa, the anterior SI joint, and the proximal pelvic brim. Retraction can be performed with lever retractors placed on the anterior SI joint and the pelvic brim.

**Figure 2.6.** The first window of the II approach.

The second window (Fig. 2.7), which is accessed by retracting the iliopsoas and femoral nerve laterally and the external iliac vessels medially, gives access to the pelvic brim from the anterior SI joint beyond the pec-lineal eminence. It also gives access to the quadrilateral surface for reduction of posterior column fractures. The iliopsoas can be retracted fairly vigorously laterally without danger of injury to the femoral nerve. Take care with medial retraction of the external iliac vessels; this is usually done with a ribbon retractor, with its tip placed against the quadrilateral surface. After retraction of the vessels, check the pulse repeatedly to be certain that too great a force has not been applied.

**Figure 2.7.** The second window of the II approach.

The third window lies medial to the vessels and gives access to the superior pubic ramus and the symphysis pubis as well as the quadrilateral surface (Fig. 2.8). The spermatic cord may be retracted medially or laterally.

**Figure 2.8.** Access to the retropubic space and symphysis through the third window.

It is often desirable to obtain access to the external aspect of the ileum to manipulate the anterior column segment for placing bone-holding forceps around the bone. Gain access by releasing the inguinal ligament and sartorius from their origins on the anterior superior spine. Elevate the tensor fascia lata and gluteus minimus muscles from the anterior iliac wing as necessary. Detachment of rectus origin and anterior hip capsule has been described for the purpose of visualizing the articular surface following reduction, but I believe that this procedure is unwise because it can easily devascularize fracture fragments of the anterior column or wall.

At the completion of the procedure, place a suction drain in the space of Retzius. Also drain the internal iliac fossa and true pelvis adjacent to the quadrilateral surface. If the lateral ilium has been exposed, drain it as well.

If the sartorius and inguinal ligament have been released from the anterosuperior spine, reattach them using suture through drill holes in the bone. Then reattach the abdominal fascia to the fascia lata along the iliac crest. For the repair along the iliac crest, draw the abdominal muscles anteriorly and distally, because attachment of the abdominals in too proximal a position along the crest prevents a satisfactory closure along the inguinal ligament.

**Kocher-Langenbeck (KL) Approach**

The KL approach is the primary approach to the posterior column of the acetabulum. It affords excellent exposure of the retroacetabular surface, the greater and lesser sciatic notch, the ischial tuberosity, and the inferior portion of the iliac wing. The anterior column can often be reduced and stabilized by manipulation through the greater sciatic notch or by intraarticular manipulation through the acetabulum.

Position the patient prone and on the Tasserit or other suitable table. Keep the knee flexed at least 60° and the hip extended during the operation to prevent tension on the sciatic nerve.

**HINTS AND TRICKS**

**Ilioinguinal Approach**

- Place a suture as a marker in the abdominal muscles at the anterior superior spine when they are taken down. Placing this suture back in position is a helpful guide to closure, ensuring proper tension on the abdominal muscles.
- Then reattach the common origin of the internal oblique and transverse abdominis to the inguinal ligament and the transversalis fascia to the inguinal ligament.
- Then repair the conjoint tendon and tendon of the rectus abdominis. Faulty repair of the transversalis fascia can produce an inguinal hernia.
- Reapproximate the aponeurosis of the external oblique, then close the subcutaneous tissues and skin.

- Start the incision about 5 cm lateral to the posterosuperior spine, and extend it anteriorly and distally to the tip of the greater trochanter and then distally along the axis of the femur to approximately the midportion of the thigh (Fig. 2.9).
Split the gluteal fascia in line with the fibers of the gluteus maximus, and split the fascia lata over the femur. Incise the trochanteric bursa, and bluntly split the fibers of the gluteus maximus. Halt the splitting of the gluteus maximus when the neurovascular bundle of the inferior gluteal nerve is reached as it crosses through the muscle fibers (Fig. 2.10). It is possible to continue with the splitting if additional exposure is needed, but the superior portion of the gluteus maximus will be denervated. Transect the tendon of the gluteus maximus at its femoral insertion. Beware of the large bleeder in this area.

Locate the sciatic nerve as it crosses the posterior aspect of the quadratus femoris. Follow the nerve proximally to where it disappears beneath the piriformis muscle. To follow the nerve to this point, it is necessary to clamp and cauterize a small vascular pedicle that crosses posteriorly and laterally to the nerve. Transection of this pedicle allows more nerve mobility and better posterior column exposure.

Locate the tendon of the piriformis muscle, tag it with suture, and transect it at its trochanteric insertion. Reflect it posteriorly to expose the greater sciatic notch. Identify the tendon of the obturator internus, which is paralleled by the two gemelli superiorly and inferiorly. Tag these structures with suture, and transect them at the trochanteric insertion. Reflection of the obturator internus and the two gemelli from the retroacetabular surface is an essential part of the exposure that is often missed. This tendon leads to the lesser sciatic notch and the bursa of the obturator internus, where the tendon passes through the lesser notch. As the tendon with its accompanying gemelli are reflected posteriorly and medially, the inferior portion of the retroacetabular surface and superior pole of the ischial tuberosity are clearly exposed.

With a periosteal elevator, clear the retroacetabular surface and the superior pole of the ischial tuberosity. Use subperiosteal elevation on the inferior aspect of the iliac wing and anteriorly superior to the hip capsule to expose this area. In the area of the greater sciatic notch, avoid damaging the superior gluteal vessels or nerve with the elevator. An elevator may also be placed in the greater sciatic notch to clear the periosteum and obturator internus origin from the quadrilateral surface. This technique allows assessment of the fracture reduction by palpation of the quadrilateral surface as far anteriorly as the pelvic brim.

A Hohmann retractor with its tip driven into the bone may be placed on the inferior iliac wing for retraction of the abductors, but do not retract too proximally in this area; a stretch injury of the superior gluteal nerve could result. Cobra retractors or a specialized sciatic nerve retractor are normally placed with its tip in the greater or lesser sciatic notch, but be careful not to stretch the sciatic nerve (Fig. 2.11). If more anterior access to the inferior wing is necessary, the gluteus medius tendon may be partially or completely transected at its insertion, or a trochanteric osteotomy can be performed.

At the completion of the operation, place suction drains to drain the greater sciatic notch and inferior iliac wing area. Reattach the tendons of the piriformis and obturator internus muscles to the trochanter. Repair of these muscles provides a soft-tissue barrier between the sciatic nerve and internal fixation plate on the posterior column. Repair the maximus tendon, and close the fascia and skin.

Leave suction drains in place for approximately 48 hours. Mobilize the hip and begin gait training when the patient is comfortable.

**Extended Iliofemoral (EIF) Approach**

Emile Letournel developed the EIF approach to provide simultaneous access to both columns of the acetabulum. It is primarily an approach to the external aspect of the innominate bone, giving access to the entire external aspect of the iliac wing, the entire retroacetabular surface, and the posterior column, including the ischial tuberosity (Table 2.1). The internal aspect of the bone may also be exposed, with exposure of the distal portion of the internal iliac fossa to the anterior SI joint and the anterior column distally to the pectineal eminence. This exposure follows a logical neurovascular interval, reflecting muscles innervated by the superior and inferior gluteal nerves posteriorly and laterally and muscles innervated by the femoral nerve medially. Exposure of the posterior column is equal to that which can be obtained through the KL approach. The anterior column exposure, however, is less extensive than the II approach provides.

Place the patient in the lateral position, preferably on the Tasserit table.

Start the incision at the posterior superior iliac spine, and carry it anteriorly along the crest to the anterior superior spine and then anterolaterally down the thigh.

Sharply incise the peristeum over the iliac crest, and release the fascia lata from the crest. Subperiosteally dissect the gluteal muscles and the tensor fascia lata from the lateral aspect of the iliac wing (Fig. 2.12).
The incision in the deep fascia proceeds from the anterior superior spine in a distal and slightly more lateral direction. Split the fascia lata overlying the tensor fascia lata muscle to a point approximately halfway down the thigh or until the distal extent of the tensor fascia lata muscle is reached. Reflect the tensor fascia lata muscle posteriorly from its medial fascial compartment.

- Longitudinally split this medial fascia to expose the rectus femoris muscle. Medial retraction of the rectus exposes another layer of fascia and aponeurotic fibers directly posterior to it. Split this fascia and associated aponeurosis longitudinally. Clamp and ligate the internal femoral circumflex vessels, which are found immediately beneath this fascia (Fig. 2.13).

Opening this fascial plane exposes the vastus lateralis and anterior portion of the trochanter with the insertion of the gluteus minimus. Tag the portion of the trochanter with the insertion of the gluteus minimus. Tag the tendon of the gluteus minimus with a suture and transect it in its midsubstance, leaving a 1 cm stump with the trochanter and another 1 cm with the origin. It is also necessary to dissect sharply the gluteus minimus insertion from the superior hip capsule and continue elevation of the gluteal muscles until the greater sciatic notch is exposed.

- Identify the gluteus medius tendon at its insertion on the lateral aspect of the greater trochanter, and transect it in its midsubstance, leaving a 1 cm stump on the trochanter. Tag the tendon on the muscle side with multiple sutures to facilitate identification and repair (Fig. 2.14). Alternatively, after transecting the gluteus minimus tendon in the usual fashion, perform an osteotomy of the greater trochanter to detach the gluteus medius insertion.

Identify the piriformis tendon at its insertion on the superior aspect of the trochanter. Tag it with suture and transect it near its insertion to further expose the greater sciatic notch. Tag the tendon of the obturator internus and the two gemelli with a single suture, and transect them near the trochanter. Reflection of this tendon and the two gemelli from the retroacetabular surface exposes the lesser sciatic notch and the bursa of the obturator internus, where the tendon slides in the lesser sciatic notch from inside the pelvis.

- Use subperiosteal dissection as necessary to expose the bone surface and fracture lines. Subperiosteal dissection along the posterior border of the greater sciatic notch gives access to the quadrilateral surface and helps protect the superior gluteal vessels and nerve, as they now fall away from the bone in a posterior and medial direction.

Excise the reflected head of the rectus femoris muscle from the superior hip capsule to expose more of the anterior column. A capsulotomy may be performed at the level of the rim of the acetabulum to expose the internal aspect of the joint. Distraction of the femoral head aids this exposure (Fig. 2.15).

The internal iliac fossa may be exposed by detachment of the abdominal muscles from the iliac crest, and by detachment of the sartorius and inguinal ligament from the anterior superior spine. Dissection may be carried out posteriorly and medially to the anterior SI joint and the pelvic brim.

- Transection of the direct head of the rectus femoris at its bony origin completes the maximum access to the anterior column (Fig. 2.16). Exposure beyond the pelvic brim allows access around the bone, which is particularly useful for callus excision during surgery on old fractures.

With exposure of both sides of the iliac wing, there is a danger of devascularizing large segments of the anterior column. Carefully preserve vascular muscle pedicles to the bone to maintain vascularity. In the case of a high anterior column fracture that takes the anterior border of the iliac wing, it is wise to preserve its attachments to the anterior hip capsule and rectus femoris and, if possible, to additional muscle pedicles.

- Take care with dissection around the greater sciatic notch. Injury to the superior gluteal vessels or nerve in this area could compromise the blood and nerve
supply to the large abductor muscle flap. Place a wet sponge over the muscles to prevent desiccation during the operation.

- At the completion of the operation, place suction drains along the course of the rectus femoris and vastus lateralis muscles to drain the external iliac fossa and greater sciatic notch. If the internal aspect of the bone has been exposed, drain it as well. Reattachment of the rectus femoris and sartorius origins is facilitated by placement of a suture through a drill hole in the bone. Reattach the tendons of the piriformis and obturator internus muscles to the trochanter with suture. Repair the tendons of the gluteus medius and minimus muscles at the trochanteric insertion with multiple sutures. Reapproximate the fascia lata to the abdominal fascia at the iliac crest, and close the fascia lata anterolaterally over the thigh.
- Keep the suction drains in place for about 48 hours after surgery. During the initial postoperative period, use an abduction pillow while the patient is in bed. Start passive mobilization of the hip within a few days but avoid passive abduction. Begin gait training when the patient’s symptoms allow.

**APPROACHES TO THE PELVIC RING**

- To approach the pelvic ring, position the patient on a radiolucent table, with the sacrum centered over a radiolucent area at least 1.5 m in length. This positioning allows angulation of the image intensifier to facilitate assessment of the reduction and to guide fixation.
- Place the patient supine for the approach to the symphysis or anterior SI joint or prone for the approach to the posterior pelvic ring. When both anterior and posterior reduction and fixation are required, position the patient prone for the posterior approach and subsequently turn the patient supine.

**OPERATIVE TECHNIQUES**

**Approach to the Symphysis Pubis**

- Position the patient supine on the operating table.
- Insert a Foley catheter in the bladder before the operation.
- Make either a transverse incision 2 cm proximal to the symphysis pubis or a vertical midline incision (Fig. 2.17). The transverse incision gives a more cosmetic result, whereas the vertical incision can be extended for intraabdominal access in the case of multiple injuries.

- **HINTS AND TRICKS**

  Positioning the patient laterally for combined simultaneous anterior and posterior approaches typically does not save time and introduces significant problems: access to the bone becomes more awkward (especially anterior), the image intensifier is more difficult to use, and sterility is compromised. In some cases, it is preferable to approach the anterior and posterior lesions simultaneously through the II approach with the patient supine. In other cases, the skin incision may appear as the II but the deep dissection is done as for the approach to the symphysis and the approach to the anterior SI joint.

  - In either case, locate the two heads of the rectus abdominis. In the acute symphysis diastasis, one of the heads of the rectus is commonly torn from its bony attachment. Separate the two heads of the rectus abdominis from each other by a vertical incision along the linea alba (Fig. 2.18). Identify the pyramidalis muscle just proximal to the symphysis: Split it vertically along the line of the linea alba. Directly beneath the abdominal wall lie the preperitoneal fat proximally and the bladder distally. In an acute injury, the bladder falls away from the posterior surface of the symphysis, although it may adhere to the bone in an old injury. If the bladder adheres to the bone, free the bladder carefully with a periosteal elevator along the posterior aspect of the bone to avoid injury to it.

- Leave the two heads of the rectus abdominis attached to the anterior and outer aspect of the symphysis, although the posterior portion of their insertion may be freed by sharp dissection along the superior aspect of the symphysis and superior pubic ramus. A long proximal split of the linea alba enhances exposure.
- Place the point of a narrow Hohmann retractor over the superior pubic ramus on each side of the symphysis, and retract the two heads of the rectus laterally (Fig. 2.19). Use a large malleable retractor in the space of Retzius to retract the bladder posteriorly. Periosteal elevation along the superior part of the symphysis and the superior ramus completes the exposure necessary for reduction and plate application.

**Figure 2.17.** Skin incision for the approach to the symphysis pubis.

**Figure 2.18.** Incision along the linea alba.

**Figure 2.19.** Retraction of the two heads of the rectus abdominis.

- The superior pubic ramus can also be approached through this interval without transecting the rectus abdominis if reduction and fixation of the ramus are indicated.
- Identify the obturator nerve and artery, which lie posterior to the most lateral portion of the superior pubic ramus.
- It is also possible to continue with proximal exposure of the pelvic brim and posterior exposure of the quadrilateral surface, as is done with the Stoppa approach (1).
- If the fixation of the superior ramus is planned or contemplated, it is advisable to prep the skin over the iliac crest to allow extension of the incision to the II
approach in case it is necessary to extend a plate into the internal iliac fossa.

At the completion of surgery, place a suction drain in the retropubic space. Closure is normally simple, with approximation of the two heads of rectus abdominis along the linea alba and closure of the subcutaneous tissues and skin.

**Approach to the Posterior Ring**

A single incision can be used to approach fractures of the sacrum, dislocations of the SI joint, or fracture dislocations of the SI joint.

- Position the patient prone on a fully radiolucent table, if available.
- Make a vertical incision 2 cm lateral to the posterosuperior spine. Start the incision 5 cm lateral to the iliac crest, and end it 5 cm distal to the superior border of the greater sciatic notch (Fig. 2.20).

**Figure 2.20.** Skin incision for the approach to the posterior pelvic ring.

- Locate the very thin fascia overlying the gluteus maximus, just beneath the subcutaneous tissue. Elevate the subcutaneous tissue off the gluteal fascia medially to expose the point of origin of the gluteus maximus from the posterior crest of the ilium and from the posterior aspect of the sacrum more distally.
- Reflect the gluteus maximus from its point of origin along the posterior ilium, and reflect it from the sacrum. Immediately beneath the portion of the maximus that overlies the sacrum is the fascia that overlies the multifidus muscles of the spine. Reflect the maximus off this fascia (Fig. 2.21).

**Figure 2.21.** Reflection of the gluteus maximus muscle from the posterior crest and multifidus fascia.

- Also reflect a portion of the medius and minimus laterally from the iliac wing to expose the posteroexternal aspect of the wing. Take care to not injure the superior gluteal vessels and nerves as the gluteal muscles are reflected from the wing immediately superior to the greater sciatic notch.
- Exposure of the greater sciatic notch is necessary for reduction of the SI joint. It allows the surgeon to pass a finger through the notch to palpate the anterior SI joint or to palpate a sacral fracture on the anterior portion of the sacrum. It also permits assessment of the position of the neural foramina and positions of fractures around the neural foramina. As you detach the gluteal muscles from the posterior crest and sciatic notch area, also detach the piriformis muscle from its origin at the greater notch.
- If the sacrum is fractured, it is necessary to expose the fracture line as it traverses the posterior sacral lamina. Elevate the multifidus muscles from the posterior aspect of the sacrum in a lateral to medial direction starting at the lateral edge of the sacrum. Small nerve branches that exit through the posterior sacral foramina supply some sensation to the skin overlying the sacrum and additionally innervate the multifidus muscles. It is usually possible to preserve them, even when the sacral foramina are exposed posteriorly; if they must be sacrificed, the resulting disability is negligible (Fig. 2.22).

**Figure 2.22.** Completed exposure of the posterior ilium, SI joint, and sacral lamina.

- Although palpation is not necessary in most cases, it is possible to obtain access for palpation of the internal iliac fossa and anterior aspect of the superior SI joint by releasing the erector spinae muscles and abdominal muscles from the superior portion of the crest and by placing a finger over the top of the crest into the internal iliac fossa.
- At the completion of the operation, drain the lateral ilium. Drain the greater sciatic notch; if the internal iliac fossa has been exposed, drain it as well. Closure is simple: Reproximate the gluteal fascia to the fascia overlying the multifidus and erector spinae muscles.

For bilateral posterior lesions that require both reduction and fixation, I recommend bilateral simultaneous approaches.

**Approach to the Anterior SI Joint**

In some cases, anterior exposure of the SI joint may be desirable.

- Position the patient supine.
- Start the incision in line with the il approach, about 5 cm medial and distal to the anterosuperior spine, and proceed posteriorly along the iliac crest about two thirds of the way along the crest.
- Sharply incise the periosteum over the iliac crest. Release the abdominal muscles from the crest by superiosteal dissection. Incise the aponeurosis of the external oblique muscle in line with the skin incision and reflect it distally.
- Split the lateral portion of the inguinal ligament to detach the lateral portion of the origin of the internal oblique and transversus abdominis muscles. Split the inguinal ligament with care to avoid transecting the lateral cutaneous nerve of the thigh.
- Elevate the iliacus from the internal iliac fossa medially to the SI joint and as far distally as the pelvic brim. It is necessary to dissect subperiosteally along the anterior aspect of the sacral ala, but take care to avoid too vigorous medial dissection. The L-5 nerve root, which crosses the anterior sacral ala, can suffer stretch injury from vigorous retraction exposure. Visualize the anterior SI joint for reduction. Facilitate exposure by the use of deep, straight-tipped, broad retractors or sharp-tipped Hohmann retractors whose tips can be driven into the anterior sacrum.
Approach to the Iliac Wing

For isolated fractures of the iliac wing, proceed as follows.

- Position the patient lateral or supine.
- Incise the skin over and parallel to the iliac crest.
- Cut the periosteum sharply along the superior aspect of the crest. From this point, expose the external or internal aspect of the wing by elevating the gluteal muscles, the iliacus, or both, as necessary, for reduction and fixation.

Exposure of the Ischium, by Michael W. Chapman

Isolated exposure of the ischium, although rarely required, is most commonly used for debridement of osteomyelitis due to an overlying decubitus ulcer. It is also used occasionally for biopsy.

- Position the patient supine on a regular operating table and place the legs in the lithotomy position using obstetric leg holders.
- Prepare and drape the perineum; use adhesive plastic drapes to exclude the anus from the field.
- Make a vertical incision as long as necessary for the exposure, directly over the ischium but somewhat lateral; 7.5 to 10 cm, (3 to 4 inches) usually suffice.
- Dissect directly down to the ischium. Exposure is usually facilitated by using an electric cautery knife to reflect the muscle origins directly off the bone.
- Avoid injury to vital structures by staying on bone. Remember that the pudendal nerve runs in Alcock's canal on the medial aspect of the ischium.
- If good hemostasis is obtained, then layered closure without a drain is possible. Infected wounds are often packed open.

HIP

ANTERIOR APPROACHES

Hardinge Approach

The Hardinge approach is a direct lateral approach to the hip described by Kevin Hardinge in 1982 (1) for total hip arthroplasty, based on a modification of the original description of this approach by McFarland and Osborne (4). Hardinge described its use with the patient supine; however, most surgeons today use the lateral/decubitus position because it provides better access for two surgeons standing on opposite sides of the table. It also allows for increased mobility of the operated extremity (Fig. 3.1). The advantage of the supine position is that it makes orientation of the components easier and facilitates comparison of leg lengths for correction of discrepancy.

Figure 3.1. With the patient in the lateral decubitus position, notice that anterior superior iliac spines are vertically aligned.

The Hardinge approach is useful for hemiarthroplasty for femoral neck fracture, as well as for total hip arthroplasty. It allows the surgeon direct visualization of the acetabulum and excellent access to the entire circumference. It avoids morbidity from osteotomy of the greater trochanter and maintains the continuity of the abductor mechanism. Because the posterior portion of the gluteus medius muscle, with its thick tendon, is left intact, early rehabilitation is possible. Partial weight bearing with crutches is usually possible immediately after surgery.

- Begin the skin incision about 3–4 inches (7 to 10 cm) distal to the prominence of the greater trochanter in the midportion of the lateral aspect of the thigh, directly over the femur. Extend it in line with the femur over the prominence of the trochanter, inclining about 20° posteriorly in the proximal one-third of the wound. The total incision length is usually 8–10 inches (20 to 25 cm); in obese or muscular patients, a longer incision is necessary (Fig. 3.2).

Figure 3.2. Make the initial incision in line with the neutral axis of the femur.

- Incise sharply down to the deep fascia with minimal undermining of the subcutaneous tissue. Divide the gluteal fascia and iliotibial band in line with the skin incision. Retract the tensor fascia lata anteriorly, separating it from its conjoined origin with the gluteus medius. Avoid injury to the superior gluteal nerve and artery by dissecting this interval with a relatively blunt instrument. We prefer a large-key periosteal elevator (Fig. 3.3).
Figure 3.3. Charnley initial incision retractor in place.

At the trochanteric ridge formed by the origin of the vastus lateralis, at the mid-lateral point of the greater trochanter, use an electrocautery knife set on “cutting” to incise the gluteus medius longitudinally, extending distalward through the vastus lateralis, curving slightly anteriorly. Control bleeding from the transverse branch of the lateral circumflex artery in the vastus lateralis origin. Reflect the gluteus medius insertion and vastus lateralis muscles in continuity anteriorly off the greater trochanter, taking care to stay on bone to maintain the maximum thickness of tendon. Do not cut across the muscle fibers of the gluteus medius proximally; split them in line with the incision with a large-key periosteal elevator. Do not split proximally more than 5 cm above the trochanter to avoid injury to the superior gluteal nerve (Fig. 3.4).

Figure 3.4. Anterior insertion of the gluteus medius is mobilized.

Retract the gluteus medius; in the supine position, adduct the thigh to facilitate exposure of the gluteus minimus, which is reflected off the hip joint capsule superiorly. In his original description, Hardinge incises the capsule, does not excise it, and repairs it following arthroplasty. To permit adequate access to the acetabulum for noncemented cups, we prefer to isolate the hip joint capsule, placing a cobra retractor anteroinferiorly and superoposteriorly to expose the capsule. We then excise the anterior two thirds of the capsule intact (Fig. 3.5).

Figure 3.5. Expose the capsule.

Dislocate the hip by flexing and adducting it while levering the femoral head out of the acetabulum, cutting the ligamentum teres. When using the lateral decubitus position, drop the leg off the edge of the table into a sterile pocket formed from a large drape sheet. Transect the femoral neck with an oscillating saw (Fig. 3.6).

Figure 3.6. A: Superior retractor is held in place by 1/8 in. Steinmann pins or drill bits. B: Place the tibia in a pouch positioned vertical to the floor.

This position gives ideal exposure of the femur for insertion of a prosthesis. Protect the insertion of the posterior portion of the gluteus medius during preparation of the femur with appropriate retractors, which also elevate the trochanter to provide better exposure (Fig. 3.6B).

When preparing and inserting the acetabulum, keep the leg on the operating table in line with the torso, using specially designed or sharp-tipped Hohmann retractors to facilitate exposure of the acetabulum.

For repair of the gluteus medius, place a series of heavy (we prefer #5 Tevdek) sutures through the bone of the greater trochanter. Then direct the suture in a horizontal mattress fashion through the tendinous portion of the gluteus medius, securing it firmly to bone. Make these holes and place the sutures prior to insertion of the prosthesis using an awl, drill-point, or towel-clip. Next, repair the longitudinal split in the gluteus medius and vastus lateralis with #1 sutures. Close the split in the deep fascia and iliotibial band in a similar fashion (Fig. 3.7).

Figure 3.7. A: Reattachment of the gluteus minimus. B: Suturing of the gluteus medius and vastus lateralis.
Smith-Petersen Approach

Refer to Chapter 2 for the extended iliofemoral approach.

Watson-Jones Approach

The Watson-Jones anterior approach to the hip joint, femoral neck, and proximal femur is useful for capsular incisions, reduction of femoral neck fractures, upper femoral osteotomies, and internal fixation of proximal femoral fractures. One advantage of this approach is that it exposes the femoral neck, thereby allowing the surgeon to accurately identify femoral anteversion.

- At a point 2–3 cm posterior to the anterosuperior iliac spine, begin the incision directed toward the midpoint of the greater trochanter (Fig. 3.8A). Then angle the incision into a straight lateral orientation and proceed distally 10–15 cm.

Figure 3.8. Watson-Jones anterolateral approach to the hip. A: Skin incision. B: The vastus lateralis is retracted anteriorly, as is the tensor fascia, exposing the anterior hip capsule. 1, Gluteus medius; 2, nerve to tensor fasciae latae; 3, hip joint capsule; 4, illoposas; 5, lateral circumflex femoral vessels; 6, vastus intermedius; 7, vastus lateralis (reflected); 8, greater trochanter. (From Schlumpf R. Proximal Femur: Lateral Approach. In: Rüedi T, von Hochstetter AHC, Schlumpf R, eds. Surgical Approaches for Internal Fixation. Berlin: Springer-Verlag, 1984:115–121.)

- Identify the interval between the gluteus medius and tensor fascia lata, best done at a point halfway between the anterosuperior iliac spine and the greater trochanter.
- Place a pointed retractor posterior to the tensor fascia lata with the point on the anterior rim of the acetabulum. With posteriorly directed retraction of the gluteus medius, expose the hip capsule (Fig. 3.16). Chapman (personal communication, 1993) facilitates this exposure by first splitting the fascia lata distally. As the dissection is carried proximally, the interval between the bellies of the tensor fascia lata and gluteus medius muscles becomes more obvious. Thus it is easier to identify the superior gluteal artery and nerve and avoid wandering in the wrong interval.
- Incise the hip capsule in line with the femoral neck in its midportion. To gain greater exposure to the femoral neck and head, extend the capsular incision perpendicular to the plane of the initial incision by dissecting the capsule off the intertrochanteric ridge superiorly and inferiorly.
- For greater exposure of the proximal femoral shaft, detach the vastus lateralis from the vastus tubercle portion of the anterior intertrochanteric line. From this point distally, split the vastus longitudinally or retract it anteriorly, and detach it from the insertion on the most proximal portion of the linea aspera to gain access to the femoral shaft.
- For wider exposure to the intracapsular femur, detach the anterior fibers of the gluteus medius from the anterior one half of the tendinous insertion on the greater trochanter, leaving a cuff of tendon on the trochanter for later repair.

Harris Approach

Joint reconstructive procedures that require wide exposure of the femoral neck and acetabulum call for the Harris anterolateral approach to the hip joint. This approach is useful in that the hip can be dislocated anteriorly or posteriorly.

- Place the patient in the lateral position with the unaffected hip facing down. Bean bags, kidney rests, or "hip positioners" attached to the operating table help to maintain the true lateral position. Abduct the affected limb 60° and keep the hip extended and the knee flexed. A Mayo stand with a pillow and sterile cover relieves the assistants of considerable burden in maintaining this position.
- Make a lazy U-shaped skin incision beginning 5 cm posterior and 2 cm proximal to the anterosuperior iliac spine. Curve the incision distally toward the posterior greater trochanter (Fig. 3.8A), and extend it distally and slightly anteriorly for a distance of 15 cm.

Figure 3.9. Harris anterolateral approach to the hip. A: Skin incision. B: The anterior aspect of the gluteus maximus insertion on the iliotibial tract is incised 1.5 cm posteriorly to allow greater exposure of the posterior aspect of the greater trochanter. C: The trochanter is osteotomized, exposing the external rotators and hip capsule. 1, Gluteus medius; 2, gluteus minimus; 3, greater trochanter (osteotomized); 4, piriformis; 5, obturator internus; 6, obturator externus; 7, illoposas. (From Rosenthal S. Surgical Approaches. In: Crenshaw AH, ed. Campbell's Operative Orthopaedics, 6th ed. St. Louis: CV Mosby, 1980:70.)

- Working distally to proximally, divide the iliotibial band in line with its fibers. At the level of the trochanter, direct the fascia lata incision 1 cm anterior to the insertion of the gluteus medius on the greater trochanter, and continue the incision of this layer anteriorly in line with the incision.
- To provide posterior exposure, make an oblique incision in the deep surface of the posteriorly reflected fascia lata and into the substance of the gluteus medius for a distance of 5 cm (Fig. 3.8B). Place a pointed Hohmann retractor on the anterior acetalbulum to retract the anterior part of the tensor fascia lata and iliotibial band anteriorly.
- Sharply dissect the origin of the vastus lateralis from the vastus tubercle portion of the intertrochanteric line. Isolate the abductors from the joint capsule anteriorly by blunt dissection.
- Elevate the periosteum from the proximal femur transverse to the long axis of the femur at a distance of 3–3.5 cm from the tip of the trochanter. At this point, before osteotomizing the greater trochanter, the surgeon may choose to predrill or measure holes for later osteotomy screw or wire fixation. Direct the osteotomy superiorly and medially toward a point 5 mm lateral to the superior hip capsular attachment on the femoral neck (Fig. 3.8C).
- Free the superior part of the joint capsule from the abductors. By virtue of the posterior fascia lata and gluteus medius incision, posterior exposure is now possible. Divide the piriformis and external rotators at their femoral insertions. For arthroplasties, excise the posterior and anterior capsule, as necessary.
- Place a narrow Hofmann or Bennett retractor deep to the rectus femoris on the anteroinferior iliac spine to improve visualization anteriorly. To expose the illoposas tendon, flex the hip and rotate it externally. This tendon can be divided and sutured to a remnant of intact anterior capsule if desired to correct a flexion contracture. The hip can be dislocated anteriorly to gain access to the entire femoral head and neck by placing the greater trochanter into the acetabulum. For exposure of the acetabulum, retract the greater trochanter superiorly and dislocate the femoral head posteriorly. Maintain the abducted position of the limb for trochanteric reattachment and wound closure.

POSTERIOR APPROACHES
Moore Approach
The Moore or “Southern” exposure provides excellent access to the posterior femoral neck for bone graft procedures, posterior drainage of septic joints, or reconstructive procedures of the proximal femur.

- Place the patient in the lateral position with the unaffected side facing down. Bean bags, kidney rests, or “hip positioners” attached to the operating table are excellent adjuncts for maintaining the true lateral position. Alternatively, the procedure can be done with the patient prone. The prone position may be recommended for certain femoral neck bone grafting procedures.
- Begin the incision 10 cm distal to the posterosuperior iliac spine, and extend it laterally and distally in line with the gluteal fibers (Fig. 3.10A) to the posterior margin of the greater trochanter. Then carry the incision distally for a distance of 15–20 cm in line with the femoral shaft.

- Divide the thick fascia lata distally and the thin gluteal fascia proximally in line with the skin incision. Divide the deep fibers of the gluteal musculature bluntly using a finger-spreading technique, preserving the branches of the superior gluteal nerve and vessels in the proximal dissection. Partially divide the distal insertion of the fibers of the gluteal musculature from their femoral insertion to allow distal retraction. Retract in a plane perpendicular to the gluteal split, and expose the greater trochanter.
- Identify the sciatic nerve in the medial portion of the wound and carefully protect it. Divide the external rotators and the tendon of the piriformis at their femoral insertions, and retract them medially, forming a protective sling over the sciatic nerve (Fig. 3.10B). Expose the posterior part of the hip capsule, and incise along the axis of the femoral neck. For exposure of the femoral neck, dissect the distal insertion of the capsule from the posterior intertrochanteric ridge. Protect the medial femoral circumflex artery inferiorly; it supplies the femoral head in its terminal branch, the lateral epiphyseal artery. For procedures that require hip dislocation, flex the hip to 90°, keeping the knee flexed, and externally rotate the thigh.

Ludloff Medial Approach
The Ludloff medial approach is most useful for open reduction of congenitally dislocated hips; for resection of small, primary, benign bone tumors in the region of the lesser trochanter; and for obturator neurectomies.

- Position the patient supine, with the affected hip flexed, abducted, and externally rotated. This position brings the lesser trochanter closer to the skin surface.
- Make a longitudinal incision on the medial thigh, starting 3 cm distal to the pubic tubercle in line with the adductor longus, which is easily palpable (Fig. 3.11A). Develop the plane between the adductor longus and brevis muscles anteriorly and the adductor magnus and gracilis muscles posteriorly. The posterior branch of the obturator nerve is visible on the belly of the adductor magnus; protect it unless it is to be cut to relieve muscular spasticity. The anterior branch lies on the anterior surface of the adductor brevis and is protected by retraction of this muscle. The lesser trochanter is visible in the base of the wound (Fig. 3.11B). Isolate the iliotibial band with blunt dissection. It is then easily transected, allowing greater exposure of the medial hip capsule.

![Figure 3.11. Ludloff medial approach to the hip. A: Skin incision; patient positioning. B: The adductor longus is retracted anteriorly, exposing the lesser trochanter, inferior hip capsule, and posterior branches of the obturator nerve. 1, Adductor longus; 2, lesser trochanter; 3, adductor brevis; 4, gracilis; 5, adductor magnus; 6, obturator nerve, posterior branch. (From Thomas HA. In: Hoppenfeld S, deBoer P, eds. Surgical Exposures in Orthopaedics: The Anatomic Approach. Philadelphia: JB Lippincott, 1984:349, 351.)](image)

- Open the capsule in line with the inferior capsular attachment, and extend the capsular incision in a perpendicular orientation; this favors visualization of the acetabulum and femoral head.

THIGH—FEMORAL SHAFT

Lateral Approach
The lateral or posterolateral approach to the femur is useful for tumor resection or internal fixation of shaft fractures. It is the preferred approach to the femoral shaft for most situations.

- Position the patient in the lateral or the supine position. Elevate the hindquarter 30° to 45° with a pad under the buttock.
- Make an incision of the necessary length along a line between the greater trochanter and the lateral femoral condyle (Fig. 3.12A). Divide the superficial and deep fascia in line with the incision.

![Figure 3.12. Lateral approach to the femoral shaft. A: Skin incision and level of cross section. B: Plane of dissection shown in cross section. C: The vastus lateralis has been mobilized anteriorly and the perforating vessels ligated, exposing the entire femoral shaft. 1, Vastus lateralis; 2, lateral circumflex femoral vessels; 3, joint capsule (knee); 4, lateral superior genicular artery; 5, perforating arteries, posterior vastus branches; 6, lateral intermuscular septum; 7, incision. (From Schlumpf R. Femoral Shaft: Lateral Approach. In: Rüedi T, von Hochstetter AHC, Schlumpf R, eds. Surgical Approaches for Internal Fixation. Berlin:](image)
For the preferred posterolateral approach, retract the vastus lateralis anteriorly, and dissect the muscle off the lateral intermuscular septum where it attaches to the linea aspera of the femur (Fig. 3.12B). Make the incision 2–3 cm more posterior to help with this part of the exposure.

Carefully identify, isolate, and divide the perforating branches of the profunda femoris in the middle third of the femoral shaft (Fig. 3.12C). If the surgeon inadvertently transects at the level of the septum, these vessels can retract to the medial side of the septum, producing impressive hemorrhage.

For the lateral approach, divide the vastus lateralis and intermuscles in line with the incision. As in the posterolateral approach, identify and ligate the perforating branches of the profunda femoris with the descending branch of the lateral femoral circumflex artery in the proximal third of the femoral shaft, and the superolateral geniculate artery in the distal third.

**Anterolateral Approach**

The anterolateral approach to the femoral shaft is useful if poor skin or violation of muscle compartments by tumor render the posterolateral or lateral approaches impossible. It is not the exposure of choice for most conditions, because postoperative quadriceps adhesions can result, particularly if the knee cannot be mobilized immediately after surgery. Combined with an anterolateral approach to the knee joint, it becomes a versatile and wide exposure for T-type intra-articular fractures of the distal femur. Meticulous layered closure and immediate mobilization of the knee joint prevents loss of motion due to quadriceps adhesions. M. W. Chapman, the editor of this book, prefers this approach for comminuted intra-articular fractures of the distal femur (personal communication, 1999).

Make a skin incision along the line between the anterosuperior iliac spine and the lateral border of the quadriceps tendon as it inserts into the patella. Incise the superficial and deep fascia in line with the incision, and develop the interval between the rectus femoris medially and the vastus lateralis laterally (Fig. 3.13A). This interval is easily identified proximally.

Figure 3.13. Anterolateral approach to the femoral shaft. **A:** Skin incision and level of cross section. **B:** Plane of dissection between the rectus femoris and vastus lateralis through the vastus intermedius. (From Schlumpf R. Distal Femur: Lateral Approach. In: Rüedi T, von Hochstetter AHC, Schlumpf R, eds. Surgical Approaches for Internal Fixation. Berlin: Springer-Verlag, 1984:132-135.) **C:** Retraction of the vastus intermedius and rectus femoris anteriorly and vastus lateralis inferiorly exposes the entire femoral shaft. **D:** The dissection can be carried out distally to expose the articular surface of the distal femur and knee joint. 1, Vastus lateralis; 2, rectus femoris; 3, vastus intermedius; 4, periosteum; 5, femur; 6, lateral circumflex femoral artery. (From Thomas HA. The Femur. In: Hoppenfeld S, deBoer P, eds. Surgical Exposures in Orthopaedics: The Anatomic Approach. Philadelphia: JB Lippincott, 1984:372.)

Divide the thinnest and midline portion of the vastus intermedius in line with its fibers, and expose the femur by subperiosteal dissection (Fig. 3.13B). The exposure is best limited to the distal two thirds of the femoral shaft, because proximally the innervation to the vastus lateralis limits exposure.

If it is desirable to expose the articular condyles and knee, carry the incision through a lateral parapatellar approach to the knee. The patella can be dislocated medially (Fig. 3.13C, Fig. 3.13D).

**Posterior Approach**

The posterior approach, as originally described, is useful only for the middle three fifths of the femoral shaft. It is probably indicated only for treatment of tumors and exploration of the sciatic nerve. It can be extended into Henry’s exposure of the sciatic nerve to provide a comprehensive extensile approach to the posterior thigh.

Position the patient prone on the operating table, using appropriate bolsters to allow free abdominal and chest movement. Align the incision with the femur from 5 cm distal to the gluteal fold to 10 cm proximal to the popliteal crease (Fig. 3.14A). Incise the superficial and deep fascia in line with the skin incision, avoiding the posterior femoral cutaneous nerve.

Identify the interval between the biceps femoris and the vastus lateralis. In the proximal part of the dissection, detach the short head of the biceps femoris sharply from the linea aspera. Then reflect it medially (Fig. 3.14B) to expose the femoral shaft.

In the distal half of the wound, retract the long head of the biceps laterally to expose the sciatic nerve (Fig. 3.14C). Gently retract the sciatic nerve laterally to expose the femur. Take the adductor magnus and biceps femoris off the linea aspera sharply. For sciatic nerve explorations, begin the deep dissection in this distal half of the wound.

**Medial Approach**

The medial approach is useful primarily for repair of the femoral artery; usually such arterial injuries are associated with fractures. It is also occasionally useful for medial internal fixation of fractures or osteotomies.

With the patient supine and the hip flexed and externally rotated, position the knee in flexion. Begin the incision at the mid thigh and extend it distally to 5 cm distal to the adductor tubercle (Fig. 3.15A). Carefully incise the superficial fascia and the deep fascia, which is quite thin in this region; at the same time, avoid the saphenous vein and nerve, which are superficial.
Anatomic Approach.

The anterior cruciate ligament; approaches is the same. 

Required or when later reconstructive procedures are anticipated. Use it whenever possible, because it gives the best possible route for reexploration, whenever repeat procedures may be 

Fractures, and synovectomy. The anteromedial deep dissection can be combined with a straight anterior skin incision (loose bodies, stabilization of osteochondral fractures, ligament or meniscal repair, drainage procedures, ligament reconstructions, fixation or excision of patella

Position the patient prone and outline the “question mark” incision (Fig. 3.16A). Avoid injury to the posterior cutaneous nerve of the thigh as it exits from beneath the gluteus maximus and runs distally down the thigh. After incising the deep gluteal fascia, develop the interval between the gluteus medius and maximus. 

Cut the gluteus maximus free from its insertion into the femur, and fold the entire gluteus maximus flap back medially on its neurovascular bundle. The sciatic nerve, proximally exposed, is easily traced to the superior margin of the long head of the biceps femoris, where it passes deeply to this muscle (Fig. 3.16B). From this point distally, the entire exposure is as previously described for the posterior approach.

KNEE

ANTERO-MEDIAL APPROACHES

Anteromedial Approach

The anteromedial approach allows adequate exposure of the knee joint for most intraarticular problems. The list includes meniscectomy (total or partial), removal of loose bodies, stabilization of osteochondral fractures, ligament or meniscal repair, drainage procedures, ligament reconstructions, fixation or excision of patella; fractures, and synovectomy. The anteromedial deep dissection can be combined with a straight anterior skin incision (Fig. 3.17) for more extensive exposure for these conditions and for total knee replacement. Use it whenever possible, because it gives the best possible route for reexploration, whenever repeat procedures may be required or when later reconstructive procedures are anticipated.

For the anterior incision, make a straight incision midline extending 10 cm above the patella to 3 cm below the tibial tubercle (Fig. 3.17A). For the anteromedial incision, begin on the medial side of the quadriceps tendon, 5–7 cm above the patella. Curve the incision around the superomedial border of the patella, then distally to the medial side of the tibial tubercle. Preserve the infrapatellar branches of the saphenous nerve whenever possible.

The deep dissection is identical for both procedures (Fig. 3.17B). Divide the vastus medialis muscle from the quadriceps tendon on the medial side, leaving a 5 mm cuff of tendon on the muscle side. Extend the quadriceps tendon split proximally to the extent of the skin incision. Divide the capsule and synovium together, 5 mm lateral to the mediolateral border of the patella.

Carry this deep dissection down to the medial side of the tibial tubercle. Flex the knee, completely divide the synovium in line with the capsular incision, and dislocate the patella laterally (Fig. 3.17B) to expose the notch of the femur, revealing the anterior cruciate and medial meniscus. Carefully preserve the patellar tendon insertion if the patella is to be inverted for joint replacement procedures. Subperiosteal dissection of the medial one half of the tendon at the joint line will

Henry’s Exposure of the Sciatic Nerve

Henry (4) described a combination of approaches that allow the sciatic nerve to be explored from its extrapelvic origin to the popliteal fossae (2).

Position the patient prone and outline the “question mark” incision (Fig. 3.16A). Avoid injury to the posterior cutaneous nerve of the thigh as it exits from beneath the gluteus maximus and runs distally down the thigh. After incising the deep gluteal fascia, develop the interval between the gluteus medius and maximus.

Cut the gluteus maximus free from its insertion into the femur, and fold the entire gluteus maximus flap back medially on its neurovascular bundle. The sciatic nerve, proximally exposed, is easily traced to the superior margin of the long head of the biceps femoris, where it passes deeply to this muscle (Fig. 3.16B). From this point distally, the entire exposure is as previously described for the posterior approach.

KNEE

ANTERIOR APPROACHES

Anteromedial Approach

The anteromedial approach allows adequate exposure of the knee joint for most intraarticular problems. The list includes meniscectomy (total or partial), removal of loose bodies, stabilization of osteochondral fractures, ligament or meniscal repair, drainage procedures, ligament reconstructions, fixation or excision of patella; fractures, and synovectomy. The anteromedial deep dissection can be combined with a straight anterior skin incision (Fig. 3.17) for more extensive exposure for these conditions and for total knee replacement. Use it whenever possible, because it gives the best possible route for reexploration, whenever repeat procedures may be required or when later reconstructive procedures are anticipated.

For the anterior incision, make a straight incision midline extending 10 cm above the patella to 3 cm below the tibial tubercle (Fig. 3.17A). For the anteromedial incision, begin on the medial side of the quadriceps tendon, 5–7 cm above the patella. Curve the incision around the superomedial border of the patella, then distally to the medial side of the tibial tubercle. Preserve the infrapatellar branches of the saphenous nerve whenever possible.

The deep dissection is identical for both procedures (Fig. 3.17B). Divide the vastus medialis muscle from the quadriceps tendon on the medial side, leaving a 5 mm cuff of tendon on the muscle side. Extend the quadriceps tendon split proximally to the extent of the skin incision. Divide the capsule and synovium together, 5 mm lateral to the mediolateral border of the patella.

Carry this deep dissection down to the medial side of the tibial tubercle. Flex the knee, completely divide the synovium in line with the capsular incision, and dislocate the patella laterally (Fig. 3.17B) to expose the notch of the femur, revealing the anterior cruciate and medial meniscus. Carefully preserve the patellar tendon insertion if the patella is to be inverted for joint replacement procedures. Subperiosteal dissection of the medial one half of the tendon at the joint line will
The Bruser approach permits good exposure of the entire lateral meniscus. Resection of the meniscus does not require release of the fibular collateral ligament.

Anterolateral Approach

The anterolateral approach does not yield as complete exposure to all joint structures as do the anteromedial and the anterior approaches. It is useful for exposure of the anterior two thirds of the lateral meniscus, for isolated lateral compartment reconstructive procedures, and for internal fixation of lateral tibial plateau or femoral condyle fractures, particularly if combined with anterolateral exposure of the femoral shaft.

- With the knee in slight flexion, begin the incision 10 cm proximal to the patella in line with the insertion of the vastus lateralis on the quadriceps tendon (Fig. 3.18A). Curve the incision gently at the lateral patellar border, and extend it distally to the level of the tibial tubercle lateral to it. The deep capsular incision is 5 mm lateral to the insertion of the vastus lateralis on the quadriceps tendon.

![Figure 3.18. Anterolateral approach to the knee. A: Skin incision. B: Medial subluxation of the patella exposes the anterior cruciate and lateral meniscus. 1, Patella; 2, posterior cruciate ligament; 3, lateral femoral condyle; 4, anterior cruciate ligament; 5, fibular collateral ligament; 6, lateral meniscus; 7, transverse ligament; 8, fibular head; 9, tibial tuberosity; 10, lateral tibial surface. (From McConnell J. Surgical Approaches. In: Edmonson AS, Crenshaw AH, eds. Campbell's Operative Orthopaedics, 6th ed, vol 1. St. Louis: CV Mosby, 1980:44.)](image)

- Incise the synovium in the same plane, and sublux the patella medially to expose the anterior cruciate and lateral meniscus (Fig. 3.18B). The patella cannot be inverted medially because of the strong medial orientation of the quadriceps attachments.

POSTEROLATERAL APPROACHES

Henderson Approach (3)

The posterolateral approach to the knee is most frequently used for lateral extraarticular ligament reconstructions or in combination with an anteromedial approach for an intraarticular reconstruction. It is also useful for exposure of the posterior half of the lateral meniscus and for explorations of the common peroneal nerve and its branches.

- With the knee flexed 90°, make a gently curved 15 cm incision (dotted line in Fig. 3.19A) just anterior to the biceps femoris tendon and fibular head to expose the fascia lata. Keep the position of the common peroneal nerve (Fig. 3.19B) in mind constantly.

![Figure 3.19. Henderson's posterolateral approach to the knee. A: Skin incision can be extended proximally (dotted line) for exposure of the fascia lata. B: Exposure of the common peroneal nerve and fibular collateral ligament. 1, Biceps femoris; 2, common peroneal nerve; 3, lateral head of gastrocnemius (cut); 4, lateral femoral condyle; 5, fibular head; 6, fibular collateral ligament; 7, vastus lateralis; 8, iliotibial band.](image)

- Proximally, follow the anterior surface of the lateral intramuscular septum back to the linea aspera. At this point, the nerve is just posterior to the dissection.
- Expose the lateral femoral condyle and fibular collateral ligament origin in the midportion of the wound. The lateral head of the gastrocnemius muscle is evident posteriorly and protects the nerve at that level. The posterior half of the lateral meniscus is visible posterior to the fibular collateral ligament with the popliteus tendon coming up from posterior to the posterior-midmeniscus region (Fig. 3.19B). This tendon may be retracted posteriorly as the capsule and synovium are opened through a longitudinal incision above the menisci.

Bruser Approach

The Bruser approach permits good exposure of the entire lateral meniscus. Resection of the meniscus does not require release of the fibular collateral ligament.

- Position and drape the patient to allow full flexion; more than 100° of flexion is helpful. Make the incision parallel to the lateral meniscus, beginning anteriorly at the lateral border of the patellar tendon (Fig. 3.20A). Its posterior limit is at a line between the fibular head and lateral femoral condyle. Divide the subcutaneous tissue in line with the incision, and divide the iliotibial band in line with its fibers.

- The knee must be flexed during this part of the dissection to prevent transection of the iliotibial band. Divide the iliotibial band along the lines of its fibers to Gurde's tubercle, expose the fibula, collateral ligament, and the torn lateral meniscus central to it. The relaxed fibular collateral ligament must be protected posteriorly when this incision is made (Fig. 3.20B). The inferolateral geniculate artery should be ligated, because it lies at the posterolateral corner of the meniscus. Incise the synovium, allowing complete exposure of the meniscus.
Posteromedial Approach

The posteromedial approach described by Henderson (2) is useful for exposure of the posteromedial corner of the knee joint for posterior meniscal horn resections, posteromedial corner reconstructions, or repair or reconstruction of the posterior cruciate ligament.

- Position the patient supine with the hip in external rotation and the knee flexed 90°.
- Make a 10 cm incision from the adductor tubercle along the course of the tibial collateral ligament and anterior to the pes anserine tendons (Fig. 3.21A).

![Image]

**Figure 3.21.** Henderson's posteromedial approach to the knee. A: Skin incision. B: The deep dissection is carried out anterior to the pes anserine tendons. 1, Sartorius; 2, gracilis; 3, semimembranosus; 4, semitendinosus; 5, medial femoral condyle; 6, medial meniscus. (From Thomas HA. In: Hoppenfeld S, deBoer P, eds. Surgical Exposures in Orthopaedics: The Anatomic Approach. Philadelphia: JB Lippincott, 1984:400, 415.)

- Incise the oblique portion of the tibial collateral ligament in line with the tendons, and also incise the capsule below (Fig. 3.21B). This incision exposes the medial meniscus and allows access to the posteromedial compartment. For capsular and posterior cruciate reconstructions, it is necessary to develop the interval between the capsule and the pes anserine tendons and semimembranosus.
- Retract the hamstrings and medial head of the gastrocnemius muscle posteriorly. For wider exposure, take down the origin of the medial head of the gastrocnemius.

**Posterior Approach**

The posterior approach to the knee is rarely needed, but it provides invaluable exposure of the posterior neurovascular structures and joint capsule. Indications for its use include exposure of the popliteal neurovascular structures, posterior cruciate ligament repairs, release of posterior knee contractures, and resection of popliteal masses.

- Position the patient prone. Initiate an S-shaped incision (Fig. 3.22A) with the superior arm lateral and the transverse portion at the level of the posterior crease (orient the incision transversely along the flexion crease and direct it superolaterally and inferomedially). Carefully incise the popliteal fascia in the midline.

![Image]

**Figure 3.22.** Posterior approach to the knee. A: Skin incision. B: A linear split of the deep fascia. 1, Semimembranosus; 2, popliteal vein; 3, medial head of gastrocnemius; 4, small saphenous vein; 5, medial sural cutaneous nerve; 6, popliteal fascia; 7, lateral head of gastrocnemius; 8, biceps femoris; 9, common peroneal nerve; C: Sectioning of the gastrocnemius heads. 1, Semimembranosus; 2, tibial nerve; 3, medial head of gastrocnemius; 4, popliteal vein; 5, posterior joint capsule; 6, popliteal artery; 7, oblique popliteal ligament; 8, medial inferior genicular artery; 9, medial head of gastrocnemius; 10, small saphenous vein; 11, medial sural cutaneous nerve; 12, fascia; 13, lateral head of gastrocnemius; 14, plantaris; 15, lateral inferior genicular artery; 16, common peroneal nerve; 17, arcuate ligament; 18, lateral head of gastrocnemius; 19, plantaris; 20, biceps femoris. (From Thomas HA. The Knee. In: Hoppenfeld S, deBoer P, eds. Surgical Exposures in Orthopaedics: The Anatomic Approach. Philadelphia: JB Lippincott, 1984:431.)

- Linear split of the deep fascia exposes the common peroneal nerve, the popliteal vein, and two heads of the gastrocnemius. Identify the sural nerve as it rests in the midline in the distal portion of the wound, and trace it proximally until it leads you to the tibial component of the sciatic nerve (Fig. 3.22B).
- Identify the common peroneal nerve from proximal to distal as it runs along the posterior border of the biceps femoris. The popliteal vein lies over the tibial nerve at the level of the gastrocnemius muscle heads. The popliteal artery lies deep and medial to the tibial nerve. There are few geniculate arteries that limit retraction of the artery. One of the branches may have to be ligated, depending on the direction that the dissection needs to take.
- To reach the posteromedial or posterolateral corners of the joint section, the medial head or lateral head of the gastrocnemius muscle can be sectioned, leaving a tendinous cuff to repair (Fig. 3.22C). In this way, the entire posterior capsule (popliteal artery, tibial nerve, and deep capsular structures) in its medial and lateral extent can be exposed. The capsule must be opened transversely to expose the posterior cruciate ligament in the midline.

**TIBIA AND FIBULA**

**PROXIMAL ANTERIOR APPROACH FOR MEDIAL OR LATERAL DEEP EXPOSURE**

We highly recommend the straight anterior approach for reduction of medial or lateral tibial plateau fractures, or for resection of tumors or infectious processes involving this region of the tibia.

- With the knee gently flexed, make the distal half of the straight anterior approach to the knee joint, beginning at the superior pole of the patella. After incising the subcutaneous tissue in the incision, subcutaneously dissect in the lateral or medial direction (or both), with the knee flexed to 90° (Fig. 3.23).

![Image]

**Figure 3.23.** Anterior approach to the proximal tibial shaft. The skin incision of the anterior approach to the knee (see Fig. 3.17) can be extended distally to expose the proximal tibia. The pes anserine tendons can be released subperiosteally (dotted line) to expose the medial tibial condyle. 1, Quadriceps tendon; 2, quadriceps femoris; 3, vastus medialis; 4, suprapatellar recess; 5, infrapatellar fatty body of Hoffa; 6, lateral tibial tuberosity; 7, anterior cruciate ligament; 8, posterior cruciate ligament; 9, anterior horn, medial meniscus; 10, pes anserinus. (From Schlimpf R. Knee Joint and Proximal Tibia: Lateral Parapatellar Approach. In:
To gain exposure medially, elevate the pes anserine insertion and superficial portion of the medial collateral ligament subperiosteally. Divide the meniscotibial ligament (i.e., the deep portion of the medial collateral ligament) beneath the meniscus, allowing visualization of the tibial joint surface. Leave enough tissue attached to the tibia to allow reattachment of the meniscus.

To gain exposure laterally, open the joint capsule laterally to the patellar tendon. Elevate the musculature of the anterior compartment subperiosteally posterior to the level of the fibular collateral ligament. Elevate Gurdé's tubercle with an osteotome or reflect the iliotibial band insertion to allow more complete exposure for application of plates to the proximal lateral tibia. Examine the joint surface by incising the meniscotibial attachments of the anterior half of the lateral meniscus.

HENRY’S EXPOSURE OF THE PERONEAL NERVE AND PROXIMAL FIBULA

Henry (4) described a complete exposure of the fibula that, in its proximal half, allows complete exposure of the peroneal nerve.

- Position the patient laterally with the affected limb up. Make the skin incision in line with the fibula distally (to trace the superficial branch of the peroneal nerve) and biceps femoris proximally, curving posteriorly at the joint line at an angle of 45° (Fig. 3.24A).

![Figure 3.24](Image 102x568 to 302x710) Henry's exposure of the peroneal nerve and proximal fibula. A: Skin incision. 1, Common peroneal nerve; 2, head of fibula. B: The peroneal muscles have been divided transversely and retracted anteriorly to expose the motor divisions of the deep peroneal nerve proximally. 1, Common peroneal nerve (lat. popliteal); 2, head of fibula; 3, gastrocnemius; 4, soleus; 5, peroneus longus. (From Stead Z. In: Henry AK, ed. Extensive Exposure, 2nd ed. Edinburgh: Churchill Livingstone, 1973:293, 295.)

- Identify the common peroneal nerve where it lies deep to the biceps tendon in the proximal portion of the wound. Handle the nerve gently in a rubber sling for retraction. Divide the deep fascia in line with the nerve, developing a plane of division between the soleus and peroneal muscles. A thin extension of the peroneus longus origin must be divided at the fibular neck (Fig. 3.24B). The nerve is now freed as it curves anteriorly, dividing into muscular branches. Elevate the peroneal muscles subperiosteally to expose the upper one half of the fibula.

TIBIAL SHAFT: ANTERIOR APPROACH

The entire shaft of the tibia can be exposed by the anterior route for osteotomies, internal fixation of fractures or nonunions, excision of bone tumors, or drainage of infectious processes.

- Position the patient supine with a pad under the affected hip to gain slight internal rotation of the leg. Make the incision 10–15 cm lateral and parallel to the crest of the tibia (Fig. 3.25). Distally, incise along the medial border of the anterior tibial tendon to allow intraarticular exposure, if required. Reflect the skin and periosteum as a single layer for a medial exposure. Alternatively, lateral subperiosteal dissection allows retraction of the anterior compartment musculature. Avoid complete soft-tissue elevation medially and laterally because of the effect on bone blood supply with this radical exposure.

![Figure 3.25](Image 102x1013 to 302x1154) Anterior approach to the tibial shaft. A: Skin incision, just lateral to the tibial crest can be extended proximally and distally to expose the entire shaft (dotted lines). 1, Tibial tuberosity; 2, anterior border; 3, medial malleolus. B: A cross section of the mid calf reveals the plane of dissection to the lateral surface of the tibia and medially to the fascia of the deep posterior compartment (arrows). 1, Extensor digitorum; 2, tibialis anterior; 3, extensor hallucis longus; 4, deep peroneal nerve; 5, peroneus longus; 6, peroneus brevis; 7, superficial peroneal nerve; 8, lateral head, gastrocnemius; 9, medial head, gastrocnemius; 10, soleus; 11, plantaris; 12, flexor hallucis longus; 13, tibialis posterior; 14, flexor digitorum longus; 15, peroneal artery; 16, tibial nerve with posterior tibial vessel; 17, sural nerve with small saphenous vein; 18, saphenous nerve with great saphenous vein. (From Schlumpf R. Tibial Shaft: Anterior Approach. In: Rüedi T, von Hochstetter AHC, Schlumpf R, eds. Surgical Approaches for Internal Fixation. Berlin: Springer-Verlag, 1984:155, 156.)

TIBIAL SHAFT: POSTEROMEDIAL APPROACH

In cases of fracture, nonunion, malunion, bone tumor, or infection associated with poor anterior skin coverage, elect a posteromedial approach to the tibial shaft, particularly for the proximal third. The two-incision method of compartment release also calls for a posteromedial approach for release of the deep posterior compartment.

- Position the patient supine. Flex the affected hip and rotate it externally with the knee flexed. Make the incision in line with the tibia 1–2 cm posterior to the posterior border of the tibia (Fig. 3.26A). Protect the saphenous vein and nerve as the subcutaneous tissue is incised in line with the skin incision.

![Figure 3.26](Image 102x959 to 302x1154) Posteromedial approach to the tibial shaft. A: Skin incision. B: The deep dissection exposing the fascia. 1, Saphenous nerve; 2, great saphenous vein; 3, crural fascia (superficial); 4, medial condyle, tibia; 5, medial malleolus. (From Schlumpf R. Tibial Shaft: Posteromedial Approach. In: Rüedi T, von Hochstetter AHC, Schlumpf R, eds. Surgical Approaches for Internal Fixation. Berlin: Springer-Verlag, 1984:159, 161.)
Divide the superficial compartment fascia 5 mm posterior to the posterior border of the tibia. Carry out the deep dissection exposing the fascia of the lower leg posterior to the saphenous nerve and vein. Divide the deep fascia posterior to the border of the tibia in line with the fibers of the flexor hallucis longus proximally, flexor digitorum longus in the mid tibia, and posterior tibialis distally (Fig. 3.26). Retract the muscles posteriorly, exposing the tibia for the required procedure.

**TIBIA AND FIBULA SHAFTS: POSTEROLATERAL APPROACH OF HARMON (2)**

The posterior exposure allows access to the middle two thirds of the tibia and is also useful when the anterior and anteromedial aspects of the leg have poor soft-tissue coverage. It is the classic exposure for bone grafting of tibial nonunions.

- Position the patient prone or on his side with the affected leg up. Make the skin incision (Fig. 3.27A) longitudinally along the lateral border of the gastrocnemius (Fig. 3.27B). The deep plane is between the peroneal musculature (laterally) and the superficial and deep posterior compartment musculature (medially), exposing the intramuscosseous membrane.

![Figure 3.27](image)

**Figure 3.27.** Harmon posterolateral approach to the tibial shaft. A: Skin incision. B: The deep plane is between the peroneal musculature and the superficial and deep posterior compartment musculature. 1, Tibia; 2, interosseous membrane; 3, soleus and gastrocnemius; 4, fibula; 5, peroneal muscles. (From Edmonson AS, Crenshaw AH, eds. Campbell's Operative Orthopaedics, 6th ed, vol 1. St. Louis: CV Mosby, 1980:39.)

- Develop the plane between the triceps surae posteriorly and peroneal muscles anteriorly, exposing the posterior surface of the fibula. Elevate the flexor hallucis longus portion of the posterior tibial muscle that originates from the intramuscosseous septum, and strip the muscle medially off the posterior surface of the tibia. Take care in the proximal one third of the wound to avoid the peroneal artery and vein. The posterior tibial artery and nerve lie between the flexor hallucis longus and the posterior tibial muscle and are not easily seen; avoid medial retraction at any place other than the subperiosteal level.
- With careful subperiosteal dissection, expose the posterior surface of the middle two thirds of the tibia. In nonunions for which this approach is most commonly used, callus, scar, and loss of the interosseous membrane can make exposure in the region of the nonunion difficult. To facilitate exposure, use a long incision. Expose the interosseous membrane and posterior tibia first in areas of undisturbed anatomy proximally and distally to the fracture. Once you have established the proper plane of dissection, it is fairly easy to expose the nonunion. As you pass medial to the peroneal muscles and follow the fibula to the interosseous membrane, the line of dissection is more or less directly anterior. To avoid perforating the membrane, use a large-key or Cobb elevator to develop the exposure. In compartment syndrome where compartment fasciotomy is required, swelling and hematoma can obscure the fascial septae dividing the anterior, lateral, and posterior compartments. In this situation, develop the skin and subcutaneous tissue flaps for 2.5–3 cm anteriorly and posteriorly. In the midportion of the wound, make a transverse incision through the deep fascia. Identification of the longitudinally running fascial divisions between the compartments is then easy.

**ANKLE**

**Anterior Approach**

The anterior approach to the ankle is useful for many techniques of ankle arthrodesis, internal fixation of distal tibia (i.e., intraarticular) fractures, joint debridement and removal of loose bodies, synovectomy, drainage of septic joints, and joint replacement arthroplasty. Through this approach, both malleoli and the whole articular surface of the distal tibia can be exposed.

- Position the patient supine with a folded sheet under the hip of the affected side in order to internally rotate the limb. Make a longitudinal 15 cm incision midway between the lateral and medial malleoli, beginning 10 cm proximal to the joint line (Fig. 3.28A). Identify and protect the terminal branches of the superficial peroneal nerve. Incise the deep fascia of the leg in line with the skin incision. Identify the interval between the extensor hallucis longus and the extensor digitorum longus. Protect the anterior tibial artery and the deep peroneal nerve, which are just medial to the extensor hallucis tendon.

![Figure 3.28](image)

**Figure 3.28.** Anterior approach to the ankle. A: Skin incision. B: Division of the extensor retinaculum exposes the extensor hallucis and extensor digitorum tendons. 1, Extensor digitorum longus; 2, deep peroneal nerve and anterior tibial artery (neurovascular bundle); 3, extensor retinaculum; 4, extensor hallucis longus. C: Division of the joint capsule exposes the joint. 1, Extensor digitorum longus; 2, joint capsule of ankle; 3, extensor retinaculum; 4, dome of talus; 5, distal tibia; 6, extensor hallucis longus. (From Thomas HA. The Ankle and Foot. In: Hoppeneild S, deBoer P, eds. Surgical Exposures in Orthopaedics: The Anatomic Approach. Philadelphia: JB Lippincott, 1984:472, 473.)

- Retract the tendon of the extensor hallucis medially, taking the neurovascular bundle with it, and the extensor digitorum longus laterally (Fig. 3.28B). Distally, at the level of the ankle joint, the neurovascular bundle crosses the ankle joint behind the extensor hallucis tendon. Mobilize it carefully as the joint is exposed.
- The capsule is visible beneath the tendons and can be longitudinally incised or dissected off the distal tibia as the procedure requires (Fig. 3.28C).

**Anteromedial Approach**

We recommend the anteromedial approach to the ankle for internal fixation of intraarticular fractures of the distal tibia and medial malleolus. It is an extensive continuation of the anterior approach to the tibial shaft (Fig. 3.29).

- Following the course of the tibialis anterior tendon, curve the incision medially toward the tip of the medial malleolus, beginning 5 cm above the ankle joint (Fig. 3.29). Identify the saphenous vein and nerve. Divide the ankle capsule anterior to the deltoid ligament. Deeply develop the interval between the tibialis anterior tendon and the medial malleolus. Retract the tendon laterally, and open the joint by longitudinal incision and subperiosteal dissection.
Anterolateral Approach

The anterolateral approach extended distally allows exposure of the joints of the hind foot and the ankle joint. It is useful for ankle arthrodesis, triple arthrodesis, and takedown.

- Make a 15 cm incision centered over the distal tibiofibular joint, beginning 5 cm proximal to the ankle joint (Fig. 3.30A). Curve the incision anteriorly, crossing the ankle joint 2 cm medial to the tip of the lateral malleolus and extending onto the dorsum of the foot 2 cm medial to the base of the fifth metatarsal. The incision crosses the distal tibiofibular joint and angles anteriorly over the cuboid. Identify and protect the branches of the superficial peroneal nerve and the saphenous vein.

- Develop the interval between the major peroneal muscles laterally and the extensor muscles anteriorly. The deep dissection is conducted between the extensor tendons and the peroneal tendons, exposing the sinus tarsi distally (Fig. 3.30B).
- Retract the extensor tendons medially to expose the ankle capsule (Fig. 3.30C). The origin of the extensor digitorum brevis can be elevated off the calcaneus to expose the calcaneocuboid and talonavicular joints and the fat within the sinus tarsi.

Posterior Approach

The posterior approach is useful for tendon lengthenings, release of the posterior capsule of the ankle, and exposure of posterior malleolus fractures.

- The skin incision is based on the medial border of the triceps surae tendon. Make a 10 cm longitudinal incision along the posterolateral border of the tendo calcaneus to its insertion on the calcaneus (Fig. 3.31A). Protect the terminal branches of the sural nerve laterally. Retract the tendo calcaneus medially (Fig. 3.31B). Lengthening of the tendon can be performed if the procedure requires it. Divide the areolar tissue anterior to the tendon, and enter the space between the flexor hallucis longus tendon medially and the peroneal tendons laterally.

- Deep dissection carries the triceps surae tendon and neurovascular bundle medially. Sharply dissect the lateral fibers of the flexor hallucis muscle belly from the posterior fibular border, and develop this interval, exposing the distal tibia, posterior ankle joint, and posterior talus (Fig. 3.31B). The retracted flexor hallucis longus protects the medial neurovascular structures.

Posteromedial Approach

The posteromedial approach is indicated for clubfoot release, exploration of the neurovascular structures, exposure of posterior malleolus fractures, and tendon lengthenings or transfers.

- Position the patient supine in the figure-four position, with the affected ankle resting on the opposite thigh.
- Make a 10 cm longitudinal incision along the posterior tibial tendon, midway between the medial malleolus and the tendon calcaneus (Fig. 3.32A). Incise the deep fascia in line with the skin incision (Fig. 3.32B). Division of the superficial retinaculum exposes the posterior tibia, flexor digitorum, and flexor hallucis tendons and the posterior tibial artery and nerve.
Retract the tendon of the flexor hallucis longus medially after dissecting its lateral fibers off the fibula, protecting the nerve and artery, and exposing the distal posteromedial corner of the tibia with the ankle joint capsule.

**Posterolateral Approach**

The posterolateral approach is useful for visualization of posterior malleolus fractures, posterior capsulotomy, posterior subtalar facet arthrodesis, and tendon lengthenings and transfers.

- Position the patient prone. Make a longitudinal 10 cm incision halfway between the posterior border of the lateral malleolus and the lateral border of the Achilles tendon (Fig. 3.33A). The lateral border of the triceps surae tendon is a landmark for the incision. Protect the terminal branch of the sural nerve. The peroneus brevis consists of a muscle belly in this region, and the peroneus longus is tendinous. Incise the peroneal retinaculum to allow easy repair.

- Detach the lateral fibers of the flexor hallucis longus where they arise from the fibula. Retract this muscle medially, exposing the posterolateral ligament complex (Fig. 3.33B). Longitudinal subperiosteal dissection exposes the distal tibia, and a linear capsular incision exposes the joint.

**EXPOSURES FOR ANKLE FRACTURES**

For simple fractures of the malleoli, straight longitudinal skin incisions directly over the malleoli (rather than curved incisions) permit direct access, are extensile, and have low morbidity (Fig. 3.34).

**FOOT**

**SKIN INCISIONS**

In general, skin incisions in the foot should be longitudinal and extensile. They should give optimal exposure to the area required and have the possibility of extension to the proximal or distal joint. Preserve cutaneous nerves and veins if it is technically possible to do so.

**TARSUS**

**Anterior Approach**

The more distal extension of the anterior approach to the ankle joint allows good exposure of the talonaviculocuneiform joint, and the first metatarsal–cuneiform joint. Preserve the dorsal veins and gain direct exposure of the joints of the mid foot between the tendons of the extensor digitorum. More distal exposure and deep dissection exposes the bases of the metatarsals.

- Beginning proximally, make the anterior incision (Fig. 3.35) in line with the lateral aspect of the second metatarsal, and continue it distally. Retract the deep peroneal nerve and dorsalis pedis artery medially with the extensor hallucis longus and tibialis anterior tendons, exposing the dorsal capsular structures of these joints.
Incise the capsule of the involved joint longitudinally and dissect subperiosteally to expose the joint(s) for arthrodesis or open reduction of articular surfaces.

**Lateral Kocher Approach**

The lateral Kocher approach yields combined exposure of the ankle, midtarsal, and subtalar joints (Fig. 3.36).

![Image: Lateral Kocher Approach](image)

**Figure 3.36.** Lateral approaches to the tarsus: Kocher and Ollier. A: Skin incisions. 1, Skin incision, Kocher approach; 2, skin incision, Ollier approach. (From Stead Z. Exposure of the Distal Two-Thirds of the Anterior Neurovascular Bundle. In: Henry AK, ed. Extensive Exposure, 2nd ed. Edinburgh: Churchill Livingstone, 1973:277.) B: Deep dissection of the Ollier approach consists of detaching the extensor digitorum brevis and retracting distally exposing the midtarsus. The deep exposure of the Kocher approach is similar in its distal arm but yields better access to the subtalar joint because of its proximal arm. 1, Anterior talofibular ligament; 2, sinus tarsi fat pad; 3, posterior talocalcaneal joint; 4, peronei; 5, calcaneocuboid joint; 6, extensor digitorum brevis; 7, talonavicular joint. (From Thomas HA. The Ankle and Foot. In: Hoppenfeld S, deBoer P, eds. Surgical Exposures in Orthopaedics: The Anatomic Approach. Philadelphia: JB Lippincott, 1984:503.)

- Begin the incision as far proximally as indicated, and proceed longitudinally 2 cm posterior to the fibula. Gently curve the incision anteriorly at the distal flare of the fibula, and reach the midpoint of the bone 2.5 cm distal to the tip (Fig. 3.36A). Curve the incision 110° anteriorly in the direction of the talonavicular joint. Incise the peroneal fascia, and retract the tendons posteriorly, protecting the sural nerve.
- Divide the talocalcaneal ligament to expose the subtalar joint capsule (Fig. 3.36B). If possible, avoid dividing the peroneal tendons because of the risk of scarring within the sheath; if necessary, use a step-cut technique. The calcaneonavicular joint capsule can be visualized by dissection further distally, following the peroneus brevis tendon.
- To visualize the articular surface of the tibia, divide the anterior talofibular ligament and sublux the talus by varus stress. Divide the capsule and synovium anterior to the fibula, revealing the articular surfaces of the fracture.

**Lateral Ollier Approach**

The lateral Ollier approach provides excellent exposure of the talonavicular joint, calcaneocuboid joint, and lateral subtalar joint. It provides an excellent cosmetic result because of the abundance of soft tissue in the area.

- Begin the incision 3 cm posterior to the calcaneocuboid joint (Fig. 3.36A). Follow the skin lines in an anteromedial direction, and end the incision over the dorsal aspect of the talonavicular joint. Do not undermine the skin flaps.
- Detach the origin of the extensor digitorum brevis, and retract it distally (Fig. 3.36B). If possible, preserve the fat within the sinus tarsi to maintain the contour of the foot and improve soft-tissue coverage. Medially, retract the extensor tendons to expose the talonavicular joint. Laterally, retract the peroneal tendons to fully expose the calcaneocuboid joint and the posterior facet of the subtalar joint. The joint capsules can be sharply dissected free in line with the joint surfaces to expose the joints as necessary.

**Lateral Gatellier and Chastung Approach**

Open reduction of large posterolateral distal tibial fractures in the setting of a trimalleolar ankle fracture calls for the lateral Gatellier and Chastung approach. This method can also be used for anterolateral osteochondral fractures.

- Make the incision along the fibula, beginning 15 cm proximally from the tip (Fig. 3.37A). Curve the incision anteriorly along the pathway of the peroneal tendons at the tip of the fibula. Expose the fibula subperiosteally. Incise the periosteal tendon sheath, allowing the tendons to sublux anteriorly, and turn the fibula distally through the fracture.

![Image: Lateral Gatellier and Chastung Approach](image)

**Figure 3.37.** Lateral approach to the tarsus of Gatellier and Chastung. A: Skin incision and level of fibular osteotomy. B: The fibula has been osteotomized and reflected, based on the calcaneofibular ligament. Sectioning of the anterior and posterior talofibular ligaments exposes the ankle joint. (From Stead Z. Exposure of the Fibula and Nerves Related to It. In: Henry AK, ed. Extensive Exposure, 2nd ed. Edinburgh: Churchill Livingstone, 1973:293.)

- Alternatively, make an osteotomy 7–10 cm from the fibular tip to allow this same maneuver. The calcaneofibular and talofibular ligaments serve as the hinge for the fibula to allow complete exposure of the distal tibia and ankle joint (Fig. 3.37B). Fix the fracture or osteotomy of the fibula anatomically and rigidly, and carefully reconstruct the peroneal tendon sheath. The disadvantage of this approach is devascularization of the distal tibia.
CALCANEUS

Medial Approach

The medial approach is occasionally indicated for open reduction of the calcaneus and for management of bone tumors.

- Make the incision from an anterior position located 3 cm anterior and 4 cm inferior to the tip of the medial malleolus. Extend the incision in a straight line to the medial border of the Achilles tendon. Divide the deep fascia in line with the incision, and similarly divide the fat deep to this layer.
- Retract the abductor hallucis inferiorly, and expose the body of the calcaneus subperiosteally. Divide the plantar aponeurosis and strip the muscle origins inferiorly to expose the plantar surface. Whenever possible, minimize the dissection of the specialized plantar tissues because of the highly specialized septa that originate in the body of the calcaneus.

Lateral Approach

The lateral exposure allows excellent observation of the subtalar joint for isolated subtalar arthrodesis or open reduction of this joint.

- Begin the incision at the lateral border of the tendo calcaneus at its insertion (Fig. 3.38). Extend the incision obliquely to a point 4 cm distal to the lateral tip of the malleolus. Protect the terminal branch of the sural nerve posteriorly.

**Figure 3.38.** Lateral approach to the calcaneus. The skin incision is essentially that of Figure 3.36, extended 2 cm distally. The peroneal tendon sheath is opened, and the tendons are subluxed anteriorly to expose the subtalar joint. 1, Lateral malleolus; 2, posterior talocalcaneal joint; 3, peroneal fascia; 4, peroneal tubercle; 5, peroneal tendons. (From Thomas HA. The Ankle and Foot. In: Hoppenfeld S, deBoer P, eds. Surgical Exposures in Orthopaedics: The Anatomic Approach. Philadelphia: JB Lippincott, 1984:506.)

- Expose the peroneal tendons, and retract superiorly to expose the bone and subtalar joint. In extreme circumstances, the tendons can be sectioned and resutured. Handle the fragile skin and soft tissues carefully in cases of trauma to lessen the relatively high risk of wound complications after this exposure.

Benirschke popularized a “hockey-stick” approach for internal fixation of fractures of the calcaneus because it allows better exposure of the posterior calcaneus (personal communication, 1988). It is essentially a lateral approach, but the skin incision parallels the Achilles tendon as far as 1–2.5 cm above the weight-bearing surface of the foot, where it then turns anteriorly, parallel to the plantar aspect of the heel (Fig. 3.39). Carry the incision to the calcaneocuboid joint, and develop the proximal flap at a subperiosteal level. The sural nerve and peroneal tendons are maintained within this thick flap. Do not make the corner too short. Avoid excessive fixed retraction to prevent slough of the corner of the flap.

**Figure 3.39.** Lateral approach to the calcaneus for open reduction and internal fixation (ORIF), as popularized by Benirschke. A: The skin incision is more vertical and posteriorly placed than the standard lateral approach (see Fig. 3.38). This enables full exposure of the calcaneal tuberosity. The incision is curved anteriorly at the inferior border of the calcaneus. B: The flap is elevated and includes the skin and subcutaneous fat, the calcaneal fibular ligament and perineal tendon sheaths. Kirschner wires can be placed in the talus to retract the flap.

“U” Approach

The “U” approach can be used for radical clubfoot releases and exposure of the entire subtalar joint for arthrodesis.

- Position the patient prone. Connect the posterior two thirds of the medial and lateral approaches at the level of the insertion of the tendo calcaneus. To expose the subtalar joint completely, step-cut to lengthen the tendo calcaneus. Carefully preserve the sural nerve during this exposure. Expose the body of the calcaneus medially and laterally by subperiosteal dissection.

Split Heel Approach

The only indication for the split heel approach of Gaenslen is osteomyelitis of the calcaneus.

- Position the patient prone. Make a longitudinal incision in the middle of the heel (Fig. 3.40A).

**Figure 3.40.** Gaenslen's split heel approach to the calcaneus. A: Skin incision. B: The specialized fibrofatty tissue of the heel pad has been divided in line with the incision. The tuber of the calcaneus and the plantar fascia has been divided and the plantar neurovascular bundle protected distally. 1, Calcaneus; 2, plantar nerve; 3, plantar artery; 4, plantar fascia. (From Edmonson AS, Crenshaw AH, eds. Campbell's Operative Orthopaedics, 6th ed, vol 2. St. Louis: CV Mosby.
Split the tuber of the calcaneus 2–3 cm; make certain that the skin incision is long enough to allow the split. Divide the plantar aponeurosis from the plantar surface of the calcaneus at the level of the abductor digiti quinti (Fig. 3.40).

Protect the lateral plantar artery and nerve and retract them medially in the distal portion of the wound. Divide the quadratus plantae longitudinally with sharp dissection and split the calcaneus longitudinally with a sharp osteotome. Spread the two halves to allow complete resection of necrotic bone. Preserve the cortical shell as much as possible.

METATARSALS

Dorsal Approach

The metatarsal shafts are best exposed through longitudinal incisions on the medial side of the foot over the first metatarsal, on the lateral side of the foot over the fifth, or through the second-to-third or third-to-fourth metatarsal intervals. For multiple metatarsal fractures, the middle three bones can be reached through the two intervals. If feasible, preserve veins along with minor cutaneous nerve branches. Retract the extensor tendons medially or laterally, and directly expose the bone.

Plantar Approach

The plantar approach is advisable for direct exposure of the individual neurovascular bundles. Use the dorsal approach for metatarsal bony problems because of the multiple layers of flexor tendons. The intervals for the incisions are the same as the dorsal incisions. Incise the deep fascia in line with the skin, and retract the flexor tendons medially or laterally as indicated. The neurovascular bundles lie among the flexor digitorum brevis, abductor hallucis, abductor digiti quinti, and the long flexor tendons.

METATARSOPHALANGEAL JOINTS

Dorsal Approach

Approach the second through fifth metatarsophalangeal joints through dorsal incisions lateral to the extensor tendons (Fig. 3.41). In the case of the fifth metatarsophalangeal joint, make the incision on the medial side of the extensor tendon.

Retract the tendons, and open the joint capsule by a longitudinal incision.

For resection of common digital (Morton's) neuromas, make a longitudinal incision over the dorsum of the web space of concern. Dissect deeply, taking care to identify and retract the extensor tendons and superficial sensory nerves. Identify the digital nerves and trace them proximally to the common digital nerve.

Plantar Approach

Some surgeons prefer a plantar, more direct approach to the common digital nerves. A plantar approach is indicated as well in cases of metatarsophalangeal joint sepsis. Make longitudinal incisions between the metatarsal heads. The neurovascular bundles are located deep to the long flexor tendons, which must be retracted to expose the metatarsophalangeal joints to the side of least resistance. Although earlier teaching indicated that plantar scars are painful, well-placed ones usually are not.

First Metatarsal Head Exposure

Approach the first metatarsophalangeal joint best through a 4 cm dorsomedial incision. Protect the dorsal digital nerve, and turn the joint capsule back on a distally based flap for reconstructive bunion procedures.

INTERPHALANGEAL JOINTS

Approach the toe interphalangeal joints dorsally with straight linear incisions by retracting the extensor mechanism to one side. Carefully repair the extensor mechanism. The interphalangeal joints can also be exposed by mid-lateral incisions, carefully retracting the neurovascular bundles plantarward. In general, we do not recommend a plantar incision, because the stout flexor tendons and neurovascular bundles are problems from this approach.

Conventional Radiography

Continued progress in radiology and the introduction of new imaging modalities have significantly improved our capabilities for diagnosing orthopaedic conditions. Although conventional radiography remains the primary diagnostic tool, ancillary techniques are used to characterize the abnormality more accurately, to predict possible complications, and to monitor postoperative recovery. The newer imaging modalities, however, are expensive (e.g., magnetic resonance imaging, or MRI), may expose the patient to radiation (e.g., computed tomography, or CT), and are frequently employed unnecessarily or inappropriately.

This chapter sets forth the principles and limitations of current imaging modalities, and sets guidelines for choosing particular modalities. Time and cost considerations should discourage redundant studies. The surgeon familiar with these techniques can confidently order the least number of tests necessary to dictate a course of therapy.

Radiologists and orthopaedic surgeons are frequently concerned about which modality they should use for a particular problem. Although there are numerous algorithms for evaluating various problems at different anatomic sites, the answer cannot always be succinctly stated (22). The choice of techniques for imaging bone and soft-tissue abnormalities is dictated by the clinical presentation, equipment availability, expertise, cost, and restrictions referable to individual patients. For example, allergy to ionic or nonionic iodinated contrast agents may preclude the use of arthrography; the presence of a pacemaker may preclude the use of MRI; and physiologic states such as pregnancy may preclude the use of ionized radiation, favoring instead sonography.

No matter which ancillary technique is used, a plain film must be available for comparison. The choice of imaging technique is usually dictated by the type of suspected abnormality. If osteonecrosis is suspected, for example, and the radiographs are normal, the physician should proceed immediately to MRI examination, the most sensitive modality. It can detect necrotic changes in bone long before plain films, tomography, CT, or scintigraphy can provide positive evidence.

In evaluation of internal derangement of the knee, obtain plain films first; if the abnormality is not obvious, proceed with MRI, because this modality provides an exquisite contrast resolution of the bone marrow, articular cartilage, ligaments, meniscus, and soft tissues. In evaluating rotator cuff abnormalities, particularly partial or complete tears, arthrography and MRI are currently the most effective procedures. Although ultrasound can also detect rotator cuff tears, because of its low sensitivity (68%) and low specificity (75% to 84%) it is seldom used as the definitive diagnostic procedure (9,36,62). Figure 4.1 depicts the gamut of standard and special radiographic projections and various ancillary imaging techniques currently available for evaluating injury of the shoulder girdle.

Figure 4.1. Standard, special, and ancillary imaging techniques used to evaluate injury to the shoulder girdle.

In evaluating wrist pain, start with conventional radiographs and trispiral tomography before proceeding to arthrotomography or CT-arthrography. In this case, MRI is a less desirable technique, because it is less sensitive and specific than CT-arthrotomography in detecting abnormalities of the triangular fibrocartilage and various intercarpal ligaments, particularly if three-compartment injection is used (40,41). If one suspects carpal tunnel syndrome, however, MRI is preferred because it provides inherent high-contrast differences among muscles, tendons, and ligaments. Similarly, if osteonecrosis of the carpal bones is suspected and the plain films are normal, MRI is the preferred method. In evaluating fractures and fracture healing of carpal bones, trispiral tomography is still the procedure of choice because it gives a high degree of spatial resolution.

In evaluating bone tumors, conventional radiography and tomography are still the gold standard for diagnostic purposes. To evaluate intraosseous and soft-tissue extension of tumor, however, use CT or the more accurate MRI. In evaluating results of treatment of malignant tumors by radiotherapy and chemotherapy, dynamic MRI using gadolinium diethylene triamine penta-acetic acid (Gd-DTPA) for contrast enhancement is much superior to scintigraphy, CT, or even plain MRI.

Figure 4.2 depicts an algorithm helpful in evaluating bone lesions discovered on standard radiographs. Notice that the proper order for employing various imaging modalities depends on two factors: whether the plain film findings are diagnostic for any particular tumor, and the lesion's uptake of a tracer on the bone scan. Scintigraphy plays a crucial role in dictating the use of different techniques. The use of CT or MRI may depend on the features found on conventional radiographs. If there is no evidence of soft-tissue extension, CT is superior to MRI for detecting subtle cortical erosions and periosteal reaction, and it provides an excellent means to determine the intraosseous extension of the tumor. If, however, the radiographs suggest cortical destruction and a soft-tissue mass, MRI is the preferred modality because it provides exquisite soft-tissue contrast and can determine the intraosseous extension of the tumor better than CT can.
Figure 4.2. Algorithmic evaluation of bone lesion discovered on the standard radiographs. *ST, soft tissue.

CONVENTIONAL RADIOGRAPHY

STANDARD PROJECTIONS

The most important modality for the evaluation of bone and joint disorders, particularly traumatic conditions, is conventional radiography. Obtain at least two views of the involved bone at 90° angles to each other, with each view including the two joints adjacent to the injured bone; this decreases the risk of missing an associated fracture, subluxation, or dislocation at a site remote from the apparent primary injury. In children, it is frequently necessary to obtain a radiograph of the normal, unaffected limb for comparison. The standard films usually comprise the anteroposterior and lateral views; occasionally, oblique and special views are necessary, particularly in the evaluation of fractures of complex structures, such as the elbow, wrist, ankle, and pelvis. A weight-bearing view may be of value for dynamic evaluation of the joint space during weight bearing.

Special projections may be required to demonstrate abnormalities of the bone or joint to further advantage.

SPECIAL PROJECTIONS

Grashey Projection of the Shoulder

In imaging the shoulder, Grashey projection permits the glenoid to be seen in profile. To obtain this view, place the patient in a 40° posterior oblique position with the central beam directed toward the glenohumeral joint. The film in this projection shows the glenoid in true profile, and the glenohumeral joint space is clearly visible. This is particularly effective in demonstrating suspected posterior dislocation (4).

West Point View of the Shoulder

If the patient is unable to abduct the arm and cannot be positioned for a conventional axillary view, the West Point view may be similarly effective. To obtain this view, position the patient prone on the radiographic table, and place a pillow under the affected shoulder to raise it about 8 cm. Position the film cassette against the superior aspect of the shoulder. Angle the radiographic tube toward the axilla at 25° to the patient's midline and 25° to the table's surface. On the film in this projection, the relationship of the humeral head and the glenoid can be evaluated as well as it can be evaluated on the axillary view, but the anteroinferior glenoid rim, which is seen tangentially, is better visualized.

Angled View of the Acromioclavicular Joint

To evaluate the acromioclavicular articulation, use a special low-kilovoltage technique with the central beam directed 15° cephalad toward the clavicle. Reduce exposure factors to about 33% to 50% of those used in obtaining the standard anteroposterior view of the shoulder. The film in this projection shows the acromial end of the clavicle, acromion, and acromioclavicular joint (4).

Y-Projection of the Shoulder Girdle

The Y-projection, also known as the trans-scapular view, is very effective for evaluation of the scapula. Have the patient stand erect, with the injured side against the raised radiographic table. Rotate the trunk about 20° from the table to allow separation of the two shoulders. Slightly abducted the arm on the injured side and flex the elbow, with the hand resting on the ipsilateral hip. Direct the central beam toward the medial border of the protruding scapula. The film in this projection provides a true lateral view of the scapula as well as an oblique view of the proximal humerus.

Radial Head–Capitellum View of the Elbow

The radial head–capitellum view is used to evaluate the elbow joint. It is a variant of the lateral projection that overcomes the major limitation of the standard lateral view by projecting the radial head ventrad, free of overlap by the coronoid process (Fig. 4.3). It has proved to be a particularly effective technique to demonstrate the capitellum, the coronoid process, and the humeroradial and humeroulnar articulations (32).

Norgaard View of the Hands

The Norgaard view, a semisupinated oblique view of the hand and the wrist (i.e., the “allstate” or ball-catcher’s view) effectively demonstrates the radial aspects of the metacarpal heads and the base of the proximal phalanges in the hand and the triquetrum and pisiform bones in the wrist (10).

Merchant View of the Patella

In the knee joint, the special axial projection of the patella known as the Merchant view is helpful in evaluating the patellofemoral joint. This view is particularly effective in detecting subtle subluxations of the patella (45). For this view, position the patient supine on the radiographic table, with the knee flexed about 45° at the table's edge. A device keeping the knee at this angle also
holds the film cassette. Direct the central beam caudally through the patella at a 60° angle from the vertical. On the film in this projection, the articular facets of the patella and femur are well demonstrated.

Lauren View of the Patella

For the Lauren view, position the patient as for the Merchant view, but direct the central beam cephalad through the patella.

Harris-Beath View and Broden View of the Ankle

Evaluation of the ankle frequently necessitates special projections to demonstrate the details of the subtalar joint. To demonstrate the posterior and middle facets of this joint, use the posterior tangential view (i.e., the Harris-Beath). To demonstrate the posterior facet, talofibular joint, and tibiofibular syndesmosis, use the Broden view (Fig. 4.4). (4)

Figure 4.4. A special view of the ankle obtained at 30° cephalad angulation (Broden view) demonstrates the posterior facet of the subtalar joint, talofibular joint, tibiofibular syndesmosis, and sustentaculum tali.

Fuchs View of the Odontoid

I recommend the Fuchs view for the demonstration of the odontoid process if its upper half is not clearly shown on the open-mouth view (4). For this view, position the patient supine on the radiographic table, with the neck hyperextended. Direct the central beam vertically to the neck just below the tip of the chin. The radiograph obtained in this projection clearly reveals the odontoid, especially its upper half.

MAGNIFICATION RADIOGRAPHY

Magnification radiography is occasionally used to enhance the bony details not well delineated on the standard radiographic projections. This technique involves a special screen--film system and geometric enlargement that yields magnified images of the bones and joints with increased sharpness and bony detail. The technique is particularly effective for demonstrating early changes in some arthritides and metabolic disorders. It may be useful for demonstrating subtle fracture lines not seen on routine projections.

STRESS VIEWS

Stress views are important in the evaluation of ligamentous tears and joint instability. In the hand, obtain abduction-stress film of the thumb if gamekeeper's thumb, resulting from disruption of the ulnar collateral ligament of the first metacarpophalangeal joint, is suspected. In the lower extremity, the stress views of the knee and ankle joints are frequently obtained. Evaluation of knee instability due to ligament injuries may require this technique in cases of suspected tear of the medial collateral ligament, and less frequently for evaluating insufficiency of the anterior and posterior cruciate ligaments.

To obtain a stress film of the knee joint for evaluation of the medial collateral ligament, position the patient supine with the knee flexed about 15° to 20°. With the thigh fixed, apply pressure against the medial aspect of the leg below the knee, forcing the knee into valgus. The films thus obtained show the anteroposterior projection. To obtain a stress film of the knee joint for evaluation of the anterior cruciate ligament, position the patient on his side, with the knee flexed 90°. Apply pressure against the posterior aspect of the upper leg (anterior-drawer stress). The films show the lateral projection.

Evaluation of ankle ligaments also requires stress radiography. Inversion (adduction) (Fig. 4.5) and anterior-drawer stress films are most frequently obtained; only rarely is an eversion (abduction) stress examination required. To obtain an inversion stress film of the ankle joint, position the patient supine with the lower leg fixed, and apply pressure on the lateral aspect of the foot, adducting the heel and forcing the foot into varus position. For anterior-drawer stress examination, position the patient on her side with the lower leg fixed, and apply posterior stress to the heel. The films show the lateral projection.

Figure 4.5. The anteroposterior view of the ankle after application of inversion stress shows widening of the lateral compartment of the ankle joint, indicating a tear of the lateral collateral ligament.

SCANOGRAM

Scanogram is the most widely used method for measurement of limb lengths. This technique requires a slit-beam diaphragm with a 1.5 mm opening attached to the radiographic tube, and a long film cassette. The radiographic tube can move in the long axis of the radiographic table. During the exposure, the tube traverses the whole length of the film, scanning the entire extremity. This technique allows the x-ray beam to intersect the bone ends perpendicularly, and limb lengths can be compared. A modified technique may be used with three separate exposures over the hip joints, knees, and ankles if a motorized radiographic tube is not available. In this technique, an opaque tape measure is placed longitudinally down the center of the radiographic table.

Occasionally, a so-called orthoroentgenogram is indicated. For this technique, position the patient supine with the lower limbs on a 3-ft-long cassette and a long ruler at one side. Make a single exposure, centered at the knees and including the entire length of both limbs and the ruler.

FLUOROSCOPY AND VIDEOTAPING

Fluoroscopy is a fundamental diagnostic tool for many radiologic procedures, including arthrography, tenography, bursography, arteriography, and percutaneous bone
or soft-tissue biopsy. Fluoroscopy combined with videotaping is useful in the evaluation of the kinematics of joints. Because it delivers a high dose of radiation, it is used only occasionally (e.g., in evaluating joint movement and detecting transient subluxation). It occasionally is used in follow-up examination of the healing process after fractures to evaluate the degree of bone union. Fluoroscopy is still used in conjunction with myelography if it is important

- to observe the movement of the contrast column in the subarachnoid space,
- to check proper placement of the needle and monitor the flow of contrast medium,
- to assess intraoperatively the reduction of a fracture or the placement of hardware.

**DIGITAL RADIOGRAPHY**

Digital (computed) radiography is the process of digital image acquisition using an x-ray detector. The detector comprises a photostimulable phosphor imaging plate and image reader/writer that processes the latent image information for laser printing on film. A major advantage of computed radiography over conventional film and screen radiography is that, once acquired, the digital image data are readily manipulated to produce alternative renderings. In addition, energy subtraction imaging may be acquired: Two images, acquired either sequentially or simultaneously with different filtration, are used to reconstruct a soft tissue–only image or a bone-only image.

Digital subtraction radiography uses a video processor and a digital disk added to a fluoroscopy imaging system to provide on-line viewing of subtraction images (23). This technique is most widely used to evaluate the vascular system; it is occasionally used in conjunction with arthography. Use of high-performance video cameras with low-noise characteristics allows a single video frame of precontrast and postcontrast images to be used for subtraction. Spatial resolution can be maximized using a combination of geometric magnification, electric magnification, and a small anode-to-target distance. The subtraction technique removes surrounding anatomic structures and isolates the opacified vessel or joint, making it more conspicuous.

Use nonvascular digital radiography to evaluate bone abnormalities and, in conjunction with contrast injection (i.e., digital arthography), to evaluate subtle abnormalities of the joints, such as tears of the lunate-triquetral ligament or the abnormalities of the triangular fibrocartilage in the wrist (Fig. 4.6). It is helpful for delineating the extent of the fracture line (Fig. 4.7), evaluating the healing process, and evaluating nonunions (51). It is also useful in evaluating tumor and tumorsike lesions (e.g., the nidus of an osteoid osteoma, a calcific matrix in an enchondroma or chondrosarcoma). Small cystic and sclerotic lesions and subtle erosions are well demonstrated. Tomograms are better interpreted with plain radiographs for comparison.

**CONVENTIONAL TOMOGRAPHY**

Tomography is body-section radiography that enhances visualization of lesions too small to be seen on conventional radiographs. It is also effective for demonstrating anatomic detail that is obscured by overlying structures. It employs continuous motion of the radiographic tube and film cassette in opposite directions throughout exposure, with the fulcrum of the motion located in the plane of interest. The technique blurs structures above and below the area being examined, thereby sharply outlining the object to be studied on a single plane of focus. The newly developed tomographic units can better localize the image and can detect lesions as small as 1 mm in diameter.

The simplest tomographic movement is linear, with the radiographic tube and film cassette moving on a straight line in opposite directions throughout exposure, with the fulcrum of the motion located in the plane of interest. The technique blurs structures above and below the area being examined, thereby sharply outlining the object to be studied on a single plane of focus. The newly developed tomographic units can better localize the image and can detect lesions as small as 1 mm in diameter.

Trispiral tomography is superior to conventional radiographs in the visualization of subtle fractures (35). It is helpful for delineating the extent of the fracture line (Fig. 4.7), evaluating the healing process, and evaluating nonunions (51). It is also useful in evaluating tumor and tumorsike lesions (e.g., the nidus of an osteoid osteoma, a calcific matrix in an enchondroma or chondrosarcoma). Small cystic and sclerotic lesions and subtle erosions are well demonstrated. Tomograms are better interpreted with plain radiographs for comparison.

**COMPUTED TOMOGRAPHY**

Computed tomography is an indispensable modality in the evaluation of many traumatic conditions and various bone and soft-tissue tumors because of its cross-sectional imaging capability. In trauma, CT is extremely useful because of its abilities to define the presence and extent of fracture or dislocation, to evaluate such intra-articular abnormalities as damage to the articular cartilage or presence of noncalcified and calcified osteocartilaginous bodies, and to evaluate adjacent soft
tissues. CT is important in the detection of small bony fragments displaced into the joints after trauma, in the detection of the small displaced fragments of the fractured vertebral body (Fig. 4.8), and in the assessment of concomitant injury to the cord or thecal sac.

Figure 4.8. CT section through the level of T3 accurately demonstrates the comminuted fracture of the vertebral body and laminae. Notice small bony fragment encroaching on the spinal cord.

Advantages of CT over conventional radiography are its ability to provide excellent contrast resolution, accurate measurement of the tissue attenuation coefficient, and direct transaxial images. Another advantage is its ability to image the bone in coronal, sagittal, and oblique planes, using reformation technique. This multiplanar reconstruction is particularly helpful in evaluating vertebral alignment (Fig. 4.9), demonstrating horizontally oriented fractures of the vertebral body, and evaluating complex fractures of the pelvis or calcaneus, abnormalities of the sacrum and sacroiliac joints, sternum, sternoclavicular joints, temporomandibular joints, and wrist.

Figure 4.9. Sagittal CT reconstructed image effectively shows the flexion tear-drop fracture of C5. Malalignment of the vertebral bodies and narrowing of the spinal canal are well demonstrated.

Modern CT scanners employ collimated fan beams directed only at the tissue layer under investigation. Recently developed spiral (helical) scanning permits three-dimensional reconstruction for analysis of regions with complex anatomy, such as the face, pelvis, vertebral column, wrist, foot, and ankle (Fig. 4.10) (11,27,42). The CT data may be used to create three-dimensional plastic models of the area of interest, which can facilitate operative planning and allow rehearsal of complex reconstructive procedures.

Figure 4.10. Three-dimensional CT reconstruction of the wrist demonstrates a nonunited fracture of the scaphoid (arrow) complicated by osteonecrosis of the proximal fragment.

Although CT by itself is rarely helpful in making a specific diagnosis of bone and soft-tissue tumors, it can provide a precise evaluation of the extent of the bone lesion and may demonstrate a break through the cortex and the involvement of surrounding soft tissues (Fig. 4.11). Moreover, CT is helpful for delineating a tumor in bones having complex anatomic structures, such as the scapula, pelvis, and sacrum, which may be difficult to image fully with conventional radiographic techniques or even conventional tomography. CT examination is crucial in determining the extent and spread of a tumor in the bone and surrounding soft tissues if limb salvage is contemplated, allowing a safe margin of resection to be planned. It is also useful for monitoring the results of treatment and evaluating recurrence of resected tumor.

Figure 4.11. CT section through the proximal thigh of a patient with osteosarcoma of the femur. The tumor involves the bone marrow (arrow) and is breaking through the cortex, producing a large soft-tissue mass (curved arrows).

Computed tomography is an important modality for successful aspiration or biopsy of bone or soft-tissue lesions because it provides visual guidance for precise
The ability of CT to measure the attenuation coefficients of each pixel provides a basis for accurate quantitative bone mineral analysis in cancellous and cortical bone (8, 26). Evaluation of bone mass measurement underscores continuing progress in our understanding of bone metabolism and provides valuable insight into improvement of evaluation and treatment of osteoporosis and other metabolic bone disorders (55).

Disadvantages of CT include the so-called average volume effect, which results from insufficient resolution to describe inhomogeneities of the tissue. Because of this, the Hounsfield's units represent average values of the different components of the tissue. This effect becomes particularly important if normal and pathologic processes interface within a section under investigation.

Another disadvantage of CT is poor tissue characterization. Despite the ability of CT to discriminate some density differences, a simple analysis of attenuation values does not permit precise histologic characterization. Moreover, if the patient moves at all, the result is artifacts that degrade the image quality. Similarly, metal (e.g., prosthesis, rods, screws) produces significant artifacts. Finally, the radiation dose may occasionally be high, particularly if contiguous and overlapping sections are obtained during an examination.

ARTHROGRAPHY

Arthrography is the introduction of a contrast agent into the joint space. Positive contrast describes iodide solution, and negative contrast refers to air. Despite the evolution of newer diagnostic imaging modalities, such as CT and MRI, arthrography has retained its importance in daily radiologic practice (25). Arthrography is technically simple, and interpretation is much easier than interpretation of ultrasound, CT, or MRI (33). Although virtually every joint can be injected with contrast, arthrography is most frequently performed in the shoulder, wrist, ankle, and elbow.

It is important to obtain preliminary films before any arthrographic procedure, because contrast may obscure some joint abnormalities (e.g., osteochondral body) that can be easily detected on the plain film. Arthrography is particularly effective in demonstrating rotator cuff tear (Fig. 4.12) and adhesive capsulitis in the shoulder, osteochondritis dissecans, osteochondral bodies, and subtle abnormalities of the articular cartilage in the elbow joint. In the wrist, it is still a very effective procedure for evaluating abnormalities of the triangular fibrocartilage complex (53). The introduction of three-compartment injection techniques combined with digital technique and postarthrographic CT examination has made this modality almost always the procedure of choice in evaluating a painful wrist (40).

Figure 4.12. After injection of contrast agent into the shoulder joint, there is opacification of the subacromial-subdeltoid bursae complex (arrow), indicating a rotator cuff tear.

Although arthrography of the knee has been almost completely replaced by MRI, it still may be used to demonstrate injuries to the soft-tissue structures, such as the joint capsule, menisci, and various ligaments (Fig. 4.13). It also provides important information on the status of the articular cartilage, particularly if the surgeon suspects subtle chondral or osteochondral fracture or requires confirmation of osteochondral bodies (e.g., osteochondritis dissecans).

Figure 4.13. Double-contrast arthrogram of the knee demonstrates a bucket-handle tear of the posterior horn of medial meniscus (curved arrow) and a popliteal cyst (straight arrow).

In the examination of any joint, arthrography can be combined with tomography (i.e., arthrotomography), with CT (i.e., arthro-CT), or with digitization of an image (i.e., digital subtraction arthrography) to provide additional information (Fig. 4.6) (63).

There are relatively few absolute contraindications to arthrography. Even hypersensitivity to iodine is only a relative contraindication, because a single contrast study using only air can be performed.

TENOGRAPHY AND BURSOGRAPHY

Contrast material is occasionally injected into the tendon sheath to evaluate the integrity of a tendon, in a procedure known as a tenogram. CT and MRI have superseded this procedure, but it is still used, mainly to evaluate traumatic or inflammatory condition of tendons of the lower extremity, such as peroneus longus and brevis (Fig. 4.14), tibialis anterior and posterior, and flexor digitorum longus, and to outline the synovial sheaths within the carpal tunnel in the upper extremity.

Figure 4.14. Tenogram demonstrates irregular accumulation of the contrast in the proximal portion of the sheath of the peroneus brevis tendon (arrow), indicating
Bursography involves the injection of contrast agent into bursae. This procedure has mostly been abandoned, and only occasionally the subacromial-subdeltoid bursae complex is directly injected with contrast agent to demonstrate partial tears of the rotator cuff.

**ANGIOGRAPHY**

In arteriography, contrast agent is injected into the arteries and films are obtained, usually in a rapid sequence. In venography, contrast is injected into the veins. The technique is used most frequently to detect vascular trauma.

In evaluating tumors, arteriography is used mainly to map bone lesions, to demonstrate the vascularity of the lesion, and to assess the extent of disease (Fig. 4.15). It is also used to demonstrate the vascular supply of a tumor and to locate vessels suitable for preoperative intraarterial chemotherapy. It is useful in demonstrating the area suitable for open biopsy, because most vascular parts of a tumor contain the most aggressive component of the lesion. Occasionally, arteriography can be used to demonstrate abnormal tumor vessels, corroborating findings with plain film radiography and tomography. Arteriography is often extremely helpful in planning limb-salvage procedures by demonstrating the regional vascular anatomy and permitting a plan to be drawn for the resection procedure. It is sometimes used to outline the major vessels before resection of a benign tumor. It can be combined with an interventional procedure, such as embolization of hypervascular tumors, before surgery. It also plays a major role in assessing the effectiveness of chemotherapy in the treatment of malignant bone and soft-tissue tumors.

**MYELOGRAPHY**

During myelography, water-soluble contrast agents are injected into the subarachnoid space, mixing freely with the cerebral spinal fluid to produce a column of opacified fluid with a higher specific gravity than the clear fluid. Tilting the patient allows the opacified fluid to run up or down the thecal sac under the influence of gravity. The puncture usually is done in the lumbar area, at L2–L3 or L3–L4 levels. For examination of the cervical area, a C1–C2 puncture is performed. Myelographic examination has been almost completely replaced by high-resolution CT and high-quality MRI.

**DISCOGRAPHY**

Discography is an injection of contrast material into the nucleus pulposus. Although many surgeons have abandoned the use of this controversial procedure, under tightly restricted indications and immaculate technique a discogram can yield valuable information (29,59). Discography is a valuable aid for determining the source of a patient’s low-back pain. It is not a pure imaging technique, because the symptoms produced during the test (e.g., pain during the injection) are considered to have even greater diagnostic value than the radiographs obtained (66). Always combine it with CT examination (Fig. 4.16). According to the official position statement on discography by the Executive Committee of the North American Spine Society in 1988, this procedure “is indicated in the evaluation of patients with unremitting spinal pain, with or without extremity pain, of greater than 4 months duration, when the pain has been unresponsive to all appropriate methods of conservative therapy” (21). According to the same statement, before discography is performed, the patient should have undergone investigation with other modalities (e.g., CT, MRI, myelography), and surgical correction of the patient’s problem should be anticipated.
SKELETAL SCINTIGRAPHY

One of the major advantages of skeletal scintigraphy (i.e., radionuclide bone scan) over all other imaging techniques is its ability to image the entire skeleton at once. A bone scan can confirm the presence of the disease, demonstrate the distribution of a lesion (Fig. 4.17), and help to evaluate the activity of a pathologic process. Indications for skeletal scintigraphy include traumatic conditions, tumors (primary and metastatic), arthritides, infections, and metabolic bone disease. The detected abnormality may consist of decreased uptake of bone-seeking radiopharmaceutical (e.g., early stage of osteonecrosis) or increased uptake (e.g., fracture, neoplasm, focus of osteomyelitis). Some structures under normal conditions may show increased activity (e.g., sacroiliac joints or normal growth plates).

Figure 4.17. Bone scan obtained after injection of 15 mCi of technetium-99m methylene diphosphonate demonstrates increased uptake of the radiopharmaceutical at the site of multiple rib fractures. The increased uptake at the level of L1 is secondary to the compression fracture of the vertebral body (arrows).

Scintigraphy is a sensitive imaging modality, but it lacks specificity. It is impossible to differentiate between various processes that can cause increased uptake. Occasionally, however, the bone scan may yield very specific information and even suggest the diagnosis, as in multiple myeloma or osteoid osteoma. In the search for myeloma, scintigraphy is helpful for differentiating bony metastases. In most cases of myeloma, there is no significant increase in the uptake of the radiopharmaceutical; in skeletal metastases, however, invariably the uptake of the tracer is significantly elevated. In osteoid osteoma, there is a typical appearance of the bone scan that demonstrates a “double-density sign.” There is more increased uptake in the center, due to the nidus, and less increased uptake at the periphery, related to the reactive sclerosis surrounding the nidus.

Radionuclide bone scan is an indicator of mineral turnover; because there is usually an enhanced deposition of bone-seeking radiopharmaceuticals in areas of bone undergoing change and repair, a bone scan is useful in localizing tumors and tumor-like lesions in the skeleton. This is particularly helpful in fibrous dysplasia, eosinophilic granuloma, or metastatic cancer, in which more than one lesion develop. It also plays an important role in localizing small lesions, such as osteoid osteoma, which may not always be seen on the plain film, but may be demonstrated on radionuclide bone scans. In most cases, radionuclide bone scans cannot differentiate benign lesions from malignant tumors, because both conditions have an increased blood flow with resultant increased isotope deposition and increased osteoblastic activity. It may, however, permit differentiation of benign lesions, such as bone islands, that usually do not absorb the radioactive isotope.

In traumatic conditions, scintigraphy is extremely helpful in the early diagnosis of stress fractures, which may not be seen on conventional radiographs or tomographic studies. It also has value in diagnosing fractures of the scaphoid or the femoral neck in elderly patients if the routine radiographic examinations appear normal (13, 39).

In metabolic bone disorders, bone scintigraphy is helpful in establishing the extent of skeletal involvement in Paget’s disease and assessing the response to treatment. Although it is of no use in the evaluation of patients with generalized osteoporosis, it may occasionally be helpful in differentiating osteoporosis from osteomalacia and in differentiating multiple vertebral fractures resulting from osteoporosis from those occurring in metastatic carcinoma.

Skeletal scintigraphy is frequently used to evaluate infections. In particular, 99mTc-methylene diphosphonate (99mTc-MDP) and 111In-labeled leukocytes (111In) are highly sensitive in detecting early and occult osteomyelitis (2). For detecting recurrent active infection in patients with chronic osteomyelitis, 111In-labeled leukocytes appear to be the tracer of choice. It must be stressed, however, that 111In-labeled leukocytes accumulate in active bone marrow, and this tendency limits their sensitivity for the detection of chronic osteomyelitis. To improve the diagnostic ability of this technique, some advocate a study that combines 99mTc-sulfur colloid bone marrow with 111In-labeled leukocytes. In chronic osteomyelitis, imaging with 99mTc-gallium (99mTc) citrate is more accurate in detecting the response or lack of response to treatment than 99mTc-phosphate bone imaging. A three-phase technique can be effectively used to differentiate soft-tissue infection (cellulitis) and osteoosseous infection (osteomyelitis).

In neoplastic conditions, the detection of skeletal metastasis is probably the most common indication for skeletal scintigraphy. It also is frequently used to determine the extent of a lesion or the presence of skip lesions or intraosseous metastases. It is not the method of choice to determine the extent of the lesion in the bone. Scintigraphy alone cannot diagnose the type of the tumor, but it may be useful in detecting and localizing some primary tumors and multifocal lesions (e.g., multicentric osteosarcoma).

99mTc-MDP scans are used primarily to determine whether a lesion is monostotic or polyostotic, information essential in the staging of a bone tumor. Although the degree of abnormal uptake may be related to the aggressiveness of the lesion, this finding does not correlate well with histologic grade. Gallium-67 may be taken up in a soft-tissue sarcoma and may help to differentiate a sarcoma from a benign soft-tissue lesion.

Although a bone scan may be useful in demonstrating the extent of the primary malignant tumor in bone, it is not as accurate as CT or MRI. It may be useful in the detection of local recurrence of tumor and occasionally may indicate the response or lack of response to radiotherapy or chemotherapy.

In the evaluation of arthritides, a bone scan can demonstrate the distribution of the lesion in the skeleton; this method has completely replaced the previously used radiographic joint survey. Scintigraphy can determine the distribution of arthritic changes in large and small joints and in areas usually not detected by standard radiography, such as the sternomambrual and temporomandibular joints (38).

Several bone-seeking tracers are available for scintigraphic imaging (44).

Diphosphonates Gamma-emitting agents have been developed for diagnostic radionuclide imaging. The radiopharmaceuticals currently in use in bone scanning include the organic diphosphonates, ethylene diphosphonates, methylene diphosphonates (MDP), and methane hydroxydiphosphonates, all labeled with 99mTc, a pure gamma-ray emitter with a 6-hour half-life. MDP is more frequently used, particularly in adults, typically in a dose that provides 15 mCi of 99mTc radiation. After intravenous injection of the radiopharmaceutical, approximately 50% of the dose localizes in bone. The remainder circulates freely in the body and eventually is excreted by the kidneys.

A gamma camera is used in a procedure known as three-phase isotope bone scan. The first phase, the radionuclide angiogram, is the first minute after injection, when the serial images demonstrate the radioactive tracer in the major bone vessels. In the second phase, the blood-pool scan, which lasts from 1 to 3 minutes after injection, isotope is detected in the vascular system and in the extracellular space in the soft tissues before being taken up by bone. The third phase, or static bone scan, usually occurs 2 to 3 hours after injection and discloses the presence of radiopharmaceutical in the bone. This phase may be divided into two stages. In the first stage, the isotope diffuses passively through the bone capillaries. In the second stage, the radionuclide is concentrated in bone. The most intense localization occurs in differentiating multiple vertebral fractures resulting from osteoporosis from those occurring in metastatic carcinoma.

Gallium-67 67Ga-citrate is frequently used to diagnose infectious processes in bone and joints. The sensitivity of 67Ga for abscess detection varies from 58% to 100% and specificity from 75% to 99%. The images are usually obtained 6 and 24 hours after the injection of 5 mCi of this radiopharmaceutical. These images have been shown to be extremely accurate in monitoring response to therapy of chronic osteomyelitis and infectious arthritis. The changing activity of 67Ga uptake parallels the patient’s clinical course in septic arthritis more closely than the images obtained after injection of 99mTc-diphosphonate. A gallium scan is also used to differentiate sarcomas from benign soft-tissue lesions.
Indium Controversy still exists regarding diagnostic advantage of T11In oxine-labeled leukocytes over other bone-seeking radiopharmaceuticals for detecting inflammatory abnormalities in the skeletal system (45). Because T11In-labeled leukocytes are not usually incorporated into areas of increased bone turnover, indium imaging presumably reflects inflammatory activity only, and early experience has shown it to be specific in the detection of abscesses or acute infectious processes, including osteomyelitis and septic arthritis. The sensitivity varies from 75% to 90%, and specificity is approximately 91% (57). False-negative results often occurred for patients with chronic infections in which there was reduced inflow of circulating leukocytes. False-positive results were seen for patients who had an inflammatory process without infection (e.g., rheumatoid arthritis mistaken for septic arthritis).

**Nanocolloid** In Europe, very small particles of 56mTc-colloid of human serum albumin were tried as a bone marrow imaging agent. About 86% of these particles are 30 nm or smaller, and the remainder are between 30 and 80 nm. When this “nanocolloid” is used for detection of osteomyelitis in the extremities, it has a sensitivity equal to that of T11In-leukocytes.

**SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY**

Pathologic processes produce significantly different, characteristic, nonuniform distribution of administered radiopharmaceutical tracers. Imaging the distributions yields information about the functional status of bony tissues. A perfect image of such an object would be an exact three-dimensional replica of the distribution of activity within the area of interest (6). This goal has been partially achieved through the tomoscaner and dual Anger-type scintillation cameras operated in the conjugate counting mode, or single photon emission computed tomography (SPECT).

The recent development of single photon emission tomography (SPET) and SPECT has tremendously increased diagnostic precision in evaluating bone and joint abnormalities. The efficiency of instrumentation for SPECT is improving with multiple crystal detectors, fan beam and cone beam collimators, detection of a greater fraction of photons, and improved algorithms. Compared with planar images, SPECT provides increased contrast resolution, using a tomographic mode that eliminates the noise from tissue outside the plane of imaging; in this regard, it is similar to conventional tomography. It provides quantitative and qualitative information on the uptake of bone-seeking radiopharmaceuticals.

**MAGNETIC RESONANCE IMAGING**

Magnetic resonance imaging is based on the reemission of an absorbed radiofrequency signal while the patient is in a strong magnetic field (31). An external magnetic field is usually generated by a magnet with field strengths of 0.2 to 1.5 tesla. The system includes a magnet, radiofrequency coils (transmitter and receiver), gradient coils, and a computer display unit with digital storage facilities.

The ability of MR to image body parts depends on the intrinsic spin of atomic nuclei with an odd number of protons or neutrons (e.g., hydrogen), which generates a magnetic moment. Nuclei of tissues placed within the main magnetic field tend to align along the direction of that field. Application of radiofrequency (rf) pulses induces resonance of particular sets of nuclei. The required frequency of the pulse is determined by the strength of the magnetic field and the nucleus under investigation. The energy absorbed during the transition from the induced high-energy state to the normal low-energy state is released; this can be recorded as an electrical signal, which provides the data from which digital images are derived (59).

Two relaxation times, T1 and T2, are employed. The T1 relaxation time is a term used to describe the return of protons to equilibrium after application and removal of the rf pulse. T2 relaxation time is a term used to describe the associated loss of coherence or phase between individual protons immediately after the application of rf pulse. A variety of rf pulse sequences can be used to enhance the differences in tissue relaxation times T1 and T2, providing the necessary image contrast.

The most commonly used sequences are partial saturation recovery, inversion recovery, and fast scan technique. Inversion recovery sequences can be combined with multiplanar imaging to shorten scan time. Spin echo short pulse repetition (TR £ 0.5 sec) and short echo delay (TE £ 40 msec) sequences (or T1) provide good anatomic detail. Long TR (³1.5 sec) and long TE (³90 msec) pulse sequences (or T2) provide good contrast, sufficient for evaluation of pathologic processes. With a short inversion time in the range of 100 to 150 msec, the effects of Prolonged T1 and T2 relaxation times are cumulative, and the signal from fat is suppressed. This technique is short time inversion recovery (STIR), and it has been useful for evaluating bone tumors (3).

Fast imaging techniques have become increasingly popular because they provide advantages compared with much slower spin echo imaging. In particular, gradient recalled echo (GRE) pulse sequences using variable flip angles (5° to 90°) have gained rapid acceptance in orthopaedic radiology because they represent the most effective means of shortening the time to acquire an image.

Several different types of GRE methods in clinical use, each of which relies on using a reduced flip angle to enhance the signal with short TR. These techniques are known by a variety of acronyms such as FLASH (fast low-angle shot), FISP (fast imaging with steady procession), GRASS (gradient-recalled acquisition), and MPGR (multiplanar gradient recalled).

In most examinations, obtain at least two planes (axial and coronal or sagittal); for many injuries, all three planes are necessary. For adequate MR imaging, surface coils are necessary because they provide improved spatial resolution. Most surface coils are designed specifically for different areas of the body, such as knee, shoulder, wrist, and temporomandibular joints.

The musculoskeletal system is ideally suited for evaluation by MRI because different tissue types display different signal intensity on T1- and T2-weighted images. The images displayed may have a high, intermediate, or low signal intensity. High signal intensity of fat planes and differences in signal intensity of various structures allow separation of the different tissue components. Fat, bone marrow, and hematoma display relatively high signal intensity on T1- and T2-weighted images; cortical bone, air, ligaments, tendons, and fibrocartilage display low signal intensity on T1- and T2-weighted images; muscle, nerves, and hyaline cartilage display intermediate signal intensity on T1- and T2-weighted images. Most tumors display low to intermediate signal intensity on T1-weighted images, and high signal intensity on T2-weighted images.

The use of MRI in orthopaedic radiology is confined primarily to trauma and tumors.

**TRAUMA**

Magnetic resonance imaging evaluation of trauma to the knee, particularly meniscal and ligamentous abnormalities, has high negative predictive value (19). This test can be used to screen patients before surgery and avoid unnecessary arthroscopies. Some types of meniscal tears may be difficult to detect, such as bucket-handle tears, tears of the free edge, and peripheral detachments. Medial and lateral collateral ligaments, anterior and posterior cruciate ligaments, and tendons around the knee joint are well visualized on MRI (3). Abnormalities of these structures can be diagnosed with high accuracy (37). Osteochondral fractures and lesions of osteochondritis dissecans can also be effectively imaged (Fig. 4.16). In the shoulder, impingement syndrome and most complete and incomplete rotator cuff tears can be accurately diagnosed (Fig. 4.19).

![Figure 4.18.](image-url) Coronal (A) and sagittal (B) MR images of the knee demonstrate a necrotic segment of bone (arrow), separated from the medial femoral condyle by a low-signal-intensity band, representing a sclerotic margin of reactive tissue at the interface between necrotic and viable bone (open arrow). The articular cartilage is intact (curved arrow), indicating an in situ lesion of osteochondritis dissecans.
Much more difficult to diagnose is a tear of the cartilaginous labrum. Traumatic lesions of the tendons, such as biceps tendon rupture, can easily be diagnosed with this technique. MRI effectively delineates traumatic joint effusions and hematomas, as well as the changes of osteonecrosis at various sites (Fig. 4.20). This modality can detect the early changes of osteonecrosis, even when conventional radiography, tomography, and radionuclide bone scan are normal (12). MRI of the ankle and foot has been used in diagnosing tendon ruptures and posttraumatic osteonecrosis of the tibia. In the wrist and hand, MRI has been successfully used in the early diagnosis of posttraumatic osteonecrosis of the scaphoid. Nevertheless, it is not the technique of choice for evaluating abnormalities of triangular fibrocartilage complex, for which arthrography is preferred, particularly with the combination of CT and digital imaging.

Figure 4.20. Coronal MR image of the pelvis (spin echo, TR = 600, TE = 20) demonstrates advanced osteonecrosis of the right femoral head.

Magnetic resonance angiography (MRA) has become popular in recent years. The diagnostic accuracy of this technique may exceed that of conventional MRI. It better demonstrates the intra-articular structures because they can be separated by capsular distention. Such distention can be achieved with intra-articular injection of contrast material such as diluted gadopentate dimeglumine (gadolinium diethylenetriamine penta-acetic acid, or Gd-DTPA) or saline. The generated images are very similar to those obtained with the joint with preexisting joint fluid (joint effusion). In clinical practice, MRA is used predominantly in the evaluation of shoulder abnormalities, such as internal derangement, glenohumeral joint instability, rotator cuff disorders, or articular cartilage and cartilaginous labrum abnormalities. Indirect MRA is a procedure in which, prior to the MRI examination of the joint, an intravenous injection of gadolinium is given. Like direct MRA, this technique may improve detection of rotator cuff tears, labral pathology, and adhesive capsulitis.

Magnetic resonance angiography can help the physician visualize blood vessels. Unlike conventional contrast angiography, it does not demonstrate the blood volume itself, but rather it depicts a property of blood flow. One of its advantages lies in fact that after a three-dimensional MR angiography data set is collected, the physician may choose any number of viewing directions. This feature also eliminates vascular overlapping.

Numerous pulse sequences have been proposed to produce angiographic contrast. Some rely on the rapid inflow of relaxed blood into the region in which the stationary tissue is saturated. These methods are time-of-flight (TOF) or flow-related enhancement (FRE). Others, which rely on the velocity-dependent change of phase of moving blood in the presence of a magnetic field gradient, are the phase-contrast methods. Some methods involve the subtraction of flow-dephased images from flow-compensated images. The application of MR angiography in orthopedic radiology includes evaluation of the vascular structures in patients with trauma to the extremities, and in assessment of vascularity of musculoskeletal neoplasms.

The greatest use of MRI is in trauma of the spine, the spinal cord, the thecal sac, and nerve roots, and in the evaluation of disc herniation (34). MRI is also useful in evaluating spinal ligament injury. Demonstration of the relationship of vertebral fragments to the spinal cord with direct sagittal imaging is extremely helpful, particularly in the cervical and thoracic areas.

TUMORS

Magnetic resonance imaging is indispensable in evaluating bone and soft-tissue tumors. Particularly in the evaluation of soft-tissue masses, MR offers distinct advantages over CT. Tissue planes surrounding the lesion can be more adequately visualized, and neurovascular involvement can be evaluated without the use of intravenous contrast (62).

A number of pulse sequences can be used to evaluate musculoskeletal tumors. These include spin-echo (SE) sequences, inversion recovery (IR) sequences, STIR sequences, GRE sequences, and fast T2 or fat-suppression T2-weighted sequences. SE sequences are the most effective for identification and staging of most skeletal tumors. The signal intensity for normal tissues is predictable using these sequences. On T1-weighted images, fat and bone marrow have a high signal intensity that changes to intermediate intensity on T2 weighting. Muscles have intermediate signal intensity on both T1 and T2 sequences. Cortical bone and fibrocartilage have low signal on both sequences. Fluid has intermediate signal on T1-weighted and high signal intensity on T2-weighted images. This modality can detect the early changes of osteonecrosis, even when conventional radiography, tomography, and radionuclide bone scan are normal (12). MRI of the ankle and foot has been used in diagnosing tendon ruptures and posttraumatic osteonecrosis of the tibia. In the wrist and hand, MRI has been successfully used in the early diagnosis of posttraumatic osteonecrosis of the scaphoid. Nevertheless, it is not the technique of choice for evaluating abnormalities of triangular fibrocartilage complex, for which arthrography is preferred, particularly with the combination of CT and digital imaging.

Table 4.1. MRI Signal Intensities of Various Tissues
Magnetic resonance imaging is crucial in evaluating intra- and extraosseous extensions of tumors (1,48,62). It can determine soft-tissue invasion by a tumor with great accuracy (Fig. 4.21). MRI in many instances is superior to CT, particularly in the coronal plane, in delineating the extraosseous and intramedullary extent of the tumor and its relationship to surrounding structures. Showing sharper demarcation between normal and abnormal tissue than CT, especially in evaluating the extremities, MRI reliably identifies the spatial boundaries of tumor masses, encasement and displacement of major neurovascular bundles, and the extent of joint involvement. T1-weighted spin-echo images enhance tumor contrast with bone, bone marrow, and fatty tissue (Fig. 4.22A) and T2-weighted spin echo images enhance tumor contrast with muscle and accentuate peritumoral edema (Fig. 4.22B). Axial and coronal images have been employed in determining the extent of soft-tissue invasion in relation to important vascular structures. Compared with CT, MR images do not clearly depict or allow characterization of calcification in the tumor matrix; large amounts of calcification or ossification are occasionally undetectable. Moreover, MRI has shown itself less satisfactory than CT, and even less satisfactory than plain films and tomography, in demonstrating cortical destruction and periostal reaction.

Figure 4.21. On the MR axial image (T2-weighting), the involvement of the bone marrow is demonstrated by high signal intensity of the tumor (Ewing's sarcoma). The soft-tissue extension of the tumor displaying intermediate signal intensity is well demonstrated (arrows).

Figure 4.22. A: T1-weighted coronal MR image demonstrates good contrast between the tumor in the right femur (dedifferentiated chondrosarcoma), which displays low signal intensity, and normal bone marrow, which displays high signal intensity. B: T2-weighted axial MR image of the same patient enhances the contrast between tumor, displaying high or intermediate signal intensity, and normal muscles, displaying low signal intensity.

Several investigators stressed the advantage of contrast enhancement of MR images using intravenous injection of Gd-DTPA. Enhancement was found to give better delineation of the tumor in richly vascularized parts, in compressed tissue immediately surrounding the tumor, and in atrophic but richly vascularized muscle (59). The contrast studies also improved the differentiation of necrotic tissue from viable areas in various malignant tumors (18).

According to recent investigations, MRI may have an additional application in evaluating tumor response to irradiation and chemotherapy and in evaluating local recurrence (54). Although static MRI was of little value for assessment of response to the treatment, dynamic MR imaging using Gd-DTPA had a higher degree of accuracy (85.7%) and was superior to scintigraphy, particularly in patients who were receiving intra-arterial chemotherapy (19,20). The latest observation suggests that MR spectroscopy may also be useful in evaluating patients undergoing chemotherapy (17,61).

Magnetic resonance imaging is usually not suitable for establishing the precise nature of a bone tumor, and too much faith has been placed in MRI as a method for differentiating benign from malignant lesions (63). Trials using combined 1H MRI (proton imaging) and 31P MR spectroscopy failed to differentiate most benign lesions from malignant tumors (49). Despite the use of various criteria, the application of MRI to tissue diagnosis has rarely brought satisfactory results, because the small number of protons in calcified structures renders MRI less useful in evaluation of bone lesions (1). The physician can miss valuable evidence related to the production of the tumor matrix using this modality, because it is unsatisfactory for demonstrating small calcified structures. Moreover, MRI has been an imaging modality of low specificity. T1 and T2 measurements are generally of limited value for histologic characterization of musculoskeletal tumors.

Quantitative determination of relaxation times has not proved to be clinically valuable in identifying tumor types, although it has proved to be an important technique in the staging of osteosarcoma or chondrosarcoma (63). T2-weighted images are a crucial factor in delineating extraosseous extension of tumor and peritumoral edema and assessing the involvement of major neurovascular bundles. Necrotic areas change from low-intensity signal in the T1-weighted image to a very bright, intense signal in the T2-weighted images and can be differentiated from viable, solid tumor tissue.

Although MRI cannot predict the histology of bone tumors, it is a useful tool for differentiating round cell tumors and metastases from stress fractures and medullary infarcts in symptomatic patients with normal radiographs. It can occasionally differentiate benign from pathologic fractures (3,63).

Magnetic resonance imaging also has disadvantages, which include the contraindications of scanning patients with cardiac pacemakers or cerebral aneurysm clips, and those who are claustrophobic. The presence of metallic objects, such as ferromagnetic surgical clips, causes focal loss of the signal with or without distortion of image. Metallic objects create “holes” in the image, but ferromagnetic objects cause more distortion (48). MRI still lacks high resolution for evaluating osseous anatomy and fractures compared with CT and conventional tomography. As in CT, an average volume effect may be observed in MR images, rendering occasional pitfalls in the interpretation. Motion artifacts can be eliminated using fast imaging techniques.

RATIONALE FOR PREOPERATIVE PLANNING

Success of surgery is increasingly being measured by the patient's satisfaction and functional outcome. Not only must the procedure be performed technically well, but also all the associated factors, from preoperative evaluation to postoperative therapy and follow-up, must be efficient and well coordinated.

Preoperative preparation includes careful evaluation of the patient's medical and social situation to minimize the risks of perioperative complications and problems. Preoperative clearance may require consultation with a medical specialist or anesthesiologist. It may be necessary to coordinate autologous blood donations. Additionally, it may be necessary to make discharge plans, which could involve home care or transfer to a rehabilitation or skilled nursing facility.

Preoperative patient education is on the rise as the frequency and duration of inpatient hospitalization decline. Patient education prepares patient and family for the anticipated surgery and the postoperative recovery period. Patients’ understanding of their role in this process is important to a successful outcome.

Increasing demands on their time require surgeons to perform efficiently without sacrificing quality. With preoperative planning, the surgeon thinks through the operation ahead of time, which allows the operation to run more smoothly and quickly and provides important time-management benefits.

Additionally, increasing technological complexity demands increased preoperative preparation. For example, there are now a multitude of implants available for surgeons to choose from. Preoperative preparation enables the surgeon to select the optimal implant for a given patient and become familiar with its use, and to be sure that all necessary equipment is available for the procedure. Being well prepared includes having backup plans to handle any contingencies that might arise.

PERIOPERATIVE MEDICAL MANAGEMENT

Over the course of an orthopaedist's career, some complications are inevitable and nonpreventable (37). Careful perioperative management can help minimize their occurrence, thus increasing the patient's chances for a successful outcome. It can also provide a solid medical-legal defense should any serious complication arise.

For both elective and emergent procedures, medical consultation may be necessary to manage chronic medical conditions that may be exacerbated by surgery. Orthopaedists can anticipate treating a larger proportion of elderly patients, many of whom have multiple chronic medical problems and decreased functional reserves.

Findings from the patient's medical history dictate the need for further testing and consultation. Using a list (Table 5.1) can help ensure that all possible conditions are covered. Written questionnaires, some of which can be computer coded, are also available. If written forms are used to collect medical data, review them carefully with the patient to ensure that the history is accurate and complete. Make certain that the patient understands the terminology; for example, a patient who has had several “heart attacks” may answer no to questions about myocardial infarctions because he is unfamiliar with the term's medical terminology.
Preoperative laboratory tests serve to evaluate existing medical conditions, to screen for asymptomatic conditions, and to identify patients who are at increased risk of adverse postoperative outcomes (152). Performing standard testing (e.g., electrocardiogram, chest x-ray, blood chemistries) on all preoperative patients has been shown to be not only unnecessarily costly, but also of limited benefit in identifying patients with potential medical problems. Instead, current practice calls for individualized evaluation and presurgical testing based on each patient’s medical history, family history, age, and physical examination (Table 5.2) (72,90). Although the value of routine screening tests in predicting postoperative complications has also been shown to be extremely low (72), abnormalities in electrocardiograms, chest x-rays, and nutritional status have been shown to be associated with postoperative complications in a general surgical population (152). Velanovich found a strong association between postsurgical complications and the American Society of Anesthesiologists’ classification used to assess patients’ anesthetic risk (Table 5.3) (152).

**Table 5.3. The American Society of Anesthesiologists’ Clinical Classification System**

The American Society of Anesthesiologists’ Clinical Classification System is a grading system used to assess the anesthetic risk of surgical patients. The grading system ranges from I (low risk) to V (highest risk). The system is based on various medical conditions and patient characteristics. The grading system is used to guide the anesthesiologist in determining the appropriate level of care for the patient.

**CARDIAC DISEASE**

Cardiac disease, highly prevalent among many orthopaedic patient populations, has a significant impact on perioperative morbidity and mortality. Question patients specifically about chest pain and shortness of breath on moderate exertion, in addition to any history of myocardial infarction. Physical examination findings that may suggest congestive heart failure include jugular venous distention, rales, or an S3 gallop.

Goldman developed a multifactorial risk index to stratify patients into low, medium, and high risk for cardiac complications (52,53) (Table 5.4 and Table 5.5). Patients with unstable angina, severe aortic stenosis, or a 6-month history of myocardial infarction are at highest surgical risk. Medical evaluation of patients with cardiac disease may call for preoperative echocardiograms and stress tests, which usually require advance scheduling.

**Table 5.4. Calculation of Multifactorial Cardiac Risk Index**

The calculation of the multifactorial cardiac risk index involves assessing various patient characteristics and assigning a score to each. The final score is then used to determine the patient’s risk for cardiac complications.
insulin. Patients with type II adult onset diabetes are not at risk for ketoacidosis. They may be managed by either sliding-scale subcutaneous or continuous intravenous insulin and glucose while fasting. Provide intravenous fluids containing dextrose while they are fasting and either sliding-scale subcutaneous or continuous intravenous insulin.

Insulin-dependent patients with type I juvenile onset diabetes must be carefully monitored after surgery for development of ketoacidosis. Type I diabetics require both insulin dosage for blood sugars greater than 250 mg/dl. It may be necessary to hold long-acting oral hypoglycemics preoperatively to decrease the risk of hyperglycemia.

Patients who take oral hypoglycemics to control their diabetes are usually managed after surgery with fingerstick glucose levels every 6 hours and a sliding-scale insulin with close monitoring of the patient’s metabolic status, electrolyte balance, and blood pressure of these patients, and avoid using potentially hepatotoxic medications. Disturbances in hepatic function may lead to increased risk for perioperative complications.

Consider preoperative evaluation of the coagulation system in patients with liver disease, since they may also have impaired hemostasis. Closely monitor the fluid status, electrolyte balance, and blood pressure of these patients, and avoid using potentially hepatotoxic medications. Disturbances in hepatic function may lead to prolonged action of anesthetic agents that are metabolized in the liver. Sedatives, narcotic analgesics, and intravenous induction agents should be used with caution, as they may cause a prolonged depression of consciousness and precipitate hepatic encephalopathy if used in standard doses. Resistance to curare-like neuromuscular blocking agents may require large dosages for effectiveness, leading to problems with anesthetic reversal after surgery.

RENAL DISEASE

Patients with chronic renal insufficiency and end-stage renal disease are at increased risk for perioperative complications (75). Volume status, blood pressure, and electrolyte abnormalities must be carefully managed. These patients are at risk for developing hyperkalemia leading to cardiac arrhythmias. Patients with end-stage renal disease may have uremic platelet dysfunction leading to increased thrombosis and a higher risk of infection. Dosages of medications excreted by the kidneys need to be adjusted in these patients. Avoid the use of nephrotoxic medications, which might cause further renal damage.

Acute renal failure may occur in any patient who becomes severely volume depleted and hypotensive. The postsurgical risk is particularly great in patients with limited reserve, such as the elderly and those with diabetes, congestive heart failure, or preexisting renal disease. Rhabdomyolysis leading to acute renal failure is a risk in trauma patients who sustain a significant crush injury or extremity ischemia. Laboratory findings include myoglobin in the urine and elevated skeletal muscle creatine kinase. Treatment includes alkalization of the urine with sodium bicarbonate, intravenous furosemide (Lasix), and intravenous mannitol. Carefully monitor electrolytes because these patients may become hyperkalemic.

Patients with chronic renal insufficiency and end-stage renal disease are at increased risk for perioperative complications (75). Volume status, blood pressure, and electrolyte abnormalities must be carefully managed. These patients are at risk for developing hyperkalemia leading to cardiac arrhythmias. Patients with end-stage renal disease may have uremic platelet dysfunction leading to increased thrombosis and a higher risk of infection. Dosages of medications excreted by the kidneys need to be adjusted in these patients. Avoid the use of nephrotoxic medications, which might cause further renal damage.

Acute renal failure may occur in any patient who becomes severely volume depleted and hypotensive. The postsurgical risk is particularly great in patients with limited reserve, such as the elderly and those with diabetes, congestive heart failure, or preexisting renal disease. Rhabdomyolysis leading to acute renal failure is a risk in trauma patients who sustain a significant crush injury or extremity ischemia. Laboratory findings include myoglobin in the urine and elevated skeletal muscle creatine kinase. Treatment includes alkalization of the urine with sodium bicarbonate, intravenous furosemide (Lasix), and intravenous mannitol. Carefully monitor electrolytes because these patients may become hyperkalemic.

LIVER DISEASE

The risk of perioperative complications and death in patients with liver disease increases with the severity of their disease. Patients who have evidence of hepatic decompensation (hyperbilirubinemia, coagulopathy, ascites, encephalopathy) are at the greatest risk. In patients with cirrhosis, the risk correlates with Child's classification. Elective surgery is contraindicated in patients with decompensated cirrhosis (Child's class C), acute alcoholic hepatitis, and acute viral hepatitis. Patients with chronic hepatitis without evidence of cirrhosis or hepatic decompensation generally do not have an increased complication risk (42).

Consider preoperative evaluation of the coagulation system in patients with liver disease, since they may also have impaired hemostasis. Closely monitor the fluid status, electrolyte balance, and blood pressure of these patients, and avoid using potentially hepatotoxic medications. Disturbances in hepatic function may lead to prolonged action of anesthetic agents that are metabolized in the liver. Sedatives, narcotic analgesics, and intravenous induction agents should be used with caution, as they may cause a prolonged depression of consciousness and precipitate hepatic encephalopathy if used in standard doses. Resistance to curare-like neuromuscular blocking agents may require large dosages for effectiveness, leading to problems with anesthetic reversal after surgery.

DIABETES MELLITUS

Patients with diabetes mellitus often have coexisting cardiac, renal, and neurologic disease (45). A patient may have severe cardiac disease with a history of silent myocardial infarctions without being aware of it. Patients with diabetes mellitus also have increased risk for postoperative infections and problems with wound healing. Most experts recommend that surgery be done on diabetic patients early in the day to simplify insulin administration and glucose monitoring (64).

Patients who take oral hypoglycemics to control their diabetes are usually managed after surgery with fingerstick glucose levels every 6 hours and a sliding-scale insulin dosage for blood sugars greater than 250 mg/dl. It may be necessary to hold long-acting oral hypoglycemics preoperatively to decrease the risk of hypoglycemia.

Insulin-dependent patients with type I juvenile onset diabetes must be carefully monitored after surgery for development of ketoacidosis. Type I diabetics require both insulin and glucose while fasting. Provide intravenous fluids containing dextrose while they are fasting and either sliding-scale subcutaneous or continuous intravenous insulin. Patients with type II adult onset diabetes are not at risk for ketoacidosis. They may be managed by either sliding-scale subcutaneous or continuous intravenous

Alcohol

surgery, to minimize nicotine's adverse effects on wound healing (80).

Recent studies have also demonstrated the deleterious effect of smoking on bone healing (80).

Smoking adversely affects pulmonary function. Cessation of smoking before surgery may improve a patient's pulmonary function.

NUTRITION

Protein and calorie malnutrition has a significant effect on the healing of wounds and fractures, as well as on immunocompetence (138). Protein-calorie malnutrition is associated with depression of multiple aspects of the immune system response, including decreases in polymorphonuclear leukocytes and bactericidal activity, circulating opsonins, complement levels, cell-mediated immunity, lymphocyte blastogenic responses to mitogen, number of T lymphocytes, function of T-helper cells, new antibody synthesis, and secretory IgA levels (1).

Many severely malnourished patients require emergent surgical intervention; they will likely benefit from increased postoperative nutritional support. Trauma and elective surgery both markedly increase a malnourished individual's nutritional needs.

EFFECTS OF SUBSTANCE ABUSE

Tobacco

Smoking adversely affects pulmonary function. Cessation of smoking before surgery may improve a patient's pulmonary function.

Recent studies have also demonstrated the deleterious effect of smoking on bone healing (80, 120). In addition, nicotine is suspected of increasing the risk of postoperative wound infections. Studies have recommended that tobacco use be discontinued from a half day to a week prior to surgery, and for at least a week after surgery, to minimize nicotine's adverse effects on wound healing (80).

Alcohol

A large percentage of traumatic injuries occur as a result of alcohol abuse, and the problem extends to patients in all communities. While it may be easy to identify the inebriated trauma patient, it may be far more difficult to identify alcohol abuse in a businessperson seeking a routine total joint arthroplasty. Approximately 10% of chronic alcoholics who abruptly discontinue drinking may develop significant alcohol withdrawal, possibly associated with a hyperkinetic state, hallucinations, and seizures. Consider treating all patients with suspected alcohol abuse with benzodiazepines, thiamine, and multivitamins. Advanced liver disease in chronic alcoholics may lead to bleeding disorders. Obtain a prothrombin time to screen for coagulation disorders, a platelet count to rule out thrombocytopenia, and a bleeding time to rule out instability, which could result in neurologic injury during intubation or operative positioning.

HUMAN IMMUNODEFICIENCY VIRUS

Advances in the medical management of human immunodeficiency virus (HIV) have extended the length of time before infected patients advance to acquired immunodeficiency syndrome (AIDS). It is expected that an increasing number of asymptomatic HIV-positive patients will require orthopaedic surgical procedures. Issues concerning the risk of transmission to the surgeon are addressed later in this chapter (see the section on Surgeon's Safety).

In the late 1980s and early 1990s, some surgeons expressed concern that the suppressive effect of anesthesia and surgical trauma on cellular immunity could be detrimental to the immunologic competence of patients with HIV infection. Initial concerns about potential disease progression as a result of surgery were based mainly on emotional preconceptions and anecdotal misconceptions (129). A more substantial concern has been the potential for an increased postoperative infection rate in HIV-positive patients. In general, the risk of postoperative infection in patients with HIV who have not advanced to AIDS is not higher than that in the general population (88). The risk of surgical complications increases with the progression of disease. Factors reported to have the greatest correlation with outcome risk are a history of opportunistic infection, a CD4 level less than 200, a serum albumin less than 25 g/l, and cutaneous anergy (89). In a review of orthopaedic surgery in the HIV-positive patient, Luck (88) provides a surgical-risk rating system (Table 5.7). Attempts to correlate surgical outcome with CD4 lymphocyte counts alone has provided conflicting results; it is now generally accepted that CD4 counts alone are not a predictor of poor surgical outcome.

Table 5.7. Surgical Risk-rating System for HIV-positive Patients

The rate of early postoperative infection and wound healing complications has been reported to be increased in patients with AIDS, but it is generally not increased in patients who are HIV positive without AIDS. In hemophilic patients, the incidence of late infection of prosthetic joints has been reported to be increased in patients who are also HIV positive, especially when their CD4 count is less than 200 (119, 148). The incidence of late prosthetic joint infections in patients with hemophilia was higher than in the general population prior to the HIV pandemic. The infection risk may be even higher in the HIV-positive hemophilic patient, but current studies have not shown a statistically significant increase. At this time, there are no data to show that this risk applies to the HIV-positive nonhemophilic patient with a prosthetic joint (88a).

Several interventions may improve the medical status of patients with advanced-stage AIDS who must undergo surgery. Patients who have an unacceptably low white blood cell count (absolute polymorphonuclear leukocyte count < 1,000) may be treated with granulocyte-stimulating factor. Measles, mumps, and rubella vaccine should be updated 2 weeks before surgery in patients who are anergic (88). Many of the medications used to suppress HIV and to provide prophylaxis against AIDS-related opportunistic infections suppress bone-marrow function (89). As a result, AIDS patients may have chronic anemia that may benefit from treatment with erythropoietin (62). Patients with thrombocytopenia (platelet count < 60,000) should receive a platelet transfusion immediately before surgery.

NUTRITION

Protein and calorie malnutrition has a significant effect on the healing of wounds and fractures, as well as on immunocompetence (138). Protein-calorie malnutrition is associated with depression of multiple aspects of the immune system response, including decreases in polymorphonuclear leukocytes and bactericidal activity, circulating opsonins, complement levels, cell-mediated immunity, lymphocyte blastogenic responses to mitogen, number of T lymphocytes, function of T-helper cells, new antibody synthesis, and secretory IgA levels (1).

Many severely malnourished patients require emergent surgical intervention; they will likely benefit from increased postoperative nutritional support. Trauma and elective surgery both markedly increase a malnourished individual's nutritional needs.

EFFECTS OF SUBSTANCE ABUSE

Tobacco

Smoking adversely affects pulmonary function. Cessation of smoking before surgery may improve a patient's pulmonary function.

Recent studies have also demonstrated the deleterious effect of smoking on bone healing (80, 120). In addition, nicotine is suspected of increasing the risk of postoperative wound infections. Studies have recommended that tobacco use be discontinued from a half day to a week prior to surgery, and for at least a week after surgery, to minimize nicotine's adverse effects on wound healing (80).

Alcohol

A large percentage of traumatic injuries occur as a result of alcohol abuse, and the problem extends to patients in all communities. While it may be easy to identify the inebriated trauma patient, it may be far more difficult to identify alcohol abuse in a businessperson seeking a routine total joint arthroplasty. Approximately 10% of chronic alcoholics who abruptly discontinue drinking may develop significant alcohol withdrawal, possibly associated with a hyperkinetic state, hallucinations, and seizures. Consider treating all patients with suspected alcohol abuse with benzodiazepines, thiamine, and multivitamins. Advanced liver disease in chronic alcoholics may lead to bleeding disorders. Obtain a prothrombin time to screen for coagulation disorders, a platelet count to rule out thrombocytopenia, and a bleeding time to rule
out platelet dysfunction.

OTHER DRUGS
Cocaine abuse has become increasingly prevalent. Withdrawal from cocaine is not medically dangerous; the half-life of cocaine is approximately 90 min, allowing most surgery to be delayed until after the period of acute intoxication. Cocaine abuse has been associated with several cardiac complications, and chronic abuse may accelerate coronary atherosclerosis, interstitial myocardial fibrosis, and congestive heart failure. Chronic abuse may also lead to recurrent pneumonia, pulmonary barotrauma, diffuse alveolar hemorrhage, and asthma (140).

Opioid dependence may result from both prescribed and illicit drug use. Patients with chronic preoperative pain may have developed dependence on opioids, a class of drugs that includes heroin, morphine, codeine, oxycodone, and meperidine. Withdrawal symptoms may develop as the patient's postoperative analgesia is reduced. To make the diagnosis of opioid dependence, the physician must observe at least three signs and symptoms of opioid withdrawal (Table 5.8). Treatment of opioid withdrawal may require methadone, a long-acting opioid, from which the patient may be weaned in an outpatient drug dependency program. Clonidine 0.1–0.3 mg may also be helpful in reducing the signs of opioid withdrawal, especially in patients with hypertension (140).

Table 5.8. Signs and Symptoms in Opioid Withdrawal

The abuse of benzodiazepines (lorazepam, alprazolam, oxazepam, diazepam, and chlordiazepoxide) is extremely common and may lead to physiologic dependence and withdrawal. Signs and symptoms of withdrawal may include lethargy, ataxia, irritability, dysphoria, fatigue, tremor, and, rarely, seizure. Place patients who develop withdrawal symptoms on a longer-acting benzodiazepine (diazepam, chlordiazepoxide), which can be slowly tapered over 6–12 weeks. Propranolol, 20 mg every 6 hours, can be used for the treatment of hypertension, tachycardia, and anxiety that may occur during benzodiazepine withdrawal (140).

BLOOD TRANSFUSIONS
The use of blood transfusions in orthopaedic surgery has become the focus of intense interest largely in response to concerns about posttransfusion disease and its consequences. Transfusion of donated blood can be minimized through the use of predonation autologous blood and through perioperative blood salvage (8). The Joint Committee on Hospital Accreditation now requires an audit of the appropriateness of all transfusions as part of its hospital accreditation process. Failure to obtain informed consent and inappropriate or unnecessary transfusion have even become the focus for plaintiff's attorneys in cases of posttransfusion AIDS. The patient's physician, not the blood bank, has been the target of litigation in these cases (96).

Orthopaedic surgeons are frequently confronted with emergency or elective cases involving large amounts of blood loss. As the physicians responsible for prescribing transfusions, they must therefore be thoroughly familiar with the indications for specific blood components as well as the dangers of blood product transfusion.

Blood component therapy (using the individual components of fractionated whole blood) is based on the concept that patients are best treated by administration of only the specific blood product they require. The use of pooled blood products from multiple donors has been reduced to minimize the risk of disease transmission.

PACKED RED BLOOD CELLS
Packed red blood cells (PRBC) are prepared by removing most of the plasma from a donor unit of whole blood. A unit of PRBC contains the same amount of hemoglobin as a unit of whole blood, but its hematocrit, depending on the preservative solution, is at least doubled (to 70%). Transfusion of PRBC rather than whole blood allows the recipient to receive the equivalent number of red cells without unnecessary expansion of the plasma volume. The use of PRBC allows blood banks to use supernatant cells and plasma to prepare other components. Neither whole blood nor PRBC is sterilized, so any plasma-or cell-associated organisms not detected by donor screening may be transmitted to the recipient by transfusion of these products.

Transfusion with PRBC is indicated when tissue oxygen delivery, particularly delivery to vital organs, is inadequate. A threshold for transfusion based on a given hemoglobin level cannot be set, since oxygen delivery depends on several factors, including hemoglobin level, inspired oxygen concentration, cardiac output, and pulmonary gas exchange. Increased cardiac output in a young, healthy patient may easily compensate for a low hemoglobin level, but an older patient with cardiac disease or one who is taking beta-blocker medication may be unable to increase cardiac output and will require transfusion.

Factors to consider when deciding whether a patient requires a PRBC transfusion include the patient's physiologic state, underlying medical condition, ability to compensate for diminished oxygen-carrying capacity, oxygen requirements of vital organs, and ongoing and anticipated blood loss (5).

PLASMA AND ITS DERIVATIVES
A single unit of frozen plasma (FFP) contains the plasma separated from one unit of whole blood obtained from a single donor. It contains normal plasma levels of labile (factors V and VIII) and stable clotting factors, albumin, and gamma globulin. ABO compatibility testing is mandatory for all recipients, and Rh compatibility testing by donor screening may be transmitted to the recipient by transfusion of these products. Neither whole blood nor PRBC is sterilized, so any plasma-or cell-associated organisms not detected by donor screening may be transmitted to the recipient by transfusion of these products.

In 1998, the U.S. Food and Drug Administration licensed solvent/detergent plasma. This component is prepared from pools of 2,500 donor units, and it is treated with a solvent, N-butyl) phosphate, and a detergent, Triton X-100, to inactivate lipid-enveloped viruses, including hepatitis B, hepatitis C, and HIV. Its drawbacks relate to the pooling process, which increases patient exposure to non-lipid-enveloped viruses such as hepatitis A and parvovirus B19. Solvent/detergent plasma is indicated for the rapid reversal of warfarin anticoagulation and therapeutic plasma exchange for microangiopathic hemolytic anemia. Its approximate volume is 200 cc and it must be used within 24 hours of thawing.

Cryoprecipitate is prepared by collecting the precipitate that forms during slow thawing of FFP at refrigerator temperature. It contains fibrinogen, fibronectin, and factor VIII. One unit of cryoprecipitate contains approximately 10 ml of plasma and an average of 200 mg of fibrinogen, or 80–120 units of factor VIII activity. Cryoprecipitate is especially useful as a source of fibrinogen in consumptive coagulopathies. It is also indicated for the treatment of patients with hypofibrinogenemia and those with mild hemophilia A. Patients with severe classic hemophilia are treated with factor VIII concentrate.

PLATELETS
In view of the changing availability of stored coagulation products, one unit of cryoprecipitate contains approximately 10 ml of plasma and an average of 200 mg of fibrinogen, or 80–120 units of factor VIII activity. Cryoprecipitate is especially useful as a source of fibrinogen in consumptive coagulopathies. It is also indicated for the treatment of patients with hypofibrinogenemia and those with mild hemophilia A. Patients with severe classic hemophilia are treated with factor VIII concentrate.
Delayed hemolytic transfusion reactions may occur more often than acute reactions and may frequently be missed. In one series, one third of the patients with delayed previous sensitizing event, but that is no longer detectable in pretransfusion testing. The patient usually manifests only anemia, or no increase in hemoglobin in transfused erythrocytes, followed by hemolysis within 1 to 7 days (Delayed hemolytic transfusion reactions are less dramatic events than acute hemolytic transfusion reactions. A delayed reaction is characterized by initial survival of an adequate renal blood flow. If there is no diuresis, indicating renal failure, cease attempts at hydration. Intravenous furosemide may be necessary to maintain potassium levels may be necessary in patients with overt hemolysis. If hyperkalemia due to hemolysis is suspected, an electrocardiogram will confirm the diagnosis and obtaining serum bilirubin and urinary urobilinogen. Hemoglobin concentration, platelet count, partial thromboplastin time, serum fibrinogen level, and serum the blood bank. Verify that the identity of the unit and the requisition correspond to the patient, confirming that the patient has received the intended unit of blood.

COMPLICATIONS OF BLOOD TRANSFUSION

Although significant strides have been made to ensure a safe blood supply, the recognition of new transfusion-related complications, and the inability to totally eradicate previously recognized complications, reaffirms the admonition that blood should be transfused only when absolutely necessary (11). Most of the complications associated with transfusion of blood and blood products are related to an immune response to incompatible units, to an adverse physiologic response to transfusion, or to infectious disease transmission (Table 5.9). Safe transfusion practice requires strict policies with meticulous guidelines for patient identification, blood collection and labeling, pretransfusion testing, and transfusion administration and monitoring. These policies are necessary to decrease the risk of human error; a fatal transfusion reaction can occur from administration of an improperly labeled specimen, confusion of specimens in the laboratory, or transfusion of blood to the wrong patient.

Nonhemolytic Transfusion Reactions

The most frequent adverse reactions associated with blood transfusions are nonhemolytic transfusion reactions, which occur in as many as 2% to 5% of all transfusions (11). Although they may cause discomfort to the transfusion recipient, these reactions are usually not serious. Febrile reactions, the most common of these complications, most often result from the recipient's antibody response to leukocyte antigens in the donor blood. Chills, fever, headache, myalgia, nausea, and, occasionally, severe rips may occur during the transfusion or up to several hours after it has been completed. Treatment of febrile reactions is supportive and rarely requires cessation of the transfusion. Approximately 15% of patients who have such a reaction will react similarly with future transfusions. Leukocyte-removal filters diminish the likelihood of febrile reactions, but use of such filters is expensive and retards blood flow. For these reasons, they should be reserved for those patients who have had at least two adverse reactions.

Allergic transfusion reactions are mild, consisting only of slight urticaria. Like febrile reactions, they usually occur toward the end of the transfusion of erythrocytes. Allergic transfusion reactions, thought to be related to the presence of foreign protein in the transfused blood, can cause urticaria associated with itching, shaking chills, fever, and erythema. The more serious findings of laryngeal edema and bronchospasm (anaphylaxis) fortunately are much less frequent, occurring in less than 1% of such reactions (52). For most patients, treatment is supportive and the reaction may be anticipated to subside spontaneously within several hours of the transfusion. The risk of an allergic response is increased for individuals with hay fever, atopy, or asthma. These patients may benefit from pretreatment with diphenhydramine HCl or possibly with hydrocortisone. Patients who have previously had multiple severe allergic reactions to transfusions are at high risk of developing these reactions. These reactions may be ameliorated by using washed components.

Hemolytic Transfusion Reactions—Acute and Delayed

Hemolytic transfusion reactions are uncommon, but the high morbidity and mortality rates associated with them mandates a thorough knowledge of their manifestations and treatment. Estimates of the risk of hemolytic transfusion reactions range from 1:4,000 to 1:25,000 (83,100,115). Of the fatal reactions, nearly half have arisen from administrative and clerical errors, including mislabeled samples and incorrect patient identification. Hemolytic transfusion reactions occur with small quantities of transfused erythrocytes, usually less than 50 cc (10). The classic signs and symptoms include chills, fever, chest pain, and flank pain. Less commonly, patients experience nausea, hemoglobinuria, shock, and a subjective sensation of impending death.

General anesthesia masks many of the classic signs and symptoms. In that situation, the patient's only manifestation may be the oozing that occurs because of the consumption of clotting factors. The consequences of hemolytic transfusion reactions are serious and may be fatal, arising mainly from the effects of intravascular hemolysis on the renal and coagulation systems. Immediately stop the transfusion and return the unused blood and a sample of the patient's own blood to the blood bank for recrossmatching.

Of greatest importance is immediate determination of the presence of hemoglobinemia. Visually compare the postreaction serum with the pretransfusion specimen in the blood bank. Verify that the identity of the unit and the requisition correspond to the patient, confirming that the patient has received the intended unit of blood. Perform a direct antiglobulin test on the patient's red cells. Other tests indicated when hemolytic reaction is strongly suspected include retyping the transfused blood, and obtaining serum bilirubin and urinary urobilinogen. Hemoglobin concentration, platelet count, partial thromboplastin time, serum fibrinogen level, and serum potassium levels may be necessary in patients with overt hemolysis. If hyperkalemia due to hemolysis is suspected, an electrocardiogram will confirm the diagnosis before the clinical laboratory determination.

Management of the patient with an immediate acute hemolytic reaction initially involves hydration with generous administration of fluids and diuretics. Monitor urinary output with an indwelling catheter and maintain output at 75–100 ml/hour. Use intravenous fluids and pressors, if necessary, to prevent hypotension, thereby ensuring an adequate renal blood flow. If there is no diuresis, indicating renal failure, cease attempts at hydration. Intravenous furosemide may be necessary to maintain adequate renal perfusion. Contact consulting services immediately; consider transferring the patient to an intensive care unit.

Delayed hemolytic transfusion reactions are less dramatic events than acute hemolytic transfusion reactions. A delayed reaction is characterized by initial survival of transfused erythrocytes, followed by hemolysis within 1 to 7 days (116,159). The reaction results from an anamnestic response of an antibody that was formed after a previous sensitizing event, but that is no longer detectable in pretransfusion testing. The patient usually manifests only anemia, or no increase in hemoglobin in response to the transfusion, but he may also have chills, fever, and jaundice. Renal failure is extremely rare.

Delayed hemolytic transfusion reactions may occur more often than acute reactions and may frequently be missed. In one series, one third of the patients with delayed
hemolytic transfusion reactions were asymptomatic and were diagnosed only when a second transfusion was ordered (100). If you are considering returning to surgery a postoperative patient in whom there is continued occult blood loss from a traumatic or surgical source, first rule out delayed hemolytic transfusion reaction as a possibility. Unnecessary surgery can be avoided if the diagnosis of delayed hemolytic transfusion reaction is made.

Complications of Massive Transfusion

Significant problems may arise when large amounts of blood are transfused. The term massive transfusion refers to transfusion of more than 10 units of blood in a 24-hour period. Hemostatic defects, hypothermia, and metabolic abnormalities have been reported in association with the transfusion of such volumes of blood. Anticipating these problems and taking appropriate measures to treat or prevent their development can be life-saving.

Abnormal bleeding associated with massive transfusion may result from dilutional thrombocytopenia, disseminated intravascular coagulation, low levels of factors V and VIII, or the occurrence of a hemolytic transfusion reaction. Dilutional thrombocytopenia is the most common cause of a hemorrhagic diathesis in a patient who has received a massive transfusion, since the transfused stored blood lacks functional platelets. Patients who manifest acute thrombocytopenia develop a hemorrhagic diathesis at a much higher platelet count than do patients with chronic thrombocytopenia, and a platelet count of 100×10^9 or less is a reasonably accurate guide to predicting a bleeding problem from dilutional thrombocytopenia.

Other coagulation factor deficiencies that may occur with massive transfusions include deficiencies of factors V and VIII. These factors gradually decrease to 15% and 50% of normal, respectively, after 21 days of storage (27), and they are therefore in lower concentrations in stored blood than in fresh blood or plasma. Hemostasis is unaffected even though levels of factors V and VIII are reduced to as low as 10%–20% of normal; therefore, their deficit is an unlikely primary cause of bleeding during massive blood transfusion. Nevertheless, these deficiencies may intensify bleeding from other causes (59). Disseminated intravascular coagulation is fairly uncommon and is associated with a high rate of mortality. Discussion of this entity is beyond the scope of this chapter.

The possibility of a hemolytic transfusion reaction must be considered when a hemorrhagic diathesis develops following blood transfusion. A massive transfusion may demand such speed in blood processing that the risk of human error increases significantly.

Rapid infusion of large volumes of unwarmed blood, which has been stored at 4°C, can cause rapid lowering of the core body temperature by as much as 10–15°C. Hypothermia causes shivering, which increases oxygen consumption dramatically and may increase ventilatory irritability and even induce cardiac arrest if the hypothermia is profound. Blood may be warmed toward body temperature, but it should not be warmed above 37°C. Warming must be done with a special device that warms the blood during its passage through the transfusion set. The warming system must be equipped with a visible thermometer and, ideally, with a warming system to prevent overheating. Blood will hemolyze if heated above 45°C.

A number of metabolic abnormalities, such as acidosis, hyperkalemia, and reduction in the level of ionized calcium, have also been associated with the transfusion of massive volumes of stored blood. Monitor patients closely for these problems and try to prevent them by appropriate treatment.

Effect of Allogenic Transfusions on the Immune System

Several studies have highlighted the potential adverse effects on the immune system of large homologous blood transfusions. The concern is an increased risk of postoperative infections following allogeneic blood transfusions (56,62,73,101). Other investigators have questioned how large an effect, if any, allogeneic blood transfusions have on the postoperative infection rate (151).

Concerns have also been raised about the potential of blood transfusions to impair the immunosuppressive response, decreasing the patient’s ability to combat cancer recurrence or metastatic disease. In one study of 155 patients with nonmetastatic osteosarcoma treated with amputation and adjuvant chemotherapy, perioperative blood transfusion was associated with a significant decrease in disease-free state and overall decreased survival (27).

TRANSFUSION-TRANSMITTED DISEASE

The potential for disease transmission has been substantially reduced through donor education, medical and social history review, exclusion of anonymous donors, and improved serologic screening methods. Despite these improvements, risk of disease transmission remains a concern with any blood transfusion. The greatest threat to the safety of the blood supply is blood donation by sorogeneive donors who are infectious but who have not yet undergone seroconversion (143).

Although new techniques of testing, such as direct viral detection tests, will improve the safety of the blood supply, it remains unlikely that any test or combination of tests will ever decrease the risk for disease transmission to zero (151).

Hepatitis B Virus

Screening blood donors for hepatitis B virus (HBV) surface antigen (HBsAg) has greatly reduced the incidence of transfusion-related hepatitis B. Infection risk is estimated to range from 1 in 200,000 transfusions to 1 in 800,000 (63). Ten percent of patients infected with HBV develop chronic hepatitis, and less than 1% develop fulminant hepatitis. Acute HBV infection is self-limited in approximately 90% of cases.

Hepatitis C Virus

Hepatitis C (known previously as non-A, non-B hepatitis) is a serious health threat. It is estimated that as many as 4 million Americans (1.5% of the population) are infected with HCV. While acute HBV infection is self-limited in 90% to 95% of cases, 85% of patients with acute hepatitis C develop chronic infection (58). Chronic HCV infection can lead to cirrhosis, liver failure, and hepatocellular carcinoma. In the United States, HCV accounts for approximately 20% of cases of acute hepatitis, 70% of chronic hepatitis, and 30% of end-stage liver disease (69). HCV infection is the disease that most often necessitates liver transplantation. Approximately 10,000 people die each year from HCV infection, and the number is expected to triple in the next 10–20 years.

The natural history of HCV infection has not been fully characterized. The clinical course of HCV infection is variable, with fewer than 20% of patients developing symptoms of infection. Since most infections are asymptomatic, patients do not know that they are infected. Chronic HCV infection is typically a very slow process in which symptoms may not be noted for decades after infection. One investigator estimates that cirrhosis occurs in at least 20% of patients within 20 years of infection (103). The risk of hepatocellular carcinoma increases after the development of cirrhosis, with a reported 5-year risk of 7% and a 10-year risk of 14% (39).

Although viewed as less threatening by patients, transmission of HBV and HCV has occurred far more often than transmission of HIV. Patients who received blood transfusions prior to the introduction of screening tests for HCV in 1990 are at risk for having contracted chronic HCV infection. Widespread testing and educational efforts have been directed to identify this group of patients who are at risk. Patients who received blood transfusions prior to July 1992, when more sensitive screening tests were introduced, should be tested for exposure to hepatitis C virus. A nationwide “targeted look-back” has begun in the United States, in an attempt to find patients who received blood from donors who subsequently tested positive for hepatitis C. The risk of HCV infection prior to implementation of anti-HCV testing in mid 1990 was conservatively estimated at 1% per unit of transfused blood. These estimates predict that during that time, 40,000 people acquired HCV infection yearly from blood transfusions (3). With the current screening methods, the risk of HCV transmission is about 0.001% per unit of blood transfused (58).

Human Immunodeficiency Virus

Before HIV antibody screening of blood began in 1985, the risk of receiving a seropositive unit of a blood component was approximately 0.04% (2). By November 1995, the number of cases of transfusion-associated cases of AIDS diagnosed and reported in the United States was 7,700 (24). Many previously asymptomatic patients continue to be diagnosed each year from transfusions administered prior to 1986.

After the introduction of HIV antibody screening, however, the number of transfusion-associated AIDS cases that have occurred from screened transfusions fell to less than 20 cases per year from 1988 to 1991 (152). Concern over potential transmission of the HIV virus has resulted in new laws requiring consent for blood transfusion, alteration in transfusion protocols, and use of protective techniques to avoid homologous blood transfusion.

Several mechanisms to minimize the risk of transfusion-transmitted AIDS are in place. Elimination of the “high-risk” blood donor through questioning or through exclusion has proven partially effective. A result of the prevalence of HIV-positive donors was reduced by nearly two thirds from 1985 to 1987 (113). A second and more effective additive mechanism was the implementation of anti-HIV testing (153). Used for screening since 1985, this test is more than 99% sensitive. All positive results detected by repeated enzyme immunoassay must be confirmed by western blot testing. Since the advent of screening methods, the risk of transfusion-transmitted HIV infection has been estimated to be 1 in 493,000 (95% confidence interval, 202,000 to 2,778,000) (131)—about one-fifth the risk of HIV
transmission by blood transfusion.

Because of the time period that exists between the onset of the infection and the development of detectable antibodies, there remains a small risk of HIV transmission from screened blood donors. Reinfecions in the screening assays have narrowed this period to approximately 22 days (131). The polymerase chain reaction technique can be used to identify viral nucleic DNA or RNA before an antibody response develops and may further reduce the risk of disease transmission (154). The advent of AIDS greatly increased interest in directed donation programs, in the use of autologous blood, and in avoidance of blood transfusion unless specifically indicated. Patients who have undergone transfusion-associated hemophilia are far less likely to have developed transfusion-associated AIDS than any other patient group in a typical orthopaedic surgery practice. Previously, factor VIII and factor IX concentrate used in the treatment of hemophilia was derived in commercial lots from 10,000 to 30,000 donors, resulting in an extremely high risk of disease transmission. The risk of new HIV infection in these patients is directly related to the volume of clotting factor and blood component used, and it has decreased markedly since the introduction of heat-treated concentrates prepared from plasma screened for HIV antibody. Development of factor VIII concentrate derived from recombinant techniques has significantly reduced the risk of transfusion-associated AIDS in this patient population.

Other Transmissible Infectious Agents

Transmission of another human retrovirus, HTLV-I, has also been reported as a result of blood transfusion. HTLV-I infection has been associated with adult T + cell leukemia and HTLV-I–associated myelopathy (HAM), also termed tropical spastic paraparesis (127). The incubation period between infection and manifestations of these diseases can be extremely long. This retrovirus is most common on the island of Kyushu, Japan, and in parts of the Caribbean basin. Only a small percentage of the population in the United States is believed to be HTLV-I seropositive (approximately 0.025% of donors tested). Nevertheless, blood-donor screening for antibody to HTLV-I was initiated in 1989 due to these disease associations (25). Seroconversion for antibody to HTLV-I is reported to have occurred in one patient, who developed an isolated myopathy following multiple trauma and subsequent transfusion with many units of banked blood products. The report of this seroconversion underscores the potential value of screening blood donors for antibody to this virus (39).

Cytomegalovirus (CMV) may be the most common viral agent transmitted via blood transfusion, although it is likely that many of the cases of posttransfusion CMV infection are due to reactivation of existing infection—possibly because of immunosuppression in the patient—rather than to primary infection (156). The prevalence of CMV infection, endemic in the United States, increases with age, so that as many as 70% of blood donors over age 60 are infected by CMV. Posttransfusion CMV infection is not known to be a significant clinical problem in the immunocompetent transfusion recipient, and blood is not routinely tested for this agent. Current indications for blood products that are from donors with a negative test for IgG anti-CMV include AIDS patients who are CMV-seronegative, CMV-negative bone marrow transplantation recipients, and solid-organ transplant recipients who receive organs from CMV-seronegative donors (146). Since CMV is carried in the transplanted organ, leukocyte-removal filters can be used to further reduce the risk of transfusion-transmitted CMV to these patients. Concern also exists over the possible transmission of priorn, which cause spongiform encephalopathies such as variant Creutzfeldt-Jakob disease, in which there is rapidly progressive dementia and motor dysfunction (23). In March 1987, the World Health Organization concluded that there has been no proven or even probable transmission of Creutzfeldt-Jakob disease through blood products (13).

Although, theoretically, a large number of other infectious diseases could be transmitted by blood transfusion, few pose clinical problems. Blood donor testing and the use of screening to exclude donors who have been exposed to malaria, syphilis, toxoplasmosis, yersiniosis, salmonellosis, typhus, trypanosomiasis, herpesvirus infections, brucellosis, Colorado tick fever, leishmaniasis, Epstein-Barr virus, and filariasis minimize the potential risk of transmission of such diseases through donated blood.

METHODS TO MINIMIZE USE OF HOMOLOGOUS BLOOD TRANSFUSIONS

The risk of infection and death associated with blood transfusion cannot be completely eliminated, even with the best screening methods. The goal of reducing the risks associated with transfusions, therefore, is directly related to reducing the number of transfusions required by surgical patients. The methods available for minimizing blood transfusions include meticulous hemostasis in the operative field, hypotensive anesthesia, hemodilution, use of prebanked autologous blood, intraoperative and postoperative blood salvage, and acceptance of a lower hematocrit "transfusion trigger." Concern about transmission of human immunodeficiency virus has heightened interest in these methods for orthopaedic surgeons and their patients and has made blood conservation an important part of every surgeon’s practice.

Minimizing Intraoperative Blood Loss

Intraoperative blood loss can be minimized by both the surgeon and the anesthesiologist. The most effective way to reduce the need for blood transfusion is to control the amount of blood lost during surgery. Methods under the surgeon's control include careful operative exposure through avascular tissue planes; good hemostasis using an electrocautery and ligatures; short operating time, and the judicious use of collagen pads, thrombin powder, sterile bone wax, and tourniquets (13).

Hypotensive Anesthesia

Multiple studies have shown that using hypotensive anesthesia can effectively reduce intraoperative blood loss in orthopaedic surgical patients, particularly during spine surgery and total hip arthroplasty surgery (91,109). A series of 24 Jehovah's Witness patients had a 30% reduction in intraoperative blood loss with the use of hypotensive anesthesia, compared with the blood loss for the previous arthroplasty on their contralateral hip under normotensive anesthesia (105). Nelson et al. recommend the combined use of narcotic and inhalant anesthetics to achieve the goal of a stable hypotensive level throughout the surgical procedure. They further recommend that the patient be kept warm to reduce endogenous release of blood vessels at the surgical site, adhering closely to the use of local measures to minimize blood loss (107). These recommendations deserve close attention.

Hemodilution

Another technique that has been shown to decrease the need for blood collected preoperatively is transfused after the major blood loss has ceased, or before it is necessary because of hypoxemia, hypotension, or tachycardia. The hemodilution technique has been recommended for any elective surgery procedure in which a 1,000 cc blood loss is anticipated (108).

Autologous Blood Donation

Procuring predonated autologous blood is a safe and simple procedure (15,149,161). After a patient is determined to be medically eligible for autologous transfusion and informed consent has been obtained, blood is collected and stored. During the donation period, place patients on oral iron supplementation. The rate of donation of the patient to reduce endogenous release of blood vessels at the surgical site, adhering closely to the use of local measures to minimize blood loss (107). These recommendations deserve close attention.

Intraoperative Blood Salvage and Reinfusion

Intraoperative blood salvage was initially associated with serious risks, including disseminated intravascular coagulation, fatal air embolism, hemoglobinemia, and hemolytic nephrotoxicity (16,78). Recent improvements in the design of the autotransfusing device have eliminated many of the problems that had been associated with intraoperative autologous transfusion. Intraoperatively, lost blood is suctioned into an enclosed system in which the blood cells are separated from the debris and serum through a centrifugation process. The autologous red cells are washed, suspended in a saline solution, and then reinfused. As much as 50%–60% of the shed red blood cells may be salvaged by this technique. Mean transfusion requirements are significantly less when intraoperative autologous transfusion is used than when it is not used, and the combined use of preoperatively deposited and intraoperatively collected autologous blood can often eliminate the need for homologous transfusion (67). The technique has been shown to be effective in orthopaedic patients undergoing spine surgery, revision total joint arthroplasty, and acubactar fracture surgery (131,157–159). Indications for its use include patients in whom the estimated intraoperative blood loss is expected to be more than 900–1,500 cc (44,150). Potential complications of this technique include
Postoperative Blood Salvage and Reinfusion

Postoperative salvage has also been shown to be safe and effective for both adults and children (9,17,43,61,73). Postoperative salvage consists of reinfusing unwashed, filtered salvaged blood from surgical drains during the early postoperative period (first 4–6 hours) when drainage is at its greatest. Unwashed shed blood is deficient in coagulation factors and platelets and may contain free hemoglobin and fibrin degradation products from hemolysis and lysis of clots, in addition to fat particles, bone fragments, methyldemethylacrylate monomer, and vasoactive mediators.

These may cause adverse effects such as hypotension and hyperthermia when the shed blood is reinfused. Postoperative autologous transfusion with unwashed shed blood should be limited to two units, and reinfusion should occur within 6 hours after the start of the collection (63). Relative contraindications for the postoperative salvage of shed blood include tumor and infection (63).

Lowering the "Transfusion Trigger"

Several years ago, most physicians regarded a pericorporeal hemoglobin level of 10 g/dl as an indication for transfusion (141). The physiologic basis for this value was not well proven. A better appreciation of the risks associated with the administration of blood products, however, has brought about the need to reevaluate the "transfusion trigger" for pericorporeal blood administration. Studies have demonstrated that patients can safely undergo anesthesia and surgery with preoperative values as low as 8 g/dl (142). Some patients with chronic anemia, such as those with chronic renal failure, tolerate hemoglobin levels less that 7 g/dl (192).

When deciding the threshold below which transfusion should be performed, consider the physiologic parameters unique to the individual patient rather than arbitrary hemoglobin or hematocrit levels. The decision to transfuse should take into account the duration of the anemia, the intravascular volume, the extent of the operation, the magnitude of massive blood loss, and the presence of coexisting medical morbidity, such as impaired pulmonary function, inadequate cardiac output, myocardial ischemia, or cerebrovascular or peripheral vascular disease (192).

Monitoring with intraarterial lines, pulmonary artery catheters, and continuous electrocardiography, as well as frequent sampling for hemoglobin levels, has proven beneficial in determining when to transfuse (84). Instead of scheduling invasive monitoring for every patient, Nelson et al. (107) have recommended dividing patients into high-risk and low-risk categories on the basis of clinical judgment. They suggest monitoring hypovolemia in low-risk patients by following routine vital signs. It may be successfully managed with the infusion of crystalloid solutions if the hemoglobin is above a level of approximately 7 g/dl or the hematocrit is above 20%.

In this scheme, patients in the high-risk category require not only more invasive monitoring but also, as a rule, higher hemoglobin and hematocrit levels than do low-risk patients. In these high-risk patients, the relationship between anemia and signs such as tachycardia, tachypnea, and low mixed venous oxygen saturation should be evaluated more rigorously, and transfusion of PRBC is recommended until the physiologic signs of anemia are reversed (107).

Erythropoietin

Natural erythropoietin is secreted by the kidney in response to hypoxemia and hemorrhagic stress. It binds to receptors in the bone marrow, stimulating the production of red blood cells (83). Recombinant human erythropoietin has a wide variety of potential clinical applications. It is approved for the treatment of anemia due to several conditions, including chronic renal failure and malignancy, and in HIV-positive patients undergoing treatment with zidovudine. Its potential uses in orthopaedic surgery are currently being explored (19).

One possible role for erythropoietin in orthopaedics is as an adjunct during preoperative autologous blood donations for elective surgery (55). Often, the number of units that can be donated is limited as the patient becomes anemic. Some orthopaedic patients also have medical conditions resulting in mild chronic anemia. Many patients' preoperative hematocrits are lowered following autologous donation, and 10% to 20% still require allogeneic blood transfusions (84). Anemia (a hematocrit of 35% or less) at the time of the first autologous donation is reported to be the most important indicator that a patient will require allogeneic blood transfusions in addition to autologous units (56).

Recombinant human erythropoietin has been shown to be of no clinical benefit in patients without preexisting anemia (hematocrit > 35%) undergoing preoperative autologous blood donation, as these patients were able to stimulate sufficient erythropoiesis through their endogenous erythropoietin response (54). In patients undergoing autologous blood donations who have preexisting anemia, the role of recombinant human erythropoietin remains controversial. Recombinant human erythropoietin has been shown to be effective in decreasing the need for allogeneic blood transfusions in hip arthroplasty patients who did not donate autologous blood (21,38).

Directed Donor Blood

More and more patients are requesting donor-designated blood transusions, or directed donations, as an alternative to standard homologous blood transfusions. This transfusion practice, unlike autologous blood transfusion, is controversial. There is no evidence to suggest that it is any safer than homologous blood transfusion, and under some circumstances (e.g., graft-versus-host disease in surgical patients who have received blood, graft-versus-host disease in patients with a hematocrit of first-degree relatives), it may be extremely deleterious (51,65,159,147). In addition, there is concern that individuals asked to donate for family members may feel compelled to violate the usual voluntary self-exclusion criteria. Our blood bank provides directed donor service for patients who desire it solely for reasons of public relations rather than for any medical reason.

PREOPERATIVE SURGICAL PLANNING

The value of surgical planning has been well described, and its importance has grown as surgery has become more technically complex. Surgeons who think through the operative procedure in advance can easily alter the sequence of steps to provide the optimal outcome, a luxury not often available in the middle of surgery. Preoperative surgical plans have most commonly been used for complex acute and reconstructive trauma, osteotomies, total joint arthroplasty, and other technically challenging procedures (52). The benefits of preoperative planning can also be applied to simple, straightforward cases.

Planning should include making both a drawing of the planned procedure and a written series of steps and reminders. Mast et al. have described the "surgical tactic" as an outline of sequential steps used in the operating room that will bring about the desired end result (93). While a well-thought-out preoperative plan is not a guarantee of success, it may reduce the potential for intraoperative error and allow the operation to proceed smoothly from step to step. It is important to share these plans with the anesthesiologist and operating room staff, so that they will be able to anticipate all the needs of both surgeon and patient.

In setting forth the steps of the operation, advance planning helps ensure that all necessary equipment is requested and available, and that all support personnel have been brought on board. As the steps are planned, the required equipment is listed.

Several techniques have been described for creating preoperative drawings:

- Using the direct overlay technique
- Using a reverse tracing of the uninjured or unaffected side
- Using the anatomic knee joint axis or mechanical axis of the limb

No single technique is superior: different methods may be better suited for different situations. In some cases, a combination of methods may be obtained to obtain the best possible preoperative plan.

A number of items are required to make preoperative drawings:

- Good-quality anteroposterior (AP) and lateral radiographs of the injured or affected extremity or joint
- Good-quality anterior-posterior (AP) and lateral radiographs of the contralateral uninjured or unaffected extremity or joint
- Tracing paper or clear overexposed x-ray film
- Colored pens or pencils
- A marker
- Implant templates

The AO (Arbeitsgemeinschaft für Osteosynthesefragen) preoperative planning kits, which include templates for all the AO fracture implants, are an excellent resource.
for planning operative fracture care. The textbook Planning and Reduction Technique in Fracture Surgery by Mast, Jakob, and Ganz (83) provides numerous case examples with preoperative plans and surgical techniques for fracture reduction and fixation. Obtaining adequate, good-quality x-ray films is a major hurdle in preoperative planning in trauma patients. Radiographs obtained without overlying plaster splints are best for imaging individual fracture fragments. Traction views are frequently beneficial in correcting overlap or malrotation of fragments. Traction views may be especially helpful in the supracondylar femur and distal humerus fractures, where muscle pull often malrotates the distal fragments.

Radiographs vary in their magnification depending on the body habitus of the patient and the length of the beam from the cassette. The amount of magnification can vary from 6% to 36% with a 40-inch exposure distance, and from 3% to 17.5% with a 72-inch exposure distance (144). Most templates are magnified by 10% to 15% to account for the radiographic magnification. Special radiographic magnification markers can be applied to the skin at the level of the bone to determine the individual magnification, but this degree of accuracy may not always be necessary. Exact measurements can also be obtained from computed tomography.

In cases where an angular deformity is present, the greatest deformity usually exists in a plane other than either the AP or the lateral view. Mathematical formulas can be used to determine the maximal deformity (117,123). A properly planned oblique osteotomy can provide multiplanar correction of a malunion (69,125,128). Plain radiographs also do not account for rotational deformities that may be present. Rotational deformities may be evaluated by physical examination, and if necessary more precise evaluation can be obtained by axial computed tomography (CT) scans. (See Chapter 32 for more details.)

TECHNIQUES FOR CREATING PREOPERATIVE DRAWINGS

Direct Overlay Technique

The direct overlay technique is best employed in the case of fractures involving the shaft of relatively straight bones. Follow these steps for a simple fracture:

- Obtain a radiograph of the fracture (Fig. 5.1A).
- On separate pages, trace the proximal fragment, the distal fragments, and any intervening comminution or butterfly fragments (Fig. 5.1B).
- Draw a vertical line on a separate piece of paper.
- "Reduce" the proximal and distal fragments by aligning their long axes with the vertical line (Fig. 5.1C).
- "Reduce" any comminution or butterfly fragments into a best-fit position.
- Make a final composite drawing of the reduced fracture (Fig. 5.1D).
- Using selected templates, trace the appropriate fixation implant (Fig. 5.1E).
- Write out the surgical tactic, listing all sequential steps required to achieve the planned result (Fig. 5.1F).

Rather than using separate sheets of paper for each fragment, simple fracture patterns may be drawn onto a single sheet of tracing paper by rotating the paper into correct alignment as each fragment is drawn. Alternatively, cut out the individual fracture fragments, creating a jigsaw puzzle of fracture fragments.

Occasionally, individual fracture fragments will not fit into place—when the fragment is malrotated and its radiographic projection does not match either the true AP or lateral view. In these cases, make an approximation of the size and shape of the fracture fragments, which may sometimes be inferred from the space left over after other fragments are drawn in their "reduced" positions.

Reverse Tracing of the Opposite Extremity

To use a reverse image of the uninjured or unaffected extremity as a template for planned reconstruction, follow these steps (Fig. 5.2):

- Obtain radiographs of the injured and uninjured extremities (Fig. 5.2A, Fig. 5.2B).
- Reverse the radiograph of the uninjured or unaffected extremity and trace its outline (Fig. 5.2B, Fig. 5.2C).
- Place the tracing over the radiograph of the injured or affected extremity, and align the shafts or articular surfaces (align whichever appear more similar).
- Trace the fracture lines, adjusting the paper until all major fracture lines have been traced (Fig. 5.2D, Fig. 5.2E and Fig. 5.2F).
- Using selected templates, trace the appropriate fixation implant (Fig. 5.2G).
- Write out the surgical tactic, listing all sequential steps required to achieve the planned result (Fig. 5.2H).

Knee Joint or Limb Axis Model

An understanding of the normal axis of the knee joint or the mechanical and anatomic axes of the lower limb may be utilized to create a preoperative plan (Fig. 5.3).
Use the knee joint axis template (Fig. 5.4E) to do preoperative planning for fractures involving the distal femur or proximal tibia. This template provides not only the normal axis lines of the knee joint but also the anatomic axes of the femoral and tibial shafts (Fig. 5.4).

Figure 5.4. Preoperative planning for supracondylar femur fracture using the joint axis template. A: Radiograph of fracture. B: Knee joint axis template. C: Tracing of individual fracture fragments. D: Reduction of the two most distal fracture fragments. E: Reduction of the metaphyseal and shaft component. F: Use a template to draw initial fixation of the intercondylar split; show insertion of the two 5.5 mm cancellous screws. Insert a guidewire parallel to the articular fragments, aligning the metaphyseal fragment along the shaft axis (Fig. 5.4E). G: Use templates to draw in side plate and screws of the appropriate length. Indicate the use of the articulated tensioning device if necessary to aid the reduction and achieve interfragmentary compression. H: The surgical tactic.

OSTEOTOMY

Blount highlighted the importance of careful preoperative planning for osteotomies, stating that, “Nowhere in surgery is preoperative planning and careful planning of more value” (18). Numerous different types of osteotomies have been developed, which are described in Chapter 26, Chapter 27, Chapter 28, Chapter 29, Chapter 30, Chapter 31 and Chapter 32 and Chapter 104. Careful planning of an osteotomy may permit multiple simultaneous corrections, including length, rotation, angulation, and displacement. An understanding of the normal mechanical axis and the anatomic axis of the lower limb is an essential part of any planned osteotomy of the lower limb (Fig. 5.3). Standing long-cassette radiographs may be necessary to plan the degree of correction required.

An osteotomy must be carefully planned and its steps sequentially executed. When a blade plate is required, the preoperative plan must identify the location where the path for the blade is best cut before you make any of the osteotomy cuts. The osteotomy becomes the final step prior to the planned fixation. Intraoperatively, confirm restoration of alignment with fluoroscopy, using an electrocautery cord as a radiopaque “plumb” line. Center one end of the cord over the femoral head and the other over the ankle joint, reproducing the new mechanical axis. Then visualize the location where the mechanical axis (electrocautery cord) crosses the knee joint and compare it with the preoperative plans.

Kirschner (K-) wires inserted proximal and distal to the planned osteotomy site can also serve as markers for rotational or angular corrections. If a blade plate is to be used, K-wires may also be used as alignment guides for placement of the seating chisel. You can also score the cortical bone to judge rotational corrections.

TOTAL JOINT ARTHROPLASTY

Most manufacturers can supply clear acetate templates of arthroplasty implants for preoperative planning. For total hip arthroplasty, these templates allow the surgeon to plan the size and position of the implants. Variables that should be considered include the location of the hip center, the neck cut, the implant position, and the anticipated implant neck length. Different implants provide varying amounts of femoral offset, a factor that may influence abductor muscle function. Further details of preoperative planning for total joint arthroplasty are provided in Chapter 101, Chapter 102 and Chapter 103, Chapter 105, Chapter 106, Chapter 108 and Chapter 109.

COMPUTERIZED PLANNING TECHNIQUES

Computer programs have also been developed to assist in the preoperative planning of osteotomies and total joint replacement. These systems require digitization of the radiographs. Once all the data have been acquired, the computer offers the benefit of allowing the surgeon to easily try different degrees of correction (143). In some cases, three-dimensional CT may be helpful to better visualize certain deformities or complex fractures (73). Reconstruction models can also be made from CT data to assist in the planning of extremely complex correction involving deformed bones or joints (112). (See Chapter 17.)

INTRAOPERATIVE SURGICAL MANAGEMENT

Good results from surgery are achieved with intelligent and informed decision making, appropriate indications for surgery, complete preoperative planning, technically precise surgery, gentle soft-tissue technique, and a well-designed and well-executed postoperative rehabilitation program. Good results from a surgery depend on many seemingly insignificant aspects of surgical technique that lead to precision and efficiency and minimize complications.

THE SURGEON’S ATTITUDE AND CONDUCT

Good preoperative planning permits surgeons to approach the operation with an attitude of confidence and with the assurance that they will be able to handle any contingencies or unexpected complications. Establish a businesslike attitude in the operating room. Lighthearted conversation and background music in the operating room are appropriate in some circumstances but must not distract from the conduct of the surgery. Distractions slow down the operating team and may lead to...
**ANTIBIOTICS**

The use of prophylactic antibiotics in clean orthopaedic surgery remains controversial. In our hospital and in most institutions in North America, prophylactic antibiotics are used when wound exposure time is expected to be more than 2 hours, or when major orthopaedic implants will be used. The antibiotic used most commonly for prophylaxis in orthopaedic surgery is cefazolin (104).

Cefazolin is an inexpensive first-generation cephalosporin that provides broad-spectrum gram-positive coverage; it has a high peak serum level and a long half-life. We generally give 1 g cefazolin sodium intravenously with the preoperative medications; although some authors recommend an initial dose of 2 g to achieve a higher antibiotic level in bone (157). If you plan to use a tourniquet, administer the antibiotic at least 5 minutes before it is inflated (112).

If vancomycin is required in the potentially infected patient, infuse it slowly over at least 1 hour to avoid anaphylactoid reactions that can occur from rapid infusion. When there is a question of possible infection, hold prophylactic antibiotics until intraoperative cultures are obtained. For operative procedures of longer duration, administer an additional intraoperative dose of antibiotics at approximately 4 hours. Depending on the nature of the operative procedure, continue antibiotics postoperatively, at 1 g every 8 hours for 24 hours; then discontinue. Some surgeons prefer to administer prophylactic antibiotics for a longer period of time, but there is no concrete evidence showing that longer duration is beneficial (106). Other antibiotics may be required if there has been major prior surgery, previous infection, or contamination. When the wound is large or has been exposed for more than 2 hours, we thoroughly irrigate it with a low-pressure mechanical irrigator with sterile normal saline, followed by bacitracin solution, 25,000 units per liter of saline.

Antibiotics also may be added to the methylmethacrylate in total joint surgery. Methylmethacrylate beads impregnated with antibiotics have been advocated to treat open fractures and bone infections. These applications are discussed in more detail in Chapter 12, Chapter 105, Chapter 106, Chapter 132, Chapter 133, and Chapter 135.

As important as the use of prophylactic antibiotics is the operating room environment (104). The majority of postoperative wound infections are caused by airborne contamination. The orthopaedic table is used to position patients for internal fixation of hip fractures, femur fractures, fractures of the tibia, and other special situations.

**POSITIONING THE PATIENT**

The four most common positions for surgery are the supine, prone, and right and left lateral decubitus positions. Specialized positions are used for surgery to the cervical spine, shoulder, and low back (see specific chapters). The orthopaedic table is used to position patients for internal fixation of hip fractures, femur fractures, fractures of the tibia, and other special situations.

Positioning is the responsibility of the anesthesiologist and the surgeon. Particularly when the patient will undergo a prolonged procedure, take care to avoid putting pressure on neurovascular structures, muscle compartments, and bony prominences. Position the patient to allow free expansion of the thoracic cavity and movement of the diaphragm. Place gel or foam pads in areas of high pressure concentration to avoid injury to the skin.

**Supine Position**

- Place the patient on her back on a well-padded, standard operating table, and insert pads under the occiput and heels. For lower extremity surgery, place upper extremities on padded arm boards and gently secure them. Avoid placing tension on the brachial plexus and axillary artery by abducting the arms no higher than 90°, and preferably no more than 60°. Insert disposable foam elbow pads under the elbows.
- When access to these areas is necessary, use shepherd’s hook designs to allow pressure directly above the trunk on the operating table. For upper extremity surgery or other surgery not involving the lower extremities, place a pillow under the calves to keep the knees and hips slightly flexed. Place disposable foam pads on the heels. Avoid crossing the legs.

**Prone Position**

- Place the patient prone. Position bolsters alongside the ventral thorax and abdomen to permit expansion of the thorax and downward movement of the diaphragm. Make the bolsters by rolling blankets and taping them into rolls approximately 4 inches in diameter. The bolsters contact the anterior shoulder, avoiding the axilla, and end slightly below the anterosuperior iliac spine. Avoid placing pressure on the lateral femoral cutaneous nerve just medial to the
Lateral Decubitus Position

- Place the patient in the lateral decubitus position. Stabilize the trunk with a bean bag or appropriately positioned kidney rests placed beneath the mattress.
- Provide additional support for small patients, using folded sheets or towels. Position kidney rests to support the patient at the pelvis, unless they will interfere with the surgical approach.
- To avoid placing pressure on the shoulder and axillary vascular bundle on the downside, place a lateral chest roll made with a rolled bath towel or a cloth-covered liter saline bag transversely supporting the thorax just below the axilla. Unless surgery is to be performed on the upper extremities, gain additional stability by placing upper extremities on an airplane splint secured to the operating table. It is necessary to use elbow pads and appropriate padding to protect the extremities.
- If the lower extremities are not involved in the operative procedure, place a blanket beneath the lower leg for padding and a pillow between the legs to cushion them. Place blankets over the upper thigh and secure them with the strap from the operating table to further stabilize the patient. Carefully pad above and below the peroneal nerve on the lower leg to avoid placing pressure on it.
- If the surgery involves the upper leg, such as in total hip arthroplasty, surround the lower leg with layers of sheets. Build the sheets up to the level of the upper leg to provide a smooth platform for the surgery and to protect the lower leg. Do not tape across the chest wall; taping may produce excessive downward pressure and interfere with respiration.

Supine Position on the Orthopaedic Table

Positioning of the patient on the orthopaedic table varies considerably according to the table type and the operative procedure. The general principles of positioning a patient for surgery of an intertrochanteric hip fracture, however, apply in most cases.

- Place the patient in the supine position on the padded table top, using the general principles already described for a regular table. Use a radiolucent perineal post; pad it, and position it to one side of the genitalia.
- Place the lower extremity designated for surgery into traction on a foot piece (Fig. 5.5). If the manufacturer has not provided a special foot holder, use appropriate padding and proper wrap to protect the soft tissues and heel, particularly in elderly patients. Secure the foot to prevent intrasurgical loss of traction.
- Before placing the patient in the lateral position, insert a large-threaded Steinmann pin transversely through the tibia at or slightly below the tibial tubercle (in adults). Pad the skin around the pin with sterile dressings, and secure it to the traction device.
- If the lower extremities are not involved in the operative procedure, place a blanket beneath the lower leg for padding and a pillow between the legs to cushion them. Place blankets over the upper thigh and secure them with the strap from the operating table to further stabilize the patient. Carefully pad above and below the peroneal nerve on the lower leg to avoid placing pressure on it.

Figure 5.5: A: Supine position on the Chick-Langren Orthopaedic table for internal fixation of a right hip fracture. B: Positioning for internal fixation of a right hip using bilateral lower extremity traction. We prefer this position to that shown in (A), because it stabilizes the pelvis better and permits more effective traction for reduction of the fracture. (Courtesy of Chick Orthopaedic, Chick Medical Products, Greenwood, SC.)

- Place the other lower extremity in the lithotomy position in a leg holder and abduct it to allow clearance for the C-arm fluoroscope. We have found it most effective to place the healthy leg in traction as well. Be careful when placing patients in the lithotomy position to avoid placing excess pressure on the popliteal fossa. Limit the length of time in this position to avoid complications of compartment syndrome (95,137).
- Use bilateral traction to centralize the pelvis on the perineal post and avoid pelvic rotation. Bilateral traction permits more effective fracture reduction that can be better maintained. It also facilitates radiography. Bilateral traction presents problems only when a patient has a hip adduction contracture. Abduction to 45° is usually necessary for positioning of the C-arm fluoroscope. Occasionally, in very comminuted intertrochanteric or subtrochanteric fractures, it is necessary to support the shaft of the femur or provide an upward push on the trochanters. Some operating tables have attachments for this purpose.
- Alternatively, place a well-padded crutch beneath the patient at which upward pressure is desired and push it into place. The rubber foot of the crutch prevents it from shifting, and the oblique position of the crutch usually prevents it from interfering with the swing of the C-arm. Position the C-arm fluoroscope so that it swings freely from the AP to the lateral position without impinging on the patient. Test the swing before draping the patient.

Lateral Decubitus Position on the Orthopaedic Table

The general precautions for lateral decubitus positioning described previously apply when the orthopaedic table is used.

- The torso has a tendency to roll into the supine position. To prevent this, gently lock the elbow into full extension and secure the forearm to an airplane splint with broad adhesive tape (Fig. 5.6). Protect the ulnar nerve. Use a vertical pelvic post with a well-padded perineal post positioned so that the patient’s anterosuperior iliac spine lies adjacent to and slightly above the pelvic post. This position stabilizes the pelvis and permits adequate flexion of the hip.

Figure 5.6: A: Posterior view of a patient in the lateral decubitus position for closed intramedullary nailing of the right femur. If the right upper extremity is secured to the arm board with the elbow in extension, the torso is stable and the cross-body strap is not necessary. The affected limb is in skeletal traction with a pin in the proximal tibia. If a large-threaded Steinmann pin is used, the auxiliary foot support is not necessary in most cases. The unaffected limb rests on a well-padded foot board. Extend the board proximal to the knee to avoid injury to the common peroneal nerve, pad the leg, and secure the leg to the board with muslin or 3-inch tape. B: On this frontal view, note that the pelvic post is positioned just caudal to the anterosuperior iliac spines (it is behind the C-arm). The perineal post can be used to support a short proximal fragment. With a stout Steinmann pin in the tibia, the foot support is not necessary. (Courtesy of Chick Orthopaedic, Chick Medical Products, Greenwood, SC.)

- Secure the uppermost lower extremity that is designated for surgery (usually for closed intramedullary nailing) using tibial pin skeletal traction to the tibial pin-holding device on the orthopaedic table. Not all orthopaedic tables provide this extremely useful device.
- Before placing the patient in the lateral position, insert a large-threaded Steinmann pin transversely through the tibia at or slightly below the tibial tubercle (in adults). Pad the skin around the pin with sterile dressings, and secure it to the traction device.
- Place the extremity in traction, and position it as necessary for the procedure. Secure the downside lower extremity to a well-padded leg board that attaches to the orthopaedic table. Securely wrap the extremity to the leg board, which must extend proximal to the knee. Take care to avoid pressure on the peroneal nerve. Additional details on the position used for closed intramedullary nailing of the femur are provided in Chapter 11 and Chapter 20.
THE TOURNIQUET

Use of a tourniquet greatly facilitates extremity surgery; it provides a bloodless field, which is essential for most surgery of the hand and foot. There are, however, potential dangers associated with the use of the tourniquet, and you must be familiar with its proper use. Use a constant-pressure-regulated tourniquet that is inflated with nitrogen. We apply it only to the upper arm and proximal thigh (finger and toe tourniquets fashioned from Penrose drains are described in the chapters on hand surgery). Even with modern, reliable pneumatic tourniquets, it is possible to apply excessive pressure. Use a calibration gauge to check the accuracy of tourniquet pressure readings before each use.

Tourniquets are available in various lengths and widths for various sizes of extremities. The pressure pattern produced by a tourniquet is cone shaped, diminishing in width as the depth of the extremity is reached. Therefore, wide tourniquets are necessary for large extremities; do not use narrow tourniquets on large limbs.

Securing the Tourniquet

In obese people, the tourniquet tends to migrate distally as it is inflated; in certain procedures in the distal arm and thigh, therefore, it is necessary to secure the tourniquet in a proximal position to allow adequate room for the surgery.

- Place three strips of 2-inch tape on the anterior, lateral, and posterior surfaces of the upper thigh or upper arm. After the tourniquet is in place, fold them upward over the tourniquet and secure them with circumferential tape around the tourniquet (Fig. 5.7).

**Figure 5.7.** Tourniquet in place on the upper thigh, wrapped and secured to the thigh to prevent tourniquet migration.

- Before applying the tourniquet, pad the extremity with several smoothly applied layers of soft cast-padding material to prevent wrinkling and pinching of the skin as the tourniquet inflates. Apply the tourniquet snugly, and be it securely. Improper application may result in “unwrapping” of the tourniquet during the surgery, and the result can be soft-tissue or neurovascular injury.

- Failure of the tourniquet during surgery is a great inconvenience and in some cases also a significant interference. Check all components of the tourniquet system before use. Keep prep solutions and chemicals away from the tourniquet and padding materials. Before preparing the skin, cover the tourniquet with an adhesive plastic towel drape. Sterile disposable tourniquets are available for application after a sterile field is established.

- In most cases, exsanguinate the limb before inflating the tourniquet by wrapping the limb with an Esmarch or rubber bandage from distal to proximal. Esmarch bandages, once used as tourniquets, are no longer recommended because their pressure cannot be monitored, and damage to neurovascular structures can occur.

- Do not exsanguinate the limb if infection or tumor is present.

- Appropriate tourniquet inflation pressure is just enough to prevent arterial blood flow into the limb—no higher. This pressure depends on the age of the patient, the status of the vasculature, the blood pressure, and the size of the extremity. Reid, Camp, and Jacob recommend a pressure of 50–75 mm Hg above systolic blood pressure (i.e., 135 to 225 mm Hg) in the upper extremity. Pressures of 100–150 mm Hg above systolic blood pressure (i.e., 175 to 305 mm Hg) are usually necessary in the lower extremity. Inflatable tourniquets quickly to prevent venous noxia, which may fill the venous tree before occlusion of arterial blood flow.

Precautions

The length of tourniquet ischemia that can be tolerated by the limb without residual effects varies considerably from patient to patient and depends on the condition of the limb and the pathology being treated. In general, tourniquet times should not exceed 2 hours and are best kept at 1½ hours or less. In many procedures, it is possible to complete the exposure and obtain good control of potential bleeding vessels within 1–½ hours of tourniquet time. At that point, the tourniquet often can be deflated and not require reinflation for the remainder of the procedure.

Total tourniquet time of more than 2 hours almost always results in some temporary posttourniquet problems. The most common complaints are partial anesthesia and tingling, and hypersensitivity in the limb for 1 to 2 days following surgery. Rarely, muscle weakness accompanies these symptoms. With tourniquet times of 2 hours or less, true palsies almost never occur; if they do, they are usually the result of pressure on a peripheral nerve, rather than ischemic changes from tourniquet use.

Repeated inflation of the tourniquet is possible but not advisable. Do this only when the tourniquet is absolutely essential and when the advantages justify the risks. If the tourniquet is in place for 1 hour, deflate it for at least 20 minutes to restore normal oxygenation, pH, and chemistry of the limb. Tourniquet time may be extended to 3 hours if the tourniquet is deflated for at least 20 minutes at the end of each hour. Deflation for 20 minutes every hour, however, usually interferes with the operative procedure, so it is wiser to proceed with the tourniquet for 2 hours and then discontinue its use. When the tourniquet is deflated, it sometimes causes a venous-tourniquet effect and must be removed from the limb during the operative procedure.

Once the tourniquet is released, ensure that perfusion to the extremity has been restored, especially when more than a single operative procedure is involved. In such cases, a tourniquet could potentially remain inflated and in place long beyond the accepted limits. It is also critically important to identify adequate peripheral pulses when vascular damage could potentially occur, such as during a total knee replacement. Diagnosis of the vascular injury while the patient is still in the operating room may save hours.

SKIN PREPARATION

Ask patients to clip and clean the nails of the affected limb before surgery, and to remove nail polish. Warn them to avoid activities for 3 weeks before surgery that could cause minor scratches and abrasions to the affected extremity. For clean individuals, special bathing before surgery is not necessary. Shaving in advance of the operation may save hours.

In obese people, the tourniquet tends to migrate distally as it is inflated; in certain procedures in the distal arm and thigh, therefore, it is necessary to secure the tourniquet in a proximal position to allow adequate room for the surgery.

- Before applying the tourniquet, pad the extremity with several smoothly applied layers of soft cast-padding material to prevent wrinkling and pinching of the skin as the tourniquet inflates. Apply the tourniquet snugly, and be it securely. Improper application may result in “unwrapping” of the tourniquet during the surgery, and the result can be soft-tissue or neurovascular injury.

- Failure of the tourniquet during surgery is a great inconvenience and in some cases also a significant interference. Check all components of the tourniquet system before use. Keep prep solutions and chemicals away from the tourniquet and padding materials. Before preparing the skin, cover the tourniquet with an adhesive plastic towel drape. Sterile disposable tourniquets are available for application after a sterile field is established.

- In most cases, exsanguinate the limb before inflating the tourniquet by wrapping the limb with an Esmarch or rubber bandage from distal to proximal. Esmarch bandages, once used as tourniquets, are no longer recommended because their pressure cannot be monitored, and damage to neurovascular structures can occur.

- Do not exsanguinate the limb if infection or tumor is present.

- Appropriate tourniquet inflation pressure is just enough to prevent arterial blood flow into the limb—no higher. This pressure depends on the age of the patient, the status of the vasculature, the blood pressure, and the size of the extremity. Reid, Camp, and Jacob recommend a pressure of 50–75 mm Hg above systolic blood pressure (i.e., 135 to 225 mm Hg) in the upper extremity. Pressures of 100–150 mm Hg above systolic blood pressure (i.e., 175 to 305 mm Hg) are usually necessary in the lower extremity. Inflatable tourniquets quickly to prevent venous noxia, which may fill the venous tree before occlusion of arterial blood flow.

- Repeated inflation of the tourniquet is possible but not advisable. Do this only when the tourniquet is absolutely essential and when the advantages justify the risks. If the tourniquet is in place for 1 hour, deflate it for at least 20 minutes to restore normal oxygenation, pH, and chemistry of the limb. Tourniquet time may be extended to 3 hours if the tourniquet is deflated for at least 20 minutes at the end of each hour. Deflation for 20 minutes every hour, however, usually interferes with the operative procedure, so it is wiser to proceed with the tourniquet for 2 hours and then discontinue its use. When the tourniquet is deflated, it sometimes causes a venous-tourniquet effect and must be removed from the limb during the operative procedure.

- Once the tourniquet is released, ensure that perfusion to the extremity has been restored, especially when more than a single operative procedure is involved. In such cases, a tourniquet could potentially remain inflated and in place long beyond the accepted limits. It is also critically important to identify adequate peripheral pulses when vascular damage could potentially occur, such as during a total knee replacement. Diagnosis of the vascular injury while the patient is still in the operating room may save hours.

- SHIELD the incision and move in a centrifugal fashion outward until the appropriate area has been prepared. For extremity surgery, prepare the entire extremity, from the tips of the fingers or toes to the tourniquet.

- Take care to avoid dripping excessive soap or solution, which can cause burns of sensitive mucosal membranes, onto the genitalia. Also avoid dripping it onto the operating table. If you use alcohol, take extreme care to prevent it from pooling beneath the operative field and posing a fire hazard during use of electrocautery.

- Wash and dry the limb or surgical site with sterile towels. Then apply povidone-iodine solution either from a prepackaged spray bottle, which is safest from the standpoint of contamination, or with sponge sticks, working from the site outward. Let this solution dry in place, because its antibacterial action continues for a certain period of time.

- Wash and dry the limb or surgical site with sterile towels. DRAPIING

To avoid contamination of the limb during draping, lay the extremity on a sterile sheet or have an assistant support it using sterile gloves or towels. This maneuver is exceedingly difficult with heavy extremities that are unstable because of fractures. Take care to avoid contamination, particularly proximally.

There are many different satisfactory draping routines. We present general guidelines for satisfactory draping and three typical draping routines: one for the upper or lower extremity, one for the shoulder, and one for the hip. They use the standard sheets available in an average general surgery pack without specialized split and extremity sheets as well.

Although it is possible for one person to drape a patient satisfactorily, ideal technique requires three people. One assistant supports the extremity and maintains its sterility as it is being draped, and the other two obtain the draping materials from the back table and deploy them. Perform draping after the scrub nurse, surgeon, and assistant are fully gloved and gowned. Drape with double gloves, because inadvertent contamination can occur. Strip off the outer set of gloves after the drape and put on a new second set for the procedure.

Upper or Lower Extremity Draping

- Place a cover sheet over the end of the table to protect the surgeon and assistants from accidentally contaminating their gowns by brushing against the nonsterile operating table. Roll a double-layered tubular stocking or waterproof cover over the extremity (Fig. 5.8). Use a folded, sterile towel to cover the tourniquet. Secure it snugly around the thigh or the arm just distal to the tourniquet with one or two towel clips.

- Roll the stockinet into place, up to or over the tourniquet, to prevent accidental contamination of sterile gloves and gown. In addition, if incisions are carried far proximally, the towel prevents accidental exposure of unprepared skin. Place a second half-sheet with the proximal end folded downward 6 inches beneath the extremity, taking care not to contaminate the folded edge. Lay the limb down on this sheet. Place a second half-sheet with its distal edge folded double for a distance of approximately 1 foot over the proximal portion of the limb, matching the folded edge of the underlying half-sheet. Secure these two sheets snugly together and to the rolled stockinet with four towel clips (Fig. 5.8B).

- Next, place the limb through the hole in a large laparotomy or extremity sheet. If a laparotomy sheet is used, secure it snugly around the limb with two towel clips just below the previously applied two half-sheets. Leave no exposed underlying half-sheets (Fig. 5.8C).

We strongly recommend that draping be done only with disposable paper sheets. This draping routine—the equivalent of more than four standard cloth sheets plus a waterproof layer—provides optimal protection against contamination. When the drape is completed, incise the stockinet with a pair of scissors and fold it back to expose an adequate area for the surgery. We cover the skin with a povidone-impregnated adhesive plastic sheet. If you do not wish to use plastic incision drapes, suture or staple skin towels to the skin after the incision is made. If a povidone-impregnated adhesive plastic skin drape is used, defat the skin with alcohol before applying the drape to ensure optimal adhesion. Adhesive drapes that remain in place provide nearly ideal protection from the surrounding skin.

Loose plastic skin drapes increase the risk of contamination. If the plastic drape loosens during the procedure, we recommend removing and replacing it with standard skin towel drapes. Carry the preparation and drape up to the tourniquet, so that the entire limb is available if necessary.

Upper Extremity and Shoulder Drape

The basic principles already outlined apply to the use of the upper extremity drape.

- For surgery on the upper extremity distal to the shoulder, drape as for the lower extremity; use a hand table if desired.

- For shoulder surgery, carry the skin preparation well up on to the neck and anterior and posterior chest wall. Cover the torso and legs with a water-impervious barrier sheet.

- Roll a tubular stockinet to the elbow. Secure a sheet into the axilla and across the chest. Cover the proximal extent of the shoulder with a second sheet posteriorly and a third anteriorly, which meet on the lateral neck. Secure these drapes with an adhesive drape and then pass the limb through an extremity or laparotomy sheet, and secure it with staples and another adhesive drape (Fig. 5.9).

Figure 5.9. This shoulder drape is completed. Note that the sheets are attached high on the neck and wide on the chest wall to provide full exposure.

Hip Drape

Perform the drape for surgery of the hip in the lateral decubitus position in nearly an identical manner. Modify as necessary to be certain that the perineum is draped out of the operative field to provide freedom of movement of the limb, which is necessary for hip arthroplasty. Do not use a tourniquet.

- Position the initial barrier sheet. Roll a tubular or water-impervious stockinet over the extremity to the mid thigh. Bring the first half-sheet into position, and secure it with staples to the medial surface of the thigh, approximately 8 inches distal to the perineum. Bring it carefully proximal along the anterior and posterior aspects of the thigh and onto the torso.

- Secure this drape to the skin with large skin staples. Towel clips can be used as well, but they tear through paper drapes and interfere with radiography. Carry both the skin preparation and drape well proximally onto the rib cage.

- Put the second sheet in place, and use skin staples to secure it at the uppermost margin of the operative field, proximal to the iliac crest. Fold the lower sheet into the groin. Further secure these sheets with application of a povidone-impregnated adhesive plastic drape (Fig. 5.10A).
reviewing the anatomy and surgical approach before surgery. Neurovascular bundles can be safely dissected out with a #15 blade if the surgeon knows the anatomy and works from proximal to distal to avoid cutting into the axillae. Most atraumatic and rapid technique. Dissection with the scalpel, particularly in the region of important neurovascular bundles, requires precise knowledge of anatomy. Rapid, precise dissection with the scalpel where tissues must be cut, and blunt dissection with the finger or an elevator where tissue planes can be split bluntly, is the certain areas where subcutaneous and muscle hemorrhage is a particular problem, as in the spine, electrocautery is used more frequently with minimal morbidity. After you have made the initial cut, continue dissection with a sharp knife. Avoid blunt spreading with scissors or cutting current. For easy closure and best cosmetic results, make incisions at right angles to the skin. It is often difficult in orthopaedic procedures when dealing with very irregular surfaces to make such incisions. Take care to remain at right angles to the skin even as the incision curves across the surface of the limb. Make skin incisions with a fresh scalpel blade and never with a pair of scissors or cutting current. For easy closure and best cosmetic results, make incisions at right angles to the skin. It is often difficult in orthopaedic procedures when dealing with very irregular surfaces to make such incisions. Take care to remain at right angles to the skin even as the incision curves across the surface of the limb. After you have made the initial cut, continue dissection with a sharp knife. Avoid blunt spreading with scissors or electrocautery, which adds to soft-tissue damage. In certain areas where subcutaneous and muscle hemorrhage is a particular problem, as in the spine, electrocautery is used more frequently with minimal morbidity. Rapid, precise dissection with the scalpel where tissues must be cut, and blunt dissection with the finger or an elevator where tissue planes can be split bluntly, is the most atraumatic and rapid technique. Dissection with the scalpel, particularly in the region of important neurovascular bundles, requires precise knowledge of anatomy. Neurovascular bundles can be safely dissected out with a #15 blade if the surgeon knows the anatomy and works from proximal to distal to avoid cutting into the axillae of nerve and vascular branches. The good surgeon treading in an anatomic region that she visits infrequently will greatly improve her surgical technique by thoroughly reviewing the anatomy and surgical approach before surgery.

Figure 5.10. A: Draping in the lateral decubitus position for hip surgery. B: Exposed skin is covered with a large povidone-impregnated plastic drape. C: The extremity is brought through the hole in a laparotomy sheet.

- Place the extremity through the hole in a laparotomy sheet, and secure it to the medial thigh in the same location as the previous sheets. Enlarge the hole in the drape with a pair of scissors; bring it proximally over the extremity, and secure it to the patient with skin staples. Secure this drape with a large povidone-impregnated plastic sheet. With this draping arrangement, a number of impervious layers are placed around the operative site. The limb is free to move because the sheets are not brought directly into the groin, and the groin is well draped out of the field (Fig. 5.10B). We have found this fairly lightweight drape suitable for all reconstructive surgery around the hip and pelvis. Some surgeons prefer to add additional impervious layers, particularly if prolonged surgery involving considerable blood loss is expected. Special draping sets using combinations of adhesive-backed U-drapes work very well also, but are usually somewhat expensive.
- Bring the extremity through the holes in a laparotomy sheet cut to fit the exposure desired (Fig. 5.10C). Staple it in place and secure it with a second plastic drape. This method avoids draping into the groin and gives ample sheet in the groin area for movement of the extremity.

**Draping for Intramedullary and Hip Nailing**

Draping for intramedullary nailing and hip nailing on the orthopaedic fracture table is similar to that just described for the hip. Square off the operative site with sterile sheets secured to the skin with staples and an adhesive drape (Fig. 5.11A). Place the final drape, a laparotomy sheet, on the hip. The extremity is not draped free. Appropriate draping in both procedures allows the C-arm to move beneath the drapes, preserving the sterile field (Fig. 5.11B). With the C-arm in the lateral position, place the drapes so that they hang 2 inches or so off the floor. Note that the entire hip and thigh are available for the operative procedure. Drape only the C-arm receiving head; do not drape the arm itself. Draping hinders movement and nearly always results in contamination. For hip fractures, a vertical adherent clear plastic drape works very well when full access to the extremity is not necessary.

Figure 5.11. A: Drape for intramedullary nailing of the femur. B: Lateral decubitus position on a fracture table.

For intramedullary nailing of the tibia, similar principles apply (Fig. 5.12). First cover the vertical posts and other table parts that might be contacted during surgery. Place a large drape sheet above the knee and secure it circumferentially with staples. Apply a similar drape around the ankle. Leave enough room for distal cross-screw insertion. Then create a ‘mesenteric’ drape with a laparotomy sheet. Secure it with an adhesive plastic skin drape. The entire leg is left free, and the mesentery covers the C-arm in the lateral position.

Figure 5.12. Drape for intramedullary nailing of the tibia on a fracture table.

**SKIN INCISION AND SOFT-TISSUE TECHNIQUE**

Gentle, atraumatic, rapid, soft-tissue surgical technique with good hemostasis is essential for good results. Straight skin incisions generally provide the best exposure, the least risk of skin necrosis, and the best cosmetic results. Incisions can be longitudinal between the joints and over the extensor surface of joints. Over the flexor surface of joints, incisions must be transverse. When it is necessary to extend incisions that cross the flexor surface of joints, make curvilinear ones. In the torso, follow Langer’s lines (see Chapter 1, Chapter 2 and Chapter 3). Hoppenfeld and deBoer’s text, Surgical Exposures in Orthopaedics, provides numerous detailed drawings and descriptions of various surgical approaches as well (67).

Make skin incisions with a fresh scalpel blade and never with a pair of scissors or cutting current. For easy closure and best cosmetic results, make incisions at right angles to the skin. It is often difficult in orthopaedic procedures when dealing with very irregular surfaces to make such incisions. Take care to remain at right angles to the skin even as the incision curves across the surface of the limb. After you have made the initial cut, continue dissection with a sharp knife. Avoid blunt spreading with scissors or electrocautery, which adds to soft-tissue damage. In certain areas where subcutaneous and muscle hemorrhage is a particular problem, as in the spine, electrocautery is used more frequently with minimal morbidity. Rapid, precise dissection with the scalpel where tissues must be cut, and blunt dissection with the finger or an elevator where tissue planes can be split bluntly, is the most atraumatic and rapid technique. Dissection with the scalpel, particularly in the region of important neurovascular bundles, requires precise knowledge of anatomy. Neurovascular bundles can be safely dissected out with a #15 blade if the surgeon knows the anatomy and works from proximal to distal to avoid cutting into the axillae of nerve and vascular branches. The good surgeon treading in an anatomic region that she visits infrequently will greatly improve her surgical technique by thoroughly reviewing the anatomy and surgical approach before surgery.
In the lateral approach to the hip, it is common practice to use a curved Mayo scissors to split the fascia lata and expose the posterior border of the tensor fascia lata muscle, but this is totally unnecessary. The surgeon wastes time in switching from the knife to the scissors and back again. Most scissors are too dull and result in slow, traumatic surgery. The knife is precise and quick. In certain situations, the spread-and-cut technique with scissors is permissible. It must be recognized, however, that using the scissors for spreading and cutting is usually slow and traumatic. It is most effective in dissecting out neurovascular structures where heavy scraping is present, and in finding the digital neurovascular bundles in the hand and foot.

Even if a tourniquet is in place, obtain hemostasis layer by layer as the dissection proceeds. Isolate small vessels, clamp with the tip of a forceps, and coagulate. Ligate larger vessels with an appropriate-size suture. Major arteries and veins in the proximal portions of the limb generally require double ligature, usually with a suture ligature in the arteries, using appropriate-size, nonabsorbable suture material. In the subcutaneous fat, it is sometimes quicker to control hemorrhage with light pressure from a sponge or laparotomy tape and then touch the bleeding points with the electrocautery.

HINTS AND TRICKS

- Prolonged and overvigorous retraction is damaging. Use self-retaining retractors sparingly and with minimal pressure.
- Retract only tissues that need to be retracted, and avoid the skin edges.
- Broad blades or tines cause less injury than narrow ones.
- Do not use self-retaining retractors on neurovascular bundles. Hand-held retractors can also cause nerve injury if used with excessive force.
- Be certain to place the retractors in the correct position, and avoid placing pressure on sensitive structures.
- Advise the assistant to be diligent in maintaining the proper position and pressure.

Handle tissues with toothed forceps rather than with clamps. Be careful not to crush the tissue with the forceps; instead, use only one time of the forceps to retract the tissue (Fig. 5.13A). During suturing, for example, rather than pinching the tissue, it is better to pass the needle between the tines of the forceps, which are used to support the tissues (Fig. 5.13B). This technique avoids skin trauma and places the forceps in an ideal position to grasp the end of the suture needle.

For the most part, retraction is used more than necessary. Do not use it unless you have to. Do not repeatedly handle tendons or neurovascular bundles. When necessary, place neurovascular bundles in an appropriate-size Penrose drain loop, which is then used for gentle retraction. Surgical exposures that exploit the intervals between muscles are less traumatic than those that split muscles. Minimize wound exposure to limit contamination and keep tissues moist. Cover the portions of the wound not in the active surgical field with saline-moistened sponges. In some instances, particularly in prolonged procedures where a portion of the wound is not being used, it may be appropriate to use temporary retaining sutures to hold the tissues approximated, or staples in the skin. When a second wound is necessary, such in as bone-grafting procedures, close the ancillary incisions as soon as possible rather than leaving the wound open until you close the main wound.

After prolonged surgery, irrigate and debride the wound as in an open fracture before closure. Excise all damaged and nonviable muscle. Copiously irrigate with sterile saline using a mechanical pulsatile lavage-type irrigator.

SURGICAL TECHNIQUE ON BONE

When handling bone, preserve its vascular supply and avoid exposing it to excessive heat, which is necrogenic. To preserve vascular supply, expose only the portion of the bone absolutely essential to the operation. In the mid diaphysis, the periosteum and contiguous muscle envelope supply little blood to the cortex; therefore, subperiosteal dissection is permissible. Preserve the nutrient artery, perforating vessels, and ligament and tendon insertions, if possible. Bone fragments with only minimal muscle attachments are probably devascularized, but if they are anatomically and securely fixed they may become revascularized.

Necrosis of bone during orthopaedic procedures usually results from overheating of the bone by cutting and drilling instruments, especially if they are dull and run at excessive speeds. Keep all cutting and drilling tools sharp, and cool them with saline during use. Replace drill points and saw blades frequently. Sharp hand instruments are essential for precise, skilful, and rapid carpentry of bone. Avoid stress-risers in bone, which may later lead to pathologic fracture. Holes or windows in bone, particularly in the mid diaphysis, are significant stress-risers. Holes smaller than 5 mm in diameter present few problems, but holes more than 10 mm in diameter, or more than 30% of the diameter of the bone, lower the strength of bone, particularly in torsion. Make windows as smooth and round as possible. Terminate cuts in bone at a drill hole to dissipate the stress-riser effect.

Hemostasis in bone, particularly cancellous bone, can be a problem. We prefer bone wax for hemostasis. Soften the wax by kneading it, and apply it to the bleeding area with the finger protected by a laparotomy tape. Remove all excess wax.

WOUND DRAINAGE

Because orthopaedic surgery frequently leaves large, bleeding bone surfaces, suction-drainage is frequently utilized, although some authors question the necessity of routine drainage (14,30,82,134). Many drains and methods are available. Take care when placing suction drains directly on raw, bleeding bone surfaces or in intramedullary canals to avoid exanguination. Pass the trocar through the soft tissues at an angle. This technique may better allow the drainage tract, which exits the various fascial barriers at separate locations, to seal. It prevents the development of a persistent draining tract. Direct connection to wall suction is generally contraindicated because of the risk of excessive bleeding. Commercially available, self-activated suction reservoirs are safest. On occasion, it may be prudent to delay activation of suction until several hours after the completion of surgery to allow formation of a clot on bone surfaces.

Inadvertent sutureng of drains is easily preventable. After inserting and cutting the drain at the appropriate length (Fig. 5.14A), pull the drain back into the wound so that the cut end remains visible during wound closure (Fig. 5.14B). Close the entire wound or fascia with the exception of the part nearest the exposed cut end of the drain (Fig. 5.14C), then advance the drain to the premarked point, making sure that the drain is free. Then close the remaining wound. If a drain is inadvertently sewn in, postoperative removal may be possible; attach a 5-pound weight to break the offending suture. Inspect all drains upon removal to ensure that breakage has not occurred.
A surgeon’s concern about personal safety can be an emotional issue. Inadvertent percutaneous self-injury may be anxiety provoking, especially if the patient is

**SURGEON’S SAFETY**

or sequential compression devices. Delay can be minimized if the surgical team performs these tasks rather than waiting for written postoperative orders to be followed.

should initially remain uncovered and elevated on cloth blankets or towels until the heat is dispersed. It is important not to place splints against rubberized pillows, as the heat generated as the plaster sets may be severe enough to cause a superficial skin burn. Splints applied tightly may shear the skin and cause blisters. Dress patients who have a history of tape sensitivity with hypoallergenic tape or no tape at all. An elastic bandage tape or a burn stocking. Use tape with care in orthopaedics, because considerable postoperative swelling often occurs. Strong adhesive tape, such as paper tape, applied tightly may shear the skin and cause blisters. Dress patients who have a history of tape sensitivity with hypoallergenic tape or no tape at all. An elastic bandage (Ace-wrap) applied in spica fashion around hip incisions holds the dressing in place and also provides gentle compression.

It is important not to place splints against rubberized pillows, as the heat generated as the plaster sets may be severe enough to cause a superficial skin burn. Splints should initially remain uncovered and elevated on cloth blankets or towels until the heat is dispersed. Immediately after the conclusion of the procedure, the surgical team can elevate the limb, position any necessary traction devices, or reapply thromboembolic stockings or sequential compression devices. Delay can be minimized if the surgical team performs these tasks rather than waiting for written postoperative orders to be followed. Additionally, the surgeon can then be sure that the appropriate devices and position are used.

**SURGEON’S SAFETY**

A surgeon’s concern about personal safety can be an emotional issue. Inadvertent percutaneous self-injury may be anxiety provoking, especially if the patient is
perceived to be in a high-risk category or known to be infected with a transmissible disease. Having accurate information about the potential for disease transmission is the most effective way to minimize anxiety.

The AIDS epidemic has focused an increased awareness on the safety of the surgical team, especially for orthopaedic surgeons, who are frequently exposed to sharp bone fragments and use power tools that aerosolize particles. The actual risk of AIDS transmission is low, the risk of transmission of other infectious diseases, namely hepatitis B and C, is much greater. While adequate prophylaxis to hepatitis B may be obtained through vaccination, the operating team must take precautions to minimize their risk of contracting hepatitis C and other infectious organisms. Universal precautions have been developed to minimize the surgical team’s risk of intraoperative infection exposure (47).

HEPATITIS B VIRUS

The development of an effective vaccine has made hepatitis B (HBV) a preventable disease. Because of the high risk of percutaneous injury, all operating room personnel should receive hepatitis B vaccine. HBV is much more contagious than other viruses; the risk of transmission of infection has been estimated to be 30% following a single percutaneous exposure to blood from a patient whose HBV disease is in the most infectious period (136).

Development of an effective vaccine against hepatitis B has effected a dramatic decrease in the transmission of HBV to health care workers through blood exposure. In 1993, an estimated 1,450 health care workers became infected with HBV though exposure to blood and body fluids, a 90% decrease from the number infected in 1985. Between 5% and 10% of those infected with HBV develop chronic hepatitis and are at risk for developing cirrhosis and hepatocellular carcinoma. An estimated 100 to 200 health care workers have died annually during the 1990s as a result of complications related to chronic HBV infection (25). Among the orthopaedic surgeons surveyed at the 1991 meeting of the American Academy of Orthopaedic Surgeons, 67% had received the hepatitis B vaccination. The incidence of vaccination was inversely proportional to the age of the surgeon. Ninety percent of surgeons between 20 and 29 years old had been vaccinated, while only 35% of surgeons 60 years or older had been vaccinated. Thirteen percent of individuals showed evidence of infection with HBV and less than 1% showed infection with hepatitis C. The prevalence of both infections increased with age. Only 3% of those in their third decade of life were infected with HBV, while 27% of surgeons 60 years or older showed serologic evidence of HBV infection (133).

Antibodies to HBV decline with time after vaccination. Up to 60% of those vaccinated lose detectable antibodies over 12 year (25). Despite declining antibody levels, vaccination remains a key defense against clinical HBV disease (69). Further periodic serologic testing is not currently recommended once adequate antibody response has been confirmed following primary vaccination (25).

HEPATITIS C

Hepatitis C (HCV), a serious health threat affecting a large percentage of the population, is a potential risk for practicing orthopaedic surgeons since no effective vaccine exists. The risk of infection from needle sticks in HCV is intermediate between that of HIV and HBV (103). The risk to health care workers from a random needle stick has been estimated to be about 0.1% (55). Several studies have reported that the risk of seroconversion in health care workers sustaining a percutaneous exposure to blood from anti-HCV-positive patients ranges from 0% to 6% (41,77,81). There appears to be a higher risk from hollow-bore needle sticks than from the more common suture needle sticks or the other sharp objects surgeons are exposed to. In one study, four seroconversions were seen following 331 hollow-bore needle sticks, while no seroconversions were reported following 105 injuries with suture needles or other sharp objects (116).

It is recommended that health care workers exposed to hepatitis C be tested after exposure and again 6–9 months later to detect hepatitis C antibodies (49). If hepatitis C infection is diagnosed, liver function studies should be performed to evaluate for chronic hepatitis.

In the past, treatment with immune globulin was recommended following exposure to non-A, non-B hepatitis (now known as hepatitis C). The immune globulin, which came from pooled plasma (some from donors infected with HCV), was felt to confer passive immunity. Since 1992, however, patients who are hepatitis C-positive have been excluded as plasma donors. Current data do not support the use of immune globulin for prophylaxis against hepatitis C.

Alpha interferon has been shown to be effective in the short term in the treatment of chronic HCV infection. Treatment is recommended for patients who are at greatest risk of progression to end-stage cirrhosis. This group includes patients with a persistently elevated alanine aminotransferase, presence of HCV RNA in the blood, and a liver biopsy showing either portal or bridging fibrosis and at least a moderate degree of inflammation and necrosis (103). Combination of the antiviral medication ribavirin with alpha interferon has shown promise in early studies (121).

HUMAN IMMUNODEFICIENCY VIRUS

The risk of HIV transmission from an infected patient to an orthopaedic surgeon is unknown. While the risk of seroconversion after a single percutaneous exposure may be low, great concern remains about the cumulative risk to orthopaedic surgeons, who often sustain numerous percutaneous injuries over the course of a lifetime. The cumulative risk has been estimated to be as high as 1% to 4% (160).

While no one knows the exact risk, this figure may represent an overestimate for several reasons. The risk of HIV transmission is affected by the degree of viremia in the patient, the volume of the exposure, and the seroprevalence in the patient population, which varies greatly by geographical region. An estimated 5% to 10% of acute trauma patients in certain urban areas may be HIV positive (68). It is believed that the greatest risk of transmission is from a percutaneous injury, and that aerosolized particles, mucous membrane exposure, and exposure to intact skin present a low risk of disease transmission. Percutaneous injury with a hollow-bore needle is believed more likely to result in HIV transmission than injury by a solid suture needle, which is more commonly the experience of orthopaedic surgeons (88). Virus transmission has not been documented with a solid-core suture needle injury. Needle type, size, and depth of penetration have been shown to be independent predictors for the volume of blood transferred in a percutaneous needle stick. The volume of blood transmitted is reduced by at least 50% when the needle passes through a glove made of any kind of material (94). The probability of transmission of infections may be more associated with the patient's viral titer than with the amount of the inoculum (114). Prospective studies of health care workers have estimated that the average risk of HIV transmission after a percutaneous exposure to HIV-infected blood is approximately 0.3% (95% confidence interval, 0.2% to 0.5%) (15).

As of June 1997, the Centers for Disease Control and Prevention had received 52 reports of documented U.S. health care workers who had seroconversion following occupational HIV exposure. Possible occupational HIV transmission has been reported in 114 cases in which the health care worker had no other known risk factor but there was no specific documented exposure (26). A seroprevalence survey involving 48% of the orthopaedic surgeons attending the 1991 annual meeting of the American Academy of Orthopaedic Surgeons found only two HIV-positive individuals (0.06%), and both of these surgeons reported additional nonoccupational risk factors (23).

A brief window of time exists after primary HIV infection before systemic infection occurs. During this time, postexposure antiretroviral intervention may modify viral replication. The U.S. Public Health Service has established recommendations for postexposure prophylaxis based on the risk of infection following the exposure and the infectivity of the exposure source (20) (Fig. 5.15). These recommendations are likely to continue to evolve as new retroviral agents or combination of agents are approved for use in clinical practice (20).

While postexposure antiretroviral therapy does not necessarily alter the natural course of HIV infection, it may provide a significant advantage to health care workers during the most effective time to prevent disease progression. The most recent findings suggest that high-risk individuals not previously exposed to HIV can achieve durable suppression of viral replication with demonstrated prevention of disease progression (20). The combination of antiretroviral agents demonstrated in clinical trials can suppress HIV replication for extended periods (20). The use of antiretroviral agents to support health care personnel in high-risk situations can provide substantial benefit and should be seriously considered (20).

MMWR.
Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

In one study, 74% of surgeons’ documented exposures to blood during surgery were potentially preventable by the use of additional barrier precautions, such as face shields and fluid-resistant gowns (111). Although there have been no documented cases of transmission, the possibility has been raised that HIV could be transmitted via aerosolized particles produced by power tools (79). Use face shields to prevent this kind of contamination (79) and splash shields to minimize the spread of the aerosolized fluids from mechanical pulsatile lavage. Double gloving, initially popularized in total joint arthroplasty as a way of minimizing the risk of the surgeon's contaminating the patient (55), has become important in protecting the surgeon. Latex glove perforation occurs frequently. The use of double gloves has been shown to be effective in minimizing the risk of perforation. Double gloving may result in a 60% to 80% decrease in inner glove perforation and visible blood contamination (49). Some authorities recommend inspecting and routinely changing latex gloves at least every 2 hours during long-duration procedures (67,128). One author has recommended that gloves be changed at least every 25 minutes (114). Cloth, Kevlar, and stainless-steel-reinforced gloves provide additional protection from perforation (63,87,126,145). Despite the use of these reinforced protective gloves, perforation of the inner gloves nevertheless occurs and may go unrecognized. Fluid sensors have been developed to alert surgeons when a glove has been penetrated.

Use fluid-impervious gowns during surgeries in which the gown may become saturated with blood or fluid. The use of a self-contained air exchange system may also offer protection, but the benefit it confers may be outweighed by communication difficulties it causes that could lead to accidental injury (28). Alternatively, an impervious urology apron worn under the surgical gown effectively prevents contamination of the trunk and lower extremities (49). Knee-length rubber boots or impervious shoe covers are recommended for cases in which the potential for blood loss is significant, or during arthroscopy.

The American Academy of Orthopaedic Surgeons (AAOS) has recommended changing surgical methods to reduce the risk of injury: Be aware and cautious, use pop-off needles, avoid having more than one person suture at a time, announce the passage of sharp instruments and pass them in a kidney basin or other device. Take care to avoid digital palpation of fracture sites or sharp bone surfaces. Cover pins and wires with protective caps. Periodically inspect gloves and gowns (8).

In the event of a percutaneous exposure, the AAOS recommends the following procedure (4):

- Wash the affected area immediately.
- Bleed the wound.
- Apply 70% isopropyl alcohol on the wound directly.
- Report the incident.

POSTOPERATIVE PATIENT CARE

Postoperative care varies tremendously depending on the operation performed and the condition of the patient. Several general principles apply to the majority of patients, however. Elevate limbs postoperatively to improve venous and lymphatic return, but not so high that arterial input is compromised. In general, the ideal level is where the most distal portion of the extremity is 10 cm above the heart. Elevation on pillows is usually more comfortable for the patient and less hazardous than slings. Immobilize only joints that must be immobilized. Unless contraindicated, all mobile parts must be moved after surgery, either by active, active-assistive, or passive exercises.

Early mobilization of patients into a chair at bedside, to the toilet, and subsequently for ambulation is important. With today’s surgical techniques, enforced bed rest after surgery is unusual. If a patient is on enforced bed rest, it is important to institute an in-bed physical therapy program to maintain joint range of motion, muscle strength, and, if possible, aerobic conditioning. Not only does such a regimen play a major role in mobilizing the patient later, but it also provides great psychological benefit.

VENOUS THROMBOEMBOLISM PROPHYLAXIS

Prevention of thromboembolic disease is a critical issue in orthopaedic surgery. Recent studies have highlighted the pervasiveness of this problem among several orthopaedic patient populations (50,130,158). Without prophylaxis, a deep venous thrombosis may occur in 40% to 60% of patients undergoing total hip or knee arthroplasty. Proximal deep venous thrombosis may occur in 15% to 20%, and a fatal pulmonary embolism may occur in 0.5% to 2% (65). Risk factors that have been identified for thromboembolic disease include age (becoming clinically important by age 40 and increasing thereafter); prolonged immobility or paralysis; history of prior thromboembolism; cancer; major surgery (particularly operations on the pelvis and lower extremities); obesity; varicose veins; congestive heart failure; myocardial infarction; stroke; fractures of pelvis, hip, or leg; and possibly high-dose estrogen use (29).

Numerous methods of prophylaxis have been investigated, and authorities recommend both mechanical and pharmacologic methods. Intraoperative anesthetic techniques including hypotensive and epidural anesthesia have been shown to reduce the risk of thromboembolism (86,134). Mechanical methods include use of compression stockings and various pneumatic compression devices. Pharmacologic methods include dextran, aspirin, warfarin, heparin, and low-molecular-weight heparin.

Diagnosis of thromboembolic complications, most of which are asymptomatic, remains difficult. Methods for diagnosis of deep venous thrombosis include impedance plethysmography, fibrinogen I-125 scanning, venography, and duplex ultrasound. Diagnostic methods for pulmonary embolism are ventilation-perfusion scanning and pulmonary angiography. There is controversy over the ideal diagnostic testing modality because of variation in sensitivity and specificity of the different tests. They also vary in their ability to image different parts of the venous system, and in the invasive risk they pose to the patient.

In cases where deep venous thrombosis is diagnosed, controversy also exists over whether all thrombi should be treated, what method of treatment should be used, and how long treatment should last. Low-molecular-weight heparin, which does not require laboratory monitoring, is increasingly the treatment of choice in the outpatient management of deep venous thrombosis (155). The numerous investigations and recommendations on this important subject are beyond the scope of this chapter. While many therapeutic methods have been shown to reduce the risk of thromboembolism, no single method is completely effective or applicable to all situations. Metaanalysis of recent randomized clinical trials has shown low-molecular-weight heparin to be superior to warfarin in prevention of deep venous thrombosis, but its use is associated with a greater number of minor bleeding complications (110). Each surgeon must assess the varying risk that thromboembolism presents to each individual patient, selecting the prophylactic method that appears to provide the greatest risk reduction when balanced against any potential risk of the treatment itself.

CHAPTER 6
INSTRUMENTATION AND IMPLANTS

To perform effective, safe, and rapid surgery, the surgeon must have sharp and functioning instruments. The care, maintenance, and ownership of surgical instruments and implants is, for the most part, the province of the hospital and its operating room staff. A few surgeons, particularly in highly specialized fields such as microvascular surgery or arthroplasty, own their own surgical tools. Surgeons might want to consider purchasing, maintaining, and using their own instruments in the case of particularly delicate instruments, those that are ineffective if damaged, and those that as a rule are not in good condition in the average, busy operating room.

The neglect of a simple maintenance operation—lubricating the instrument—may result in its destruction, requiring replacement or major overhaul. Care of these expensive, sophisticated instruments cannot be casual. The operating room staff must set up a mandatory maintenance program.

The surgeon has a responsibility not to abuse or misuse instruments, to be familiar with the instruments and implants, and to inform the operating room staff well in advance if specialized or backup instrumentation or implants are required for a particular procedure. After the instruments are open on the back table, review the steps of the surgery with the scrub nurse to be certain that all instruments are present, in good shape, and functioning. Do this review before the skin incision is made; do not delegate this responsibility.

If the surgeon is using new instrumentation for the first time, it is wise to go over the instrumentation at a time separate from the first surgery. In hospitals that have motor skills workshops, it may be worthwhile to go through a motor skills exercise using the equipment.

CARE OF INSTRUMENTS

NONPOWERED INSTRUMENTS

In orthopaedic surgery, there is frequently a need to grasp and manipulate large, tough structures such as tendons, ligaments, and bone. Most forceps and clamps used in general surgery are not designed to handle these structures and can be damaged if used inappropriately.

The metals for instruments are fabricated with less regard to corrosion resistance and are designed more to meet functional needs, such as cutting, wear resistance, and weight. After each use, clean instruments thoroughly, usually with an ultrasonic cleaner. Some must be disassembled for proper cleaning. After cleaning, dry them thoroughly and store them properly to avoid corrosion.

The following are guidelines for the use of nonpowered surgical instruments that will spare problems for the surgeon, patient, and instruments.

- Never use microsurgical instruments for routine hand surgery.
- Handle tendon, ligaments, periosteum, and other soft tissues with toothed forceps, which provide a better grip, crush less, and have a smaller surface area of contact than do nontoothed forceps. The teeth of a large Kocher clamp provide such advantages if you must firmly grip or pull a tendon or ligament.
- Do not use Kelly clamps, hemostats, mosquitoes, or other similar instruments to grasp musculoskeletal tissues. Using them in such a way springs the tines and makes them useless for routine soft-tissue use.
- To suture tendons and ligaments, use a heavy-duty needle holder with diamond-patterned jaws to grip the needle firmly. Round needles are very difficult to pass through ligaments. Instead, use a cutting needle unless you think the suture may cut out of the tissue.
- The only instrument that should be used for hammering is a mallet. In particular, do not use the handles of power instruments, whose delicate machinery may be broken by any type of pounding.
- Do not use dull or chipped osteotomes, chisels, gouges, or periosteal elevators. It is particularly damaging to sharp instruments to use them to remove hardware. Metal-to-metal contact chips and dull blades. Ask the operating room staff to set aside a special set of older sharp instruments to be reserved for hardware removal.
- Sharp, straight drill points are essential to avoid bone necrosis and to obtain secure fixation. Because drill points are difficult to resharpen correctly, replace them frequently.

POWERED INSTRUMENTS

The major responsibility of caring for powered instruments belongs to the operating room staff. The surgeon can help by being certain that the power tool is properly assembled and that it is not used for anything other than its intended purpose.

Proper assembly is important to performance; improper assembly may damage power transfer interfaces. Know your power instruments and make sure that the scrub nurse assembles them properly. Excessive noise or overheating could be an indication of mechanical problems or inadequate lubrication. Stop using the instrument immediately; continued use may result in freezing of the components.

The neglect of a simple maintenance operation—lubricating the instrument—may result in its destruction, requiring replacement or major overhaul. Care of these expensive, sophisticated instruments cannot be casual. The operating room staff must set up a mandatory maintenance program.

Power tools, ranging from large reamers for the acetabulum to fine powered instruments for arthroscopy, are delicate instruments. Most are gas powered; treat the hose carefully to avoid gas leakage and loss of power. Do not sharply angulate, crimp, or penetrate the hose. Use compressed air or nitrogen. Never use oxygen because of the danger of fire.

Optimal operation requires proper operating pressures, as designated by the manufacturer. For most instruments, proper pressure is approximately 6 bar (90 psi).
Nevertheless, a central air system should have the capacity to provide 9.6 to 12 bar (145 to 180 psi). It is best if power systems evacuate their gases out of the operative field. The gas must be sterile, and sterility is usually accomplished by means of a filter. If instruments are run by compressed air from a central system, use of a filter may be necessary to eliminate condensed water, dirt, or rust, which may interfere with the function of the power equipment.

A standard assortment of orthopaedic power instruments is illustrated in Figure 6.1. Most power instruments are damaged if immersed in water. After each use, they must be wiped, thoroughly cleaned with an air jet, and immediately oiled. See the manufacturer’s directions for maintenance.

**Figure 6.1.** Assorted power tools, including reciprocating and oscillating saws. The middle tool serves as a reamer or drill. A single power source is used. (Courtesy of Hall Surgical, Division of Zimmer, Santa Barbara, CA.)

### CARE OF IMPLANTS

Orthopaedic implants come packaged individually from the factory with high-quality surface finishes. Maintenance of the finish is critical. Avoid scratching or nicking it to prevent the formation of stress risers that can lead to premature implant failure. Store implants in their original containers, and return them to their containers if they are opened in the operating room. A second choice is a properly designed storage rack that holds the implants securely, does not scratch them, and prevents implants from rubbing against each other. Never store implants loose and unprotected in a tray or drawer.

Inspect implants carefully before implantation. Significant scratches or nicks are justification for rejecting an implant, particularly in the case of a prolonged implantation (e.g., total hip prostheses) or high-stress situations (e.g., plate fixation of a nonunion). Never reuse implants that have been removed from patients; they have been subjected to fatigue stress, and they may be close to failure. Discard screws used temporarily for external compression or other high-stress uses.

Contour plates to fit the bone as smoothly as possible to minimize formation of stress risers. Avoid bending through screw holes, and use templates so that bending of the plate is accomplished with minimal manipulation. Excessive bending of a plate, particularly reverse (back-and-forth) bending, increases its likelihood of failure. The only implants that can be reused are unstressed ones—for example, a screw that has been replaced because it is of incorrect length.

Do not mix implants from different manufacturers. Although the designs appear identical, small differences often exist that can cause mechanical or material incompatibility.

### SURGICAL INSTRUMENT SETS

Organize surgical instruments into a series of sets. A general instrument set is required for the incision and exposure of soft tissues and for closure. Major orthopaedic operations usually require a general surgery soft-tissue instrument set. A second set contains orthopaedic instruments needed for most bone surgery, such as periosteal elevators, chisels and osteotomes, gouges, mallets, drills and drill points, rasps, forceps, rongeurs, and bone-holding instruments. A third set contains some type of powered equipment for drilling and cutting bone. A fourth set contains specialized instruments for the procedure at hand. For fracture fixation, it consists of internal fixation instruments and implants, and, in total joint replacement, instruments for total joints. These specialized instruments are discussed in separate chapters, with the surgical procedures. General instruments are discussed in this chapter.

#### PERIOSTEAL ELEVATORS (FIGURE 6.2.)

Periosteal elevators are chisel-like instruments with rounded tips that are designed to elevate periosteum and muscle fibers from bone. Unless they are kept very sharp, they are ineffective in cutting ligament and inserting tendon, for which a scalpel is more useful. Use a periosteal elevator against the acute angle of muscle fiber insertions. When used on the obtuse angle, it skids off into the soft tissues. Examples include (A) the Langerbeck periosteal elevator, 8 in. (20 cm) long, and (B) the Key periosteal elevator, which is available with blades from ½ in. (6.4 mm) to 1 in. (25 mm) wide. Handles are from 6½ in. (171 mm) to 8½ in. (210 mm) long. These are the most useful elevators for general bone work, excluding the spine. The Freer septum elevator (C) has both sharp and blunt blades available with a 7 ½ in. (191 mm) handle. The Freer and Joseph elevators are useful in foot, hand, and spine injury and in pediatric cases. Many styles of Cobb periosteal elevators (D) are available. They are most useful in spinal surgery. They have 11-in. (279 mm) handles in most cases and have blades from ½ in. (13 mm) to 1¼ in. (32 mm) wide. (Courtesy of Zimmer, Warsaw, IN.)

**Figure 6.2.** Periosteal elevators.

#### RETRACTORS (FIGURE 6.3.)

...
Specialized soft-tissue retractors are described with the procedures that require them. Several useful retractors are designed to bear against bone while atraumatically retracting the soft tissues. Hohmann, cobra, and Bennett retractors, used singly or in combinations, are essential in most major long-bone surgery and particularly surgery of the hip and pelvis. Small-tipped retractors such as the Hohmann retractor are preferable because they cause less stripping of the periosteum than other types do. The Hohmann retractor (A) is available with blades from $\frac{1}{16}$ in. (17 mm) to $1\frac{11}{16}$ in. (43 mm) and handles from 9½ in. (235 mm) to 10½ in. (273 mm). Aufranc cobra retractors (B) have pointed, blunt, and blunt serrated tips. Overall lengths are approximately 10 to 11 in. (25 to 28 cm). These are used widely for hip surgery. Bennett retractors (C) are available in two blade widths—$\frac{3}{8}$ in. (44 mm) and $2\frac{1}{2}$ in. (64 mm). They are the most useful retractors in hip fracture repair and in major long-bone surgery. The Blount retractor (D) is designed to be used as a pair on either side of the bone. Length is 10½ in. (273 mm). These are available with a single tine. (Courtesy of Zimmer, Warsaw, IN.)

CHISELS AND OSTEOTOMES (FIGURE 6.4.)

Chisels and osteotomes are derived from woodworkers’ tools. Chisels have a cutting edge with a flat back parallel to the long axis of the tool and a beveled edge; osteotomes are tapered on both sides. These instruments are available in sets with widths varying from 4.7 to 50 mm ($\frac{3}{16}$ to 2 in.). For general orthopaedic use, these instruments should have large, knurled handles that enable them to be grasped easily and that minimize fatigue of the hand. They are designed to be used with mallets. Smaller varieties are available for hand surgery, such as the Smith-Petersen osteotome (A). Notice the double taper on the cutting edge. Overall length is 8 in. (20 cm). These are available in $\frac{1}{4}$-in. to 1½-in. widths, with straight or curved blades. The Lambotte osteotome (B) has a length of 9½ in. Straight and curved blades are available, and widths are $\frac{1}{4}$ to $\frac{1}{2}$ in. The Hibbs chisel (C) has a length of 9 in., may be straight or curved, and comes with widths of $\frac{1}{4}$ to $\frac{1}{2}$ in. One side of the blade tip is straight. The Hoke osteotome (D) is 5½ in. long, is straight or curved, and comes in widths of $\frac{1}{8}$ to $\frac{1}{2}$ in.; it is useful for work on small bones. (Courtesy of Zimmer, Warsaw, IN.)

GOUGES (FIGURE 6.5.)

Gouges also derive from woodworking tools. They are curved from side to side and are designed to scoop bone away. They may be straight or curved in the long axis. Gouges are used primarily to harvest bone grafts and to prepare bone for the receipt of a bone graft. Hibbs gouges (A) are available with straight or curved blades in widths from $\frac{1}{4}$ in. (6.4 mm) to 1½ in. (38 mm). Handles are 9 in. (229 mm) long. Both the Hibbs and Smith-Petersen gouges are excellent for most bone surgery. Cobb spinal gouges (B) have blades $\frac{1}{16}$ in. (7.9 mm) wide and are 11 in. (279 mm) long. The blades available are straight or curved with a medium, sharp, or reverse curve. These gauges are especially designed for spinal surgery. (Courtesy of Zimmer, Warsaw, IN.)

CURETS (FIGURE 6.6.)

Curets are spoon-shaped cutting instruments designed to scrape or remove bone with a twisting action of the handle. The most effective curets are fitted with large, long handles. The spoon sizes range from 000 to 6. The Brun bone curet (A) has a hollow handle, but others (B) may have solid handles. Curets have 6½-in. (165 mm) or 9-in. (229 mm) handles and straight or curved oval cups from size 000 to 6. Curets come in many forms, including Cobb curets. (Courtesy of Zimmer, Warsaw,
Bone-cutting forceps are based on the same construction principles as wire cutters and are available in many sizes. Single-action forceps are precise and useful for small or soft bone work. Double-action forceps are required for most applications. Forceps do not cut well near their tips and are most effective if the bone is placed in the depths of the jaws. Stabilize both sides of the bone while using forceps because sudden closure of the jaws could cause a piece of bone to be ejected from the operating field. The Stille-Liston bone-cutting forceps (A) is 10½ in. (267 mm) long; the blades are straight or curved. The Liston bone-cutting forceps (B) has straight blades with overall length from 6½ in. (140 mm) to 8½ in. (216 mm). Ruskin-Liston bone-cutting forceps (C) have straight and angled-up blades and an overall length of 7¼ in. (184 mm). Ruskin bone-splitting forceps (D) have a length of 7½ in. (184 mm) and are available with delicate and standard jaws. Stille-Horsley rib forceps (E) are 10¼ in. (267 mm) long with bayonet jaws. They are designed to transect ribs. All but the Liston forceps are double-action forceps, which have better cutting power than single-action forceps but somewhat less precision. (Courtesy of Zimmer, Warsaw, IN.)

Rongeurs (FIGURE 6.8.)

Rongeurs are based on the same mechanical principles as forceps, but the cutting end resembles a double set of opposed curets. Use of rongeurs follows the same principles as the use of forceps. One effective method of using a rongeur is to stabilize one cup against the bone surface and cut or scrape with the other cup. Rongeurs are available in 20 or more different designs. The bites are available in oval, round, and other patterns. They can be used on bone and to remove tough soft tissues such as fibrous scar. Many are specially designed for spinal or neurosurgical applications. Four typical designs are illustrated. Small, large, straight, and curved bites are available for the Ruskin rongeur (A). Its length is 7¼ in. (184 mm). The Stille-Leur rongeur (B) has a 10-mm bite and straight or curved blades. Its lengths are 8½ in. (216 mm) and 10½ in. (267 mm). The Echlin duckbill rongeur (C) has a narrow, angular jaw in the plane of the handles. Bites of 2, 3, and 4 × 10 mm can be taken. Its length is 9 in. (229 mm). The Cushing rongeur (D) has a 5-in. (127 mm) shaft with 2 × 10-mm bite and straight or up- and down-angled jaws. (Courtesy of Zimmer, Warsaw, IN.)

Bone rasps (FIGURE 6.9.)

A variety of files or rasps is available for smoothing and shaping bone surfaces. Most effective are those resembling woodworking tools. The fine patterns seen in woodworking tools fill so rapidly with bone that they are less effective. The Putti bone rasp has round and semiround ends or flat tapered and curved ends. Its overall length is 11½ in. (30 cm) or 10½ in. (27 cm). (Courtesy of Zimmer, Warsaw, IN.)

Mallets (FIGURE 6.10.)
Mallets are also designed after woodworking tools. They are not hammers. Most mallets are composed entirely of stainless steel and are available in different sizes. Most surgeons feel that the metal-to-metal contact of a steel mallet on a steel instrument provides the best proprioceptive feedback. Shock-absorbing faces of plastic or other materials are available, but their tendency to rebound makes them less effective than all-metal ones. The orthopaedic bone mallet shown here is all stainless steel. Its length is 7¾ in. (197 mm), and its weight is 1 lb (454 g) or 2 lb (908 g). Mallets are also available in aluminum with nylon or metal heads. Most surgeons prefer all metal. (Courtesy of Zimmer, Warsaw, IN.)

BONE-HOLDING INSTRUMENTS (FIGURE 6.11.)

A multitude of instruments are designed to hold and manipulate bones. For major diaphyseal fractures, one of the most useful bone holders is the Lowman bone-holding forceps (A). It is particularly useful if there is a need to hold a plate against the bone. Its disadvantage is that it requires considerable soft tissue stripping to place. The Lowman bone clamp (A) is available in three lengths [4¾ in. (121 mm) to 8 in. (203 mm)] and three jaw sizes [3/4 in. (19 mm) to 1¼ in. (32 mm)]. It is calibrated to measure the diameter of bone and can be disassembled to apply or remove. In my hands, it is the most effective bone-holding clamp, particularly for the femur and humerus. It holds plates to bone with excellent security. In the Lane bone-holding forceps (B), toothed jaws provide a firm grip on bone but are not ideal for holding plates. A ratchet makes them self-retaining, an important feature. Available in 13-in. (33 cm) and 17-in. (43 cm) lengths, they are useful only for large bone surgery. The Kern bone-holding forceps are nearly identical in appearance but are supplied in 6½ in. (165 mm) and 8½ in. (216 mm) lengths for small bone work. In self-retaining bone-holding forceps (C), the teeth are designed to grip bone. They are not to be used on plates. Verbrugge forceps (D), designed to hold plates on bone, have offset handles to facilitate placement. Tenaculum forceps (E) resemble a stout towel clip. They are excellent for reducing and holding small bone fragments, particularly in cancellous areas, and they often are used in pairs. Tenaculums are much kinder to the soft tissues. (A, B, C, E are courtesy of Zimmer, Warsaw, IN.)

BONE DRILLS (FIGURE 6.12.)

Effective, versatile power tools have reduced the use of hand drills, which are not as useful as well-designed power tools because they require the use of two hands. Additionally, the wobble introduced by the hand activating the drill handle produces a less accurate drill hole than a power drill. Nevertheless, always keep hand drills available in case the power drills fail. Hand drills are more efficient to use than power drills for tasks such as inserting traction pins. To run smoothly, drills must be cleaned and lubricated frequently. The universal bone drill (A) is available in various combinations of 11-in. (279 mm) and 13-in. (330 mm) lengths and 5/32-in. (4.0 mm) and 1/8-in. (6.4 mm) chucks. The drill uses a 2-to-1 gear ratio and is cannulated for long pins and wires. A small hand drill (B) (Bunnell type), 5-in. long, cannulated, with a 5/32-in. chuck, is designed for small bone surgery. (Courtesy of Zimmer, Warsaw, IN.)

SCREWDRIVERS (FIGURE 6.13.)
Various types of screwdrivers are available, including simple screwdrivers and automatic ones that retain the screw on the screwdriver tip and release it automatically (trinkle drive). Screw heads that require different screwdriver tips include single slot, cruciate, Phillips, woodruff (i.e., cruciate with rounded teeth), torx drive, and the hexagonal hole. The hexagon is used most commonly today, but the torx provides more turning power and is less likely to slip, particularly in titanium screws. Free bits for use in power drives are available. Do not use power to drive screws into osteoporotic or pathologic bone. Have the proper screwdriver available when removing hardware implanted by others. Sometimes you can determine which one you need by radiographic examination, but often you must review the operative report. With an automatic screwdriver (A), a grip holds the screw onto the bit. They are available with single slot, cruciate, or universal bits. These screwdrivers have a unique handle shape to increase grip power (B) and have a hexagonal tip. The torx driver provides the best turning power and is least likely to slip, particularly in titanium screws. (B is courtesy of Zimmer, Warsaw, IN.)

HAND BONE SAWS (FIGURE 6.14.)

Gigli spiral saw wires (A) are commonly used to transect bone when power tools are deemed unnecessary or dangerous. They are useful for cutting away from vital structures, such as the sciatic nerve in Salter's innominate osteotomy. To effectively use handles, keep the wire taut, and do not bend the wire more than approximately 45°. The sharper the curve of the wire, the more likely it is to jam. Protect the soft tissues with retractors. The Gigli spiral saw (A) is available in 12-in. (305 mm) and 20-in. (508 mm) lengths with a pair of handles. The Satterlee bone saw (B) is used for amputations, but most surgeons have abandoned it in favor of power saws. (B is courtesy of Zimmer, Warsaw, IN.)

PLATE BENDERS (FIGURE 6.15.)

Tools for bending plates are derived from the old corset trade. Available are hand-held bending irons for small plates (A), and presses for large plates (B). Take care not to score or crease plates during bending, and avoid weakening the plates by reverse or repeated bending.

MISCELLANEOUS INSTRUMENTS (FIGURE 6.16.)

Bone awls (A and B) are employed for perforating cancellous bone and thin cortical bone when a drill is not useful or desirable, as in a classic Bankart repair of the shoulder. Bone awls are available with curved and straight tapered tips, like the Zuelzer bone awl (A) and Rush rod awl-reamer (B) shown here. Bone hooks (C), available in various sizes and shapes, are used to retract and manipulate bone fragments. These are available in many sizes and shapes. The inside diameter of the hooks range from 3/8 in. (9.5 mm) to 1 in. (25 mm). Bone tamps (D) are used to pack bone graft into place and to countersink wires. These are 6 in. (152 mm) long, with a 3/8-in. (9.5 mm) or 1/2-in. (13 mm) end diameter. (B—D are courtesy of Zimmer, Warsaw, IN.)

CHAPTER REFERENCES

PATHOPHYSIOLOGY

For the orthopaedic patient, anesthesia and pain management involve preventing or controlling the response to acute (surgical) pain and chronic (pathologic) pain. The response to acute pain is motor (withdrawal), psychological (pain), emotional (fear), and autonomic (hypertension, tachycardia) (Table 7.1). The response to chronic pain is more complex because of the adaptations that occur. A chronic pain patient's response is somewhere between stoicism and amplified emotion. The International Association for the Study of Pain (IASP) defines pain as “An unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage” (36a). This definition does not include a description of how a patient in pain looks. Only the patient's description of his subjective experience matters.

The neurologic components involved in pain are nociceptors, primary afferent fibers, ascending nociceptive tracts, higher centers in the brain, descending pain modulating tracts, and centers in the spinal cord. The detailed anatomy and physiology of pain continues to be an area of active research. The sites where interventions are currently available are listed in Table 7.2. Despite the scientific knowledge about anesthesia and analgesia, the practices of anesthesia and pain management have a decidedly empirical nature. Drugs that block the motor and autonomic response to acute pain are well understood, as are the drugs that block nerve conduction. Promising areas of research currently focus on the role of the spinal cord, N-methyl-D-aspartate (NMDA) receptors, and gamma-aminobutyric acid (GABA) receptors in the mechanism of anesthesia and chronic pain.

PRINCIPLES OF TREATMENT

The anesthetic goal is to control the response to surgery without complications and usually with a quick return of physiologic function. This should be accomplished while minimizing the unpleasantness of the perioperative experience for the patient. There are numerous options for controlling the response to surgery, but they all have limitations and risks. Anesthetic complications arise from invasive procedures, drugs, devices, and decisions. Complications are avoided by assessing the patient,
assessing the anesthetic implications of the operation, selecting an anesthetic that will accomplish the goals, modifying the anesthetic according to the patient's response and the operative requirements, and managing the risks. Risk management consists of anticipating adverse effects, preventing them if possible, looking for them, and controlling them. Even with careful planning, unanticipated problems arise. Early recognition can often be gained by vigilant routine monitoring. This is important because the evolution of some problems is extremely rapid. Problem-solving skills and experience are needed. The source of a problem is the operation, the patient, the anesthetic, or sometimes a combination of these factors. Sometimes multiple problems arise and need to be prioritized so that the most rapidly fatal problems are dealt with first.

ASSESSMENT, INDICATIONS, RELATIVE RESULTS

Patient assessment is an essential ingredient of anesthetic risk management. Cardiovascular and pulmonary disease, obesity, pregnancy, and many other conditions increase the possibility for anesthetic-related complications. The subsets of orthopaedic patients who require careful assessment are the pediatric, the geriatric, and the trauma patients. Table 7.3, Table 7.4 and Table 7.5, respectively, summarize some of the specific considerations for these patients.

CLASSIFICATIONS

Since the early 1940s, the American Society of Anesthesiologists' Physical Status (ASA-PS) classification has been used to grade the preoperative physical condition of surgical patients (38). The current, revised classification appears in Table 7.6 (34). This classification has proven useful in assessing the effect of a patient's preoperative condition on the subsequent response to anesthetic techniques and drugs. The ASA-PS communicates succinctly to other anesthesiologists and surgeons the assessor's evaluation of the patient. It serves statistically as an ordinal covariate for an individual patient. The distribution of ASA-PS in a patient population is useful in comparing one population with another. A consistent correlation between ASA-PS and perioperative mortality has been reported in two large series (27,51). This consistency is evident despite the fact that ASA-PS does not include a priori information about anesthetic or surgical risk, such as known difficult airway or expected major blood loss. To be useful as a covariate, the ASA-PS should be consistent between different rating anesthesiologists. Consistency has been tested in a small series. When presented with 10 different patient descriptions, 4 patient characteristics that cause anesthesiologists to differ in their assignment of ASA-PS are age, anemia, a history of previous myocardial infarction, and obesity (36).

In recent years, the Mallampati classification of airway anatomy has been used to predict the likelihood of difficult endotracheal intubation (25). This classification is described in Figure 7.1. It basically estimates the relative sizes of the mouth and the tongue. The mobility of the neck is an additional factor. This classification has
become a routine part of the preoperative assessment; although it is not infallible, it indicates the possible need to prepare for a difficult intubation. Patients with class 3 or 4 Airways are increasingly likely to require nonroutine methods for intubation. Laryngoscopy grades, described in Figure 7.2, provide a succinct indication of the view during direct laryngoscopy. Patients in grades 3 or 4 are likely to be difficult to intubate because the glottic opening is not visible.

Figure 7.1. The Mallampati airway classification is based on assessing the relative size of the oropharyngeal cavity and the tongue. Classes 3 and 4 are predictive of difficult laryngoscopy. Limited neck mobility and a short neck are also predictive of difficulty.

Figure 7.2. The airway grade classification is based on the view that is obtained by direct laryngoscopy. It is partially dependent on laryngoscopy technique and skill.

Anesthetic depth is classified as either “light” or “deep.” At one time, the stages of ether anesthesia were used to describe the depth of anesthesia. With newer agents that are used in combinations, the stages are difficult to identify by simple observation and are no longer clinically relevant. It is common to rely on the end-tidal anesthetic concentration (MAC, or minimum alveolar concentration) as an indication of depth, although it is really a measure of dose. Neurophysiologic correlates of anesthetic depth have been proposed, but none has as yet been widely accepted. The bispectral index, which is based on the computer-processed electroencephalogram (EEG), is currently of interest.

Anesthetic techniques are classified broadly as general, regional, or local anesthesia with or without sedation. Anesthetic agents are also broadly classified by route of administration, pharmacologic class, and clinical application.

Chronic pain may be roughly classified as neuropathic or somatic. These classifications correspond loosely to pain arising from nerves or pain from nonneural tissues. A third category comprising psychogenic pain, arising from thought disorder, is considered to represent few patients, although many chronic pain patients fear that they will be placed in this category.

PREOPERATIVE MANAGEMENT

The shift from inpatient to outpatient surgery, the elimination of routine laboratory testing and x-rays, and the elimination of routine preoperative admission the night before surgery have been adopted to reduce the costs of surgical procedures. As with other attempts to reduce costs, care must be exercised to ensure adequate preparation for the operation and the anesthetic. Some patients benefit from preoperative medical consultation and additional testing and therapy. Others benefit from postponement of surgery until they have recovered from acute illness or exacerbation of a chronic illness. To avoid the cost of canceling a scheduled case on the day of surgery, we have a system of preoperative screening and evaluation. Patients are screened by means of a questionnaire that is completed during the preoperative surgical clinic visit. Patients who score above a threshold number of points are referred to the anesthesia presurgical unit (PSU), where they are evaluated by either a nurse practitioner or an anesthesiologist. In addition, all hospital admission requests (HAR) for surgery are screened for patients who might benefit from early evaluation. Timely medical consultations can thus be obtained. Patients who have medical problems but do not need to be seen in the anesthesia presurgical clinic are evaluated by chart review or telephone interview, or both. The evaluation results are available by computer in the operating room.

The goal is to avoid last-minute delays and cancellations for anesthetic reasons. Issues that are addressed in the PSU include identification of medical problems that should be evaluated or controlled, recommendations for perioperative management of medications, and recommendations for preoperative testing. Algorithms have been proposed for preoperative evaluation of patients with symptomatic cardiovascular disease (2, 14). See Figure 7.3 for an example. The American College of Cardiology/American Heart Association and also the American College of Physicians have published recommendations for evaluating patients who have coronary artery disease (18a). Factors that correlate with increased risk of perioperative cardiac morbidity are the presence of acute congestive heart failure, recent (within 2 months) myocardial infarction, unstable angina, diabetes, limited exercise tolerance, and the type of operation. Guidelines for preoperative testing have resulted in reductions in routine laboratory tests, chest films, and electrocardiograms (ECGs), except in specific populations. See Table 7.7 for the guidelines that we use. Lastly, misunderstandings about the management of medications can cause delays or cancellations. Our current recommendations for medications to be continued or discontinued are listed in Table 7.8. The type of anesthetic is not selected in the PSU because that is decided by the anesthesiologist who eventually cares for the patient in the operating room. Information about the various types of anesthesia is provided, however, and one hopes that this preliminary discussion will save time on the day of surgery.

Figure 7.3. The initial steps in the guidelines. The clinical predictors are grouped according to significance for severe coronary artery disease. The patient’s functional capacity and the risk of the operation determine whether further testing or medical management are indicated.
PREOPERATIVE PLANNING

CHOICE OF ANESTHETIC

The choice of anesthetic technique begins with consideration of the operative requirements. Other factors are patient illness and medications, expected duration of the procedure, position on the table, blood loss, and preferences of surgeon, patient, and anesthesiologist. It might appear that the risk of complications should be least with local anesthesia and greatest with general anesthesia, but patients under inadequate local anesthesia have experienced acute myocardial infarction and patients under spinal anesthesia have experienced respiratory arrest and anoxia. Reports that correlate morbidity or mortality with type of anesthesia are difficult to interpret when the type of anesthetic has not been randomly assigned. Furthermore, factors such as the quality of postoperative respiratory and nursing care influence the outcome from general anesthesia.

ANESTHETIC TECHNIQUE

See Table 7.9 for a summary of anesthetic techniques.

Local Anesthesia and Sedation

Peripheral nerve blocks and infiltration with local anesthetic are sufficient for limited procedures in cooperative patients. The primary risks are local anesthetic toxicity and inadequate analgesia. Allergic reactions occur to the antioxidant (bisulfite) or the preservative (methylparaben) in the commercial preparations. Although they are extremely rare, allergies to both lidocaine and bupivacaine have been reported. Skin testing with a preservative-free agent will identify true allergy to local anesthetic. Toxicity results from inadvertent intravascular injection or from excessive dose. The maximum recommended dose depends on the size of the patient, the site of injection, the particular agent, and the use of epinephrine (Table 7.10). Frequently used supplements are midazolam for sedation and amnesia, and an opiate such as fentanyl for analgesia. Oxygen, pulse oximetry, periodic verbal contact, and observation reduce the risk of hypoxia and respiratory depression.

Table 7.7. Guidelines for Preoperative Laboratory Testing*

Table 7.8. Medications that Should be Continued or Discontinued Preoperatively

Table 7.9. Anesthetic Techniques. A Brief Summary

Table 7.10. Recommended Maximum Local Anesthetic Doses for Infiltration
Seminal ventricular dysrhythmias have been associated with bupivacaine and etidocaine cardio toxicity (1). Possible mechanisms are inhibition of calcium release from sarcoplasmic reticulum (23) or use-dependent block of sodium channels on myocardial cells (19). There may also be a central nervous system (CNS) contribution to the cardio toxicity (6). The best treatment of this complication has not been determined, but recommendations include bretylium or amiodarone (19).

**Regional Anesthesia**

Subarachnoid (spinal), epidural (peridural), and brachial plexus (axillary and interscalene) blocks are the most commonly used techniques for regional anesthesia. Combination nerve blocks, such as ankle block, sciatic-femoral block, elbow block, and wrist block, are less commonly used but should be considered for high-risk patients. Epidural and sometimes spinal anesthesia is difficult to achieve in the foot or ankle (18). This may be due to the large size of the L-5 and S-1 nerve roots.

Technical difficulties and the slow onset of block both increase the time the surgeon waits before surgery can start. Clear-cut landmarks for needle insertion and easily identified endpoints for needle position (cerebrospinal fluid (CSF), arterial blood, paresthesia) make a block easier to perform; obesity and spinal deformity are sources of difficulty. A block that has been easy to perform can nevertheless take up to 20 minutes to produce adequate anesthesia. Neutralization of local anesthetics with sodium bicarbonate may hasten the onset. Agents are usually selected for the duration of block they produce. An epidural block with lidocaine lasts 1 to 2 hours or 2 to 4 hours with bupivacaine. In the less vascular vicinity of peripheral nerves, lidocaine lasts 2 to 4 hours and bupivacaine lasts 6 to 12 hours.

Nerve block or infiltration, intravenous analgesia, nitrous oxide analgesia, or general anesthesia can supplement regional blocks that are anatomically incomplete or inadequate in duration. As in the selection of anesthetic technique, the best choice depends on the patient (pain tolerance), the surgical problem (need for immobility), and the operation (time remaining to completion, intensity of noxious stimulation). One particular danger is that intravenous sedation and analgesia with or without nitrous oxide can progress insidiously to general anesthesia without protection against aspiration or without adequate ventilation and oxygenation. On the other hand, a general anesthetic superimposed on an incomplete epidural or spinal anesthetic can be complicated by the presence of a sympathetic block.

Tourniquet pain represents an incomplete or receding block. It starts to be a problem approximately 1 hour after tourniquet inflation. Under general anesthesia, progressive hypertension is noticed. Overtreatment can result in hypotension when the tourniquet is released. Tourniquet release can also cause transient hypercapnia and elevation of intracranial pressure in head-injured patients if ventilation is not temporarily increased. There is a slight temperature elevation with tourniquet inflation and a decrease after tourniquet release.

Tourniquet hypertension [30% or greater increase in either systolic or diastolic blood pressure (BP)] is more common under general anesthesia than under regional anesthesia. It is not prevented by a sympathetic block. Technical details have been shown to have some influence over the efficacy of a spinal (subarachnoid) block in the prevention of tourniquet hypertension. The amount of anesthetic; the particular anesthetic agent; the addition of epinephrine, clonidine, or morphine; and even the concentration of added glucose have been shown to have some effect. Differential blockade of some fiber types but not of others may explain the occurrence of tourniquet hypertension despite adequate sensory level as determined by pinprick. Tourniquet pain is probably mediated by unmyelinated, slow-conducting C fibers. Explanations include a gate theory mechanism of large fiber block and small fiber activity. The superiority of intrathecal bupivacaine compared with tetracline may be due to the longer residence of bupivacaine at the nerve fiber.

Recommendations to eliminate tourniquet pain and hypertension are to use subarachnoid block rather than general anesthesia or epidural anesthesia, obtain an adequate pinprick level, and add either epinephrine or clonidine but not glucose. Alkalization of the agent may improve the success with mepivacaine epidural anesthesia so that it is comparable to an intrathecal block with bupivacaine (47). Alkalization is thought to enhance the onset and intensity of a block by increasing the nonionized form and by increasing neuronal pH.

Reports have accumulated over the years documenting problems associated with tourniquet use. These problems are summarized in Table 7.11. A high incidence of venous thrombus embolism has been discovered after tourniquet deflation. Metabolic products and cooled blood may be part of the problem. When hypotension persists or is catastrophic, pulmonary embolism becomes a serious concern.

<table>
<thead>
<tr>
<th>Table 7.11. Tourniquet Problems</th>
</tr>
</thead>
</table>
| **Epidural and Subarachnoid Block** | The incidence of deep vein thrombosis during hip surgery under general anesthesia is between 60% and 70%. Regional anesthesia (both spinal (11,49) and epidural (20)) reduces the incidence of postoperative deep vein thrombosis to 20% to 40%. Proposed mechanisms include increased lower limb blood flow, reduced activation of factor VIII, reduced viscosity, and enhanced release of plasminogen activators. Additional advantages that have been claimed for regional anesthesia include a lower risk of aspiration and pulmonary complications, reduced blood loss, prophylaxis against phantom limb pain, reduction of the stress response, and the ability to continue the analgesia postoperatively.

The major side effect of both epidural and subarachnoid (spinal) block is hypotension from sympathectomy. Hypotension is more likely to occur if a patient is hypovolemic or if the block is extensive. Consequences of uncontrolled hypotension include nausea, vomiting, apnea, stroke, and myocardial infarction. The side effect that patients fear is permanent neurologic injury. Although this complication is rare, it can occur from traumatic needle insertion, infection, epidural hematoma, spinal cord ischemia, or cerebral ischemia. See also the discussion in the section on Pitfalls and Complications.

The onset of an epidural block is slower than that of a spinal block, and this factor is sometimes used to advantage in patients with potentially unstable cardiovascular responses. Disadvantages of an epidural block are that it is usually less intense than a spinal block and a larger dose of local anesthetic is required. Thus, there is greater risk of an inadequate block, and there is risk of either a total spinal block or local anesthetic toxic reaction from accidental intrathecal or intravenous injection. It is usually assumed that a failed spinal anesthetic is due to faulty technique or a defective drug, but cases have been reported in which both possibilities were excluded with the implication that certain patients are truly resistant to spinal anesthesia. In some instances, these patients were resistant to lidocaine but not to bupivacaine (40).

Postspinal headaches are more common in young females and with the use of larger gauge needles. A spinal headache may be distinguished from meningitis by its location (occurs more proximal injection sites. An axillary approach is used when the forearm or hand is the operative site. Interscalene block is used when the elbow, upper arm, or shoulder is to be operated on or when the axilla is unavailable. The technique of eliciting paresthesias is associated with persistent postoperative paresthesia, possibly due to nerve trauma (42). Location of nerves can be achieved less traumatically by using a nerve stimulator.

Intravenous regional (Bier) block is easy to perform and is rapid in onset and recovery. Tourniquet pain becomes a problem after an hour. Risk of local anesthetic toxicity is significant, especially during injection (leak under the cuff) and after release of the tourniquet, because a toxic dose is deliberately placed intravascularly. The tourniquet is usually deflated briefly and quickly reinflated to release only part of the dose over 10 to 15 minutes.
GENERAL ANESTHESIA

Although general anesthesia is almost universally applicable, there are sometimes reasons for considering alternatives. Examples include a full stomach, obesity, reactive airway disease, malignant hyperthermia (MH), generalized muscle disease, a need to monitor neurologic status, and pregnancy. There can be advantages to combining regional and general anesthesia. For long procedures and when general anesthesia might cause excessive cardiac depression, regional anesthesia reduces the amount of general anesthetic needed. When postoperative analgesia with epidural opiates is indicated, a combined anesthetic can be given for the procedure and the regional anesthetic can be continued postoperatively using opiates with or without local anesthetic. Whether the combination of general and regional anesthesia reduces the risk of deep vein thrombosis has not been tested.

INTRAOPERATIVE MANAGEMENT

AIRWAY MANAGEMENT

Subpopulations of orthopaedic patients present the anesthesiologist with airway management challenges. The pediatric patient who has skeletal deformity may also have facial and airway malformation. Elderly patients with deformity of rheumatoid arthritis may have cervical spine and arytenoid process arthritis. The trauma victim may have facial or cervical spine injury and multiple orthopaedic injuries. Key questions that should be answered before undertaking airway management are

1. Is difficult intubation likely?
2. Is difficult ventilation likely?
3. Will the patient consent to or cooperate with airway management procedures?

The answers to these questions form the basis for the following management decisions:

1. Is a surgical airway needed?
2. Will the patient consent to awake intubation?
3. Is it necessary to maintain spontaneous ventilation?

Figure 7.4. A portion of the airway algorithm that proceeds from failure to intubate after inducing anaesthesia. Other portions not shown involve the preoperative assessment and planning of airway management.

MONITORING

Decisions about monitoring are closely related to the problem of fluid management. During major procedures lasting more than 3 hours and with anticipated blood loss of more than 20% of blood volume, an arterial catheter, central venous pressure (CVP) or pulmonary artery (PA) catheter, and Foley catheter are commonly used. Invasive monitoring is likely to be required in elderly patients undergoing lengthy hip fracture surgery because the risk of myocardial infarction correlates with the duration of surgery. Conservation of blood by intraoperative hemodilution or induced hypotension also warrants closer, more invasive monitoring.

Correction of scoliosis requires monitoring for spinal cord function. Both methods in common use—somatosensory evoked potentials and the wake-up test—minimize restrictions on the anesthetic agents. In the case of somatosensory-evoked potential monitoring (posterior spinal cord function), nitrous oxide with narcotic and low concentrations of volatile anesthetics can be used. A stable anesthetic depth is required during the monitoring period, and nondepolarizing muscle relaxants are given to suppress electromyographic (EMG) interference. When the wake-up test (anterior spinal cord function) is used, low solubility volatile anesthetics, such as desflurane or sevoflurane, will prevent prolonged emergence. Recovery from nitrous oxide usually occurs in 5 or 10 minutes. A nerve stimulator can be used to maintain a partial neuromuscular block, thus avoiding excessive movement during reawakening.

In procedures that expose large veins and in total hip arthroplasty (THA), venous air embolism is a possibility. Precordial Doppler ultrasound is a sensitive monitor for air in the right side of the heart, and a central venous catheter is one method for removing some of the air. Hypotension during methylmethacrylate cementing of hip prostheses was initially attributed to monomer escape into the circulation, causing vasodilation or myocardial depression. Recent evidence implicates air embolism as the cause of hypotension in up to 57% of arthroplasty patients. This hypotension is usually inconsequential but may cause impaired pulmonary blood flow and hypoxemia or paradoxical embolism. Cardiac arrest has been reported to result from paradoxical embolism to the coronary arteries (2). In recent years, transesophageal echocardiography (TEE) has been used increasingly as a less invasive alternative to pulmonary artery catheterization. Air and thrombotic emboli can be visualized, as can ventricular dimensions and wall motion. The primary limitations to more general use are the cost of equipment and the substantial training and experience required for interpretation.

Finally, the expense and effort devoted to acquiring and applying any monitoring device is wasted if the person who should make use of the information is inattentive, distracted, or inexperienced.

POSITIONING

Nonsupine position can cause injuries, either directly (pressure or stretch) or indirectly (decreased perfusion pressure or impaired gas exchange). In addition, the transition to a new position can cause loss of monitoring, loss of intravenous catheters, or loss of the airway. Traction injuries to joints and nerves can also result from position change. The major risks of prone position are injury to the face, impaired inferior vena cava flow, and injury to nerves. Cardiopulmonary function is not significantly different from that in the supine position if the abdomen is not compressed. The lateral position is more disturbing to cardiopulmonary function. Because of the cephalad shift of the diaphragm during general anesthesia, ventilation-perfusion matching is altered, resulting in arterial blood gas changes. Thus, a patient undergoing hip surgery in the lateral decubitus position will have better gas exchange with regional anesthesia and spontaneous ventilation than with general anesthesia. The lateral position places patients at risk for nerve injury, vascular compression, and pressure injury to the dependent side of the face and head. Of particular importance is the “axillary roll” to prevent compression of the subclavian artery between the clavicle and humerus. In the lateral position, the pulse oximeter placed on the dependent arm can be used to detect arterial compression. Complications can occur from intraoperative movement out of position, so the patient's position should be monitored. Finally, nonsupine positioning and draping limits access to the patient for monitoring or other procedures.
FLUID MANAGEMENT

The objectives of fluid management are replacement of preoperative deficits, replacement of ongoing insensible losses (maintenance), compensation for third-space loss, and compensation for bloodloss. Anesthesiologists use additional fluid as a carrier for drugs and to compensate for the vasodilation of anesthesia. The amount of third-space loss is clinically unmeasured and depends on the degree of tissue trauma. For orthopaedic procedures, 2 ml/kg/hour above maintenance is commonly used. Errors in fluid management include excessive reliance on BP or urine output as endpoints, because both are indirect measures of fluid volume status. When BP or urine output are not normal after giving the most liberal estimate that can be justified, additional information is usually sought by measuring cardiac filling pressures.

Fluid management includes decisions about the need for blood products. Transfusion risks are of continuing concern, but improvements in donor screening and blood unit testing have improved to the point where some are beginning to question the need to avoid allogenic transfusion in favor of autologous donation (15a) (see Chapter 5). Measures to avoid autologous transfusion of blood products include cell saving, hemodilution, and induced hypotension. Blood loss during major hip replacement can be reduced 30% by either induced hypotension or regional anesthesia (48,52).

BLOOD LOSS MANAGEMENT

The risk and cost of transfusion has stimulated a variety of practices. Risks of transfusion are listed in Table 7.12. Tourniquet hypertension may lead to myocardial ischemia in patients with coronary artery disease or ventricular hypertrophy. Many of the serious complications occur with release of the tourniquet. To the already established use of extremely tourniquet and induced hypotension have been added measures to recover the patient's blood loss and avoid transfusion by using autologous blood (Table 7.13). A tourniquet is the traditional method to control blood loss during extremity surgery and to improve visibility.

Table 7.13. Blood Conservation

**Induced Hypotension**

Simple hydraulics suggests that the rate of blood loss should be reduced if systemic BP is reduced. Systemic BP can be reduced by anesthetics, regional anesthesia, and vasodilating drugs. Inhalation anesthetics produce both vasodilation and myocardial depression. The possibility of organ ischemia and infarction has to be considered and discussed with patients. Induced hypotension is contraindicated in patients who have coronary artery disease, cerebrovascular disease, chronic obstructive pulmonary disease, and anemia. Normovolemic hemodilution is contraindicated if induced hypotension is used. How far can systemic BP be safely reduced? Clinical studies suggest that a systolic BP less than 65 mm Hg is the lower limit. Approximately 700 ml of whole blood is conserved, and operative time is shortened (43,48).

Induced hypotension as a measure for reducing blood loss continues to generate some controversy (12). The normal brain tolerates reduction to 55 to 60 mm Hg mean arterial pressure (MAP). MAP is used rather than systolic BP because the arterial catheter system can distort the arterial pressure waveform; systemic pressure will be affected, but MAP will not. Because patients with chronic hypertension are unable to autoregulate cerebral blood flow (CBF) at 50 mm Hg MAP, their pressures should be reduced only to 50 mm Hg below their usual MAP. Contraindications to induced hypotension include fever, anemia, and occultive cerebrovascular disease. Because hypocapnia will reduce CBF, a normal PaCO₂ should be maintained. Isoflurane at high concentrations lowers MAP by vasodilation but maintains cardiac output. When evoked responses are monitored, nonanesthetic drugs such as sodium nitroprusside (SNP), nitroglycerine (NTG), and trimethaphan are used to lower MAP. SNP has a rapid onset, short duration, and consistent effect. It vasodilates with little effect on cardiac output. The side effects of SNP include cyanide toxicity, rebound hypertension from plasma renin activity, coagulopathy, pulmonary shunting, reduced tissue oxygenation, and hypothyroidism. Severe reductions in BP may impair spinal cord perfusion enough to alter evoked responses. The risk of pressure injury is increased by hypotension. Rebound hypertension can be prevented by gradual return to normal MAP, propranolol pretreatment, or captopril. Coagulopathy is due to platelet disintegration and inhibition of platelet aggregation (22,28). Pulmonary shunting is due to the vasodilatation of pulmonary vasculature (9). Tissue oxygenation may be preserved better with NTG, because SNP but not NTG diverts blood flow to arteriovenous shunts (20).

**Autologous Blood**

Preoperative autologous blood donation requires advance preparation and is limited by the time that it takes for red cell production. Erythropoiesis is not stimulated until the hematocrit is less than 30%. Exogenous erythropoietin can be used but increases the cost of the procedure. There has not been a rigorous study of risk versus benefits of preoperative donation. Mathematical modeling predicts that the benefit is small. On the other hand, the patient generally becomes anemic and the threshold for transfusion is reached earlier. The patient who donates for herself is then exposed to risks of transfusion, possibly unnecessarily. The administrative cost of preoperative donation is more than for homologous transfusion.

One method for eliminating the administrative cost of donation is phlebotomy with isovolemic hemodilution. This is done with the patient in the operating room but before surgical blood loss. The patient's blood is kept in the operating room. Diluted blood is lost, and the patient's own blood is returned to maintain hematocrit at the transfusion threshold. As with preoperative donation, mathematical modeling predicts little benefit unless large volumes of blood are withdrawn (4 to 5 units) and surgical blood loss is large (2000 ml) (4). In addition, either large volumes of crystalloid or colloid replacement must be given to achieve hemodilution without hypovolemia.

**Cell Washing**

Cell washing and reinfusion reduces the need for banked blood, with little apparent risk to the uninfected patient. Blood is collected by suction and then heparinized and washed. The concentrated red blood cells, minus clotting factors and platelets, are then available for reinfusion into the patient. The effect of autotransfusion on
coagulation has been studied using the Sonoclot device (15). A brief period of hypo-coagulability, followed by a tendency to hyper-coagulability, was observed. The conventional cell-washing devices require collection of 1000 ml before the blood can be efficiently processed. This is a significant disadvantage in smaller patients who may need to be transfused with bank blood before their own washed cells are available.

Preoperative phytebotomy, hemodilution, and posthemorrhage reinfusion of the patient's own blood are well tolerated under anesthesia because oxygen requirements are reduced. If anemia persists postoperatively, increased oxygen consumption from shivering should be prevented with small doses (12.5 mg) of intravenous meperidene.

**Transfusion**

The risk of transfusion has declined with advances in donor screening and blood testing. Of continuing concern in orthopaedics are the studies that show increased rates of postoperative infection in total joint replacement and spine surgery when allogenic blood has been used (16-31). Transfusion has also been implicated in tumor recurrence after cancer surgery.

In 1996, the ASA published a Practice Guideline for Blood Component Therapy (27). One effect of these guidelines is to encourage use of laboratory testing to establish that indications for transfusion of a component have been met. In this way, it is hoped that unnecessary component therapy and attendant risks can be avoided.

Blood substitutes, such as purified hemoglobin and perfluorocarbons, are under development. At present, limited clinical trials are in progress. These substitutes are expensive and less efficient than blood, but they may eventually be useful in normovolemic hemodilution.

**GENERAL REHABILITATION AND POSTOPERATIVE PRINCIPLES**

**POSTOPERATIVE PAIN**

Postoperative pain is acute pain. Several studies document the undertreatment of pain in hospitalized patients (13,26). Risks of inadequate analgesia include myocardial infarction, impaired ambulation and ventilation, and reduced cooperation. Risks of analgesia include impaired consciousness, respiratory depression, and delayed recognition of postoperative complications, such as myocardial infarction or compartment syndrome.

The surgeon usually manages postoperative pain. The goal is a rapid return to function. An increased interest in postoperative pain management by anesthesiologists and hospital pharmacists is reflected in the increasing availability of patient-controlled analgesia (PCA) and regional opioid analgesia.

**Preemptive Analgesia**

Acute pain is easier to control when it is treated early rather than late (53). The neural basis for this clinical observation may reside in the posterior horn of the spinal cord. Noxious stimulation produces an activation of spinal neurons that persists and enhances the response to repeated noxious stimulation. Numerous methods to reduce the need for postoperative analgesia have been tried. The effective preemptive techniques include opioid analgesia, local anesthetic infiltration of the incision site, nonsteroidal antiinflammatory drugs (NSAIDs), and regional anesthesia.

**Patient-Controlled Analgesia**

Because it compensates for the pharmacokinetic and pharmacodynamic differences between patients, PCA is particularly useful for severe postoperative pain. When given limited control for self-administration of intravenous opioids to control postoperative pain, the majority of patients do not become narcotic addicts. The constant infusion (basal rate) provides consistent analgesia for the patient who has constant pain at rest, and supplemental analgesia (bolus doses) will be available for dressing change, position change, or ambulation. Contraindications to PCA have included children, drug addicts, and patients unable to understand or unable to operate the device. In pediatric patients, there is risk that a parent will operate the device or that the child will fail to use it. However, PCA has been used successfully in children as young as 5 years old. Patients with alcoholism or other drug addiction require larger doses. Whether these patients are more difficult to wean from PCA remains controversial. Risk of respiratory depression is greatest during sleep, following abrupt reduction of painful stimulation, or following coadministration of sedatives.

**Continuous Opioid or Local Anesthetic**

With catheter placement, epidural and brachial plexus anesthesia can be continued postoperatively in infusion of local anesthetic (6,33). Good clinical demonstrations of benefit are currently lacking, but theoretical advantages are improved tissue perfusion, prevention of phantom pain, reduction in pulmonary complications, and prevention of venous thrombosis. On the other hand, an insensitive extremity places the patient at risk for unrecognized ischemic or pressure injury. Sympathectomy may predispose the patient to hypotension. Accumulation of the drug may result in local anesthetic toxicity.

The advantage of epidural opioid infusion over intravenous infusion is based on the premise that an effective concentration of spinal opioid can be achieved without producing systemic analgesic concentrations that can be produced by intravenous infusion. In addition, the side effects of spinal opioid should be comparable or less than the side effects of intravenously administered opioid. Morphine and fentanyl are the opioids that are commonly infused epidurally. Because of its relatively higher lipid solubility, fentanyl is more rapidly distributed to the epidural vascular structures and removed to the systemic circulation. Consequently, its distribution in the neuraxis is more restricted. Morphine migrates rostrally over several hours, eventually reaching the brain stem. Both drugs can produce respiratory depression.

**Epidural Analgesia**

Epidural injection of opiates, such as morphine and fentanyl, produces analgesia without sympathectomy, anesthesia, or impaired motor function. Pruritus, urinary retention, and sedation occur commonly. A less frequent but significant hazard is delayed respiratory depression from cephalic spread of the opiate, especially morphine. Sedation from the upward spread of morphine usually precedes respiratory depression. With daily monitoring, epidural catheters are used for up to a week. Systemic infection and systemic anticoagulation are contraindications.

Epidural hematoma is a catastrophic complication of epidural analgesia. Epidural analgesia has only rarely been a cause of permanent neurologic injury. An alarming incidence of this complication has recently been reported in patients receiving low-molecular-weight heparin for thromboembolism prophylaxis. The issue of anticoagulation and neuraxial anesthesia (both epidural and subarachnoid) is the subject of a recent collection of expert reviews (21). Risks are summarized in Table 7.14. Epidural hematoma frequently presents as persistent back pain with patchy analgesia or motor weakness. Rapid diagnosis by magnetic resonance imaging (MRI) and neurosurgical decompression is the only hope for reversal of neurologic deficits. The diagnosis may be delayed by the use of high concentrations of local anesthetic, intravenous sedation or analgesia, or the inability to communicate with the patient.

Epidural abscess (35) can be less dramatic in presentation than epidural hematoma. This can cause delayed diagnosis. Signs of infection may not occur until later in the course of the hospital stay or may not be evident until several days after the catheter is removed. Thirteen cases of epidural abscess have been reported in the literature. The estimated incidence is estimated to be 1:13,000 patients. Daily examination and monitoring of the catheter site for inflammation and suppuration is
considered to be essential, as are noting unexpected motor or sensory deficits. Clinical factors that may interfere with the diagnosis include immobilization that inhibits access to the patient's back for examination of the epidural site, use of local anesthetic concentrations that are high enough to produce sensory and motor block, and the presence of wound infection. Clinical signs that should raise suspicion of epidural abscess include prolonged use of the epidural catheter, incomplete analgesia, and new neurodeficits. If neural compression is not present, then antibiotic therapy with or without percutaneous catheter drainage may be successful. Otherwise, surgical drainage is necessary. The risk–benefit ratio of epidural analgesia must be carefully considered in patients who may be difficult to monitor postoperatively.

**Brachial Plexus**

Prolonged extremity block is occasionally used for postoperative analgesia or for treatment of reflex sympathetic dystrophy. Brachial plexus block by axillary or supraclavicular approaches can be used for prolonged infusion, but it is difficult to maintain a catheter in position. The interscalene approach is associated with a high incidence of complications. For long-term analgesia, the subclavian approach to the brachial plexus provides a site that is easier to maintain in terms of catheter stability and dressings. The long-acting local anesthetic bupivacaine, in 0.125% to 0.25% solution, can be infused up to 5 ml/hour. A maximum of 400 mg/24 hours is recommended. The primary hazard is accumulation of drug to toxicity levels. Because bupivacaine is eliminated by the liver, dose reduction or alternatives should be considered when hepatic function is impaired.

**GOALS FOR CHRONIC PAIN MANAGEMENT**

Because our understanding of chronic pain is incomplete, diagnosis frequently consists of syndrome classification, and therapy is largely empiric. Many problems can be handled in so-called block clinics, but intractable problems may need the combined expertise and resources of a multidisciplinary pain clinic. Psychological issues assume a larger role for the patient who has to contend with chronic pain.

The management of chronic pain is complex and frequently multidisciplinary. Anesthesiology training provides skill in the safe application of drugs by intravenous and perineural injection. The following sections discuss the techniques that are used in our pain management clinic.

**POSTTRAUMATIC PAIN CONDITIONS**

**Trigger Point Injections**

Myofascial pain is a common accompanying complaint. The relief of muscle pain and spasm by trigger point injections is empirically based. The mechanism of pain and its relief are still unsettled. Diagnoses of trigger points and the location of the pain are found in Travell and Simons' text (44). Local anesthetic injection is frequently used, but steroids, saline, and NSAIDs have also been injected with reported relief. Local therapy directed at the muscle is recommended after relieving the trigger point pain. The risks are local bleeding, infection, trauma to nerves, and in the chest wall, pneumothorax.

**Sympathetic Blocks (Stellate, Lumbar Sympathetic)**

The IASP has classified reflex sympathetic dystrophy (RSD) and causalgia as complex regional pain syndrome (CRPS) type I and type II, respectively. CRPS I is an infrequent sequela of skeletal and soft-tissue injury, usually to an extremity. CRPS II is a complication of partial injury to a mixed peripheral nerve. They are both under the broader classification of neuropathic pain. Sympathetic blocks are usually performed for the diagnosis or treatment of complex regional pain syndrome. Effectiveness of the block is most easily documented by the use of skin temperature liquid crystal strips. Skin temperature can rise to 33° to 34°C. The duration of the block's effects must be determined by pharmacokinetics of the particular local anesthetic, but the duration of analgesia may last longer. Occasionally, patients experience progressively longer periods of relief after repeated block. When relief occurs, physical therapy should immediately follow the onset of block. Other therapies for CRPS I include medications, such as gabapentin, clonidine and terazocin, biofeedback, and spinal cord stimulation.

CRPS I of the upper extremities may be relieved by local anesthetic block of the stellate ganglion (inferior cervical ganglion plus T-1 sympathetic ganglion). An anterior approach is commonly used. Take care to avoid injection into the carotid artery, the vertebral artery, or the dural sleeve. Other nerves that can be blocked are the recurrent laryngeal, the phrenic, and branches of the brachial plexus.

CRPS I of the lower extremities may be relieved by local anesthetic block of the lumbar sympathetic chain (L-1 through L-3). A posterior approach is commonly used and is efficiently executed using fluoroscopic guidance. A large volume of anesthetic is injected to achieve cephalad and caudad spread of the solution along the sympathetic chain. Take care to avoid posterior spread with resultant nerve root block and intravascular injection into the inferior vena cava (IVC) or aorta.

Repeated sympathetic block of the upper extremity can also be produced by placement of a brachial plexus catheter. The subclavian approach is used because the catheter is less likely to be dislodged. Perform this procedure with sterile conditions and dressings, followed by frequent examination for possible infection of the catheter skin site. The catheter can be used for continuous or repeated local anesthetic injections in conjunction with physical therapy.

**Intravenous Regional Block (Bretylium)**

Intravenous regional block with norepinephrine-depleting drugs can provide long-lasting sympatholysis and relief of pain from CRPS I. The procedure is similar to surgical anesthesia with the Bier block technique. An intravenous catheter is placed in the distal part of the extremity. This procedure may be difficult when venous access is limited. The clinical presentation of the classical venous distention can be produced by inflating the double pneumatic tourniquet above venous pressure range and then wrapping an Esmarch bandage in reverse direction from proximal to distal to squeeze blood into the distal portion of the venous system. If this procedure fails to produce satisfactory venous distension, a regional anesthetic block may have to be performed, for example, a brachial plexus block or epidural block. A regional block may also be used when a patient is unable to tolerate the discomfort of tourniquet ischemia. Various sympatholytic drugs have been injected (guanethidine, reserpine, and bretylium). At present, only bretylium is available in the United States. Clinical trials with guanethidine have been conducted to assess the efficacy of intravenous regional sympatholysis in CRPS I. The results suggest that, despite the clinical improvement that is observed in some patients under controlled conditions, the efficacy is small.

When the effect of repeated regional local anesthetic block is too brief, prolonged sympatholysis is usually attempted using radiofrequency or surgical ablation. Although the initial response may be gratifying relief, frequently the pain returns. This is attributed to incomplete ablation, but it may actually be a deafferentation phenomenon. A more promising technique for lasting analgesia may be achieved with spinal cord stimulation. The results of this relatively recent therapy are still being
Epidural Steroid Injection (Cervical, Lumbar, Caudal)

Epidural steroid injection is effective in reducing or relieving pain in 60% of patients at three months followup who have acute lumbar radiculopathy (11a). With chronic lumbar radiculopathy, there is less likelihood of benefit from epidural steroids. In the lumbar region, 80 mg of methylprednisolone diluted in normal saline are injected epidurally (8a,11a,41a). Watts and Silagy (52a) in a meta-analysis of the literature concluded that epidural steroids, up to 60 days followup, increased the odds ratio of pain relief (75% improvement) to 2.61 (95% confidence interval: 1.9–3.8) when compared with placebo. Although risks are minimal, they include adrenal suppression, infection, and epidural abscess.

Several steroid injection procedures are used in the management of chronic cervical and lumbar spine pain and radiculopathies. Peridural (epidural) injection, selective nerve injection, sacroiliac joint injection, and facet injection of steroid are offered empirically as injective reduction therapies. The specific corticosteroid agents and doses, the number and interval between injections, and the adjunctive therapies vary widely. Therapeutic efficacy has not been established in a way that can be easily applied to individual patients. Methylprednisolone (Depo-Medrol) and triamcinolone (Aristocort) are commonly used. Our clinic uses triamcinolone. The amount that causes significant side effects is unknown and possibly varies from one patient to the next.

Epidural steroid injection is the most frequently used steroid technique for lumbar pain. The indications vary from very conservative recommendations to an almost universal trial in patients with back pain lasting over a few weeks. The recent onset of symptoms or a recent exacerbation seem to be favorable prognostic signs for relief by epidural steroids. The procedure is similar to that used for epidural anesthesia. A sitting position is used to simplify the location of midline, particularly in large patients. The sitting position, however, tends to decrease the interspinous space, making needle insertion more difficult. This can be overcome by using the lateral paramedian approach. There is concern that what is perceived as an epidural injection is actually not in the epidural space. One often quoted result is that there is a 30% failure rate without resorting to fluoroscopy. Loss of resistance to air or saline injection can be misleading if the needle leaves the interspinous ligament and enters the paraspinal area. Quantification of the pressure required to infuse saline through the needle and injection of local anesthetic to produce a transient block have been recommended. Epidural needle placement under fluoroscopy with contrast injection is considered by many to be the gold standard and has been recommended when the patient's size or spine presents an anatomic challenge or when an injection without fluoroscopy guidance has not resulted in relief. Some advocate performing the initial steroid injection with fluoroscopy guidance in all patients.

Selective Nerve Root Block

When spinal or foraminal steroids is identified and suspected of causing radicular pain, selective nerve root injections are performed for both therapeutic and diagnostic reasons. This procedure is done with fluoroscopy. For lumbar nerve root injections, the patient is placed in a prone position with a pillow under the hips. The image of the lumbar pedicles is a landmark for directing the needle to the foramen beneath it. Outline the nerve root by injection of a small amount of contrast. To avoid epidural block, inject only small volumes of local anesthetic with steroid.

Facet Injection: Diagnostic and Therapeutic

The sacroiliac joint is occasionally the source of low lumbar pain. Patrick's test, pain on crossed-leg external rotation at the hip joint, is one of the tests used to identify sacroiliac joint pain. Injection can be performed with or without fluoroscopy.

Pain arising from disorders of the facet (zygapophyseal) joints is difficult to localize by examination. Imaging studies are not reliable in identifying pain-producing pathology of the facet joints. Frequently, a therapeutic trial injection of local anesthetic and corticosteroid of the joint capsule or the medial branch nerve at various levels is undertaken, in search of a pain-relieving procedure. When reproducible relief is achieved by either intracapsular or medial branch nerve block, the patient becomes a candidate for radiofrequency coagulation of the medial branch nerve. Fluoroscopy is essential for both the medial branch and the intracapsular injections. With the patient in prone position and with the fluoroscope tube positioned to identify the joint space, direct the needle either toward the joint space or toward the medial, upper edge of the transverse process. Facet block is a relatively low-risk procedure. Excessive volume injection into the capsule can cause capsular rupture.

Neurolytic Block (Cryoaanalgesia, Radiofrequency Coagulation, Alcohol and Phenol Injection)

Peripheral nerve injuries, such as neuroma or entrapment, are also treated as neuropathic pain syndromes. Before spinal cord stimulation, neurolytic block with phenol, freezing (cryoaanalgesia), and radiofrequency coagulation neurolysis are usually attempted. Neurolytic blocks are usually temporary, lasting from a few weeks to months. Cryoaanalgesia is sometimes produced by neuritis or possibly by the additional deafferentation. Because precision of needle placement is essential, nerve stimulation and fluoroscopy with contrast are usually employed.

Implantable Pumps for Intrathecal Opioids

Chronic benign pain can be relieved by long-term opioid administration. Long-term exposure to opioids can result in significant tolerance and corresponding large doses. Drugs can be administered continuously for spinal analgesia by means of a chronically implanted catheter and pump. This method for opioid administration has been used with success in the treatment of postamputation pain syndrome. Not every chronic pain patient is a suitable candidate for an intrathecal pump. The patient's pain must be suppressed by opioids, and the patient must demonstrate psychological stability.

Spinal Cord Stimulation

Nerve root avulsion injuries and phantom pain are forms of deafferentation pain, a subset of neuropathetic pain syndromes that do not respond to sympathetic or additional neuroablative procedures. The primary therapies are medications, such as anticonvulsants, antidepressants, opioids, and neurostimulation.

INTRAOPERATIVE THROMBOEMBOLISM

Orthopaedic patients are at increased risk for thromboembolism. When pulmonary embolism occurs intraoperatively, the combined effects of embolism, anesthesia, and blood loss may be catastrophic. Impaired cardiac output can lead to severe, refractory hypotension and tissue ischemia. Occlusion of pulmonary blood flow can lead to respiratory and circulatory collapse. Thrombosis has recently been detected using echocardiography following the release of a thigh tourniquet during total knee arthroplasty. Sudden hypotension at any time during a procedure presents a diagnostic problem, and one of the considerations is the possibility of major pulmonary embolus. The presence of a large increase in arterial-to-end tidal carbon dioxide difference, elevated venous pressure, or evidence of decreased peripheral perfusion, such as failing pulse oximeter, point to the possibility of pulmonary embolism.

LATEX ALLERGY: ANAPHYLACTIC SHOCK

Allergy to latex is increasingly recognized as a hazard to patients and health care workers (23). Orthopaedic patient populations who have frequent exposure to latex products include patients with spina bifida, congenital urologic anomalies, and spinal cord injuries. Approximately 40% of children with myelomeningocele test positive to latex in their blood. LATEX ALLERGY: ANAPHYLACTIC SHOCK

PITFALLS AND COMPLICATIONS
MALIGNANT HYPERTHERMIA

MH is a rare genetic syndrome consisting of hypermetabolism, hyperthermia, and acidosis triggered by exposure to potent inhalation anesthetics and succinylcholine. The incidence is approximately 1:15,000 (pediatric) to 1:50,000 (adults). A higher incidence of MH has been associated with some of the myopathies, such as King-Denborough syndrome and central core disease. The abnormal response of susceptible patients to inhalation anesthetics can be demonstrated in muscle biopsy specimens in the presence of caffeine stimulation. When a patient has been identified as MH susceptible by history or muscle biopsy, the anesthetic agents must be restricted to nontriggering drugs. An episode of MH is potentially fatal. Dantrolene is an effective treatment. At least 36 vials of dantrolene should be available in any location where general anesthesia is given.

Signs of MH, such as tachycardia, hypercapnia, and fever, are easily recognized. Dilemmas arise because none of the clinical signs is specific. The intraoperative diagnosis of MH is also difficult when the onset is gradual. The possibility of MH is easier to recognize when muscle rigidity, tachycardia, hypercapnia, and rapidly increasing temperature follow shortly after exposure to the anesthetic. Management of MH is summarized in Table 7.16. After a fulminant MH episode is controlled, the patient should be observed in an intensive care unit for at least 24 hours because recurrence is possible. Controversy exists among anesthesiologists as to whether to proceed with elective surgery when succinylcholine causes masseter spasm, an event that is sometimes followed by an MH episode. Consultation regarding the preoperative preparation or crisis management of MH is available through the Malignant Hyperthermia Association of the United States (MHAUS) hotline number, 1-800-MH-HYPER. Additional information is available on the MHAUS website, <www.mhaus.org>.

A skin wound is common to most operative procedures, and surgeons of every discipline are faced with soft-tissue management problems. If the wound is created in an operating room, a sterile environment is assumed, as are gentle handling of tissues, sharply incised margins, and little contamination by foreign bodies. In a wound sustained in the civilian or military environment, however, avulsive trauma, bacterial contamination, and the presence of foreign bodies are the rule. Management principles remain the same for all wounds, although certain aspects of care will need to be emphasized depending on the particular wound.

**PRINCIPLES OF WOUND MANAGEMENT**

Successful wound closure depends on adequate preparation. For a wound to heal primarily, it must be cleansed of devitalized tissue, foreign bodies, and bacteria. Although these prerequisites usually exist in the operative wound, such is not the case in the traumatic one.

Debridement of the traumatic wound prepares it for closure. The patient usually has discomfort from wound examination and cleansing; pain may compromise the surgeon’s ability to debride adequately. Therefore, administration of local, regional, or general anesthesia is usually appropriate before treatment is begun. Apply a

- Vigorous flushing of the wound with sterile saline dislodges foreign bodies and bacteria. Pulse irrigation is particularly effective in removing contaminants. Begin with irrigation and use it throughout the debridement. In type II or worse open fractures, use at least 10 L of saline.
- To minimize blood loss in an extremity wound, tourniquet hemostasis is often used, but tourniquets interfere with the ability to detect devitalized muscle.
- Perform sharp debridement using forceps, a scalpel, and scissors.
- Excise devascularized skin, fat, subcutaneous tissue, and muscle. Soft tissue of questionable viability is usually sacrificed. One exception is if removal of possibly viable skin or muscle would result in exposure of an important structure (major vessel, nerve, bone, or joint), whose integrity would then be compromised. In this case, injured but potentially viable skin or muscle can be left in place for 24 to 48 h before being reexplored. At the point where viability can be accurately determined, the injured tissue is either left in place to continue healing or debrided, and an appropriate reconstructive alternative chosen. With the routine use of microsurgical techniques, which allow replacement of larger amounts of tissue, debridement can be more extensive when necessary. It is better, however, to leave a wound open, returning the patient to the operating room for serial examinations and debridements, than to excise what would ultimately be viable tissue during the initial operation.
- A wound containing unquestionably viable or contaminated tissue should never be closed because this would predispose the patient to a serious or life-threatening infection.
- The use of prophylactic antibiotics in traumatic wounds is controversial, but most surgeons administer a broad-spectrum parenteral or oral antibiotic perioperatively.

Once the wound has been cleansed and adequately debrided, closure can commence. The goal is rapid healing and recovery of function by maximizing vascularity in the wound environment. If this requirement cannot be met by primary wound closure, another technique is chosen. The appropriate graft or flap method is selected based on the likelihood of success, expected donor-site morbidity, and anticipated appearance of the wound (including the donor site).

**WOUND CLOSURE BY SKIN APPOSITION**

**PRIMARY CLOSURE**

Primary wound closure involves secure positioning of the wound skin margins adjacent to one another during the healing process. Close approximation confines the inflammatory response to a minimal local area, permits rapid reepithelialization across a narrow gap, and yields the smallest possible scar. **(10, 25)**

- Commence closure with approximation of any fascial wound using absorbable sutures.
- Subcutaneous tissue and fat are often closed in an attempt to obliterate dead space, minimize localized fluid accumulation, and reduce the risk of infection. The potential benefits of dead space closure must be weighed against the risks of devitalizing tissue by crushing it when sutures are tied and adding additional foreign bodies (the sutures themselves).
- The skin is usually approximated in two layers. Stitches of an absorbable material are placed through the papillary and reticular dermis, and the knots are buried deeply by being tied on the side toward the subcutaneous tissue. This strongdermal layer accepts most of the tension applied across the wound.
- The more superficial layer of skin closure includes the epidermis and upper portion of the dermis. Sutures are placed in either a continuous or interrupted fashion, using absorbable or nonabsorbable materials. Continuous sutures can be placed more quickly than interrupted ones, although interrupted sutures have the theoretical advantage of producing less ischemia of the wound margins. In any event, the superficial layer of sutures provides accurate approximation of the skin edges, with the goal of minimizing the resultant scar. Because these sutures are usually left exposed where they cross the wound, they may leave visible epithelialized tracks along their entire course as well as at the sites where they enter the skin. Removing the skin sutures within 7 days of placement may minimize the severity of skin scarring.
- There are alternatives to the superficial exposed skin suturing technique. The same layer may be closed using a buried intracuticular suture that leaves no marks in the skin surface. This method requires more operative time, and, if a nonabsorbable suture is used, it may be more difficult to remove. Staples can substitute for skin sutures; these have the advantage of rapid application. They should be removed as soon as possible to minimize scarring. Surgical wound closure tapes can be placed rapidly and removed with little discomfort. Tapes are more difficult to apply accurately, however, and the swelling that occurs in the immediate postoperative period may result in increased tension and blistering of the skin along the tape margins. Tape is often used to reinforce a sutured wound or provide support once skin sutures have been removed.
DELAYED PRIMARY CLOSURE

Immediate wound closure is not appropriate in every case. Heavy bacterial contamination or the presence of important but questionably viable tissue may preclude primary wound closure even if approximation of the skin is technically possible. In some cases, local swelling may also prevent wound closure under minimal tension.

Delayed primary wound closure implies skin-edge apposition performed several days after the initial wound, usually by 5 days or so, so that the tensile strength of the wound at 14 days is the same as if it had been closed primarily.

- At the time of the original surgical intervention, a decision to delay closure is made. The wound is packed loosely with moist sterile gauze, and a bulky dressing is applied. Skin sutures may be placed at this time but not tied, obviating the need for later anesthesia.
- Once the wound environment has been shown to be free of significant bacterial contamination, devitalized tissues, and excessive swelling, closure may be done by tying the previously placed sutures or using primary suturing techniques. The interval between initial wound preparation and delayed primary closure is usually 2 to 4 days.
- Open fracture wounds are usually closed on or after the fifth day.

SECONDARY CLOSURE

Closure by secondary intention is reserved for wounds in which primary or delayed primary closure is impossible and a more complex reconstruction is not indicated. These situations arise when patients present with small skin avulsion wounds or superficial abrasions. The small full-thickness skin wound that has been left untreated for several days and some fingertip amputations are examples of wounds that may be allowed to heal secondarily. After cleansing and debridement, a nonadherent dressing is applied, and daily dressing changes are begun. The wound heals through a process of contraction, granulation, and epithelialization.

SKIN GRAFTING

SPLIT-THICKNESS SKIN GRAFTS

Some wounds are not amenable to management by primary, delayed primary, or secondary closure. Examples include large burns involving the epidermis and all layers of the dermis, sizable avulsion injuries, and extensive areas of skin loss as might occur with tumor removal. In such cases, a split-thickness skin graft (STSG) can be used for secure wound coverage (Fig. 8.1). An STSG is a sheet of skin consisting of the entire epidermis and some of the dermis (Fig. 8.1).

There are several prerequisites for a wound to successfully sustain an STSG (44). The recipient site must be free of heavy bacterial colonization or invasion, with fewer than 10^7 bacteria per gram of tissue. All necrotic tissue and foreign bodies must be removed. The site must be well vascularized, although not necessarily exhibiting growth of granulation tissue. An STSG survives poorly when applied to bone denuded of periosteum, tendon stripped of peritenon, or cartilage separated from perichondrium.

The STSG "takes" through a process that revascularizes the transplanted skin from the underlying wound bed (8,46). Adherence of the graft to the recipient bed is maintained by a fibrin clot that forms within minutes after skin transfer. For the first 24 to 48 h after transfer, the graft survives in an avascular state by imbibing nutrients from wound fluids. Within 48 to 72 h after grafting, examination of the successful STSG discloses circulating blood cells in the graft, with generalized circulation being restored by the fourth to seventh day. Processes proposed to explain this circulatory restoration include attachment of vessels from the bed to vascular channels within the graft and/or invasion of the graft by recipient-site vessels that form new vascular channels throughout the grafted dermis. Whatever the mechanism, the grafted skin begins to turn pink by the fourth or fifth postoperative day. From that point, graft adherence becomes more dependent on vascular ingrowth and fibroplasia.

Decisions that pertain to the thickness of a particular STSG are made based on the demands of the wound, availability of donor sites, and training of the surgeon. The thinner STSGs (0.008 to 0.012 in.) tend to take more easily than thicker grafts (>0.016 in.). Thicker grafts may provide more durable wound coverage and contract less than the thinner ones. An STSG of intermediate thickness (0.012 in. to 0.016 in.) often is the best compromise.

Appropriate donor sites for STSGs include the lower extremities, buttock, trunk, and occasionally the upper extremities. The scalp provides an excellent donor site for STSGs to the face, although raising a thick graft may result in alopecia. Place the donor site in an area on which the patient does not lie; avoid the posterior thigh and the back. Avoid selecting a donor site immediately adjacent to the recipient wound, so that differing site-dressing requirements do not interfere with one another. Select a donor site that is aesthetically acceptable and easily concealed, such as the buttock in a woman and the proximal thigh in a man.

Several instruments are available for raising an STSG, including free-hand knives with or without a guard, drum dermatomes, and air-driven or electrically driven devices (Fig. 8.2). Each instrument is suitable, although the air-driven and electrically driven devices are often more readily accessible, are easier to assemble and clean, and reliably raise a graft of uniform thickness. Drum dermatomes are useful in obtaining larger sheet grafts, compared with those raised by other instruments. Except for the drum dermatomes, successful graft raising using the other instruments is facilitated by antiseptic donor-site preparation, application of a lubricant (mineral oil, blood, soap used for skin cleansing), maintenance of donor-site skin tension by an assistant, and smooth, steady advancement of the instrument during the cutting process.

Figure 8.2. Dermatome and mesher are useful in skin grafts. The electric dermatome is useful for obtaining grafts of uniform thickness.
As soon as it is raised, the STSG undergoes primary contraction. Ten to twenty percent of the graft's surface area is lost, probably as a result of recoil of dermal elastic fibers.

Meshing of an STSG is a process in which multiple staggered rows of full-thickness incisions are placed in the graft (14). These incisions are made by applying the STSG to the obliquely ridged side of a plastic skin carrier, then passing skin and carrier through a device with numerous circular cutting blades. Depending on the length and location of the cuts, the resultant meshed graft can be expanded to a surface area of 1.5 or more times its original surface area. Thus, a larger wound can be covered using a smaller donor site. Fluid accumulating beneath the graft can escape through the interstices, discouraging hematoma or seroma formation. A meshed graft conforms more accurately than does an unmeshed one to an irregular wound bed, but one disadvantage of the meshed graft is its inferior esthetic appearance when compared with the unmeshed graft (Fig. 8.3).

Figure 8.3. Symmetric patterned scarring typical of a healed meshed (1.5:1) split-thickness skin graft.

Once the STSG has been raised and if necessary meshed, it should be secured to the recipient site. While final preparations are being made, the graft can be stored in a saline- or blood-soaked sponge. After an inspection of the recipient site has confirmed adequate debridement and hemostasis, transfer and trim the graft to fit the wound precisely. Avoid small areas of graft overlapping intact skin, as the STSG will not take and may become a nidus for infection. Secure the STSG into position using absorbable or nonabsorbable sutures, staples, or surgical wound closure tapes.

Application of a dressing to the grafted wound is as important as any other step in achieving a healed wound. In rare cases, no dressing is applied at all. Treat the margins with an antibiotic ointment and evacuate immediately any observed fluid accumulation. This technique is occasionally used for grafting of the face, where dressings are difficult to apply, or for STSG coverage of a free microvascular muscle flap, where constant access to the flap must be provided for monitoring its circulation. Usually the recipient site is dressed to preserve a clean environment, to prevent graft disruption by trauma from an external source, to serve as a splint to protect against patient motion with resultant shearing of the graft from its bed, and to maintain uniform, constant pressure on the graft to discourage seroma or hematoma formation.

A suitable dressing consists of one layer of nonadherent gauze covered by a soft, bulky, pliable, absorbent material held in place by tie-over sutures or, in the case of an extremity, by a circumferential wrap. This is reinforced with a splint or cast to limit joint mobility above and below the grafted site. Occasionally, if a meshed graft has been applied over a previously contaminated wound, the dressing is soaked initially and continuously with an antibiotic solution. An alternative in irregular wounds is to apply bulky saline-soaked cotton over the nonadherent gauze. This conforms well to the wound, keeps the graft moist, and acts as a wick to keep fluids from accumulating beneath the graft. Overwrap the cotton with conforming gauze rolls or a bias-cut stockinette.

After 3 to 7 days, remove the dressing and inspect the wound. Earlier dressing removal would be indicated for any local or systemic signs of infection. After the initial dressing is removed, perform a dressing change every 24 h for an additional 7 to 14 days.

The donor site may be dressed initially with a fine-mesh gauze impregnated with petroleum jelly and a topical antibiotic (3). This is covered by a bulky dressing for 24 h, at which time the entire dressing, except for the fine-mesh gauze, is removed. The gauze dries and forms a stable eschar. Reepithelialization of the donor site proceeds from basal cells contained within the residual deep dermal appendages. Over 1 to 2 weeks, the gauze separates spontaneously, leaving a closed, often scaly donor-site scar. Flaking and itching can be controlled through application of a skin lotion. Alternative methods of STSG donor-site wound management range from the use of no dressing to placement of a synthetic skin substitute, either permeable or impermeable to water.

As healing progresses, the STSG undergoes several changes. Its color changes from an early pink hue to a more waxy yellowish color, often lighter than the surrounding skin. Prolonged sun exposure may, however, result in persistent hyperpigmentation. Maturation of the STSG is accompanied by secondary contraction during approximately the first 3 months of healing, followed by a gradual softening of the scar (15). Thinner STSGs contract more than thicker grafts (45).

FULL-THICKNESS SKIN GRAFTS

A full-thickness skin graft (FTSG) consists of the entire dermis and epidermis. FTSGs shrink by up to 40% in surface area immediately on being raised as a result of elastic fiber recoil within their substance (primary contraction). When sutured in place, however, they tend to contract less than STSGs during the fibroelastic and remodeling phases of wound healing (secondary contraction). This feature is particularly important when skin grafts are planned for the hands and feet (Fig. 8.4) (26). An FTSG is often selected over an STSG when wound contracture would result in a loss of maximum joint function.

Figure 8.4. A: Simple syndactyly involving the ring and index fingers. B: Syndactyly release through the use of interdigitating flaps and full-thickness skin grafts. Scar contracture has been minimized.

The selection of an FTSG donor site depends on the amount of skin required. Because a full thickness of skin is removed, the resultant wound cannot heal by reepithelialization but must be either closed primarily, resurfaced with an STSG, or covered with a vascularized flap. A large ellipse of lower abdominal or groin skin for grafting can be removed and the resultant defect sutured under little or no tension with the patient in a sitting position. Other FTSG donor sites include the medial arm, retroauricular region, inferior gluteal fold, and supraclavicular area.

Success of an FTSG depends on a clean, well-vascularized bed, a properly prepared graft, and a secure dressing. The principles of bed preparation are the same as those for STSGs. After the FTSG has been raised, all fat and loose connective tissue are removed from the deep surface, exposing the dermis. The FTSG is sutured in place and covered with a compression dressing, and the area is immobilized in a fashion similar to the STSG technique. Wounds are usually inspected in 5 days at the time of the first dressing change. A bluish hue is typical for the FTSG when initially exposed; this changes to a more normal skin tone over 3 to 7 days (6).
SKIN FLAPS

A skin flap is created by incising the margins of a previously outlined region of skin and subcutaneous tissue, leaving it attached to the body in an area large enough to maintain flap vascularity. The skin flap carries its own blood supply, making it ideal for covering poorly vascularized wounds. Such wounds include those containing bare tendon, cartilage, or bone. Wounds in an area of previous irradiation have poor vascularity and often require a skin flap for closure.

Skin flaps may be classified based on the anatomy of their blood supply. Vascular anatomy thus characterizes the random, axial, fasciocutaneous, and musculocutaneous flaps. In every flap, the final common pathway for arterial inflow and venous egress to and from the dermis and epidermis consists of the dermal and subdermal vascular plexuses.

Random Skin Flaps

The random flap consists of skin and subcutaneous tissue elevated with the underlying dermal and subdermal vascular plexuses. Dimensions of the random flap are determined by the size of the defect to be closed. If a random flap is larger than a certain size, its tip may die. In the past, the ratio of flap length to width was thought to be important, although now it appears that absolute flap length is the more important factor in determining random flap survival. Generally, however, skin flaps are still designed with a 1:1 width-to-length ratio.

![Figure 8.5](image)

**Figure 8.5.** Random flap in which the skin is supplied by the subdermal plexus only.

Survival length may be increased by using a delay procedure. Part of the surgical margin of the flap is incised and sutured immediately. Seven to 14 days later, the flap is elevated and transposed. During this interval, the flap becomes better vascularized and/or more tolerant to ischemia, which allows it to survive to a greater length than would be possible without the delay.

Random flaps generally require less time, effort, and technical ability to elevate than do other types of flaps. They are usually designed immediately adjacent to the wound requiring reconstruction, obviating the need for a distant donor site. Sometimes the random flap's donor site cannot be closed primarily but requires a skin graft.

![Figure 8.6](image)

**Figure 8.6.** A: Neurotrophic ulcers of the heel and first metatarsal head. B: Ulcers covered with random-pattern flaps. The flap donor sites were closed with split-thickness skin grafts.

Axial Skin Flaps

The axial skin flap has a defined, recognizable artery contained within its vascular pedicle. Examples include the groin and posterior thigh flaps, containing the superficial circumflex iliac and descending branch of the inferior gluteal vessels, respectively. An axial pattern flap will survive to a greater length than will a random skin flap of similar dimensions. The pedicle of an axial skin flap can occasionally be narrowed to contain only the vascular pedicle, making it easier to transpose if somewhat more difficult to elevate. Unfortunately, not all skin territories are supplied by a single dominant vessel, which limits the number of donor sites for axial flaps.

![Figure 8.7](image)

**Figure 8.7.** Axial flap with an identifiable artery running in the longitudinal axis of the flap.
The groin flap is located lateral to the femoral artery, paralleling the inguinal ligament. It is a skin flap containing the superficial circumflex iliac artery (SCIA) and thus can be designed longer than it is wide because of its direct arterial cutaneous blood supply.

The groin flap is used primarily to resurface the hand and forearm. It is usually attached to or inset into a hand defect and then left attached for a period of 2 to 3 weeks before division of the flap from the groin. The advantages of this flap are that the vascularity is quite good and that the flap can be readily thinned before coverage of the defect. The disadvantages are that the hand remains in a dependent position and that the positioning and immobilization for some patients can be quite challenging.

- Identify and, with a marking pen, draw the superficial circumflex iliac artery location on the skin. Outline the flap by centering it over the anticipated artery location. The flap width can vary between 5 and 15 cm; the length can extend from the femoral artery out to the anterior superior iliac spine with reasonable safety. The flap can be elevated without a delay procedure.
- The SCIA originates from the femoral artery and courses laterally 2.5 to 3.0 cm below and parallel to the inguinal ligament. The flap is usually raised from lateral to medial. While dissecting medially over the sartorius muscle, dissect deeply to include the sartorius fascia with the flap over the medial half of the muscle. This avoids transecting the SCIA as it dives down to the superficial femoral artery (SFA) just superficial to the sartorius fascia on the medial border of this muscle. Staying above the deep fascia during the dissection all the way to the SFA risks transecting the main arterial pedicle (SCIA) of the flap.
- You may extensivley thin the distal or lateral aspect of the flap that is to be set into the upper extremity defect as long as the subdermal plexus is left intact.
- In most cases, the flap pedicle is divided at 2 to 3 weeks. The groin defect can often be closed primarily, without the need for a skin graft. Inset the flap at the time of division or later, when it softens.

Fasciocutaneous Flaps

The fasciocutaneous flap receives its blood supply from vessels that reach the skin by passing through fascial septa between muscle bellies and then fanning out at the level of the deep fascia, giving off perforating vessels that supply blood to the overlying skin (Fig. 8.9). This type of flap is better vascularized and will survive to a greater length than will a random flap of comparable dimensions. Fasciocutaneous flaps have been described in the head and neck region, trunk, and extremities (43). The size and location of an individual flap can be tailored to accommodate the reconstructive needs (Fig. 8.10). One disadvantage of the fasciocutaneous flap is the frequent need for a skin graft at the donor site, leaving a conspicuous deformity (18).

Muscle Flaps

The use of muscle flaps in the reconstruction of lower extremity defects was introduced in the 1970s when it was realized that muscles could be moved around a single blood vessel supply site (the pedicle) and maintain excellent vascularity. Muscles were classified by Mathes according to the number of pedicles and their relative contribution to the blood supply (52). For example, the gastrocnemius muscle has a single dominant pedicle consisting of the sural artery, whereas the soleus muscle receives a dominant pedicle from the peroneal artery and a second dominant pedicle from the posterior tibial artery. In addition, the soleus muscle has several minor pedicles given off by the posterior tibial artery distally. Muscles may be detached from their origin and insertion, and moved, tethered only by their dominant (or major) pedicle, while maintaining excellent perfusion. Their viability is less certain when a minor pedicle is used as a point of transfer or rotation. The distance a muscle can move while tethered by its vascular pedicle is known as its arc of rotation. Veins are found consistently to run with the arterial pedicles. The most appropriate muscle for transfer is one with a vascular pedicle close to or just proximal to the recipient site; this allows for an adequate arc of rotation.

Indications Muscle flaps are ideally suited for covering defects with large, irregular dead spaces or cavitary lesions with exposed bone or metal. Muscle flaps are superior to skin flaps for resisting infecion with bacterial contamination (6) and are routinely used in the treatment of osteomyelitis (33) after thorough debridement. They also are helpful in poorly vascularized wounds secondary to radiation injury or chronic scarring, and they provide excellent vascularity to support the incorporation of bone grafts. Their use is now routine for type IIIIB fractures of the lower extremity, infected total hip or knee wounds, and large traumatic wounds.
As our experience with muscle flaps continues to grow, the timing of flap coverage for significant traumatic wounds continues to be refined. Although the issue of ideal timing of flap coverage for type III tibial injuries has been debated in the literature (5,47), it is now generally agreed that coverage should be undertaken within the first 5 to 7 days after injury, before wound colonization has occurred.

Free flaps are now considered a routine option in the management of many wounds that would have received regional muscle flaps only a few years ago. Unrestricted by the anatomic limits of regional flaps, microsurgical transfers are improving function and esthetics and in some instances accelerating healing. Regional muscle flaps, however, remain the foundation of lower-extremity reconstruction proximal to the tibial distal third.

**Medial and Lateral Gastrocnemius Flaps**

**Anatomy**

The gastrocnemius muscle has two heads, each arising from a femoral condyle (Fig. 8.11). The medial and lateral gastrocnemius muscles fuse at the distal portion of the popliteal fossa and join with the soleus to insert into the Achilles tendon. The medial gastrocnemius is usually 2 to 3 cm longer than the lateral gastrocnemius and is slightly more anteromedial. This gives the medial gastrocnemius a significantly greater arc of rotation than the lateral muscle.

![Figure 8.11](https://example.com/figure811.png)

Each muscle has one dominant pedicle consisting of the sural artery and vein given off by the popliteal artery at the level of the knee joint. The sural arteries run distally with the tibial nerve branches for several centimeters before entering the muscle bellies on their anterior surfaces.

**Indications**

The medial and lateral gastrocnemius muscles can be used separately because they have separate blood supplies and may be divided at the posterior raphe. The arc of rotation of the medial muscle is much greater than that of the lateral muscle because the medial muscle is longer and the lateral muscle is restricted by the fibular head (Fig. 8.12). This is most relevant for covering anterior defects. If the lateral head is transferred anteriorly, it uses up much of the available length traversing the fibular head. For anterior knee defects, even those that are slightly anterolateral, the medial gastrocnemius is almost always more effective. Proximal tibial defects in the region of the tuberosity are the most easily covered; however, the arc of rotation is reliable over the entire knee and patella and the proximal third of the tibia.

![Figure 8.12](https://example.com/figure812.png)

**Medial Gastrocnemius Flap—Operative Technique**

1. Make a long incision under tourniquet control just posterior to the medial aspect of the tibia to within 5 to 10 cm of the medial malleolus (Fig. 8.13). Usually the saphenous vein is encountered with this incision; reflect it to either side of the wound.

![Figure 8.13](https://example.com/figure813.png)

2. Incise the deep fascia, exposing the gastrocnemius muscle head. Dissect this deep fascia away from the muscle in a loose areolar plane to the posterior midline where the raphe between the medial and lateral gastrocnemius should be identifiable. Sometimes the division of these muscles is indistinct.

3. Dissect the gastrocnemius away from the underlying soleus muscle. The plantaris tendon should be clearly visible lying on the superficial surface of the soleus muscle. The gastrocnemius muscle is easily separated from the soleus in the proximal-to-distal direction until the Achilles insertions are reached. Leave a cuff of tendon insertion in continuity with the distal gastrocnemius muscle so that this can be used for suturing later and for traction during proximal flap dissection.

4. Divide the midline raphe and free the gastrocnemius as far proximally as needed to reach and comfortably cover the defect. For defects in the tuberosity area, very little further dissection is needed.
Maneuvers to increase the arc of rotation or length of usable flap include incising the fascia near the origin of the muscle close to the femoral condyle. This may give 1 to 2 cm of extra length. Sometimes this may require taking down the insertions of the semimembranosus and semitendinosus muscles. To get further length, the origin of the gastrocnemius can be divided from the femoral condyle, although this is seldom necessary. It is also possible, as a last resort, to flex the knee and get even further reach of the flap. With division of the origin it is important not to put the pedicle under too much tension because it is no longer protected by the tendinous attachments when stretched. The flap will heal and allow straightening of the knee, usually in 2 to 3 weeks, if this maneuver is necessary.

Set the flap into the defect after thorough debridement by placing bolster sutures through the skin 2 to 3 cm from the wound edge. It is important to undermine the edges of the wound to achieve this inset. The flap can be tunneled under the skin bridge to the defect or directly inset by incising the skin between the flap and the defect. We generally do not tunnel with significant defects. The flap can be widened with multiple scorings of the fascia on the deep aspect of the muscle if needed. If the defect is very large, consider a free flap or possibly a gastrocnemius musculocutaneous flap, which has a cutaneous extension (Fig. 8.12).

Cover the flap with a meshed split-thickness skin graft. The flap will atrophy and lose some of its bulky appearance with time. This is partially dependent on whether the innervation is left intact.

Place a flat Jackson Pratt drain in the donor wound, and place another drain under the flap. Apply a posterior leg splint. Change the skin graft dressing in 3 to 5 days. The extremity remains elevated and splinted after dressing changes for 2 to 3 weeks.

Lateral Gastrocnemius Flap—Operative Technique

The lateral gastrocnemius muscle can be raised in a similar fashion with a lateral longitudinal incision. Care must be taken with the peroneal nerve, and transposition is more limited around the fibular head.

Soleus Flaps

Anatomy The soleus muscle originates from the tibia, the fibula, and the interosseous membrane. Its insertion is joined with the gastrocnemius into the Achilles tendon. The peroneal artery supplies the proximal and lateral half of the muscle, and the medial distal half of the muscle is supplied by the posterior tibial artery (Fig. 8.14). This vascular anatomy allows the muscle to be split in half longitudinally and used as a split soleus muscle flap if a smaller flap is desired. A distally based soleus flap is described based on perforating vessels of the posterior tibial artery, although this flap generally is not as reliable.

Figure 8.14. The soleus muscle is supplied proximally and laterally by the peroneal artery and medially and distally by the posterior tibial artery. The muscle may be split longitudinally for use as a hemisoleus flap. [Swartz WM, Jones NF. Soft Tissue Coverage of the Lower Extremity. Curr Probl Surg 22(6):34,1985.]

Indications The soleus muscle flap is the first choice for middle-third defects of the tibia. Even in extensively damaged extremities with midshaft fractures and lacerations of the soleus, it can still be used with confidence. The usual indication is exposed bone or a type III fracture of the middle third of the tibia with some skin loss. Use of the flap acutely will provide well-vascularized, stable coverage and ensure the likelihood of rapid recovery. The soleus flap should be considered when plates and screws are used midshaft with any compromise in soft-tissue coverage.

Operative Technique

A medial approach is easiest. Make a long incision just posterior to the medial border of the tibia from the insertions of the hamstring muscles down to within several centimeters of the medial malleolus (Fig. 8.15).

Figure 8.15. A: Type IIIB tibial fracture with exposed anterior tibial tendon and exposed fracture site. B: Radiograph of open tibial fracture and malleolar fracture, which were reduced and fixed with an interlocking nail. C: Soleus flap ready for transposition over fracture site and exposed tendon. D: Ambulatory patient 2 months postoperatively with healed wound.

Under tourniquet control, develop the plane between the soleus and gastrocnemius, which is primarily loose areolar tissue. The plantaris should be visualized on the surface of the soleus muscle. Dissect distally, identify the insertions into the Achilles tendon that join with gastrocnemius insertions. Shave a thin portion of fascia off the tendon with the soleus rather than stripping the muscle fibers off freely.

Then dissect the soleus muscle proximally, identifying perforating branches of the posterior tibial artery. Tie these off rather than cauterizing them. It is often necessary to divide the soleus sharply from the flexor digitorum muscles as the dissection proceeds proximally. The muscle can be split longitudinally to use only half of the flap (hemisoleus flap); alternatively, the entire muscle can be used, which is more common.

Transfer the muscle flap to the defect by dividing the skin between the muscle and the defect and insetting the flap as before. Cover the flap with a split-thickness skin graft on all exposed portions.

Place a drain in the donor site and under the flap. A posterior splint with elevation continues for 2 to 3 weeks.

Rectus Femoris Flap

Anatomy The rectus femoris muscle originates from the inferior iliac spine and inserts into the patella. Its blood supply consists of one or two dominant pedicles, which are branches of the lateral femoral circumflex artery, which is in turn a branch of the profunda femoris artery (Fig. 8.16). Innervation from the femoral nerve accompanies the vascular pedicles in the proximal third of the muscle. This is generally 8 to 10 cm inferior to the inguinal ligament. Rotation of the muscle around this vascular pedicle will reach the trochanter and the lateral genital area. A skin paddle can be elevated with the muscle if necessary.
Figure 8.16. Anatomy of rectus femoris muscle. Two to three pedicles from the lateral circumflex femoral artery enter the proximal third of the muscle belly. (Mathes SJ, Nahai F. Clinical Atlas of Muscle and Musculocutaneous Flaps. St. Louis: CV Mosby, 1979:44.)

Indications Meland and associates concluded that the rectus femoris was the muscle flap of choice for the recalcitrant total hip arthroplasty wound (39). After removal of their prostheses, 27 patients with chronically infected hip wounds were successfully treated with muscle flaps, 23 of which were rectus femoris flaps. All patients had their hip arthroplasty reimplanted at least 12 months following the muscle flap.

This flap can be used for any deep or chronic wound of the hip or proximal thigh. Other choices for the hip region are the vastus lateralis muscle or rectus abdominis muscle; these should be considered before resorting to a free flap.

Operative Technique

- Make a longitudinal incision over the rectus femoris muscle from just below the inguinal crease down to 5 to 10 cm above the patella. Carry the dissection through the deep fascia, identifying the rectus femoris muscle. Dissect it out from distal to proximal, taking care to avoid damaging the pedicle when entering the region 10 cm below the inguinal ligament.
- To reach the acetabulum, transpose the muscle or tunnel beneath the vastus lateralis muscle to reach the hip defect.
- Debride the edges of the hip defect to allow a layered closure. Close the donor and recipient sites over drains. If the rectus femoris does not completely fill the dead space of the acetabulum and hip wound, consider adding the vastus lateralis or another muscle flap.
- It is important to close the quadriceps muscles on either side of the rectus femoris in the midline to partially offset its functional loss.

Vastus Lateralis Muscle Flap

Anatomy. The vastus lateralis muscle originates from the trochanter of the femur, the lateral intermuscular septum, and the gluteal tuberosity, and it inserts into the patella (Fig. 8.17). Its blood supply is from descending branches of the lateral femoral circumflex artery; these branches enter the muscle close to 10 cm below the anterior iliac crest. Innervation is from the femoral nerve entering close to the vascular pedicle. The arc of rotation of this muscle is most useful for filling acetabular defects. Most other defects of the thigh can be reconstructed with skin grafts.

Figure 8.17. Anatomy of vastus lateralis muscle. The dominant vascular pedicle is the descending branch of the lateral femoral circumflex. Dotted line indicates the surgical incision from anterior and lateral view. (Collins DN, Garvin KL, Nelson CL. The Use of the Vastus Lateralis Flap in Patients With Intractable Infection After Resection Arthroplasty Following the Use of a Hip Implant. J Bone Joint Surg 69:512;1987.)

Indications The vastus lateralis is a second choice for difficult hip wounds and can be used in addition to the rectus femoris if a large dead space is present. The thigh has such abundant soft tissue that muscle flaps are rarely needed outside of the hip region, and skin grafts usually suffice.

Operative Technique

- Make a long lateral incision from the trochanter to just anterior to the lateral femoral condyle. Incise the fascia lata and expose the vastus lateralis muscle. Identify the intermuscular septum between the rectus femoris and the vastus lateralis. Dissection in this plane is aided by using a Gelpi self-retaining retractor to spread the intermuscular septum.
- Identify and protect the lateral femoral circumflex artery, its transverse branch to the tensor fascia lata muscle, and its descending branch to the vastus lateralis. This should be 8 to 10 cm distal to the anterior superior iliac spine.
- Separating the vastus lateralis from the intermedius is the most difficult part of the operation and can be quite bloody; it requires sharp dissection (Fig. 8.18). Cut the tendinous insertion of the vastus lateralis 8 cm proximal to the patella and then mobilize the muscle from distal to proximal with a periosteal elevator, heading toward the pedicle (Fig. 8.19). Mobilize enough of the muscle to fill the dead space, and close the wound comfortably.

Figure 8.18. Cross section through the distal thigh demonstrates posterior vascular perforators and the plane of transection for freeing the vastus lateralis muscle. (Collins DN, Garvin KL, Nelson CL. The Use of the Vastus Lateralis Flap in Patients With Intractable Infection After Resection Arthroplasty Following the Use of a Hip Implant. J Bone Joint Surg 69:512;1987.)

- Often a split-thickness skin graft is necessary to cover an exposed portion of the muscle flap, which should not be closed too tightly.
- Place a drain in the donor site and in the hip wound beneath the flap. Three weeks of relative immobility assists the healing of the wound.

**Tibialis Anterior Muscle Flap**

**Anatomy** The anterior tibialis muscle originates on the lateral condyle of the tibia, the upper lateral surface of the tibia, and the interosseous membrane and inserts on the base of the first metatarsal bone and the medial cuneiform bone. Its blood supply is derived from multiple perforators, usually six to eight, along the entire length of the anterior tibial artery. Innervation is via branches of the deep peroneal nerve. This type of blood supply with multiple minor pedicles is referred to as segmental supply and does not allow for significant arcs of rotation without risk of necrosis. This muscle is also important for dorsiflexion and inversion of the foot and must have its tendon continuity preserved. Techniques for longitudinal splitting of the muscle belly while preserving tendon function have been developed using a medial or external split (22,41).

**Indications** Longitudinal splitting techniques allow the tibialis anterior to close an adjacent wound with a maximum width of 5 cm and a length as long as the muscle belly. Such a flap is convenient for coverage of midtibial defects. Often this flap can serve as the lateral portion of a muscle sling around an injured tibia with the medial portion of the sling fashioned with a medial gastrocnemius flap. Splitting the tibialis anterior longitudinal muscle requires a split-thickness skin graft by design.

**Operative Technique**

- The defect is almost always directly adjacent to the tibialis anterior muscle with exposed tibia. Make the skin incision longitudinally along the edge of the defect and proceed just deep to the fascia covering the tibialis muscle. Reflect the fascia and skin laterally, exposing the muscle.
- Identify the septum when dividing the tibialis anterior and the extensor digitorum. Incise the muscle as far lateral in the septum as possible and develop a 1.5-cm-thick flap of muscle (Fig. 8.20). Leave some muscle fibers on the tibialis tendon to allow for skin graft take. Flip the anterolateral portion of the muscle over 180° to cover the tibial defect (Fig. 8.21). Inset the muscle into the undermined medial edge of the wound, and apply a split-thickness skin graft.

**Rectus Abdominis Flap**

**Anatomy** The rectus abdominis muscle is a long thin flat muscle that originates from the pubic symphysis and inserts on the costal cartilages of the fifth, sixth, and seventh ribs. It has three and sometimes four tendinous intersections that cross it in a transverse direction. Its blood supply is from the inferior epigastric artery and from the superior epigastric artery. The inferior epigastric artery is the dominant pedicle and supplies the skin overlaying the muscle as well as the muscle from the pubis to several centimeters above the umbilicus (Fig. 8.22). Flaps can be designed using the muscle alone or with a skin paddle (myocutaneous flap). Innervation is segmental from the 7th through 12th intercostal nerves. The arc of rotation can be extended inferiorly by islanding the muscle flap on the inferior epigastric pedicle and moving it inferior to the inguinal ligament. The flap can also be made longer by taking an extended skin paddle of abdominal skin. The musculocutaneous perforators of the flap can support abdominal skin overlaying the oblique muscles as far as the anterior axillary line (Fig. 8.23).
Operative Technique

When the skin paddle is included, the flap gains length and a greater arc of rotation. It can be used in the pelvis over the pubic symphysis for anastomosis with the recipient vessels. Often the muscle is transferred to distal third defects of the lower extremity or foot.

Indications

As a muscle flap alone, the gracilis can reach and fill small defects of the groin and pubic region; however, it is usually transferred microsurgically to distant sites for greatest usefulness. When the patient is in a lithotomy position, the adductor longus muscle is more easily palpated as a tendinous structure in the medial groin area originating from the pubic symphysis. Rolling over the adductor longus muscle in a posteriorinferior direction with one's fingers brings one to the anterior edge of the gracilis muscle proximally. The distal tendon inserts on the medial tibial tubercle and is often seen during the dissection in a position below the inferior edge of the sartorius muscle. It can be palpated as a round tendinous structure in this distal location.

When the gracilis is used as a muscle flap, an incision is made overlying the muscle, and the dissection is carried down to the gracilis muscle. The main pedicle is usually the medial femoral circumflex, which is a branch of the profunda femoris artery. This vessel enters the muscle approximately 8 to 10 cm from the origin of the gracilis, at the pubic tubercle. There are minor pedicles distally originating from the superficial femoral artery, but these are usually divided during elevation of the flap.

Figure 8.22. The rectus abdominis muscle originates from the pubic symphysis and inserts on the costal cartilage of the fifth, sixth, and seventh ribs. The dominant pedicle is the inferior epigastric artery; however, the entire muscle and overlying skin can survive on the superior epigastric artery as well. (Mathes SJ, Nahai F. Clinical Atlas of Muscle and Musculocutaneous Flaps. St. Louis: CV Mosby, 1979:15.)

Figure 8.23. A male patient is shown who sustained a traumatic injury of the left leg with exposure of the left trochanter. A left rectus abdominis musculocutaneous flap with an extended skin paddle was rotated 90° in a clockwise direction to cover the exposed hip. The flap was rotated around the inferior epigastric pedicle. The flap donor site is evident as a left paramedian abdominal incision.

Operative Technique

- An incision is made overlying the length of the rectus muscle (paramedian incision). At the inferior portion of the wound, the incision is sometimes angled off laterally to overlie the point at which the inferior epigastric artery and vein originate from the external iliac vessels. This allows better exposure of the inferior epigastric vessels.
- If a skin paddle is chosen, it is kept in continuity with the muscle during the flap elevation. The anterior rectus fascia is incised around the base of the skin island, and the muscle is dissected free from the posterior sheath. Areas of the tendinous intersections are quite adherent to the muscle, and dissection is tedious in these areas. If a large portion of the anterior rectus sheath is taken with a skin paddle, then synthetic mesh is used to close the anterior rectus sheath defect and prevent future herniation.
- The flap is usually transposed to the defect using a direct inset and making an incision through the skin from the flap to the defect. If the flap is transferred free, the epigastric vessels are carefully dissected down to the external iliac vessels. Often there will be two almost equal-sized inferior epigastric veins, which will join into one single vein before emptying into the external iliac vein. We often try to transect the vein at this common site.

Gracilis Flap

Anatomy

The gracilis muscle is a long thin muscle that originates from the pubic symphysis and inserts on the medial tibial condyle. As an accessory thigh adductor, it contributes minimally to thigh adduction and is thus expendable for reconstructive purposes. The main arterial pedicle is usually the medial femoral circumflex, which is a branch of the profunda femoris artery. This vessel enters the muscle approximately 8 to 10 cm from the origin of the gracilis, at the pubic tubercle. There are minor pedicles distally originating from the superficial femoral artery, but these are usually divided during elevation of the flap (Fig. 8.24). The entire muscle survives well on circulation from the proximal dominant pedicle. The gracilis muscle can be used with an overlying skin paddle, which can be as large as 10 by 30 cm.

Figure 8.24. The gracilis muscle originates from the pubic symphysis and inserts on the medial tibial condyle. The dominant pedicle is the medial femoral circumflex, which is most commonly a branch of the profunda femoris artery. The minor pedicles, located more distally, are usually divided during elevation of the flap. (Mathes SJ, Nahai F. Clinical Atlas of Muscle and Musculocutaneous Flaps. St. Louis: CV Mosby, 1979:349.)

Operative Technique

- It is not trivial to locate the gracilis muscle accurately, especially when edema, obesity, or distortion of the anatomy is present. When the patient is in a lithotomy or frog-leg position, the adductor longus can be easily palpated as a tendinous structure in the medial groin area originating from the pubic symphysis. Rolling over the adductor longus muscle in a posteriorinferior direction with one's fingers brings one to the anterior edge of the gracilis muscle proximally. The distal tendon inserts on the medial tibial tubercle and is often seen during the dissection in a position below the inferior edge of the sartorius muscle. It can be palpated as a round tendinous structure in this distal location.
- When the gracilis is used as a muscle flap, an incision is made overlying the muscle, and the dissection is carried down to the gracilis muscle. The main pedicle is found coming out between the adductor longus and magnus muscles in the fascial septum. Often one artery and two identifiable veins constitute the pedicle. If a
skin paddle is desired, care must be taken to accurately position the skin paddle over the muscle and not disrupt the connection of the muscle and its surrounding fascia to the skin. We have found that inclusion of increasing amounts of fascia around the gracilis muscle enhances the circulation to the overlying skin. It should be noted that historically the distal cutaneous territory of the gracilis muscle has not been considered reliable from a vascular standpoint.

MUSCULOCUTANEOUS FLAPS

Although not purely skin flaps, this versatile class of flaps carries a skin component and has found wide clinical application (31, 34). The musculocutaneous flap is composed of muscle and a segment of overlying skin (35). This skin segment or island is nourished by vessels originating from and draining into the underlying muscle. Left attached to its major vascular pedicle(s) or transferred microsurgically, the muscle can be separated from its origin and insertion and moved great distances to provide a stable reconstruction (Fig. 8.25).

Virtually every muscle has been investigated as a potential base for a musculocutaneous flap. Some of the most versatile ones are the latissimus dorsi, deltoid, rectus abdominis, glutaeus maximus, tensor fascia lata, and rectus femoris. Each of these flaps can be transposed through a large arc of rotation and used to provide bulk for dead space obliteration, well-vascularized tissue, and stable skin coverage at the site of reconstruction (6).

FLAP DESIGN

Flaps located adjacent to the site of reconstruction may be classified as either rotation or advancement in design. The rotation flap moves through an arc of rotation as it is lifted from its origin and placed over the defect for reconstruction (27). Although generally thought of as semicircular in shape, rotation flaps also include transposition, bilobed, and rhomboid flaps. The classic Z-plasty is in reality two transposition (rotation) flaps designed, raised, and interposed to break up, lengthen, or redirect an unfavorable linear scar (13, 18, 38). The donor site of many rotation flaps can be closed primarily without a skin graft (28).

The advancement flap is not moved through an arc of rotation but is advanced along a straight line into the required defect. Advancement flaps may be vascularized through a retained skin pedicle or by perforating vessels from underlying fascia or muscle. When it is designed in a rectangular shape and subsequently advanced, excess skin at each corner of the flap's base may need to be excised. The V-to-Y advancement flap leaves no skin excess at its site of elevation. The donor-site defect of most advancement flaps can be closed by primary suturing (Fig. 8.26).

TISSUE EXPANSION

Through tissue expansion, additional skin can be made available for advancement into an adjacent wound to achieve closure (23). The technique requires two operative procedures. Initially, a collapsed silicone rubber bag (the tissue expander) is inserted subcutaneously near the defect to be covered. Usually the expander is placed through a separate incision made at a distance from the wound margin. After 1 to 3 weeks, when healing of the skin wound is ensured, saline is introduced into the expander through a self-sealing port, either contained within the expander or attached by Silastic rubber tubing. Every 3 to 7 days 60 to 120 mL of saline is injected. The overlying skin increases in surface area as the bag expands. This increase reflects stretching of the skin, thinning of the dermis, and recruitment of skin from adjacent areas. After maximum volume has been reached, the expander is removed at a second operation, and the expanded skin is advanced over the site to be reconstructed (Fig. 8.27). Primary wound closure is usually possible.

Tissue expansion is more successful when applied to wounds proximal to the knee or elbow. This technique is best used to treat healed wounds, as placement of an expander adjacent to an open wound is often complicated by infection within the expander pocket, necessitating its removal (1, 39).
PITFALLS AND COMPLICATIONS

Complications can be divided into those associated directly and locally with the operative procedure (seroma, hematoma, infection, and technical problems with fixation devices) and those that result from systemic complications (thermoembolism, pulmonary embolism, etc.). All surgeons will encounter systemic complications, so be prepared to take appropriate steps to minimize the risk of complications and be ready to manage complications if they occur. Local wound complications are minimized by careful preoperative planning; gentle, rapid, and precise surgical technique; and appropriate aftercare. Systemic complications are minimized by careful preoperative workup, ensuring that the patient’s medical condition is as good as possible before surgery; good anesthesia practices with good pulmonary ventilation throughout the case; appropriate maintenance of blood volume; and immediate mobilization of the patient after surgery, if possible.

NECROSIS OF WOUND EDGES

Necrosis of the margins of a wound has several causes. The most common is probably excessively strong retraction for prolonged periods. Rough handling contributes as well. Curvilinear or sharply angled incisions that produce flaps may also predispose to wound necrosis because of ischemia of the tips of the flaps; this is particularly true for subseous flaps. Straight-line incisions are safest, particularly in the lower extremity. Preexisting large-vessel disease, as in arteriosclerosis, or small-vessel disease, as in diabetics, also predisposes to wound necrosis. Special precautions are necessary, particularly in diabetics undergoing foot surgery. In some cases, surgery may be contraindicated.

Tension excessive in the skin or overly tight sutures placed too closely together or too far from the wound edge also devascularize the skin along the incision. Avoid tension in wound closures. When a tourniquet is used, it is sometimes advisable to deflate it just before skin closure so that the telltale pallor of skin ischemia can be detected. If sutures are placed and the incision is required to close a wound after elective surgery, it is often prudent to leave the wound open until necrosis subsides. Closure can then be done on a delayed basis. In some cases closure with a local rotation flap or STSG may be necessary. Although cosmetically undesirable, this may be a better alternative than wound-edge necrosis, which exposes tendons, bone, or fixation devices.

Curvilinear, S-shaped, or C-shaped incisions can create problems about the knee and ankle. Most major knee surgery is best performed through a straight, longitudinal incision placed over the anterior aspect of the knee. This incision usually results in a cosmetically acceptable scar. It also provides wide exposure of the knee and is an excellent exposure if subsequent reconstructive surgery, such as total knee arthroplasty, becomes necessary. In the ankle, straight vertical incisions directly over the malleoli are preferable to the L-shaped or C-shaped incisions often advised. Straight vertical incisions provide excellent exposure and carry a minimal risk of necrosis.

If marginal wound necrosis occurs but tendons, fixation devices, and neurovascular bundles are not exposed, corrective surgery may not be necessary. Maintain cleanliness and keep the wound covered. This will allow the necrotic area to marginate and the wound to close by secondary intention. However, healing by secondary intention can take considerable time, secondary infection may occur, and the scar may be cosmetically undesirable. If enough skin is available so that closure without tension is possible, early excision of the necrotic area with repeat closure is often desirable. Early plastic reconstructive surgery may be necessary when necrosis results in exposure of metallic fixation devices.

SEROMAS AND HEMATOMAS

Good wound hemostasis will normally postoperate the formation of seromas or hematomas, particularly if suction drainage is used. However, certain factors predispose to seroma or hematoma formation: large wounds in obese patients, large exposed bone surfaces, dead space, and uncontrolled hemorrhage secondary to coagulopathies. If a tourniquet is used, it may be wise to let the tourniquet down to ensure that hemostasis has been achieved before closure. If necrotic, the tourniquet can be reinfused for a short period to allow closure. Hypotensive anesthesia may also predispose the patient to postoperative hemorrhage when the blood pressure returns to normal. In these cases, wound suction drainage is of paramount importance.

We usually change most dressings at 24 h after surgery, as the application of a fresh, dry dressing makes the patient more comfortable and the wound can be checked for formation of a seroma or hematoma. Seromas or hematomas that require intervention are those resulting in significant postoperative swelling, accompanied by moist wound edges with either serous or serosanguineous discharge. Prolongation of drainage predisposes to secondary retrograde infection of the hematoma through the wound. If a seroma or hematoma is not accompanied by local or systemic evidence of infection, it can usually be observed for a few days, with drainage changes being done as frequently as necessary to keep them dry. Careful sterile technique is necessary. If any evidence of infection develops, such as reddening about the wound or a persistent fever, or if the drainage persists for more than 72 h, return the patient to surgery for exploration of the wound and evacuation of the seroma or hematoma. At that time, try to detect and control any potential sources of hemorrhage. Close the wound in a watertight fashion over a suction drainage system. Take aerobic and anaerobic cultures of both the fluids and the tissues of the wound. Local or systemic signs of infection are present, it is prudent to begin appropriate antibiotics until the results of cultures are received. Early evacuation of a hematoma, particularly in hip and spine surgery, is important to avoid the complication of secondary infection.

ACUTE INFECTION

Acute infection often presents initially as a seroma or hematoma and is treated as outlined previously. If cultures of the hematoma are positive, assume that acute infection has occurred. Acute postoperative infection may have local signs of infection without systemic signs, systemic signs of infection without local findings, or both. When infection is present, it is usually necessary to treat it. Typical local signs of infection, such as erythema, swelling, tenderness, and edema, are often present in the wound. If a seroma or hematoma is not accompanied by local or systemic evidence of infection, it can usually be observed for a few days, with drainage changes being done as frequently as necessary to keep them dry. Careful sterile technique is necessary. If any evidence of infection develops, such as reddening about the wound or a persistent fever, or if the drainage persists for more than 72 h, return the patient to surgery for exploration of the wound and evacuation of the seroma or hematoma.

We usually change most dressings at 24 h after surgery, as the application of a fresh, dry dressing makes the patient more comfortable and the wound can be checked for formation of a seroma or hematoma. Seromas or hematomas that require intervention are those resulting in significant postoperative swelling, accompanied by moist wound edges with either serous or serosanguineous discharge. Prolongation of drainage predisposes to secondary retrograde infection of the hematoma through the wound. If a seroma or hematoma is not accompanied by local or systemic evidence of infection, it can usually be observed for a few days, with drainage changes being done as frequently as necessary to keep them dry. Careful sterile technique is necessary. If any evidence of infection develops, such as reddening about the wound or a persistent fever, or if the drainage persists for more than 72 h, return the patient to surgery for exploration of the wound and evacuation of the seroma or hematoma. At that time, try to detect and control any potential sources of hemorrhage. Close the wound in a watertight fashion over a suction drainage system. Take aerobic and anaerobic cultures of both the fluids and the tissues of the wound. Local or systemic signs of infection are present, it is prudent to begin appropriate antibiotics until the results of cultures are received. Early evacuation of a hematoma, particularly in hip and spine surgery, is important to avoid the complication of secondary infection.

COMPARTMENT SYNDROME AND NEUROVASCULAR INJURY

Compartment syndromes are discussed in detail in Chapter 13. Compartment syndrome, as a complication of surgery, usually occurs in association with acute traumatic injuries where the initial injury causes the compartment syndrome. Compartment syndrome after elective surgery is very unusual. The most common causes are closure of the deep fascia in the presence of significant muscle swelling after prolonged elective surgery and hemorrhage into a closed compartment following undetected rupture of an artery. The two most common areas in which these problems arise are the forearm and the leg.

After major surgery on the radius and ulna, swelling of the forearm musculature is common, and closure of the deep fascia is difficult. Unless absolutely no tension is present, leave the deep fascia open and close only the subcutaneous fat and skin. The same applies to procedures on the diaphysis of the tibia, particularly posterolateral bone grafting, when approximation of the muscles but not the deep fascia is indicated. Be aware of the dangers in performing surgery in the proximal third of the tibia, where inadvertent and unrecognized laceration of one of the arteries of the popliteal artery trifurcation can occur, producing a compartment syndrome.

Compartment syndrome is best prevented by the measures previously discussed. Early recognition is of paramount importance. Unexpectedly severe postoperative pain should always raise the question of compartment syndrome. Dressings must be released and the part examined to rule out increased intracompartmental pressures. If there is any question, take intracompartmental pressure measurements. Release of the surgical closure or fasciotomy may be necessary.

INJURY TO NERVES

The most common surgical injury to nerves is transection of or trauma to a subcutaneous sensory nerve, resulting in numbness in the distribution of the nerve and exposure of metallic fixation devices. There are a number of causes of nerve injury. One of the most common is the tourniquet. A tourniquet should be released if there is any question about the adequacy of the tourniquet or if the patient is not able to raise any extremity. Hypotensive anesthesia may also predispose the patient to postoperative hemorrhage when the blood pressure returns to normal. In these cases, wound suction drainage is of paramount importance.

We usually change most dressings at 24 h after surgery, as the application of a fresh, dry dressing makes the patient more comfortable and the wound can be checked for formation of a seroma or hematoma. Seromas or hematomas that require intervention are those resulting in significant postoperative swelling, accompanied by moist wound edges with either serous or serosanguineous discharge. Prolongation of drainage predisposes to secondary retrograde infection of the hematoma through the wound. If a seroma or hematoma is not accompanied by local or systemic evidence of infection, it can usually be observed for a few days, with drainage changes being done as frequently as necessary to keep them dry. Careful sterile technique is necessary. If any evidence of infection develops, such as reddening about the wound or a persistent fever, or if the drainage persists for more than 72 h, return the patient to surgery for exploration of the wound and evacuation of the seroma or hematoma. At that time, try to detect and control any potential sources of hemorrhage. Close the wound in a watertight fashion over a suction drainage system. Take aerobic and anaerobic cultures of both the fluids and the tissues of the wound. Local or systemic signs of infection are present, it is prudent to begin appropriate antibiotics until the results of cultures are received. Early evacuation of a hematoma, particularly in hip and spine surgery, is important to avoid the complication of secondary infection.

COMPARTMENT SYNDROME AND NEUROVASCULAR INJURY

Compartment syndromes are discussed in detail in Chapter 13. Compartment syndrome, as a complication of surgery, usually occurs in association with acute traumatic injuries where the initial injury causes the compartment syndrome. Compartment syndrome after elective surgery is very unusual. The most common causes are closure of the deep fascia in the presence of significant muscle swelling after prolonged elective surgery and hemorrhage into a closed compartment following undetected rupture of an artery. The two most common areas in which these problems arise are the forearm and the leg.

After major surgery on the radius and ulna, swelling of the forearm musculature is common, and closure of the deep fascia is difficult. Unless absolutely no tension is present, leave the deep fascia open and close only the subcutaneous fat and skin. The same applies to procedures on the diaphysis of the tibia, particularly posterolateral bone grafting, when approximation of the muscles but not the deep fascia is indicated. Be aware of the dangers in performing surgery in the proximal third of the tibia, where inadvertent and unrecognized laceration of one of the arteries of the popliteal artery trifurcation can occur, producing a compartment syndrome.

Compartment syndrome is best prevented by the measures previously discussed. Early recognition is of paramount importance. Unexpectedly severe postoperative pain should always raise the question of compartment syndrome. Dressings must be released and the part examined to rule out increased intracompartmental pressures. If there is any question, take intracompartmental pressure measurements. Release of the surgical closure or fasciotomy may be necessary.

INJURY TO NERVES

The most common surgical injury to nerves is transection of or trauma to a subcutaneous sensory nerve, resulting in numbness in the distribution of the nerve and exposure of metallic fixation devices.
formation of a painful neuroma. Always keep the location of important sensory nerves in mind when making incisions. Identify and protect sensory nerves in the surgical field. In some cases, injury to subcutaneous nerves is unavoidable. Long, anterior exposures of the knee usually involve the sensory branches of the infrapatellar branch of the saphenous nerve. The ilioinguinal exposure of the acetabulum involves the lateral femoral cutaneous nerve of the thigh. In these cases, warn the patient before surgery that injury to these nerves is likely and describe the consequences. The patient must accept these consequences if the surgery is to be performed.

Injury to deep motor or mixed sensory and motor nerves—such as the sciatic nerve at the hip, common peroneal nerve at the knee, and ulnar nerves—is avoided by identifying the nerve at the time of surgery and providing appropriate protection. In many cases, this involves appropriate positioning of the extremity to avoid tension on the nerve. For example, in surgery of the hip or acetabulum, keep the knee flexed to 90° and the hip extended, as retraction of the sciatic nerve is often necessary and excessive tension must be avoided. Avoid retraction of a nerve if possible. If it should prove necessary, encircle the nerve with a broad rubber (Penrose) drain and gently hold the nerve out of danger. Retract nerves gently and discontinue retraction as soon as it is no longer necessary. Dissection of a nerve free from its bed over prolonged distances risks devascularization and injury to the nerve and should be performed only if essential to the operative procedure. Intraoperative monitoring of nerve functions by somatosensory evoked potentials is now commonly used for spine surgery and pelvic and hip surgery that threatens the sciatic nerve.

If a nerve paresis or palsy is detected postoperatively, check the dressings to ensure they are not tight. Ensure that splints or other appliances are not applying pressure to the nerve. Inspect the wound to ensure that local pressure problems are not present. If the nerve was observed at surgery and protected throughout the operation, it is unlikely that injury occurred. Dissection of a nerve free from its bed over prolonged distances risks devascularization and injury to the nerve and should be performed only if essential to the operative procedure. If the nerve involvement is unexpected, if extrinsic causes of nerve pressure have been ruled out, and if you suspect that some component of the procedure may be causing pressure on the nerve that could be relieved by surgical intervention, early exploration of the nerve may be indicated.

INTRODUCTION

Bone grafting is a very old surgical procedure. The first recorded bone implant was performed in 1668. Bone grafts are used to treat various disorders, including delayed union and nonunion of fractures, congenital pseudoarthroses, and osseous defects from trauma, infection, and tumors (157). Grafts are used in reconstructive surgery to help secure prosthetic devices and perform arthrodeses, and in dentistry to reconstruct the mandibular and maxillary ridges and to treat periodontal disease. Bone grafts are also used in plastic and facial surgery for reconstruction.

HISTOLOGY AND PHYSIOLOGY

Bone grafts provide a latticework for ingrowth by host bone and supply living osteogenic cells to the host bed, and growth factors induce bone formation by the host (7, 8, 9, 22-30, 31, 48-50, 51, 53, 62, 63, 68, 73, 74, 103, 123, 127, 147, 148, 149, 150, 151, 152, 153, and 154, 159, 162, 166).

Phemister introduced the term creeping substitution (61, 115). He believed that transplanted bone was invaded by vascular granulation tissue, causing the old bone to be resorbed and subsequently replaced by the host with new bone. Phemister's concept remains valid, however. Abbott and associates have shown that, in addition, surface cells in the bone graft survive and participate in new bone formation (1, 2). Ray and Sabel (124) and Arora and Laskin (5) also confirmed the fact that superficial cells in the bone graft probably survive transplantation and contribute to new bone formation. The percentage of cells that survive transplantation is unknown, but cell survival seems to be improved by minimizing the interval between harvest and implantation and by keeping the graft moist and at physiologic temperatures.

In cancellous bone grafts, the necrotic tissue in marrow spaces and haversian canals is removed by macrophages. Granulation tissue, preceded by the advance of capillaries, invades the areas of resorption (172). Pupontential mesenchymal cells differentiate into osteoblasts, which begin to lay seams of osteoid along the dead trabeculae of the bone graft. Osteoclasts resorb the necrotic bone, and eventually most of the bone graft is replaced by new host bone. Finally, the old marrow space is filled by new marrow cells (25).

In cortical bone, the process of incorporation is similar but much slower, because invasion of the graft must be through the haversian canals of the transplant (38). Osteoclasts resorb the surface of the canals, creating larger spaces into which granulation tissue grows. As this granulation tissue penetrates the center of the cortical graft, new bone is laid throughout the graft along enlarged haversian canals. Depending on the size of the graft, complete replacement may take many months to a year or more (46).

Structure of Grafts

Bone grafts may be cortical, cancellous, or corticocancellous. If structural strength is required, cortical bone grafts must be used. However, the process of replacement produces resorption as early as 6 weeks after implantation; in dogs, it may take up to 1 year before the graft begins to regain its original mechanical strength (45). Drilling holes in the graft does not appear to accelerate the process of repair, but it may lead to the early formation of biologic pegs that enhance graft union to host bone (17).

Cancellous bone has poor mechanical strength except when loaded in compression after being packed into an area of bone defect. For example, in repairing fractures of the tibial plateau in which cancellous bone has been lost as a result of crushing, cancellous bone graft can be packed to support the articular surface of the plateau, and can bear significant loads during rehabilitation. While the strength of cortical bone combined with the more rapid incorporation that is characteristic of cancellous bone is desirable, combined corticocancellous grafts may be used. When a bone graft has a cortical and cancellous surface, incorporation is enhanced by exposing the cancellous portion to the surrounding soft tissues to facilitate vascular invasion.

Sources of Grafts

Bone graft terminology has changed, leading to some confusion. In this text, we use the new terminology. The correlation between the two is shown in Table 9.1. For most applications, autogenous bone graft is indicated. Other types of bone grafts are indicated only if autogenous bone graft is unavailable or if it is insufficient and must be augmented. Another exception is when structural whole or partial bones, with or without joint articular surfaces, are needed for reconstruction of massive whole or partial bone defects (10, 13, 19, 20, 44, 56, 57 and 58, 76, 81, 91, 92, 95, 106, 108, 146, 156, 165). This occurs most commonly in tumor surgery, in which preserved or fresh allografts are used (49,66;72,78,88,89,100,101,111,112). This is discussed in more detail later in this chapter and in Chapter 20, Chapter 106, Chapter 126, and Chapter 128. For practical reasons, isografts are almost never used in human surgery. Although xenografts have been tried in various forms in the past, they have never met with much success, because of the immunologic response of the host.

Polar moment of inertia than does the inlay technique. A common use of the strut graft is for anterior vertebral fusion at all levels of the spine. Ribs, fibula, or sections of use today has been supplanted by rigid internal fixation and cancellous onlay bone grafting. Onlay bone grafting has the additional advantage of providing a higher

The space between the two grafts and between the two ends of the bone at the nonunion site is packed with cancellous bone. In some nonunions of the humerus with osteoporotic bone, a compression plate is used, but this is supplemented on the opposite cortex by a cortical onlay graft to provide good screw fixation. Although only four screws are illustrated, this type of grafting requires a minimum of six screws with good fixation of both cortices on either side of the nonunion site. Dual onlay grafting is mostly of historic interest. See the text for further information.

The single-onlay cortical bone graft was used most commonly before the development of good quality internal fixation and was employed for both osteogenesis and fixation in the treatment of nonunions (Fig. 9.1A). The tibia is the most common source of this graft; the split fibula can also be used. The most common indication for this graft today is bone grafting and stabilizing the cervical spine, although with modern techniques it is rarely used. In osteoporotic bone, screws commonly do not achieve adequate fixation. Even metal washers and nuts are inadequate, because the bone collapses when they are tightened. In this situation, a nonunion or fracture site can be bridged with a cortical bone graft and a plate applied to the opposite cortex. The screws can then be placed through the bone into the bone graft, resulting in a reasonably solid construct. For this purpose, it is preferable to use one half or three quarters of the thickened portion of the superior border of the iliac crest rather than the tibia. If a long, straight graft is needed, the fibula is preferred. The tibia is used as a last resort, because a donor site of this size creates a large stress riser in the tibia that, unless protected for a prolonged period of time, can lead to pathologic fracture.

A sliding graft may be used to treat nonunion of the distal tibia. This type of graft is more likely to be used for a previously failed ankle fusion or for fusion in the absence of the body of the talus. Internal fixation and additional graft in the ankle joint is not illustrated. C: Strut grafts for anterior spinal fusion. Strut grafts are very useful for bridging defects in the anterior spine and for providing support for anterior spinal fusion. Grafts from the ribs, fibula, and bicortical iliac crest are useful for strut grafting, depending on the size of the graft needed. Two rib grafts are shown bridging L-2–L-4.

This technique is rarely used today, because internal fixation combined with onlay cancellous bone graft provides a better result. This technique may be combined with internal fixation if there is limited space to place a cancellous graft. The disadvantages of the sliding or reversed bone graft are that, after the cuts are made, the graft fits loosely in the bed, and it creates stress risers proximally and distally to the nonunion site. It is most safely used in metaphyseal rather than diaphyseal regions. Its use today has been supplanted by rigid internal fixation and cancellous onlay bone grafting. Onlay bone grafting has the additional advantage of providing a higher polar moment of inertia than does the inlay technique. A common use of the strut graft is for anterior vertebral fusion at all levels of the spine. Ribs, fibula, or sections of
permission.)

Treatment of Ununited Fractures. In provides the most bone, and the central section of the ilium at point D is quite thin and is of no use in bone grafting. (From Abbott LC. The Use of Iliac Bone in the

Figure 9.4. These cross sections of the iliac crest show the width of the bone and the cancellous bone available for grafting. The posterosuperior iliac spine area provides the most bone, and the central section of the ilium at point D is quite thin and is of no use in bone grafting. (From Abbott LC. The Use of Iliac Bone in the Treatment of Ununited Fractures. In American Academy of Orthopaedic Surgeons: Instructional Course Lectures, Vol. 2. Ann Arbor, MI: J. W. Edwards, 1944, with permission.)

**H-Grafts**

The H-graft is a corticocancellous graft that is usually harvested from the ilium and is specifically designed to achieve posterior fusion of the cervical spine.

**Peg and Dowel Grafts**

Dowel grafts were developed for the grafting of nonunions in anatomic areas, such as the scaphoid and femoral neck, where onlay bone grafting was impractical. In the carpal scaphoid, the dowel is fashioned from dense cancellous bone (see Chapter 42). The use of the dowel graft for the management of nonunion of the femoral neck is illustrated in Figure 9.3. Free microvascularized fibula grafts are more commonly used today. A corticocancellous graft of appropriate length and approximately 25 mm wide is harvested from the ilium or the tibia. The curvature of the ilium often makes it difficult to obtain a straight graft of sufficient length.

**Dowel Graft for Femoral Neck Nonunion**

- Use a water-cooled power saw to cut this graft to avoid breakage.
- Split the graft into two longitudinal sections. Make the cut in situ.
- Place the two longitudinal grafts back to back, with the cortex in the interior of the graft; then shape it to form a dowel.
- Temporarily fasten the two sections together with cerclage absorbable sutures.
- Ream a hole from the lateral cortex of the femur, across the femoral neck nonunion site, and into the femoral head using a standard, hip-nail reamer.
- Drive the graft into this hole across the nonunion site, taking care not to break the graft.
- Achieve additional fixation with multiple compression screws. This graft can also be combined with a compression hip screw if sufficient space is available. A fibula can be used for this purpose as well and is mechanically stronger. Yoo (163), following the technique originated by Urbaniak (see Chapter 125), uses a free microvascularized fibula with anastomosis to the lateral circumflex femoral artery for avascular necrosis of the femoral head. The usefulness of this technique in nonunions has not been established, however. On occasion, a Meyers muscle-pedicle bone graft (96) or a valgus osteotomy is used (see Chapter 29).

In most instances, dowel grafts have been replaced by microvascularized fibular grafts and, on occasion, the quadratus muscle-pedicle graft popularized by Meyers (see Chapter 29) or valgus osteotomy (96, 97, 98) and (98, 163). Peg grafts have also been used to bridge the tibia and fibula to produce proximal and distal tibiofibular synostosis (84). Occasionally, these grafts are used for spine fusions as well (64).

**Medullary Grafts**

Medullary grafts are not indicated for the diaphysis of major long bones. Grafts in this location interfere with restoration of endosteal blood supply; because they are in the central axis of the bone, they resorb rather than incorporate. The only possible use for a medullary graft is in the metacarpals and the metatarsals, where the small size of the bone enhances incorporation. Even in this location, however, internal fixation with onlay or intercalary cancellous bone grafting may be a superior method.

**Osteoperiosteal Grafts**

In osteoperiosteal grafts, the periosteum is harvested with chips of cortical bone. These grafts have not been proven to be superior to onlay cancellous bone grafting, are more difficult than cancellous bone to harvest, and may involve greater morbidity; they are rarely used today.

**Pedicle Grafts**

Pedicle grafts may be local (139) or moved from a remote site using microvascular surgical techniques (see Chapter 36). In local muscle-pedicle bone grafts, an attempt is made to preserve the viability of the graft by maintaining muscle and ligament attachments carrying blood supply to the bone or, in the case of diaphyseal bone, by maintaining the nutrient artery. Two examples are the transfer of the anterior iliac crest on the muscle attachments of the sartorius and rectus femoris for use in the Davis type of hip fusion (see Chapter 106) and the transfer of the posterior portion of the greater trochanter on a quadratus muscle pedicle for nonunions of the femoral neck (see Chapter 29) (96, 97, 98 and 99). Although technically more difficult, pedicle grafts have the advantages of a high percentage of cell survival, rapid incorporation, and increased active participation of the grafted cells in the healing process. Free, microvascularized fibular grafts are used to replace major deficiencies in long bones (see Chapter 36) and have been effectively used to treat avascular necrosis of the femoral head (see Chapter 125) (163).

**OPERATIVE TECHNIQUES: HARVESTING BONE GRAFTS**

**Ilium**

The iliac crest is an ideal source of bone graft because it is relatively subcutaneous, has natural curvatures that are useful in fashioning grafts, has ample cancellous bone, and has cortical bone of varying thickness. Removal of the bone carries minimal risk and usually there is no significant residual disability. Abbott (1) demonstrated that the posterior third of the ilium is thickest (Fig. 9.4). This is confirmed by computer tomography (CT) scans (Fig. 9.5).
Figure 9.5. This CT scan of the pelvis at the level of the posterosuperior iliac spine illustrates the thickness of the ilium posteriorly and the amount of cancellous bone available.

**Posterior Iliac Grafts**

The region of the posterosuperior iliac spine is the best source of cancellous bone.

- To procure bone, position the patient in the prone position. It can also be harvested from the uppermost crest in the lateral decubitus position. Prepare a wide area of skin and eliminate possible contamination from the rectal area by placing an adhesive plastic sheet transversely across the buttocks, fitting it carefully into the gluteal crease cephalad to the rectum.
- Make a straight vertical incision directly over the posterosuperior iliac spine or a curvilinear incision that parallels the iliac crest (Fig. 9.6A). The length of incision depends on the size of the graft needed and the obesity of the patient, but an incision of at least 7.5 cm is needed. To prevent injury to the cluneal nerves, avoid straight transverse incisions and try not to carry incisions too far laterally. A transverse incision is more likely to result in dehiscence and can be painful if it lies along the belt line.

![Figure 9.6. A posterior iliac graft is shown.](image)

- Dissect sharply through the fat to the prominence of the posterior iliac crest. Identify the origin and fascia of the gluteus maximus insertion on the crest. With a cautery knife, incise the origin of the gluteus maximus and dissect it free from the crest subperiosteally. If the entire posterior iliac area is to be harvested, take down the gluteus from approximately 2.5 cm superior to the posterosuperior iliac spine and inferior as far as the posteroinferior spine. With a large key elevator, elevate the gluteus off the outer wall of the ilium down to the level of the sciatic notch. Avoid injury to the superior gluteal nerve and vessels. Obtain retraction with two Taylor re retractors.
- The outer wall of the ilium is removed by first outlining the area to be harvested by cutting through the outer table of the ilium with a sharp osteotome, as illustrated in Figure 9.6B. If an onlay cancellous bone graft is to be performed, harvest corticocancellous strips with a curved gouge. Remove all underlying cancellous bone down to the inner table of the ilium with a curved gouge and curets of an appropriate size. There is considerable cancellous bone superiorly and medially under the rim of the ilium that requires a curet for removal. Try not to perforate the inner wall of the ilium.
- Obtain hemostasis by applying a thin layer of bone wax over bleeding points on the bone. Irrigate the donor site thoroughly and remove excess wax. Perform routine closure over suction drainage. Because bone graft sites tend to ooze considerably after surgery, apply a large, bulky dressing.

Anterior Iliac Grafts

Large grafts of cancellous and corticocancellous bone can be harvested from the anterior ilium. (Figure 9.7)

![Figure 9.7. A, B: Harvesting of an anterior iliac graft is shown. C: This cross-sectional view shows the extent of the bone harvested. The outer table is not broached.](image)

- Place the patient in a supine position. Make an incision parallel to the crest and 1 cm proximal to it. Do not incise anterior to the anterior superior iliac spine to avoid injury to the lateral femoral cutaneous nerve to the thigh. Incise with a cautery knife along the iliac crest, avoiding muscle. Posteriorly retract the overhanging abdominal musculature proximally to remain on the subcutaneous border of the ilium. This approach will significantly reduce hemorrhage and postoperative pain. Superiosteally, dissect the abdominal musculature and, subsequently, the iliacus from the inner wall of the ilium.
- Outline the area to be harvested with straight and curved osteotomes (Fig. 9.7A). Cut the strips, which will be removed. The middle ilium is paper thin, but the anterior column just above the acetabulum is quite thick.
- Harvest the corticocancellous strips with a gouge.
- Remove additional cancellous bone with gouges and curets (Fig. 9.7B). Do not broach the outer table (Fig. 9.7C).
- Closure and postoperative management are the same as for a posterior graft. We prefer to harvest from the inner wall, because it is much easier for the surgeon and the patient has less postoperative pain than with other sites. The outer wall can be harvested as well. Watch for postoperative ileus and treat appropriately.

**HINTS AND TRICKS**
To harvest a bicortical graft from the anterior aspect of the ilium, follow the procedure described below:

- Expose both sides of the ilium from the anterosuperior iliac spine posteriorly as far as is needed for the graft desired (Fig. 9.9).

**Figure 9.9.** A large bicortical graft is shown.

---

**General Principles**

- Position the patient for harvest of the pelvis to optimize skin preparation, draping, and surgical access to the donor site.
- Exclude the perineum from the operative field with an adherent plastic drape.
- Thoroughly prepare the skin for surgery and drape over a sufficiently wide area so that the skin incision can be made entirely through an iodophor-impregnated adherent plastic drape.
- Place skin incisions slightly above or below the crest to avoid painful scars over bony prominences.
- Avoid surgical injury to the lateral femoral cutaneous nerve anteriorly and the cluneal as well as sciatic nerves posteriorly through proper incision placement and careful dissection.
- Dissect directly down to the bone, minimizing any undermining of subcutaneous fat off the fascia.
- Expose bone by using an electrocautery knife on the lowest setting possible to detach the fascial origins and insertions.
- Dissect muscle off bone subperiosteally with a large key-type elevator to avoid wandering into and injuring muscle.
- Minimize soft-tissue dissection and stripping, exposing only those areas necessary to harvest the graft.
- Take only as much bone graft as is needed.
- Before beginning the bone graft harvest, be certain that there is complete control of bleeding from the soft tissues.
- Immediately control bleeding from any significant bone bleeders.
- After harvest is completed, use hemostatic agents to minimize postoperative bleeding.
- Use postoperative wound suction in nearly all donor sites because postoperative hemorrhage is difficult to predict.
- Monitor postoperative blood loss closely to permit timely management of unexpected blood loss by temporary cessation of suction, possible re-exploration, and blood replacement.
- Close the wound in layers using meticulous technique with watertight closure of the fascia, closure of the subcutaneous fat in two or more layers in obese patients, and meticulous skin closure to minimize scar formation.
- Change postoperative dressings as frequently as necessary to maintain a dry dressing.
- Protect donor sites postoperatively with limited weight bearing and activities where the risk of pathologic fracture through the donor site is high (older osteoporotic women or long bone harvest sites).

**Posterior Iliac Crest**

- Keep the skin incision small and avoid lateral extension, which risks injury to the cluneal nerves.
- A curved linear incision parallel to the posterior iliac crest placed directly over the posterior iliac spine somewhat superior and medial to the crest approximately 5 to 6 cm in length usually permits harvesting of the entire outer cortex and underlying cancellous bone. Obese patients require larger incisions.
- Do not remove the origins and insertions of the spinal fascia and musculature from the ilium unless the entire nonarticular posterior superior iliac spine portion of the crest is to be harvested.
- Identify the location of the superior and inferior gluteal neurovascular bundles as well as the sciatic nerve and avoid injury to these structures by avoiding excessive retraction and appropriate placement of retractors.
- When harvesting large grafts, avoid penetration into the sacroiliac joint.
- Perform soft-tissue closure as described above, under General Principles.
- Restriction of activity and protected weight bearing postoperatively is necessary only to relieve pain. Pathologic fracture secondary to bone graft harvest is nearly unheard of in this area.

**Anterior Iliac Crest**

- Avoid injury to the lateral femoral cutaneous nerve by keeping all dissection posterior to the anterosuperior iliac spine.
- Minimize soft-tissue dissection and use small windows on the superior aspect of the crest when limited amounts of only cancellous bone are to be harvested.
- Where corticocancellous graft is required, remain in the anterior one quarter to one third of the crest above the acetabulum, avoiding the thin, nearly purely cortical bone in the middle third.
- Expose and harvest only the inner or outer table (we prefer the inner table to avoid injuring the abductor muscles) when corticocancellous graft is required.
- When full-thickness crest is harvested, avoid fracture by remaining at least 3 cm posterior to the anterosuperior iliac spine, harvesting the graft with a water-cooled oscillating saw rather than an osteotome, and placing drill holes at the end of the saw cuts, if necessary, to minimize the stress riser effect.
- When large anterior grafts are harvested that require more posterior exposure of the crest, avoid incising the abdominal musculature by carefully identifying the interval between the abductor hip musculature and the abdominal muscles, retracting the abdominal muscles superiorward, and dissecting along the subcutaneous border of the crest.
- Meticulously close the abdominal muscles to the abductor musculature to minimize the risk of hernia.
- Protect patients postoperatively with limited weight bearing where the risk of fracture is high.

**Bicortical Grafts**

Full-thickness bicortical grafts may be necessary for spinal fusion or for replacement of major bone defects in metaphyseal regions, such as in nonunions of the distal humerus or in opening wedge osteotomies. Coronal grafts are illustrated in Figure 9.8.
With a thin, curved osteotome that is 1 cm wide, enter the iliac crest approximately 15 to 20 mm posterior to the anterosuperior iliac spine.

Make a cut parallel to and beneath the thickened rim of the crest for a distance of 7 to 10 cm, depending on the size of the patient and the size of the graft needed.

Gently pry the crest upward, producing a greenstick fracture at its posterior aspect. Posteriorly, leave the periosteum and muscle attachments intact to prevent the fragment from becoming free.

Remaining at least 2 cm posterior to the anterior border of the ilium between the two iliac spines, drive an osteotome downward to the depth of graft desired, or use an oscillating saw. It is important to remain at least 2 cm or more superior to the dome of the acetabulum.

Make a second posterior cut to produce the width of graft desired, and then connect these cuts in the depths of the wound on both sides with a curved osteotome. Using a saw results in a stronger graft.

Carefully remove the graft and place it in a moist sponge in a basin on the back table until it is ready for use.

Obtain hemostasis, and return the iliac crest to its anatomic position. Place 2 mm drill holes on either side of the initial osteotomy on the top of the crest. Through these holes, place a #1 nonabsorbable suture and tie it securely to hold the crest in place. This fixation is surprisingly stable.

Securely suture the periosteum and overlying muscles with interrupted sutures to help hold the crest in place. Use suction drainage.

Grafts that require structural strength, such as for anterior spine fusion, are best harvested with a saw, because they are stronger than those harvested with osteotomes. We use this graft about two to three times per year, and we have yet to see the donor site fill in. One fracture did occur through the anterior remnant of the ilium at its base, but this fracture healed without problems by having the patient limit activities and use crutches. No hernias have occurred, and most patients have no symptoms within 6 months of graft harvest.

**Other Sources of Cancellous Bone**

In treating small bone defects secondary to trauma or small tumors, it may be most convenient to harvest the graft from the ipsilateral extremity undergoing operation. The graft can often be taken through the same incision or through a small, separate incision. Most of these sites can be harvested through a small, 2.5 to 5.0 cm longitudinal incision placed over the subcutaneous surface of the end of the bone.

Make a small cortical window in the metaphyseal or epiphyseal region with a 6 mm osteotome or large drill. Use curets to harvest the graft. Typical sites are illustrated in Figure 9.10 (64).

The lateral location may result in trochanteric bursitis or a snapping iliotibial band. A similar technique is used to harvest bone from between the two tables of the ilium through a small window in the crest just posterior to the anterosuperior iliac spine.

For bone grafts that require structural strength—such as for anterior spine fusion—a saw is used, because it results in a stronger graft.

**Tibia**

If a long, straight, large section of a cortical or corticocancellous bone is needed, harvest it from the proximal tibia.

Use a tourniquet, and prepare and drape the extremity, as described in Chapter 5. Make a straight, longitudinal incision over the middle of the anteromedial surface of the tibia. Expose the anteromedial surface of the tibia by subperiosteal dissection. Transverse incisions through the periosteum at the proximal and distal ends of the longitudinal incision improve exposure.

Outline the graft to be taken and drill a 3 to 4 mm hole in the cortex at each of the four corners of the graft (Fig. 9.11). With a water-cooled oscillating saw, cut the graft. Avoid cutting beyond the drill holes, because fracture of the tibia is then much more likely to occur. Cut through the cortex at an oblique angle to assist in removal of the graft.

For cancellous bone grafts, a saw results in a stronger graft.

**Fibula**

Remove the shaft of the fibula through Henry's approach, as described in Chapter 3.

The entire proximal three quarters can be used, if necessary, but rarely is the proximal end needed. Avoid injury to the peroneal nerve. Never remove the distal fourth of the fibula, because it is essential to the stability of the ankle. The syndesmosis ligaments must be left intact, and a short portion with the interosseous membrane attached must also be retained.

**HINTS AND TRICKS**
Harvest from the Metaphysis of Long Bones

- Harvest is usually best from the ipsilateral extremity being operated on to avoid morbidity in another extremity.
- Long bone metaphyseal bone is much less dense than the iliac crest in most adults, and in older patients it contains less red marrow. For that reason, use metaphyseal cancellous bone only when small amounts of less dense cancellous bone are required.
- Keep skin incisions small; expose only the area to be harvested; avoid injury to local neurovascular structures; and avoid harvesting through sites where chronic bursitis or tenosynovitis might be a problem, such as the tip of the olecranon or the lateral prominence of the greater trochanter.
- Avoid harvesting excessive bone immediately adjacent to the subchondral bone of the joint.
- Avoid penetration of joints.

- The entire fibula can be removed through the interval between the peroneal muscles and the posterior compartment, avoiding transaction of any muscles. Remove the bone subperiosteally from distal to proximal to avoid injury to muscles. A number of perforating blood vessels may be encountered; these vessels must be coagulated or ligated.
- Facilitate removal by making the distal transverse cut first. Carefully dissect circumferentially around the fibula, avoiding injury to the peroneal vessels. Place two small, blunt retractors anteriorly and posteriorly to protect the muscles.

HINTS AND TRICKS

Harvest of the Midshaft Fibula

- For specific techniques related to free microvascular transfer of the fibula, see Chapter 36.
- As opposed to the advice given earlier regarding minimizing the size of skin incision, in this case a generous longitudinal incision over the subcutaneous border of the fibula is usually necessary to minimize the risk of complications to neurovascular structures.
- Depending on the level of harvest, carefully identify the portions of the common peroneal nerve at risk in the exposure used. Protect these nerves, avoiding excessive retraction.
- Use intermuscular intervals to dissect to the fibula and expose it by careful subperiosteal dissection. Avoid diving into the deep soft tissues, which risks injury to the deep neurovascular structures.
- Identify and carefully ligate arterial perforators to the fibula.
- Never harvest the distal quarter of the fibula. Leave the syndesmosis and a portion of the intramedullary ligaments intact and attached to the distal portion.
- Use Henry's extensive exposure for the common peroneal nerve and proximal fibula in harvesting the proximal third to avoid injury to neurovascular structures.

Harvest of Diaphyseal Cortical Bone

- In general, the harvest of diaphyseal cortical bone from the upper extremity and the femur is contraindicated because of the risk of fracture. This should be done only if this is the only reasonable alternative. In our careers, we have never harvested from these sites.
- In our experience, harvest of fibular diaphyseal bone is virtually never necessary today because of the availability of alternative techniques. Neither of us have harvested a diaphyseal tibial cortical graft in the last 20 years.
- If a tibial cortical graft is the only graft possible, then take the following steps to minimize the risk of complications:
  - Keep the bone graft as small as possible.
  - Use adequate-sized drill holes at the corners of the harvest site and use a sharp water-cooled oscillating saw that is kept constantly cool to harvest the graft, avoiding any overcutting beyond the drill holes.
  - If possible, harvest from either the lateral or posterior surfaces of the tibia because the muscle coverage lessens the risk of soft-tissue complications and makes it more likely that the defect will heal to the greatest extent possible.
- Harvest from the subcutaneous border is most convenient and provides the largest surface for graft but is problematic because of the thin soft-tissue coverage.
- Tibial diaphyseal harvest sites must be protected for a prolonged period of time, probably for at least 6 months in a well-fitted cast brace, with the patient's activities limited to normal sedentary walking using crutches initially and then a cane. Sports activities or more vigorous activities must be avoided for at least 1 year and, in some individuals with larger graft sites, perhaps for several years.
- Decisions regarding when to cease protection and allow the patient more vigorous activities are probably best judged through the use of CT scans of the donor site.
- Because these grafts are exceedingly rare today, no definite guidelines can be given. One of us has seen only two diaphyseal tibial graft harvest sites in the past 20 years, both of which were referred to him for secondary fracture of the tibia. One patient responded to plate fixation and autologous bone grafting. The other patient, who was infected, required multiple surgical procedures but eventually healed, after control of the infection and double plate fixation and autologous bone graft.

- Use a water-cooled saw to transect the fibula. Grasp the segment to be removed with bone-holding forceps, maintaining gentle traction on the bone, and dissect subperiosteally from distal to proximal until the segment of the fibula to be removed is exposed. Transect the upper end in a similar fashion. If the entire proximal fibula is to be removed, avoid injury to the peroneal nerve and the tricranial bone.
- After removal, repair the insertion of the biceps tendon with strong, nonresorbable suture to the remnants of the proximal fibular ligaments.

ALLOGRAFTS

INTRODUCTION

The clinical application of bone allografting became prevalent in the first two decades of the 20th century, after the experimental work of Ollier and Axhausen. In 1907, Lexer was the first to perform allogeneic whole joint transplantation, and he had performed 25 by 1925. In 1942, Inclan reported the storage of autogeneic and allogeneic bone, and this report stimulated many similar clinical efforts at preservation, sterilization, and delayed reimplantation. Although the superiority of fresh allogeneic grafts repeatedly has been confirmed in experimental studies and clinical experience, allogeneic implants preserved by freezing, freeze-drying after sterilization with ethylene oxide, chemical sterilization, or gamma irradiation are nonetheless widely used. Bone is more commonly transplanted in the body than any other tissue or organ except blood. Only recently has attention been paid to other musculoskeletal tissues for allografting, such as cartilage, tendons, ligaments, and menisci.

The terminology of bone grafting and other musculoskeletal grafting has been confusing (Table 9.1). Urist (148) recommends the term implant for nonviable bone; an example is frozen, freeze-dried, sterilized bone, a derivative of whole bone that lacks viable cellular components but potentially contains inductive protein that can stimulate osteogenesis.

A graft may be orthotopic (transplanted to the same site in the recipient that it occupied in the donor, e.g., distal femur to distal femur); heterotopic (transplanted to a different site but one occupied by the same tissue as in the donor, e.g., fibula to spine); or ectopic (transplanted to a site normally occupied by a different type of tissue, e.g., fascia lata as a tendon graft). Ectopic sites for bone grafting have been used mainly in investigating osteogenesis and, rarely, for temporary clinical storage of bone.

In general, allografts are used to fill bone defects or missing bone segments and to promote the healing of nonunited fractures. Cancellous bone or morcellized cortical bone is most often used for filling cysts or cavities (Fig. 9.13); cortical bone is optimal for reconstructing defects that require a certain form and strength (Fig. 9.13). Although a cortical bone graft is strong when first implanted, the incorporation process frequently weakens it, so a fatigue fracture may occur many months to years after implantation (14). Therefore, plates or intramedullary devices are frequently used to augment the strength of the graft during incorporation.
Figure 9.12. This is a unicameral bone cyst in a young adult with a pathologic fracture. It was curetted and packed with freeze-dried and partially decalcified allograft (AAA) bone (B). Five-year followup shows healing with excellent graft incorporation and remodeling (C).

Figure 9.13. A proximal femoral allograft was used to replace the proximal femur in a patient with a giant cell tumor. A custom metallic prosthesis was used to thread through the allograft.

Bone and Tissue Banking

Guidelines for the procurement, processing, and clinical use of bone have been established by the American Association of Tissue Banks. The goals of bone banking are to preserve the physical integrity of the implant and its inductive proteins, reduce immunogenicity, and ensure sterility. In general, a minimal interval (less than 24 hours) between the death of the donor and the time of procurement is desirable. Following the proper procedure for consent is essential.

Harvested bone is fashioned into various sizes and shapes, and soft tissues and cells are removed to reduce immunogenicity. Freezing to –70°C in a sterile state effectively decreases immunogenicity and maintains sterility; this is generally recommended for osteoarticular allografts (86). Because the osteoarticular allografts frequently need to be matched for size, the height and sex of the donor should be recorded by the bone bank to permit as close a match as possible with the recipient (69). This method of storage decreases the strength of the allograft by about 10% (7). Ethylene oxide sterilization also is effective, although it may destroy bone-inductive proteins. The bone is preserved by freeze drying after removal of ethylene oxide (79,118). Freezing to –70°C and freeze drying reduce the immunogenicity of the implant but with some compromise to its mechanical strength. Freezing bone decreases its tensile and compressive strength by about 10% each, whereas freeze drying decreases torsional strength by about 50% and compressive strength by about 10% (114). The process of replacement by host bone entails a transient reduction of approximately 50% of strength. Sterilization of bone by heating to more than 62°C, by autoclaving, or by gamma irradiation disrupts the physical and chemical nature of bone and alters its mechanical properties (10,35). Bone implants subjected to these physically damaging processing methods perform poorly. Bone subjected to freeze drying, partial demineralization, or freezing incorporates more slowly than fresh autografts or syngeneic grafts (11,107,151).

Osteoarticular shell allografts must be stored in a fresh state for 24 to 72 hours until the donor has been adequately screened. The joint surfaces usually are stored in situ in the donor body at 4°C in a morgue environment. This ensures adequate viability of the cartilage for transplantation (133,146).

Quality control measures must be enforced to avoid the transfer of bacterial, fungal, or viral pathogens to the recipient. Such measures should include patients’ histories and screening tests for hepatitis, acquired immunodeficiency syndrome (AIDS), and syphilis.

Table 9.2 shows storage techniques commonly used for various types of musculoskeletal allografts. Their applications have been well summarized by Czitrom (37).

Table 9.2. Various Methods of Storing and Using Musculoskeletal Allografts for Different Orthopaedic Needs

Biology of Allograft Incorporation

A successful bone graft eventually will be incorporated into the skeletal system of the host. In the process of incorporation, new bone deposited by the recipient envelopes and replaces the donor bone tissue. How rapidly the graft is incorporated depends on its size, structure, position, fixation, and genetic composition. The role of the graft in stimulating incorporation may encompass osteoconduction, osteoinduction, and osteogenesis.

Osteoconduction Glass tubes, porous ceramics, porous plastics, and autoclaved deproteinized bone all provide a scaffold into and around which bone formation can occur (150). This function of the graft as a scaffold for ingrowth is referred to as osteoconduction.

Induction occurs when “two or more tissues of different nature or properties become intimately associated, and alterations of the developmental course of the interactants results” (150). Bone matrix contains protein inductive factors, such as bone morphogenetic proteins (BMP), which, if released from the matrix by fracture, osteoclastic resorption, or chemical treatment, can induce nearby mesenchymal tissues to differentiate into osteoblasts. This factor is discussed in more detail later in this chapter.

Bone grafts in which preparation of the graft has not destroyed the BMP are capable of osteoinduction in addition to osteoconduction. An osteoinductive graft may be incorporated more rapidly than one that is merely osteoconductive.
Osteogenesis

Osteogenesis in a bone graft refers to direct formation of new bone by living cells of the graft. Osteogenesis, together with the absence of an immune response, is the basis for the superior clinical performance of autografts. Although most of the autogenically transplanted osteocytes die and leave empty lacunae, osteoclasts, osteoblasts, and osteocytes can survive (149). In contrast, cells from a fresh allograft quickly elicit antibody production and cell-mediated immunity, and are destroyed by the recipient.

Revascularization and Biologic Incorporation

Revascularization of a fresh autograft seldom occurs by microanastomosis with existing microvessels. This process is much more rapid in cancellous bone and is aided in cortical bone by removal of the periosteum (159). Most autografts and allografts revascularize only by invasion of capillary sprouts from the host bed during the resorption of the old matrix (creeping substitution). Creeping substitution involves invasion of the allograft by osteoclasts, and these, in turn, are followed by a blood vessel bud. New osteons are laid down around the many blood vessels that invade the graft (115).

In addition to creeping substitution, large allografts also may be incorporated by a process of serial stress fractures that result in graft remodeling. Periodically a region of stress concentration may microfracture, followed by local remodeling. Later, this process may occur in another region. The clinical manifestation of this may be a complaint of rapid onset of pain, often after very minor trauma, frequently with negative radiographic findings. The patient should be put on crutches or other support until the pain is gone, in order to prevent a catastrophic failure of the graft.

Selection and Preparation of the Graft

The criteria that characterize an ideal graft follow from the goal of restoring structural stability to bones or joints with mechanical properties equal to adjacent bone and with an acceptable cosmetic result. Therefore, the graft should be strong, potentially viable, nonreactive (nontoxic, noncarcinogenic), sterile, storable, capable of being shaped during surgery, and affordable.

The eventual choice of a graft depends on the type of structural and osteogenic functions desired, the size and shape of various donor bones, and whether viable articular cartilage needs to be transplanted. The morbidity attendant on procuring an autogenic graft is often a limiting factor in bone graft surgery; however, the use of some autogenic corticocancellous bone is almost essential in certain applications (such as posterolateral lumbar and cervical spine fusions and to supplement allografts at the osteosynthesis site). Alloimplants seldom result in fusion across transverse processes or posterior arch structures; autolyzed, antigen-extracted allogeneic (AAA) bone may be an exception (151). Some autograft bone should almost always be used with allografts but it helps to avoid nonunion and stimulates incorporation.

Types of Grafts and their Indications

Bone Allografts and Alloimplants

Fresh autogenic bone is no longer used in clinical transplantation because of the major immune response to the transplanted tissues. As discussed above, in the section on Bone and Tissue Banking, freezing and freeze-drying are useful storage measures that reduce the immunogenicity of the implant. Alloimplants may be successfully used in many applications, from craniofacial restoration to spinal operations and whole joint transplantation. Donor bone is harvested, washed, chemically or biologically sterilized with gaseous ethylene oxide or gamma irradiation (115). The bone is then frozen or freeze dried for preservation and reduction of immunogenicity.

Frozen or freeze-dried bone contains numerous transplantation alloantigens (149). Furthermore, while in the frozen or freeze-dried state, bone loses its inductive factors due to enzymatic autodigestion by biologically processed enzyme systems. Accordingly, Urist developed a protocol for the preparation of chemostereolized, AAA bone that would preserve the inductive factors (149,150 and 151,153). In this method, chloroform-methanol is used to extract lipids and cell membrane lipopolysaccharides (4 hours); 0.6 N hydrochloric acid extracts acid-soluble proteins and demineralizes the surface (24 hours); and neutral phosphate buffer in the presence of sulfhydryl-group enzyme inhibitors removes endogenous intracortical and extracortical transplantation antigens (72 hours). The bone is then frozen and freeze dried.

For this treatment, bone must be excised from the donor within 8 to 12 hours of death (minimal biodegradation time) if the donor has not been stored in a morgeon environment (4 °C). If morgue storage has been used, a 12- to 24-hour wait is acceptable. Prolonged storage at −18 °C and immediate freeze drying must be avoided, because both reduce the level of inductive factors through autodigestion. Sterilization by irradiation with more than 2.0 mrad further denatures the BMP. The principal disadvantage of AAA bone is decreased strength; therefore, it is rarely used when strength is an important consideration. Urist and Dawson have used it for spine fusions with a clinical success rate of 80% and a pseudarthrosis rate of 12% (151). Urist also reported its successful application in 8 of 10 patients who underwent arthrodesis of the knee, ankle, and wrist (150). The addition of fresh autogenic cancellous bone (including marrow) to AAA bone creates a composite graft with enhanced osteogenic capacity.

The osteoinductive capacity of demineralized bone was described by Urist (147,148). More recently, others have used demineralized allografts in craniofacial restoration (51). AAA bone is not generally available for clinical use at this time; however, other methods of partial demineralization are being used for some preparations.

Cartilage as Allograft

Allogeneic cartilage, in theory, should not trigger an immune response after transplantation because the potentially immunogenic chondrocytes are buried in the cartilage matrix and, therefore, are inaccessible to the host’s immune system. Late immune responses, such as lymph node hyperplasia, have been noted in the donor (152). Urist (153) published data that indicated in eliciting an immune response remains controversial (33,34,39,40,41,42 and 43,67,89,169). If this immune response is strong, it can lead to destruction of cartilage by a pannuslike reaction and a joint fluid inflammatory response (128,130,131,132,133,134,135,136 and 137).

The late deterioration in allograft cartilage is not clearly understood, but again this could be an immune response, cellular or humoral, to histocompatibility antigens. Avoidance of these problems requires exacting surgical technique (109) and excellent matching of donor and recipient sizes (68,129).

Large Composite Allografts

Large composite allografts of whole or half joints have been performed clinically for nearly 100 years (82,83,108,110,111 and 112,156). Mankin and colleagues reported preliminary results of massive allograft transplantations performed for malignant or aggressive bone tumors (76,89). Their improved allograft procurement technique involved freezing the segments to decrease the immunogenicity of the bony portion and glyceralizing the cartilage to maintain chondrogenic viability during freezing and thawing. The complication rate was high, but the tumor recurrence rate was low and the outcome generally successful. Poitout has also undergone arthrodesis of the knee, ankle, and wrist (150). The addition of fresh autogenic cancellous bone (including marrow) to AAA bone creates a composite graft with enhanced osteogenic capacity.

The bone is then frozen or freeze dried for preservation and reduction of immunogenicity.

Xenograft Materials

Bovine Bone Xenograft

Transfer of tissues between species typically elicits a severe immune response from the recipient; consequently, xenograft tissues must be treated to remove antigenic proteins. Xenoallograft cancellous bone usually is obtained from cattle. The freshly harvested bone is washed in water, extracted with hydrochloric acid to remove calcium and partially remove proteins, delipidized with fat solvents, and dried in acetone. It is then sterilized by gamma irradiation. The resulting product (Kiel bone or Surgibone) is structurally strong and elicits only a very weak antigenic response in humans. The deproteinizing process also deactivates or removes inductive factors, so the Kiel bone serves as an osteoconductive scaffold; it is not inductive, however, as is demineralized human bone matrix. Salama and colleagues reported preliminary results using Kiel bone soaked in autograft marrow as a composite graft material (138). Xenoallogeneic bone is more widely used in Europe than in North America.

Type I Collagen Xenografts

Another bovine xenograft material in common use is type I collagen, derived mostly from bovine skin (145). The collagen is dissolved and then reconstituted, leading to fibrillar type I collagen with other antigenic proteins removed. Collagen by itself is low in antigenicity. Collagen xenografts are most widely used in dermatology and plastic surgery; collageen sponges also are used for hemostasis in general surgery. These orthopedic applications, collagen may be combined with autogenous marrow and a ceramic composed of sintered hydroxyapatite and tricalcium phosphate to form a composite implant; such implants have shown of be equal in effectiveness to autologous bone in fresh bone defects in humans (24,32).

Composite Xenografts

Urist and others (147,149) have noted that composite implants formed from various combinations of ceramic, demineralized bone matrix, marrow, and type I collagen exhibit a synergism among the components, resulting in faster and more abundant bone formation. Although the biochemical basis of this process is not well understood, it seems likely that such composite implants may prove to be clinically useful.

IMMUNLOGICAL CONSIDERATIONS

The antigen–antibody response to allografts varies considerably in reported series (144). Studies of small osteoarticular fresh human allografts performed by Urovitz et
al. (155) have demonstrated little evidence for antihostcompatibility (anti-HLA) antibodies in the serum of the hosts, whereas patients receiving massive frozen allografts in the series reported by Rodrigo et al. (130) showed high titers of anti-HLA antibodies that remained positive as long as 5 years after transplantation.

In osteochondral grafting, fresh cartilage of low immunogenicity and fresh subchondral bone that is highly immunogenic are transplanted. With the use of a free avascular osteochondral allograft for replacement of the end of a long bone, one desires the devitalized bone to be remodeled through "creeping substitution" at an appropriate rate (52,128) and the cartilaginous surface to remain viable. Cartilage is transplanted primarily for destroyed joints in the form of shell allografts (joint cartilage plus 5 to 10 mm of subchondral bone). A strong immune response to the bone can destroy the adjacent cartilage, even though cartilage resists destruction by antibody and cellular resorptive mechanisms (33,34). In addition, the cartilage may become more immunogenic with time after transplantation. One study indicated that the cartilage cells did not express class I and class II antigens before transplantation, but they did after transplantation; the expression of antigen became stronger with time. It was suggested that an immune or inflammatory response must occur first to stimulate the chondrocytes' expression of HLA antigens by the release of lymphocytes. If the recipient develops an immune response against donor histocompatibility antigens, the protection of cartilage from destruction is only relative; a low grade, slow, immunologically mediated inflammatory response ensues, characterized by increased synovial fluid and white blood cell counts, antibody response, and pannus reactions that can destroy the cartilage (132,133).

Transplantation of allogeneic cortical and cancellous 72-143 elicits an immune response that delays healing at the osteosynthesis site and blocks revascularization, resorption, and appositional new bone formation. Long-term studies show no difference in the morphology of eventual repair of autografts and allografts (77,126,158).

OPERATIVE TECHNIQUES

Allografts for Spine Surgery

The choice of grafting material depends on the anatomic and spatial constraints of the area to be stabilized and the osteogenic capacity of the host bed in orthotopic bone grafting. In general, vertebral bodies, which are rich in cancellous bone and marrow, provide far greater numbers of osteoprogenitor cells for remolding a graft than spinous processes, facets, and transverse processes, which are composed mostly of cortical bone. Hence, demands placed on a graft destined for posterolateral areas of the spine are greater than those imposed on bone 72-143 grafted to an intervertebral body location. For posterolateral grafting of the spine, fresh autogeneic bone, either alone or in a composite graft, is considered essential because the graft provides surviving osteogenic precursor cells and inductive factors. Frozen or freeze-dried devitalized allogeneic cortical and cancellous bone may be used for cervical and lumbar interbody fusions when less is demanded of the graft and when the recipient bed is rich in marrow. At these locations, the incidence of fusion is the same with autogeneic bone and fresh autografts, although the rate at which the allograft fuses is slower (6,26,91,143).

At times, vertebral bodies of the cervical, thoracic, and lumbar spine are lost because of degenerative processes, infection, or neoplasia. Struts of allogeneic fibular bone can be used effectively to restore stability; these struts are eventually incorporated and remodeled. Even in the presence of recent osteomyelitis, devitalized allograft strut grafting can provide structural support for several vertebral levels. When large, multilevel defects are present in the cervical vertebrae, a femoral allograft frequently will fill the defect and provide the correct curvature. In these cases, additional internal fixation to protect the graft throughout its length is advocated.

Long fusions that are necessary in operations for scoliosis frequently are performed in young children who do not have enough bone present in the iliac crests to provide adequate amounts of autograft. In these cases, allograft bone (frozen, freeze-dried, or AAA bone) may be morcelized and mixed with the child's own bone to provide adequate amounts of graft material. More recently, titanium cages filled with various grafting materials have been used for interbody fusions. See Chapter 146 for more details.

- During an operation, protect the sterility of the graft at all stages. Avoid prolonged exposure to air and saline and prolonging healing, which can destroy cells and inductive factors (7,120,163). Create an optimal host bed, preferably with marrow-rich cancellous bone marrow. Healing the recipient bed with power burns or coating bleeding interface with bone wax also destroys viable host cells and impairs subsequent incorporation.
- Fashion the graft during the operative procedure to morise implants tightly into host bone. Spread the allograft contact sites with autograft, and apply supplemental barrel slant-like struts of bone graft to the osteosynthesis site. Orient the graft in situ to provide axial alignment of donor cortical bone with erect posture of the patient and maximum exposure of the cancellous areas of donor bone of the host's marrow-containing cancellous bone. Forces across the host–graft interface should maximize contact compression with ambulation of the patient.
- Use suction for the first 48 hours after the operation to reduce hematoma formation within porous soft tissues, thereby reducing pain and preventing donor bone from floating in a large blood clot. Early postoperative ambulation and mild exercise stimulate blood flow and osteogenesis within the graft, provided the graft is secure within the recipient bed. External splinting appliances, as well as the patient's muscle spasm and pain, tend to stabilize the graft. Educating the patient with respect to proper posture, weight bearing, turning, and exercising, especially when the graft is most vulnerable, is critical for avoiding fatigue fractures and pseudarthrosis.

Allografts for Tumor Surgery

Allografts for major tumor surgery have been used during the past 50 years, and recent results have approached 85% good or excellent (72,76,116,124). The needs for grafting in tumor surgery vary considerably, depending on whether the defect is diaphyseal, ligamentous, tendinous, or cavitary (cysts).

Large Diaphyseal Defects

When large diaphyseal bone losses are present, Ilizarov methods are often the best for replacement (see Chapter 32). Other alternatives for replacement include the following: sliding cortical autografts from the remaining bone above or below the defect, large corticocancellous bone grafts from the iliac crest, vascularized fibular autografts, morcelized autograft placed around an intramedullary rod (23), and allograft bone with or without autograft (79,88). Autogeneic bone allograft and allografts of cancellous bone are preferable to an unsupplemented allograft bone. When autograft sources are insufficient, allogeneic bone can be used in combination with the autograft. When allograft bone is used alone, it should be protected by a plate or rod throughout its entire length to prevent a fatigue fracture when the allograft bone weakens because of remodeling. Many years later, when the plate or rod begins to weaken, the allograft bone will have been replaced sufficiently to provide the needed strength (Fig. 9.14). In many cases, gradual stepwise removal of the plates and screws is advisable to dynamize the allograft.

Figure 9.14. A midshaft femur freeze-dried allograft for a central chondrosarcoma is shown. The allograft showed good revascularization 8 years postoperatively, when one plate was removed for bursitis.

Large Composite Defects

When bone and joint losses are present, the alternatives for replacement include the following: a large osteoarticular allograft, a large diaphyseal allograft with a custom metallic joint replacement threaded through the allograft, and a joint fusion using sliding autografts with or without allograft bone. Preliminary evidence suggests that diaphyseal allografts used in combination with joint replacements are superior to large osteoarticular allografts for replacement of large osteoarticular defects (16).

Transplantation of large whole- or half-joint allografts has been reported during the last several decades (37,88,89,100,101,108,110,111 and 112). Results were varied, and in all cases complications led to a failure of normal joint function; however, the operations worked well as salvage procedures. The more recent technique of threading a long-stem customized joint replacement through a large diaphyseal allograft (17) appears to give better results, at least in the short term.

Acetabular allografts can be fashioned from morcelized iliac crests, femoral heads, or an allogeneic acetabulum itself (Fig. 9.15). All of these grafts are best protected...
by screws, a porous fixed acetabular component, a plate, or some combination of these items.

Figure 9.15. A large acetabular allograft (B) for a low-grade fibrous histiocytoma (A) of the acetabulum is shown.

Large Cystic Defects When large cysts are present in diaphyseal bone, they can be filled with autografts in most cases. However, when the cysts are so large that there is inadequate autogeneic bone available from the iliac crests, allogeneic bone (preferably AAA bone) may be morcellized and supplemented with autograft to fill the cyst cavity (Pia. 9.12).

Allografts for Joint Surface Defects (Shell Allografts)

Because abrasion chondroplasty and arthroplastic reconstruction for joint surface defects can yield poor results (47,56,81,87), biologic resurfacing of joint defects is being tried. The concept of an autogeneous free periosteal graft coupled with continuous passive motion (105) or autogenous cartilage cell implant combined with peri-chordal bone has been studied in clinical trials and has demonstrated mixed success (see Chapter 86). The use of autogenous osteochondral allografts is an acceptable means of reconstruction (136,140,141). However, this technique has the disadvantage that the available graft materials seldom have a suitable shape for reconstructing a given defect.

Somewhat better known is the use of shell allografts, involving the transplantation of a devascularized, osteoarticular allograft with a small bony component. Studies of osteoarticular shell allografts in humans have not been followed long enough or often enough to determine their outcome, but several authors have reported promising early results (56,57 and 58,97). Of the shell allografts that have failed, some appear to have had a significant pannus reaction (75), suggesting that an immune response was induced by the cells of the subchondral bone (36,136).

The specific techniques in performing shell allografts vary to a certain extent, because the defects vary considerably.

- If a small joint surface defect exists, then make an attempt to ressect only that part of the joint surface. Press fit a clear plastic or wax material over the joint surface to use as a template, and make a cut in the cartilage approximately 3 to 4 mm around the defect. In this way, a circumferential or geometric cut is made in good viable cartilage just to the edge of the defective cartilage.
- Cut approximately 5 to 10 mm into subchondral bone with an osteotome, and remove the entire joint surface defect. Inspect the subchondral bone, and curet any remaining defective subchondral bone. If there is a large crater, as in avascular necrosis of the hip, pack it with a fresh autogeneic iliac crest bone graft.
- Prepare the small allograft piece from a donor joint that has been recently procured. Procurement requires taking the specimen in a sterile fashion and keeping it sterilely stored at 4°C with capsule intact. The end of a long bone is sufficient for small defects.
- Place the plastic template that was used to mark the size of the defect over the donor cartilage surface; mark the donor surface cartilage with a knife, and cut a corresponding piece from the donor surface, being sure to make the piece slightly larger than what was removed from the recipient. Remove approximately 1 cm of subchondral bone with the donor cartilage. Press fit the perfectly sized donor piece into the defect.
- If there is good fixation at this point, no further fixation is needed. However, it is better to err on the side of obtaining good fixation, if possible. Small threaded Steinmann pins may be drilled from the side into the subchondral bone, and small screws also may be used for this purpose. Either procedure would be better than passing screws across the cartilaginous surface through the tidemark. If the anatomy of the joint does not allow this technique, then drill four small (2.7 mm) holes in the four quadrants of the graft, bringing the drill holes out through cortical bone at some place distant from the graft along the metaphyseal region of the bone. Pass another suture in a crisscross fashion through the other two holes, and tie it over bone. This approach provides fixation of the graft until the subchondral bone heals, and by that time the suture will dissolve. The latter method is not as good as using screws or small pins, because it involves drilling through the tidemark and the pressure of suture across the donor cartilaginous surface. Another reasonable alternative is the use of bioresorbable pins placed in a divergent pattern through the allograft into recipient bone.
- Place the patient's joint in a temporary splint after adequate closure is obtained, and allow the joint to rest for 2 to 3 days. Once the bleeding has stopped and the wound has begun sufficient healing, start continuous passive motion if adequate fixation of the graft has been obtained at surgery. Continue the continuous passive motion for 3 months, if possible. Do not allow full weight bearing for 6 to 9 months, at which time radiographs should show adequate healing of the subchondral bone interfaces. If possible, evaluate the graft approximately 1 year after surgery using diagnostic arthroscopy to assess for an immune rejection phenomenon, which is characterized by pannus covering the graft. If this reaction occurs, the prognosis for the graft is poor.
- Preoperative and postoperative serum samples can help predict an immune response. Obtain serum samples before surgery and at 6 weeks, 12 weeks, and 1 year after the surgery. Test these serum samples against donor lymphocytes, if they are obtained at the time of the graft procurement, or a panel of typed lymphocytes in a standard lymphocyte toxicity assay. A strong antibody response does not necessarily mean that the graft will be rapidly destroyed. Diagnostic arthroscopy is the only sure way to determine the health of the graft.
- If a large shell allograft is needed, such as in replacement of the entire hemi-joint surface of a joint or replacement of a medial or lateral side of both the proximal and distal joint surfaces, then different techniques are needed. In these cases there is usually a large defect due to a severe traumatic episode, such as a gunshot wound.
- Procure the allograft specimen as an entire joint specimen, and transport it to the operating room in sterile saline at 4°C with the capsule intact. Transplantation of the joint surfaces should be done approximately 48 hours from the time of procurement. There is evidence to suggest that with this type of storage, the subchondral bone cells will die before the cartilage cells; this may be advantageous when trying to prevent an immune response against the subchondral bone that could eventually damage the donor cartilage (133). For this reason the specimens are not transplanted when they are fresh and warm.
- Debride the defect in the joint of all scar tissue down to healthy bleeding bone. Fashion the shell allograft pieces to fit the defect, leaving intact on the graft any ligaments needed to replace ligaments missing in the recipient. Fix the graft through subchondral bone with threaded Steinmann pins, screws, or staples placed from the side and not passing through the donor cartilage surface.
- If good fixation is obtained at the time of surgery, then begin continuous passive motion within a short time after surgery. If only marginal fixation is obtained, however, then immobilize the entire joint for 6 weeks or, at most, allow a few degrees of motion in a protective brace. Allow partial weight bearing for 3 to 6 months until adequate healing of the subchondral bone interfaces is evident on radiography; this may require tomographic evaluation. A second assessment with an arthroscopy 1 year after surgery may be desirable to determine whether a severe immune reaction is occurring. Serial preoperative and postoperative serum histocompatibility testing also can be done to monitor the immune response.

Results and Prognosis An overall success rate of approximately 75% can be expected (67). Although the results of McDermott et al. (Table 9.3), shell allografts have been most successful in patients who have suffered traumatic damage to their joint surfaces (92). These patients have had success rates of 69% to 92%. Patients with osteoarthritides also have satisfactory results with a success rate of 42%. Patients with osteochondritis dissecans and avascular necrosis have had the poorest results, with a success rate of only about 25%. The reason for this poor showing may be that there is inadequate healing of the osteosynthesis site because of a poor blood supply to the subchondral bone.
The use of bone and joint allografts after severe traumatic destruction of skeletal parts presents many more difficult problems than replacement of tumor or arthritis defects. Severe soft-tissue injuries usually accompany the bony trauma, and many of the wounds have been previously infected (Fig. 9.16). Therefore, the surgeon is frequently operating in an area of decreased blood supply, poor skin coverage, and persisting organisms from previous infections. Most of the experience with allografts in the treatment of traumatic defects has come from the wartime experience, and the following important prerequisites should be followed:

- Operating in an area of decreased blood supply, poor skin coverage, and persisting organisms from previous infections.
- Most of the experience with allografts in the treatment of traumatic defects has come from the wartime experience.

### Allografts for Revisions of Total Joint Arthroplasty—Revision Arthroplasties

Allografts for revision arthroplasties have been used primarily in the hip. Major segmental defects in the acetabulum as well as the proximal femur may occur after multiple revision arthroplasties. These defects can be reconstructed with allografts (see Chapter 106). Acetabular defects may be divided into rim defects, medial wall defects, and global defects.

#### Rim Defects

The rim defects can be subcategorized into superior rim, posterior rim, or combinations of superior and posterior rim defects. Most of the superior and posterior rim defects can be reconstructed using a bicortical piece of autogenous iliac crest. If the defect is large, as in the superior and posterior rim defect, a proximal femoral head or distal femur allograft is usually better to reconstruct the defect.

- Cut and shape the proximal graft to provide the bone stock that is necessary, and fix it to the pelvis with two to three screws.
- Use a splayed or porous ingrowth type of acetabular component that has screw holes near the rim, so that the screws securing the component can be used as additional fixation of the allograft.
- Butter the allograft with autogenous marrow and morcellized iliac crest bone to stimulate healing at the osteosynthesis site.
- The screws going through the metal backing of the acetabulum component should pass for several months until the osteosynthesis site has adequately healed. Follow graft healing on serial radiographs. Healing of the osteosynthesis site can be expected to take twice as long as normal bone healing, that is, 3 to 6 months rather than 6 weeks to 3 months. Replacement of the large grafts may take several years, and for this reason patients should use a cane for several years to protect the prostheses and the graft until it has been solidly incorporated and replaced by recipient bone. Serial bone scans are helpful in interpreting this replacement process. The allograft will become "hot" on bone scan within a few weeks to a few months after the operative procedure, and it will remain hot for several years. If quantitative bone scans can be done when the scan turns "colder," this is probably an indication that significant strength has been regained to allow full weight bearing.
- A bipolar proximal femoral component is to be used, then use an anterior as well as posterior column plate to fix the allograft.
- Coat the surfaces of the allograft with autograft to stimulate healing and union.
- A global defect of the proximal femur may encompass bone loss of several centimeters in length. In these cases, cut an entire proximal femur allograft and coating it with autogenic bone. Place the screws fixing the acetabular component so that they pass through the allograft and into recipient autogenous bone. Take care to keep the ischial part of the cage on the anterior ischial tuberosity so it does not irritate the sciatic nerve.

#### Medial Wall Defects

In medial wall defects with thinning of the medial wall, use morcellized autograft packed under a fixed porous ingrowth acetabular component. If the medial wall defect is segmental and large, then it may be adequate to use a large outer table of autogenous iliac crest, plus morcellized graft with a fixed porous component. It may be necessary also to use a femoral head allograft fashioned to fill the defect. Again, a porous acetabular component is desirable because it will fix the allograft to the recipient autogenous surfaces and protect it during remodeling.

#### Combination Medial Wall and Rim Defects

The combination of a medial wall defect and a rim defect results in a very large defect. In these cases, use a large femoral head allograft or distal femur allograft.

- Debride the allograft of all cartilage and soft tissue, and fix it with a few screws to the recipient pelvic wall. Coat the surfaces with autogenic bone and marrow before fixation.
- Once it is in position, ream the allograft using standard reaming techniques, and place a screw-fixed acetabular component, fastening additional screws through the porous component into the allograft and into the remaining recipient pelvis wall.
- Occasionally, an acetabular reinforcement cage with an acetabular component cemented into it is necessary. Prolonged protection with partial weight bearing using a cane for up to 5 years is recommended to allow complete incorporation of the allograft material.

#### Global Defects

For very large global defects, a complete acetabular allograft is necessary. When harvesting the allograft for these cases, preserve the ischial ramus, pubic ramus, and superior acetabular bone.

- Fix the graft with screws and plates to the recipient pelvic bone. If a bipolar proximal femoral component is to be used, then use an anterior as well as posterior column plate to fix the allograft.
- Coat the surfaces of the allograft with autograft to stimulate healing and union.
- If a total hip replacement is to be used, install an acetabular cage after reaming the allograft acetabulum and coating it with autogenic bone. Place the screws fixing the acetabular component so that they pass through the allograft and into recipient autogenous bone. Take care to keep the ischial part of the cage on the anterior ischial tuberosity so it does not irritate the sciatic nerve.

#### Proximal Femoral Defects

Proximal femur defects may be categorized as one of three types. The first is an intramedullary defect due to diffuse focal resorption of intramedullary bone around the bone cement interface, the second is a medial calcar defect, and the third is a global proximal femoral defect.

- The intramedullary defect is best treated with morcellized autogenous bone plus a porous ingrowth type of prosthesis. If the amount of bone lost is too great to be replaced with autogenous bone, however, mix autogenous iliac crest bone with morcellized allograft bone as a slurry, and pack the defect with this combination autograft and allograft before seating the proximal femoral component.
- For medial calcar defects, cut and fashion a medial calcar allograft to fit the defect. Fix this graft with wires, screws, or a combination of both before seating the proximal femoral component. In these cases, the porous coating should be at least two thirds the length of the stem.
- A global defect of the proximal femur may encompass bone loss of several centimeters in length. In these cases, cut an entire proximal femur allograft and fashion it to fit the defect, making a step cut at the osteosynthesis site. Prepare allograft on the back table including reaming, then cement the proximal femoral component into place in the allograft.
- Remove all excess cement from the osteosynthesis step cut site on the allograft, and then cement the distal stem into place. Additional fixation is usually necessary at the osteosynthesis site in the form of a plate, screws, or cerclage wires.
- Coat the surfaces of the allograft with a fixed porous ingrowth acetabular component.
- Debride the allograft of all cartilage and soft tissue, and fix it with a few screws to the recipient pelvic wall. Coat the surfaces with autogeneic bone and marrow before fixation.
- Use a splayed or porous ingrowth type of acetabular component that has screw holes near the rim, so that the screws securing the component can be used as additional fixation of the allograft.
- But the allograft with autogenous marrow and morcellized iliac crest bone to stimulate healing at the osteosynthesis site.
- The screws going through the metal backing of the acetabulum component should pass for several months until the osteosynthesis site has adequately healed. Follow graft healing on serial radiographs. Healing of the osteosynthesis site can be expected to take twice as long as normal bone healing, that is, 3 to 6 months rather than 6 weeks to 3 months. Replacement of the large grafts may take several years, and for this reason patients should use a cane for several years to protect the prostheses and the graft until it has been solidly incorporated and replaced by recipient bone. Serial bone scans are helpful in interpreting this replacement process. The allograft will become “hot” on bone scan within a few weeks to a few months after the operative procedure, and it will remain hot for several years. If quantitative bone scans can be done when the scan turns “colder,” this is probably an indication that significant strength has been regained to allow full weight bearing.

### Allografts for Trauma

The use of bone and joint allografts after severe traumatic destruction of skeletal parts presents many more difficult problems than replacement of tumor or arthritis defects. Severe soft-tissue injuries usually accompany the bony trauma, and many of the wounds have been previously infected (Fig. 9.16). Therefore, the surgeon is frequently operating in an area of decreased blood supply, poor skin coverage, and persisting organisms from previous infections. Most of the experience with allografts in the treatment of traumatic defects has come from the wartime experience, and the following important prerequisites should be followed:

- Operating in an area of decreased blood supply, poor skin coverage, and persisting organisms from previous infections.
- Soft-tissue injuries usually accompany the bony trauma, and many of the wounds have been previously infected (Fig. 9.16). Therefore, the surgeon is frequently operating in an area of decreased blood supply, poor skin coverage, and persisting organisms from previous infections.

### Table 9.3. Effects of Etiology on the Results of Shell Allografts

<tr>
<td>Other</td>
<td>4</td>
<td>2</td>
<td>50%</td>
</tr>
</tbody>
</table>

*Note:* The table shows the effects of etiology on the results of shell allografts with different rates of failure. The lowest failure rate is seen in arthritic patients, while the highest rate is observed in other etiological groups.
1. The distal anatomic parts are functionally intact.
2. Good skin coverage must be present or obtainable at the time of surgery. (Remember that a collapsed soft-tissue space will be filled with bone, which creates a stress on the previous skin coverage.)
3. Evidence of infection is absent.
4. Circulation is adequate.
5. Abundant cancellous autograft is available for supplementation of the bony surfaces of the allograft.
6. The graft is protected until healing is complete.

Failure to adhere to these principles places the graft at significant risk of failure.

Diaphyseal Bone Defects A number of technical principles have been developed in the treatment of diaphyseal defects. First, morcellized bone appears to incorporate faster than large segmental allografts. Jeshrani and Bencivenga found that 5 of 5 cortical grafts without morcellized grafts failed, 3 of 3 cortical grafts with morcellized graft succeeded, and 17 of 17 grafts with only morcellized bone healed well (71). Osteogenesis and revascularization of the morcellized bone begins to occur within 10 days, and bacteria are much less likely to survive in these small, rapidly revascularized pieces than in a large, nonviable piece of allograft bone (18).

Second, when a large cortical graft is needed to bridge a gap in the femur, humerus, or other isolated long bone, it is recommended that half of an allograft shaft be used with morcellized autogeneic bone packed around it (Fig. 9.17) (9). This approach has two advantages: It maximizes the morcellized graft material, and it decreases the volume of cortical bone that might distend the already shrunken surrounding soft tissue. Extreme care must be taken to protect the large cortical allograft until it has been incorporated; this may take as long as 2 to 3 years. The protection can be provided by a cast, brace, internal fixation with rods or plates, or a combination of these techniques.

Third, it is usually not advisable to use a large cortical allograft for tibial bone loss. In this case, a proximal and distal tibiofibular synostosis is obtained first; then progressive grafts made of morcellized, mixed autograft, and allograft bone are used to bridge the defect (94). This approach may require a number of successive grafts. It is possible that synthetic bone materials mixed with autogenous graft may prove to be at least as good as allograft material for filling such defects. Alternatively, bone transport by Ilizarov techniques might be the best way to bridge the defect (see Chapter 32).

Careful soft-tissue technique, avoiding infection, and the maximal use of morcellized autografts with allografts can give the results shown in Table 9.4 (15). A good result is defined as restored bone continuity and no need for a brace. Satisfactory results are those with restored bone continuity but with the need for bracing. A failure is defined as an amputation.

Articular Surface Defects When articular surface defects are due to trauma, replacement is the same as previously described in this chapter. The success rate is considerably better when shell allografts are used for traumatic defects than when used for primary arthritic conditions such as osteoarthritis and avascular necrosis (Table 9.2).

The success rates of large fresh osteochondral allografts has not yet been determined for posttraumatic conditions. The success rates could be considerably worse because of problems with avascular necrosis and collapse of subchondral bone. Using artificial joints threaded through the allograft may prove to be a better method to treat posttraumatic defects of the ends of long bone, as has been the case with large tumors or failed total joint replacements.
Induction

Osteoinduction is the process of inducing pluripotential, primitive mesenchymal stem cells to differentiate into osteoblasts. The process of induction has been intensely investigated by Urist et al., and others (7,8,143,147,148,149,150,151,152,153 and 154). Induction of bone formation occurs, in part, as a result of noncollagenous, noncollagenous bone morphogenetic proteins, as well as other inductive proteins (21,22,46,50,51,53,103,127,147,148,149,150,151,152,153 and 154). The most intensely studied of these proteins is from those composing the BMP super family. These proteins are summarized in Table 9.5.

Table 9.5. The BMP Superfamily in Mammals*

The most intensively studied of these BMPs thus far has been recombinant BMP2 (rhBMP-2) and rhBMP-7, also known as osteogenic protein-1 (OP-1).

In one of the earlier studies, Heckman et al. (63) found that when species-specific BMP was placed in a canine radius nonunion model using a polyactic acid carrier, that a higher incidence of union occurred as compared with that of controls. Yashic et al. (102), using human rhBMP2 in a critical defect model in the femora of rats, were able to demonstrate successful union compared with controls. This was dose related, requiring a large dose of 11.0 µg to achieve union. Gerhart et al. (46), using the same protein but in a segmental defect in the femur of sheep stabilized by a plate, showed no bony union in their negative control groups but complete union in their experimental group and autograph controls. Similar results were demonstrated in a rabbit critical defect model (106). A significant number of human clinical trials are now under way with these very interesting proteins. Recently published studies have demonstrated successful use of a human BMP to augment one-stage lengthening of femoral nonunions (73). When the appropriate carrier vehicles are combined with the appropriate protein or proteins, there is a high likelihood that they may replace the use of autologous bone graft and nonstructural allografts to a great extent. Future research in tissue engineering may result in synthetic structural grafts as well.

Bone Marrow

Autologous red bone marrow, usually obtained by aspiration in adults from the axial skeleton, contains a small but significant number of pluripotential mesenchymal stem cells and inductive factors that have been used to treat nonunions (27,28). Connolly et al. (27,28) have demonstrated the efficacy of repeated injection of fibial nonunions as a substitute for open operative grafting.

Conduction

As opposed to induction discussed above, conduction consists of the growth of host bone into a bone graft or matrix by the growth into available channels in the graft of vascular buds, followed by the laying down of osteoblasts along these channels with subsequent bone formation. In some cases, osteoblastic resorption along the channels may be a part of this process, but this is not necessary with many materials. From the standpoint of a material introduced into a bone defect site, this represents a passive rather than an active phenomenon as in bone induction. Bone conduction can occur through an open matrix, such as one would find in granules packed loosely together, or through structural channels, such as found in some types of coral, in which the ideal size appears to be somewhere between 250 and 600 µ in diameter. A number of synthetic or naturally derived bone-filling materials, some of which promote bone formation through conduction, are now on the market or under investigation. If these materials are used as a carrier vehicle for inductive proteins, then induction would of course also play a role. In their review of the role of bone substitutes, Hollenger et al. (69) provide a list of those available in the United States as of 1996. This list is summarized in Table 9.6.

Table 9.6. Bone Substitutes Available in the United States

For orthopaedic applications, the most commonly used materials at this time are Collagraft, Grafton, and ProOsteon 500. The Norian SRS material has received considerable attention recently, but it is still in clinical trials and is not available for general use.

Grafton

Grafton is a form of demineralized bone matrix. It is nonstructural and supplied as a particulate. It may retain some bone induction capability. Most surgeons use it to graft fracture repairs where some assistance is desired but the surgeon either does not wish to incur the morbidity of harvesting a bone graft or is not prepared to harvest a bone graft. Otherwise, most surgeons seem to be using it as an adjunct to autologous bone grafting to expand the bone graft, particularly in spine fusions.

Collagraft

Collagraft is a nonstructural graft supplied in strips that, after rehydration, becomes soft and can be packed into bone defects or laid on the surface of bone. In laboratory and clinical studies, it has proven to be equally efficacious as autologous bone graft in the experimental models and clinical applications chosen (24,32,59,90,93,102). Collagraft has not experienced much popularity, however, because the most common application of this type of material is to fill metaphyseal defects where some structural integrity is necessary that the Collagraft material does not offer.

ProOsteon

This hydroxyapatite is provided in two differing porosities with cross-connected channels and is manufactured by the chemical transformation of the calcium carbonate skeleton of a marine coral. It has been shown in canine critical defect models to incorporate well with excellent bone growth into the open channels of the graft (80,93). Currently this material is approved by the Food and Drug Administration (FDA) for the filling of metaphyseal defects. It is used at our institution for filling the defects in juxtaarticular fractures such as those in the distal radius, in tibial plateau fractures, and in pilon ankle fractures. We also use it to fill defects created by the removal of small benign bone tumors (104). This material is available both in block and granular form. Because it is a very brittle material it is difficult to work with. It is quite weak
in shear and tension. When contained in a bone cavity totally surrounded by bone, where the cavity is firmly packed with the material, it offers reasonable resistance to compression, sufficient enough that it is practical for reconstruction of tibia plateau fractures. Additional support with internal fixation is required. Excessive packing can crush the blocks and granules and reduce their porosity, potentially interfering with bone ingrowth, but this problem has not been documented in practice.

Complications from the use of these materials are few. Because it is essentially pure hydroxyapatite, it incites no immune response. Occasionally, joint surfaces will settle because of structural weakness in the material, but this can usually be avoided by appropriate internal fixation. Because it is a foreign body, it could potentially be a problem if infection were to occur. However, the studies noted earlier actually show a slightly lower infection rate with ProOsteon when compared with autologous bone. If significant infection were to occur, then resolution of the infection would most likely require removal of the ProOsteon. Lastly, the granules can occasionally get into anatomic sites that are not desirable. In packing the granules into bony defects, they often become adherent to the surrounding soft tissues. Although in our experience this results in no untoward effects, it does produce a less pleasing radiograph. It is a somewhat laborious task to pick each of the particles off the soft tissue on the day of surgery. However, in one case we encountered a pseudoaneurysm, in which the initial vascular injury was not treated. Treatment was performed early, most patients respond quickly to treatment, and chronic osteomyelitis is rare. Chronic osteomyelitis in a donor site requires thorough antimicrobial and correct surgical management.

Large seromas or hematomas usually manifest themselves within the first few days by a large swelling at the incision site with clear or serosanguineous drainage. Simple rules to minimize the risks of complications in bone graft donor sites are detailed in the Hints and Tricks sidebars throughout this chapter.

Complications in bone grafting are limited almost exclusively to the usual surgical complications that can occur at the bone graft harvest site. Complications in the use of autogenous bone grafts might include nerve injury, weakening of the bone stock, and graft failures. Infection of the graft through bone remodeling. Other major concern is disease transmission, in particular the viruses of hepatitis B, C, and human immunodeficiency virus (HIV). Through donor screening, testing, and implant processing, these risks have been minimized. The major risk remains with fresh composite allografts in which bone and cartilage are transplanted. Donor screening programs have minimized this risk, but they remain real. The complications and risks associated with the use of allografts are discussed in some detail earlier and will not be considered further here.

The risks associated with the use of synthetic bone graft materials and other types of processed bone are quite small and related primarily to either premature mechanical failure of the graft, or nonunion due to lack of incorporation of the graft, lack of ingrowth, or inappropriate use of the material for the clinical situation. The most common problem we have seen has been the packing of a fresh fracture defect site or site of a nonunion with an osteoconductive material that offers no bone induction where the bone bed is incapable of thoroughly healing the gap site, resulting in nonunion of the fracture or persistence of the nonunion. This problem can be avoided by using autologous bone and adding purely conductive materials only when necessary.

Because bone inductive proteins have not yet become available in the United States for General use and because the clinical trials reported are quite limited, potential complications of these proteins, other than lack of efficacy, or perhaps immunologic adverse response, are not yet known.

**Bone Graft Harvest Sites**

In 1989, Younger and Chapman (154) reported a major complication rate of 8.5% and minor complication rate of 20.6% at 243 bone graft donor sites harvested by all types of surgeons at their institution. Potential early complications include wound dehiscence, infection, seromas and hematomas, pain, inadvertent injury of adjacent joints, muscle or bowel herniation, and injury to important structures such as nerves, vessels, and the ureter. Intermediate and long-term complications include an ulcer of the donor site, injury to the iliac vessels, fracture, and late graft failure and nonunion. Younger and Chapman reported a higher incidence of complications in patients undergoing posterior spine fusion in which the bone graft was harvested through the same incision as used for the spine surgery. Hugh and Bohrman (70), however, focused on the incidence of fractures at the iliac bone graft harvest site, finding 14 patients with fractures out of approximately 400 fusions divided equally between the cervical and lumbar spine. These were either avulsion fractures of the anterosuperior iliac spine or fractures of the iliac wing. All patients were treated nonoperatively with excellent long-term outcomes. They identified older women with osteopenic bone as being particularly prone to this complication. In 1997, Goulet et al. (55) reviewed 170 patients from whom bone grafts were harvested. Major complications occurred in four (2.4%) in whom deep infection developed. Thirty-seven patients (21.8%) had minor complications. Several of their patients (18.7%) continued to report pain more than 2 years postoperatively. In spite of this incidence, the vast majority of patients were functioning well at 2 years postoperatively.

Simple rules to minimize the risks of complications in bone graft donor sites are detailed in the Hints and Tricks sidebars throughout this chapter.

**Seroma and Hematoma**

Large seromas or hematomas usually manifest themselves within the first few days by a large swelling at the incision site with clear or serosanguineous drainage. These lesions are usually not a problem if they are contained by a tightly closed fascia. However, a large seroma or hematoma presenting in the subcutaneous area may require aspiration and compression dressing or exploration of the wound for drainage, control of bleeding points, and repeat closure over suction drainage. This is important because these lesions can be very slow to resolve, and persistent drainage can lead to retrograde infection of the donor site.

**Infection**

Postoperative wound infection nearly always occurs early, within the first 1 to 3 weeks. Early surgical intervention to drain and debride the operative site is nearly always indicated. Gram’s stain and deep cultures are important, along with early institution of appropriate intravenous bacteriocidal antibiotics. If surgical and medical treatment is performed early, most patients respond quickly to treatment, and chronic osteomyelitis is rare. Chronic osteomyelitis in a donor site requires thorough debridement of all nonviable bone and treatment, as outlined in Chapter 133.

**Peripheral Nerve Injury with Neuritis or Causalgia**

Although most patients tolerate an area of loss of sensation, some develop painful neuromas that can be disabling and even lead to reflex sympathetic dystrophy. Simple loss of sensation due to a neuropaxia of the nerve secondary to retraction is usually managed well by appropriate counseling of the patient and watchful waiting. Persistent complaints with a definite trigger point, Tenen’s sign, or palpable neuroma usually merit surgical exploration of the nerve. Magnification should be utilized to aid in the neurologic examination of the nerve. If an intact nerve is found with minimal intraneural scarring, then simple decompression with neurolysis may suffice. If a neuroma or dense intraneural scarring is found, then resection of the injured segment with repair of the nerve, or in some cases resection with bonying of the proximal stump, may be indicated depending on the nerve involved and the patient.

**Pseudoaneurysm**

Acute vascular injuries that do not threaten the viability of important structures or the extremity are usually dealt with at the time of initial injury with ligation of the vessel. Injury of larger vessels that are important to function or limb survival require acute repair and intervention of a vascular surgeon when the orthopaedic surgeon is not qualified to perform vascular repairs. The most vexing late complication of a vascular injury is a pseudoaneurysm in which the initial vascular injury was not
appreciated by the surgeon. Most typically, these lesions present as a mass or swelling that may or may not be painful. On physical examination, they may be pulsatile or have a bruit on palpation or pulsation. Ultrasound or arteriogram, or both, is usually necessary to make a diagnosis, and vascular surgery consultation for surgical correction is nearly always indicated.

Post-harvest Fracture

The most common fracture is avulsion of the anterosuperior iliac spine or a split in the anterior column resulting in inferior and anterior displacement of the anterior fragment to which the sartorius and occasionally the rectus femoris are attached. The vast majority of these fractures can be treated nonoperatively with limited weight bearing with crutches. Union usually occurs within 6 to 10 weeks. The patient may be left with some deformity of the pelvis, but usually this is asymptomatic and not of cosmetic concern. For the most part, these fractures occur in elderly osteoporotic women. Occasionally, they occur in young active athletes. In these cases, open reduction and internal fixation may be indicated.

Fractures of long bones due to bone graft harvest in metaphyseal areas with minimal displacement can usually be treated nonoperatively. Displaced unstable mid-diaphyseal fractures, particularly in the tibia and femur, are usually best treated with closed reamed intramedullary nailing. Reaming of the medullary canal grafts the defect site, and if necessary, additional cancellous bone can be added by the intramedullary or subperiosteal route (23). Intramedullary nailing usually allows early weight bearing and return to function. Because these fractures can be very slow to heal, the intramedullary nail provides prolonged protection of the fracture site.

Dropped Bone Graft

All surgeons fear the day when an important autologous bone graft just harvested from the patient is accidentally dropped to the floor of the operating room. Little has been written about what to do in this circumstance other than to abandon the graft and harvest another one, if available. Presnal and Kimbrough (117) found that 50 surplus bone grafts dropped in the operating room in their institution and submitted for culture were sterile. Therefore, they recommended that, if a bone graft that had been dropped on the operating room floor was to be implanted in the patient, extensive sterilization was not essential. Our approach to the dropped graft is as follows:

- If a second graft can be harvested with no or minimal additional morbidity for the patient, then discard the dropped graft and harvest a second graft.
- If the dropped graft is essential and an additional harvest would subject the patient to additional morbidity, then treat the graft as follows and use it:
  - Irrigate the graft using a pulsatile irrigator with two or more liters of saline depending on the size of the graft.
  - Then soak the graft in a basin on the back table for at least 10 minutes in either an antibiotic solution or in a very dilute solution of povidone-iodine. Povidone has been shown to be cytotoxic to osteoblasts, so the solution should be weak and the surgeon must realize that this may result in death of any viable osteoblasts in the graft.
  - The graft can then be inserted directly from the antibiotic solution, or, if povidone solution was used, it should then again be irrigated to remove any residual iodophor.
  - If the graft happens to be cancellous bone, then adding an antibiotic such as tobramycin powder to the graft may be useful because cancellous bone graft has been recommended as a vehicle for local antibiotic delivery. Lindsey et al. (85) have shown that local Tobramycin does not appear to affect the normal healing characteristics of bone graft in a canine femoral defect.

Careful monitoring of the patient postoperatively and appropriate postoperative intravenous bactericidal antibiotics are appropriate. Counseling of the patient is wise.

AUTHORS’ PERSPECTIVE

For nonunions and major bone defects secondary to fractures for which lizarov techniques are not being used, we prefer autologous bone graft harvested from the iliac crest. If any significant amount of cancellous bone is needed, then we nearly always use the posterior ilium, in spite of the inconvenience of this operative site because of the large amount of bone available from this location. In addition, the morbidity of this harvest site is much less than one located anteriorly. Neither one of us does spine surgery, so the issues of bone grafting and spine arthrodesis will be addressed in the spine section.

For small fresh fracture defects, we harvest bone grafts from the metaphyseal section of the same limb segment or ipsilateral limb. For contained metaphyseal defects or have a bruit on osculation or palpation. Ultrasound or arteriogram, or both, is usually necessary to make a diagnosis, and vascular surgery consultation for surgical care. Most typically, these lesions present as a mass or swelling that may or may not be painful. On physical examination, they may be pulsatile or have a bruit on palpation or pulsation. Ultrasound or arteriogram, or both, is usually necessary to make a diagnosis, and vascular surgery consultation for surgical correction is nearly always indicated.

A. FRACTURE HEALING

Michael Madison and R. Bruce Martin

Spontaneously healed fractures are not uncommon in the skeletons of wild animals and in archaeologic human skeletons. This kind of fracture is typically a closed, locational discontinuity with only slight displacement of the bone and little or no soft tissue damage. Pain probably forced the uninjured person to protect his extremity until the fracture healed, and subsequent bone remodeling smoothed out any rough step-offs at the fracture site. The role of the surgeon in treating simple fractures of this type may indeed be as Voltaire characterized it: "to amuse the patient while nature heals the injury."

In the last 400 years, a fundamentally different type of fracture has become increasingly common. This is the high-energy industrial, vehicular, or ballistic fracture that overwhelms the body's capacity to repair it. It demands clinical intervention, the goal of which is to convert the fracture to a facsimile of a low-energy fracture that the body is biologically equipped to repair. If the reduction, fixation, and soft-tissue management of a high-energy fracture are successful, the fracture can heal by the same cascade of events that typifies healing of a low-energy fracture.

THE FRACTURE EVENT

Bone's lamellar and osteonal structures direct crack propagation in certain predetermined directions. The lamellar junctions and cement lines of bone are weak, and they crack more easily than the bulk of the material. These weak interfaces are oriented so that the cracks travel along and around the bone, rather than directly across it. Energy that would quickly break a bone is used in forming longitudinal or circumferential cracks that do not cause failure and that can be repaired by remodeling.

The material strength of bone differs in various modes of loading. It is strongest in compression, weakest in shear, and intermediate in tensile failure stresses. When a bone is fractured by compression, it tends to fail along planes that carry the highest shear stresses, which reach the failure level first; these planes typically are at an angle of 45° to the load direction. When a bone is bent, the highest stresses are tensile and compressive; failure begins on the tensile side and propagates toward the compressed side. When the crack enters the compressed tissue, it again tends to travel along the 45° planes of maximum shear, causing splitting, butterfly chips, or other types of comminution.

Bones loaded in torsion tend to break in tension and longitudinal shear because the transverse shear stress created by the twisting is across rather than along the fibers. The tensile stresses, however, lie at a 45° angle to the fibers and have only to separate them rather than to break through them to cause failure. Torsion typically produces a break that spirals around the bone at this angle and returns to its starting point along a longitudinal shear stress plane.

The greater the energy, the more likely the bone is to break into many pieces. The energy is propagated through the bone as a stress wave (similar to a sound wave or an earthquake), and the greater its magnitude, the more likely it is that many parts of the bone will reach a failure criterion simultaneously. The velocity of a stress wave in bone is about 3,000 m/sec. The energy required to break a bone is small compared with that encountered in daily activities.

For example, it takes only about 15 joules (J) of energy to break the shaft of an adult tibia or femur. The energy released when a 70 kg person falls to the ground from a standing position is about 500 J. The ability to absorb this energy using eccentric muscle contractions and deformations of soft tissues usually prevents fractures from occurring in insignificant falls. If this ability is impaired by surprise, restrictions, or incapacity, fracture occurs easily. The propensity of elderly people to fracture their bones easily reflects the weakness of their bones and the weakness of the muscles and ligaments that fail to adequately absorb the applied energy, which instead is transmitted to the bones.

Soft-tissue deformation absorbs energy during an accident in two ways. First, loads applied perpendicular to the tissues compress them and propagate stress waves up and down the body. The tissues effective in this way are skin, fat, and muscle (and fur on animals or clothing on humans). Second, tissues such as fascia, tendons, ligaments, joint capsules, and contracted muscles and ligaments absorb energy if they contract and become taut. Marrow and bone act as a filter that slows the energy propagating toward the bone.

THREE PHASES OF FRACTURE HEALING

In 1975, Cruess and Dumont proposed that fracture healing may be considered to consist of three overlapping phases: an inflammatory phase, a reparative phase, and a remodeling phase (21). This scheme, based largely on descriptive histology, has been widely reiterated. Others have divided fracture healing into four or five phases (30, 53, 59). These divisions are somewhat arbitrary and reflect differences in emphasis more than in content. Common to all is the concept that the fracture initiates a biologic cascade, a sequence of steps activated by and depending on the previous steps. For convenience, we describe fracture healing in terms of the three phases recognized by Cruess and Dumont, noting that the reparative phase combines several processes.

The inflammatory reaction immobilizes the fracture. Pain causes the patient to protect the injured part, and swelling hydrostatically splints the fracture. At the tissue level, the inflammatory phase is identical to the typical inflammatory response of most tissues to traumatic injury. Vasodilatation and hyperemia, presumably mediated by histamines, prostaglandins, and various cytokines, accompany invasion of the injury site by neutrophils, basophils, and phagocytes that participate in clearing away necrotic debris. Erythrocyte hemorrhages become organized as a reparative fibrous network that provides pathways for cell migration. It is also presumed that during the inflammatory phase, various noncollagenous protein growth factors that regulate cell migration and differentiation and that normally are trapped in the bone matrix are released into solution, where they become active (25, 59). The inflammatory phase peaks within 48 hours and is quite diminished by 1 week after fracture.

The reparative phase begins activated within the first few days after fracture and persists for many months. Its chief feature is the development of a reparative callus tissue in and about the fracture site that gradually is transformed to bone. The callus may consist of cartilage, fibrous tissue, osteoid, woven bone, and vessels.

The primary callus response is the direct response of bone to local inflammation, whether the inflammation is caused by fracture, infection, a foreign body, or a neoplastic process (44, 53). Two salient features of the primary callus response deserve mention. The first is that the response appears to be relatively independent of mechanical factors, as evidenced by the significant primary callus response to a foreign body or at the end of an amputation stump (i.e., half-fracture), or the cap of a callosus that may appear at the protruding end of a hollow intramedullary rod (44, 53). Second, the primary callus response does not continue indefinitely. If the primary callus (i.e., the provisional callus) has failed to unite two sides of a fracture within a few weeks, it may cease to grow and be resorbed, as may be observed of the callus at the amputation stump or on one side of a large segmental defect.

If the primary callus is successful in connecting the fracture ends, healing progresses to the stage of bridging callus or hard callus. Although bridging callus seems to imply the directed growth of tissue outward from the viable regions distal and proximal to the fracture, the hard callus seems to differentiate simultaneously throughout its distribution, rather than growing as an advancing front. Calcification of the callus may be by direct bone formation by osteoblasts or by endochondral ossification, depending on the local oxygen tension (6). Typically, growth of a large callus greatly outpaces the ingrowing vessels, and endochondral ossification predominates. In a small, mechanically stable defect, such as a drill hole, primary (intramembranous) woven bone formation predominates.

The cellular components of the callus derive chiefly from the marrow and the periosteum. The number of osteoblasts and osteocytes present at the time of fracture is insufficient to sustain the high anabolic demands of the growing callus. As the callus calcifies and becomes rigid, the fracture becomes internally immobilized, and the examiner may consider the fracture to be healed. The initial calcification is remodeled by osteoclasts and osteoblasts, leading to the replacement of calcified cartilage and woven bone by lamellar bone in the final (remodeling) phase of fracture healing. This phase represents the normal remodeling activity of bone, although it may remain accelerated in the region of the fracture for several years, replacing each volume several times over. In children, the remodeling phase proceeds more vigorously and includes modeling (independent resorption and formation) and remodeling (formation coupled to resorption). The result of the remodeling phase is a gradual modification of the fracture region under the influence of mechanical loads until it reaches some threshold of optimal shape, which typically is similar to the shape it had before fracture.
In the presence of perfect apposition of the fracture fragments and rigid fixation, as may be achieved for instance by compression plating an osteotomy, the callus response may be suppressed altogether. In this case, healing proceeds by normal osteonal bone remodeling. As an increasing number of osteons cross the fracture site, the two sides become united. Although primary bone healing has been considered by some to be a goal of fracture repair, it offers no particular advantage over normal, callus-mediated (i.e., secondary) bone repair (75,86). It proceeds very slowly, especially in adults, and the intermediate stages are weak. A second potential disadvantage of primary bone healing is that, unlike callus-mediated healing, it does not progress in an anaerobic environment.

**VARIABLES IN FRACTURE REPAIR**

**BLOOD SUPPLY**

The afferent supply to an intact long bone comprises three systems, which may anastomose among themselves (76,77 and 78,94,95). The medullary system, which chiefly supplies the diaphysis, derives from the nutrient artery. The metaphyseal system supplies chiefly the cancellous bone of the proximal and distal metaphyses and anastomoses with the medullary system. In a child with open physes, the epiphysis and metaphysis have separate blood supplies. After closure of the physes, these two anastomose and are thereafter referred to as the metaphyseal system.

The periosteal blood supply derives from vessels in the periosteum, especially at regions of fascial or tendinous attachments. These vessels penetrate and supply the outer third or less of the cortex. Wherever the surface of the bone is covered by articular cartilage, a periosteal blood supply is absent. Regions of bone in which a large proportion of the surface is articular, such as the talus, carpal scaphoid, and femoral head, are therefore at particular risk for ischemic damage after trauma because they lack a major source of vascularity (31,32).

The efferent vascular system of bone includes the medullary vein, which drains much of the medullary and endosteal cortical portion of the bone before exiting through the same foramen by which the nutrient artery enters, and a system of periosteal veins. Anastomosis between the afferent and efferent arms of the vascular system is through marrow sinuses in the medullary region or through small arterioles within the haversian systems. There is no capillary bed per se. Rhinelander observed that the principal direction of blood flow is centrifugal, from the endosteum to the periosteum (79). Parallel to this is a centrifugal bulk flow of interstitial fluid along a pressure gradient from approximately 20 mm Hg in the medullary canal to near zero peripherally (67,87).

The effect of fracture on the blood supply to a bone depends on the nature and severity of the fracture. In a minimally displaced fracture, the small vessels in cortical bone are disrupted, resulting in ischemic death of the osteocytes near the fracture line, but the major medullary and periosteal vessels may be sufficiently elastic to remain intact. The medullary system may be the primary source of the vascular hyperplasia that supplies the callus.

With a greater degree of displacement and disruption of the medullary vascular system, the metaphyseal or periosteal vessels may play a greater role in vascularization of the callus. Rhinelander considered that a fourth afferent vascular system, arising from adjacent soft tissues (especially muscle), could serve as the primary source of new vascular growth after a displaced fracture in which the medullary and periosteal systems were grossly disrupted (77,78). Support for this concept comes from the observation that fracture healing is enhanced by the use of muscle flaps. A study of segmental tibial fractures in dogs demonstrated significantly increased blood flow 30 days after injury for the fractures covered with muscle flaps compared with those covered by skin alone (79).

Vasoconstriction and angiogenesis occur rapidly after fracture. In experimental fractures of canine tibias, the regional blood flow near the fracture reached its maximum (six times normal) by 10 days after injury and was still elevated for 4 months later. Blood flow in the same tibia but distant from the fracture site was also elevated, reaching its peak 1–3 weeks after injury and declining gradually thereafter (68). Gupta et al. showed that blood vessels crossed the fracture line after about 3 weeks in fractured dog tibias (80). In humans, failure of transfixation vessels to form by 10 weeks, as indicated by osseous phlebography, is considered a sign of impending nonunion (74).

Internal fixation with plates and screws may cause periosteal ischemia directly beneath the plate, but the procedure otherwise does not interfere with regional revascularization (73). Placement of a reamed intramedullary nail obliterates the medullary blood supply, however, shifting the source of vessel ingrowth to the metaphyseal, periosteal, and soft-tissue systems (77). In a canine study, fixation with an intramedullary nail led to reduced blood flow at 14 and 90 days and reduced callus formation compared with fixation with a plate, although all fractures united regardless of fixation method (5). A nonreamed nail or a tight-fitting nail that is fluted leaves channels in the medullary cavity that soon are invaded by periosteal arteries.

The blood flow to bone can be manipulated pharmacologically by vasoconstrictors, vaso dilators, and their antagonists. Brinker et al. propose that use of these agents to promote local blood flow in bone may prove useful therapeutically in managing delayed unions or infected fractures (13).

**AGE**

It is well known that fractures heal much more vigorously in children than in adults. In elderly people, fracture healing may proceed very slowly, and what is normal healing in a 75-year-old patient would be a delayed union in a young person. Slow healing does not seem to be an inherent cellular problem of aging, because osteoblasts from trabecular bone grown in culture show similar metabolic characteristics regardless of the age of the donor (24).

**SEASON**

Circulating levels of vitamin D metabolites in geriatric fracture patients exhibit strong seasonal variation, with higher levels in summer, when solar radiation is greatest. It has been hypothesized that impaired dietary intake of vitamin D in the elderly shifts the balance toward endogenous vitamin D, which depends on solar ultraviolet radiation as a catalyst (56,57). This finding has been shown to correlate with the seasonal incidence of hip fractures, although an unequivocal relationship to fracture healing has not been demonstrated.

**SPECIES**

Rats and rabbits heal fractures very readily. Because neoteny has played a significant role in their evolution, rodents may be considered better models of fracture healing in human children than in human adults. Much experimental work on fracture healing and on bone induction that has been done on rodents cannot be assumed to apply directly to adult humans (12).

**TYPE OF MARROW**

At birth, most bones have red marrow. As a child ages, the red (hemopoietic) marrow in the appendicular skeleton is replaced by yellow (fatty) marrow, beginning with the toes and fingers and proceeding proximally. In the adult, the red marrow is confined chiefly to the axial skeleton, with a small amount of red marrow remaining in the proximal femur. Red marrow (i.e., highly osteogenic, and bones with red marrow (e.g., ilium, vertebral bodies, ribs) generally heal readily compared with regions of yellow marrow (e.g., tibial diaphysis).

**TEMPERATURE**

The "warm bones" (i.e., the axial skeleton) heal more readily than the "cold bones" (i.e., the appendicular skeleton) (40). The axial bones are also those that retain red marrow, a fact that may in part explain their more vigorous healing. Temperature, however, may also be a factor in fracture healing. It has been shown that fractures of vertebral bodies in mice heal much more rapidly when kept at higher temperatures (63).

**ENDOCRINE AND AUTOCRINE FACTORS**

Cortisone generally is catabolic for the skeleton and diminishes the size of a fracture callus. It also causes a deficit in the bone laid down during remodeling of the callus. Growth hormone, on the other hand, has the capacity to increase callus volume, but it is effective therapeutically only in the absence of normal endogenous growth hormone. Experimentally, growth hormone has accelerated healing in old rats (2). Parathyroid hormone and thyroxine increase the rate of bone remodeling; abnormally low values of these hormones reduce the rate of remodeling in the final phase of fracture repair. Serum calcitonin and 24,25-(OH)_2D_3 are significantly elevated during the first 6 weeks of fracture healing, but their effects on fracture healing are not entirely clear (57).

Disturbing the bone marrow (e.g., by reaming the medullary canal) appears to liberate a systemic circulating factor that stimulates bone growth or mineral apposition elsewhere in the skeleton. This phenomenon has been shown experimentally in rodents and in patients undergoing marrow aspiration (63,26). It has long been known
that patients with severe head injuries heal fractures very aggressively and have a high propensity to make heterotopic bone. Serum from these patients stimulates osteoblasts in tissue culture, compared with serum from patients with other fractures (8). These observations suggest that one or more circulating systemic agents may regulate fracture healing, but these agents have not been identified.

**METABOLIC BONE DISORDERS**

Fractures in patients with rickets or osteomalacia heal normally, but the resulting bone tissue has a mineral deficit. Similarly, fractures in osteoporotic patients heal normally, but the remodeled fracture site is osteoporotic.

**MECHANICAL ENVIRONMENT OF FRACTURE HEALING**

In general, the strength or stiffness of any structure depends on the product of a geometric factor and the strength or stiffness of the material within. If the geometric factor is made larger, the structure can be made of a weaker material and be just as strong (Fig. 10.1). A callus composed of material that is relatively weak, for example, can nonetheless achieve the strength of the intact bone if its diameter is greater.

**Figure 10.1.** For a bone loaded in bending by a force F, at any cross section there is tensile stress on the upper surface and compression on the lower surface. Consequently, there is a line through the middle of the section where the stress is zero; this is called the neutral axis. The contribution of each moiety of bone in the cross section is the product of its area and the square of its distance from the neutral axis. For a tube, the cross-sectional moment of inertia (CSMI) is \( I = \pi R^4 / 4 \). The section modulus equals the CSMI divided by R.

This principle governs the “engineering philosophy” of fracture healing: The strength and stiffness required for functional union are achieved rapidly by formation of a callus that has poor material but has a high section modulus (large diameter). Woven bone and calcified cartilage, although weaker than lamellar bone, can be produced two to five times faster. By locating much of this material farther from the center of the bone than the original cortex, nature compensates for the mechanical inferiority of the callus materials.

**Figure 10.2.** A typical long-bone fracture callus. The external callus is defined as that located outside the original bone cortex; the remainder of the callus is the inner callus. Assuming that the diameters of the endosteal, periosteal, and callus periphery are 10, 25, and 35 mm, respectively, the geometric properties of the callus are shown as percentages of the intact bone in the table. Note that the section modulus of external callus alone substantially exceeds that of the original and adjacent cortex.

Clinical intervention to stabilize the mechanical environment is one of the principles of fracture management. We now recognize that absolute rigidity should not be the goal of mechanical intervention, because it entails two potential disadvantages: Stress protection by fixation devices may cause bone resorption, and lack of motion at the fracture site inhibits callus formation (72). Fracture healing seems to benefit from a certain amount of controlled axial loading and micromotion, although how much is “just right” is unknown (34,45,54). Rib shafts heal with quite a bit of motion; a tibia probably tolerates much less. The use of less rigid materials (e.g., titanium rather than stainless steel) and the intramedullary rather than cortical placement of fixation devices (which decreases the sectional modulus) tend to increase the amount of micromotion at the fracture site (111). In a study of fractured dog femurs, Uhthoff et al. found that cortical bone loss due to stress protection beneath titanium plates was about one third that under stainless-steel plates, which were 50% stiffer than the titanium plates (87). Terjesen and Apalset found that 70% to 95% reductions in plate stiffness resulted in a 16% to 100% increase in callus size (92).

As a fracture heals, loads ideally should be borne increasingly by the bone and less by fixation devices. This gradual shift can be achieved by using unlocked intramedullary devices or by dynamizing locked nails or external fixators. Resorbable implants that are now on the market also have great potential for effecting a gradual transition of load bearing from the device to bone, provided that their resorption kinetics can be adequately regulated. Plates and screws are much less amenable to a gradual shift of load bearing to the bone.

**ELECTRICAL PHENOMENA IN FRACTURES**

When bone is mechanically loaded, so-called stress-generated potentials are produced by at least two mechanisms (1,35). Streaming potentials are produced when interstitial fluids are forced through the calcified matrix by dilatation of some regions and compression of others. Piezoelectric potentials are produced by deformation of the collagen molecules. Both electrical potentials are transient when produced by physiologic loads, because streaming occurs only while deformation is in progress, and piezoelectric potentials produced by a prolonged load are canceled by migration of oppositely charged particles produced in the interstitial fluids. A permanent electrical polarization is associated with collagen in bones, however, and this permanent polarization appears to be altered when fracture occurs (2). The fracture site becomes negatively charged (7). It has been postulated that this polarization is related to the cascade of biological events that result in repair.

This idea has its origins in the observation that cells in amphibian serum are morphologically altered when exposed to an electrical field (7,9). Because osteoblast stem cells may include circulating mesenchymal cells, investigators thought that stress-generated potentials might be responsible for the differentiation of osteoblasts and play a role in fracture healing and Wolff's law (i.e., a bone develops the structure most suited to resist the forces acting on it). Laboratory investigations show that bone formation is promoted in the neighborhood of a cathode, that fresh fractures in animals gain strength more quickly when electrically stimulated, that diuse osteopenia is inhibited by electrical treatment, and that bone and cartilage cells in culture exhibit increased DNA synthesis and other changes when electrically stimulated (28,29,35,43,47,52,65,66,82). These findings suggest that the functions of skeletal cells may be selectively altered by electrical signals arising from normal loading.
fracture, or clinical intervention. This hypothesis has been tested in numerous clinical trials involving various types of fracture nonunions.

The experiments have usually employed one of two methods for introducing alternating electrical currents in the bone. Brighton et al. implanted a cathode directly into the fracture site and passed about 20 µA of electricity to a supercutaneous anode (12). Bassett et al. passed electricity through a pair of wire coils disposed on either side of the fractured limb to induce an alternating magnetic field in the region of the fractured bone (5). Magnetic fields penetrate tissues much more readily than electrical fields, and the amount of current required is low enough to allow battery power. The alternating magnetic field induces similarly varying electrical fields and currents in the tissues at the fracture site.

Using these and similar methods, investigators have generally claimed that treatment of fracture nonunions has been substantially more dependable than more conventional methods (i.e., grafting). These claims have been disputed by critics who assert that the studies have not been adequately controlled. For various reasons, it has been difficult to do well-controlled human studies, but the laboratory work strongly supports the theory that electrical currents or fields modulate cell function in the skeleton. See Table 10.1 for a summary of factors influencing fracture healing.

### ASSESSMENT OF FRACTURE HEALING

Fracture healing is a continuing process that may progress for several years. Although the criterion is somewhat arbitrary, a fracture is usually considered healed when the bone can tolerate the loads normally experienced in everyday activities. Traditionally, healing has been determined by evidence of bridging callus on radiographs and by stiffness across the fracture site during clinical manipulation. These traditional measures of healing are sufficient for the purposes of fracture management, for some experimental studies or for careful evaluation of devices or techniques, however, a more precise determination of the progress of fracture healing is useful. Three general methods are currently available.

The motion of the bone across the fracture site in response to a known load can be measured; this is a refinement of the clinician's subjective feel of stiffness when she manipulates the fracture. Typically, a strain gauge attached to an external fixator is used to measure the deflection of a tibia in response to known applied loads (17,22). An example of fracture healing measured in this way is shown in Figure 10.3.

A second technique for measuring fracture healing is to cause the fractured bone to vibrate by tapping it with a hammer or vibrating it with a shaker, and then measuring the resonant frequency of the bone as a whole or the attenuation of the impulse as it crosses the fracture site (19,71). Healing is assessed by comparison to the intact, contralateral bone.

The third method of measuring fracture healing depends on measuring the velocity of an ultrasonic wave (from an ultrasound unit) across the fracture site (33). As the fracture heals, wave velocity increases. As with the vibrational tests, healing is measured by comparison with the contralateral uninjured bone.

### BIOLOGIC INTERVENTION IN FRACTURE HEALING

Although progress in treating fractures in the last 50 years has focused on perfecting the management of the mechanical environment, it seems likely that future progress will emphasize the biologic side of fracture healing. Currently, two avenues of biologic intervention are being developed. Stimulation of osteogenesis involves enhancement of the migration, division, differentiation, or metabolism of cells that normally carry out fracture repair. A clinical example is delayed primary fixation, in which surgical intervention a week or so after the fracture may reactivate or amplify the cascade of fracture healing (5). Electrical stimulation also is presumed to enhance osteogenesis, as is the therapeutic use of protein growth factors. Support of osteoconduction involves the provision of a substrate or scaffold along which osteogenic cells can migrate and on which angiogenesis and osteogenesis can occur. Provision of osteoconductive material is particularly important in repair of a segmental defect. Collagen is the natural osteoconductive material, although other proteins and ceramics are being used experimentally and clinically as osteoconductors. The combination of an osteoconductive material with a stimulant of osteogenesis promises to provide a very effective synthetic bone graft.

Although current clinical applications of biologic agents are still fairly primitive, this area holds great promise for further improvements in the regulation of fracture healing. Clinical application of biologic agents would fulfill a prophetic remark made by Dr. Girdlestone 70 years ago, when he foresaw the future of orthopaedics shifting from "carpentry to gardening."

### B. CLOSED TREATMENT OF FRACTURES AND DISLOCATIONS

**Michael W. Chapman**

**CLOSED VERSUS OPERATIVE METHODS**

In this century, especially since the 1970s, there has been a remarkable change in the treatment of fractures and dislocations. When I began my orthopaedic surgery resident training in 1963, the standard of care for fractures of the shaft of the femur was skeletal traction, which required an average of 3 months of hospitalization. The
The reasons for this tremendous change have been advances in anesthesia, improvements in sterile technique, and advances in the technology of internal fixation. We can now operate on patients who were previously not candidates for surgery, perform surgery with a minimal risk of infection, and internally fix on a reliable basis fractures that were previously not fixable. Operative treatment now dominates the treatment of musculoskeletal trauma to such an extent that residents today have far less training in the principles of closed management.

The predominance of operative methods in fracture treatment is driven by our outcome-oriented society. Patients expect not only that fractures will heal, but that they will heal in anatomic position with restoration of normal function. Often these expectations are unrealistic in view of the severe injuries that occur in our high-velocity society. Many injuries are now occurring in the context of the multiply injured patient, where the need for early mobilization makes nonoperative techniques impractical. For example, in the Orthopaedic Trauma Service at the University of California, Davis Medical Center, the average number of fractures per patient is 3.5. Surgical techniques offer the ability to restore anatomy close to normal. The rigid fixation obtained often allows earlier mobilization and rehabilitation, which optimizes the outcome.

Despite the many advantages of operative care, nonoperative care remains the foundation on which treatment of musculoskeletal trauma is based. There are many indications for nonoperative care, and modern orthopaedic surgeons must be as skilled in nonoperative as they are in operative techniques. A sound knowledge of nonoperative techniques also makes the use of operative techniques more effective and safer. Closed treatment requires as much thoughtfulness, technical expertise, and attention to detail as does surgery.

Although this textbook covers primarily operative orthopaedics, I feel it is essential to provide information on nonoperative care, and this information is scattered throughout the chapters in these volumes. This section of the chapter on closed treatment of fractures and dislocations lays the groundwork for the other chapters in this section of the text on treatment of fractures. Although modern textbooks on fracture care, such as those by Rockwood (80,81) and Browner (14) and their colleagues, cover these techniques in detail, the interested reader will find it very enjoyable and educational to go back to two classic works on fracture care, Watson-Jones's Fractures and Joint Injuries (98) and Charnley's The Closed Treatment of Common Fractures (18). A monograph by Bleck et al. (19) on plaster cast techniques and a manual by Freuler et al. (27) provide good detail on nonoperative management techniques using plaster and splints.

In nature, the vast majority of fractures heal in the presence of motion, although deformity is common. Union occurs because the vascular supply to the bone and surrounding soft tissues is usually good, and the physiologic stimulus of continued use of the limb enhances callus formation and strengthens the callus formed. In the initial healing process, an ensheathing callus is formed that begins to immobilize the fracture fragments. Early during fracture healing, motion can still occur at the fracture, but translation of the fracture fragments and shortening is usually impossible after the initial ensheathing callus has formed.

Charnley (19) draws an analogy to a fist gripping a stick (Fig. 10.4). Most bone in fracture callus comes from endosteal tissues, which quickly fills in the ensheathing callus. As it becomes progressively thicker, total immobilization of the fractured bone ends occurs. This method of healing has the mechanical advantage of producing a callus that is much larger than the fractured bone. It takes advantage of the increased moment of inertia created by the thick callus. After complete consolidation, in fact, this thickened area of bone is often stronger than the unaffected shaft (Fig. 10.5). The bone ends themselves are usually somewhat avascular because of the injury and do not directly participate in this early phase of healing.

Once completely immobilized within the callus, the bone ends are slowly revascularized and remodeled. The large peripheral callus is slowly resorbed and the shape of the bone returns toward normal after several years of remodeling. This type of union is virtually 100% successful in nature in ribs, clavicles, and membranous bones. In the mid diaphysis of such bones as the tibia, the limitations of blood supply and excessive motion produced by attempted use of the limb commonly lead to nonunion.

The purpose of nonoperative treatment methods, then, is to hold the broken bone in a position as close to its anatomic position as possible to prevent malunion, to reduce excessive motion in order to prevent nonunion, and to allow earlier function than would otherwise be possible. In addition, the immobilization substantially reduces pain.

By contrast, surgery, which involves soft-tissue dissection and direct mechanical trauma to bone, reduces the blood supply to bone and the surrounding soft tissues. Except for closed intramedullary nailing, bone union usually takes longer if operative methods are used. Because of the prolonged period necessary for revascularization, rigid fixation over long periods of time is usually required. With rigid fixation, bone union occurs by direct osteonal modeling and callus formation is suppressed; this results in slower and mechanically less strong union. The combined risks of devascularization, slower and weaker bone union, and operative complications must be offset by the advantages to be gained by operative treatment.

**GENERAL INDICATIONS FOR CLOSED TREATMENT**

**CHILDREN'S FRACTURES**

Internal fixation is almost never indicated in children, except for displaced intraarticular fractures; some avulsion fractures with wide displacement, such as those of the medial epicondyle of the elbow; and shaft fractures of the femur in older children who have severe, life-threatening multiple injuries. Certain fractures that are difficult to
manage by closed technique, such as supracondylar fractures of the humerus, are now routinely treated with percutaneous pin fixation.

Children have a tremendous capacity to remodel bone as they grow, and during the active growing years long-bone fractures of the lower extremity are commonly accompanied by some overgrowth. Nonunion is rarely a problem in children. Despite prolonged immobilization, in contrast to adults, the vast majority of children very quickly regain normal joint motion and muscle strength. For those reasons, children's fractures are nearly always treated with closed techniques. See Chapter 164 on the operative treatment of children's fractures.

UNDISPLACED FRACTURES

Undisplaced fractures are nearly always treated without surgery. Internal fixation is rarely indicated, as the fracture is in anatomic position and will heal rapidly. Notable exceptions include undisplaced fractures of the femoral neck, which usually require percutaneous pin or screw fixation to prevent displacement.

POOR BONE QUALITY

With our aging population, osteoporosis is becoming a common problem. Osteoporotic bone is very difficult to fix internally, and therefore nonsurgical methods are commonly indicated in the very elderly. Nonoperative treatment methods, however, can severely impede the mobility of the elderly. Methods such as cast-bracing are often used to avoid prolonged bed rest. Compromises are usually necessary so that early rehabilitation is possible. For example, Colles' fractures in the very elderly are almost always treated in short-arm casts rather than long-arm casts.

UNFIXABLE FRACTURES

Severe comminution, particularly with bone loss, is a common problem following high-energy trauma. Many intraarticular fractures, such as those of the tibial plateau and ankle, may not be fixable because of severe comminution. These cases require either external fixation or nonoperative methods.

SYSTEMIC CONTRAINDICATIONS TO SURGERY

Severe medical illness may contraindicate surgical intervention; and certain systemic diseases, such as an immunodeficiency, may make the hazards of surgery sufficiently high that nonoperative methods are required.

LOCAL CONTRAINDICATIONS TO SURGERY

Severe skin lesions, local skin infections, or other soft-tissue conditions may contraindicate surgery and make nonoperative methods necessary.

PSYCHOSOCIAL PROBLEMS

Certain types of operative intervention require excellent cooperation on the part of the patient to ensure an optimal result. Patients with psychiatric or personality disorders, or who otherwise cannot participate in postoperative care, may need to be treated by nonoperative means.

GENERAL PRINCIPLES OF CLOSED MANAGEMENT

INJURY MECHANICS AND SOFT-TISSUE HINGES

Fractures can be the result of direct or indirect forces. Direct injuries may break the bone directly under the blow, usually by imparting a bending force. Indirect injuries occur when the limb is twisted or angulated distally, causing a more proximal injury; an example is the spiral fracture of the tibia that occurs in the typical external-rotation, twisting injury associated with skiing accidents. When these injuries occur, the soft tissues tend to be disrupted on one side of the fracture and left intact as a hinge on the other. For example, in fractures of the tibia caused by bending forces, the periosteum and muscle envelope on the convex side of the fracture is often disrupted, but the soft-tissue envelope on the concave side remains intact (Fig. 10.6 and Fig. 10.7).

Figure 10.6. Soft-tissue hinge. When the fracture breaks because of bending, the soft tissues disrupt on the convex side and remain intact on the concave side. (Redrawn from Charnley J. The Closed Treatment of Common Fractures, 3rd ed. Baltimore: Williams & Wilkins, 1963.)

Figure 10.7. Three-point fixation. When the fracture is reduced and three-point fixation applied, the fracture becomes stable. (Redrawn from Charnley J. The Closed Treatment of Common Fractures, 3rd ed. Baltimore: Williams & Wilkins, 1963.)

Usually it is difficult for the patient to know the precise mechanism of injury, but it can be inferred by the configuration of the fracture. For example, in bimalleolar fractures of the ankle, a transverse fracture of the medial malleolus and a spiral fracture of the lateral malleolus are compatible with an external rotation-eversion force causing the fracture. With this knowledge, it is possible to reduce the fracture by reversing the mechanism of injury, taking advantage of the soft-tissue hinge to stabilize the fracture. With appropriate maneuvers, the soft tissues guide the displaced fragments back to their normal position. This mechanism applies to many fractures, including Colles' fractures and supracondylar fractures of the humerus and femur.

Knowing the location of the soft-tissue hinge allows the surgeon to take advantage of three-point fixation, which produces tension in the intact soft tissues and therefore compression across the fracture site. This compression immobilizes the fracture (Fig. 10.7). This principle is used in nearly all cast and splint immobilization of fractures. Applying the three-point fixation principle usually requires a splint or cast that appears overreduced. A straight cast will usually contain a crooked bone; a
curved cast will generally contain a well-aligned bone.

**SOFT-TISSUE BRIDGE AND FRAGMENT INTERLOCKING**

Although the intact soft-tissue hinge is usually an advantage, in some cases it can be an impediment to reduction. The best example is in fractures of the distal radius and ulna in children. The periosteum is quite thick. With complete dorsal displacement and overriding, straight longitudinal traction to reduce the fracture is ineffective because the soft-tissue hinge is too short to allow reduction of the fracture fragments (Fig. 10.8). In this case, reduction requires that the fracture be deformed, as in the mechanism of injury, and overreduced. Three-point fixation can then take advantage of the soft-tissue hinge to hold the reduction. Because of the extreme deformity required to reduce fractures of this type, it is usually advisable to do the reduction under general or regional anesthesia so that it can be gentle and need be performed only once or twice.

*Figure 10.8. A: Mechanism of fragment interlocking produced by an intact soft-tissue hinge, typically seen in fractures of the distal radius and ulna in children. Traction does not allow the fragments to be disimpacted and brought out to length. B: Reproduction of the mechanism of fracture to hook on the ends of the fracture. Notice that angulation beyond 90° is usually required. (Redrawn from Charnley J. *The Closed Treatment of Common Fractures*, 3rd ed. Baltimore: Williams & Wilkins, 1963.)*

**TRACTION**

The soft-tissue envelope and intact ligaments also provide an aid to reduction. An analogy is to picture pieces of macaroni strung on a string. When the string is loose, the pieces are haphazardly arranged; with tension on the string, they line up. The same principle applies to comminuted fractures of the shaft of the femur. Axial skeletal traction, by putting tension on the soft-tissue envelope around the femur, lines up the bone segments.

A soft-tissue impediment to traction alignment of fractures can be the hydraulic effect of soft-tissue swelling. Shortening in fractures is generally not caused by muscle spasm, but rather by the hydraulic effect of soft-tissue swelling. With bleeding and edema, the soft-tissue envelope around the fracture increases the pressure inside the deep fascia. Since the geometric shape that contains the largest volume is a sphere, the limb’s normal oblong, tubular shape becomes spherelike. The limb shortens, causing the bone fragments to override (Fig. 10.9). Traction to correct this overriding may cause compartment syndrome by elongating the thigh and increasing the intracompartmental pressure.

*Figure 10.9. Effect of hydraulics on fracture shortening. The normal shape of the thigh is that of a tube or sausage. With a fracture, hemorrhage into the thigh occurs, which causes it to assume the shape of a sphere, thus inducing shortening in the fracture.*

**FRACTURE STABILITY**

Oblique, spiral, and comminuted fractures are inherently unstable unless the soft-tissue envelope has been little disturbed. The initial radiograph often points to the degree of soft-tissue injury and instability. In fractures of the tibia with unstable patterns, plaster of Paris cast management alone usually results in shortening equal to that seen on the original radiograph (Fig. 10.10). Excessive shortening is a hallmark of more severe soft-tissue injury, and without special measures to prevent shortening, the fracture will heal in a shortened position. Transverse fractures with good end-to-end contact are stable against shortening; the challenge is simply to control angular and rotational deformity, which can usually be done with a cast or splint (Fig. 10.11).

*Figure 10.10. The amount of shortening seen on the initial postinjury x-rays indicates the degree of soft-tissue stripping that has occurred about the fracture site.*
In stable fractures such as this transverse fracture, shortening is rarely a problem, but care must be taken to avoid angulation and malrotation. If there is a good soft-tissue hinge and the potential for three-point fixation, then with proper immobilization many seemingly unstable fractures are potentially stable against shortening. A typical example is the Colles' fracture, which is inherently unstable in shortening. If the fracture is adequately immobilized with a three-point fixation cast, shortening can usually be prevented (Fig. 10.12).

DELAYED UNION AND MALUNION

Late deformity can be a problem in fractures that do not heal within the expected time. This is particularly a problem in the tibia, where weight-bearing treatment may make control of angulation difficult. In other fractures, the strong pull of one muscle group or another induces typical deformities such as late varus in intertrochanteric or subtrochanteric fractures of the femur, posterior angulation in supracondylar fractures of the femur, and varus in fractures in the shaft of the humerus.

PRESERVATION OF FUNCTION

In closed fractures, in the absence of sepsis, the joints above and below the fracture can be expected to gain nearly full anatomic motion and certainly functional motion, if the fracture heals within the expected time and immobilization is not prolonged. On the other hand, associated soft-tissue injuries, sepsis, and prolonged immobilization for treatment of delayed union or nonunion often lead to loss of joint motion and atrophy of muscle, which are difficult to reverse. Follow the simple rules in Table 10.1 to minimize problems with limb rehabilitation.

Certain fractures are best not immobilized at all, but treated with early, protected, gentle active motion. Examples are surgical neck fractures of the humerus in the elderly, stable fractures of the radial head and neck, and minimally displaced fractures of the calcaneus.

MATERIALS AND EQUIPMENT

Although skin-tight plasters were popular at one time, they are no longer used because they present the danger of pressure sores and compartment syndrome. Freuler et al. have shown that the additional immobilization provided by using unpadded plaster is not worth the many risks.

Tubular stockinet of cotton, synthetics, or a combination is available in widths from 2 to 12 inches and serves as a useful liner under most casts (Fig. 10.13). When treating fresh fractures, I prefer not to line the entire cast with stockinet because, if swelling occurs, the stockinet can be quite difficult to cut. Place the tubular stockinet only at the ends of the cast for trimming (Fig. 10.14). When applying stockinet around joints, avoid wrinkles by cutting the stockinet on the concave surface and overlapping it (Fig. 10.15 and Fig. 10.16). Tubular stockinet can be cut on the bias to produce a bandage material that is stretchable and conforms well to the extremity but is not elastic. It is very useful for overwrapping splints and soft dressings (Fig. 10.17). Heavier specialized knitted stockings are used for cast-braces where more uniform compression of the limb is desirable, and thicker material is necessary to protect the limb from the plaster, as the limb will be used much more actively in a cast-brace.
Figure 10.14. Tubular stockinet used to trim the ends of a short-leg cast.

Figure 10.15. To avoid wrinkles in the stockinet under casts, cut along the concave surface of joints.

Figure 10.16. After cutting the stockinet, overlap it to produce a smooth contour.

Figure 10.17. Tubular stockinet can be cut on the bias and is very useful for overwrapping splints and dressings.

For padding, most surgeons now use a sheet cotton commonly known as Webril that comes in rolls 2, 3, 4, and 6 inches wide (Fig. 10.18). This sheet cotton is fairly noncompressible and, if used thick enough over bony prominences, can serve as the only padding material in the cast.

Figure 10.18. Sheet cotton for padding casts comes in rolls in widths of 2, 3, 4, and 6 inches.

Felt is useful for providing extra padding and is available as black felt or a more dense white felt, available up to ½-inch thick. It can be stripped in half to produce thinner sheets as necessary. Also useful is synthetic foam padding with adhesive backing, which can be adhered to the limb over particularly sensitive or prominent areas. The disadvantage of synthetic foam is that it is more compressible and less likely to be effective.

Circumferential casts of differing materials have been used since first developed by the ancient Egyptians. The first plaster bandages were used by Andonius Mathijsen, a Flemish army surgeon, in 1852. The plaster of Paris used in plaster bandages is derived from gypsum. Plaster of Paris is made by pulverizing and heating gypsum to dehydrate it; the result is anhydrous calcium sulfate. When water is added, it crystallizes back into gypsum in an exothermic reaction. This exothermic reaction produces enough heat that if a cast is overly thick and laid on an impervious surface such as a plastic-covered pillow, second-degree burns can occur.
Commercial plaster bandages are made by coating gauze with the plaster of Paris, using starch as an adhesive.

Various chemicals are added to create different setting times and handling characteristics. Most plaster is available in either a standard or fast-setting variety. Extra-fast-setting plaster, which sets in 2–4 min, is useful in clubfoot casts on small children. Standard or fast-setting plaster requires 5–8 min. Setting times are affected by ambient temperature, humidity, thoroughness of wetting, and water temperature. Long crystal lengths make a stronger cast, and the ideal water temperature is about 22°C (72°F). The plaster should generally be soaked for about 4 min.

Commercial bandages are available in rolls 2, 3, 4, 5, 6, and 8 inches wide and in varying sizes of splints (Fig. 10.19 and Fig. 10.20). Splints are available in 3 × 15, 4 × 15, 5 × 30, and 5 × 45 inches. Luck describes the parameters affecting plaster strength and use (48).

Figure 10.19. Commercial plaster of Paris rolls are available in widths of 2, 3, 4, 5, 6, and 8 inches. The type of gauze used and the plaster formulation vary from manufacturer to manufacturer.

Figure 10.20. Plaster splints are available commercially in many sizes. Use them in multiple layers to create adequate strength.

Plaster rolls with elastic fibers in them are also available. The weave of the gauze and elastic fibers allows the cast to be applied more tightly and with more uniform molding over irregular surfaces. It is useful as the initial layer in cast-braces. It is very easy to apply elastic cast materials too tightly; use them with caution.

Plaster of Paris with incorporated resins that make the plaster stronger and more water-resistant is also available, but for the most part it has been replaced by entirely synthetic or fiberglass cast materials. These materials are lightweight and strong and can be applied in much thinner constructs than plaster of Paris. They are not weakened by immersion in water. They are available in many colors and are very popular with patients. The disadvantages of the synthetic materials are that they are far more expensive, much more difficult to apply, and not as versatile as plaster of Paris. In addition, it is very difficult to mold fractures through synthetic materials, and they are generally not used in the initial treatment of unstable fractures. Because of the rigidity of the fiberglass, they cannot be spread. They can, however, be quite useful as an overwrap of one or two layers on regular plaster of Paris casts to increase their strength and protect the outer surface. Allergy is also more common with the synthetic cast materials; in plaster of Paris, it is nearly unheard of.

Other materials useful in the cast room are gauze rolls, tape, muslin bandage, elastic (Ace) bandages, and various dressing materials. A plentiful supply of good-quality disposable rubber gloves is essential, as plaster should always be handled with gloved hands to prevent the rough texture of your skin from dragging the plaster out of the gauze as it is rubbed, producing a rougher and less desirable cast finish. Cornstarch and baby powder are useful for dusting the skin, particularly where skin contact, such as in the axilla, may result in irritation. Do not use talcum powder, as it is too rough.

Small blocks of wood or commercially available plastic cast wedges are useful for cast wedging and holding split casts open. Long wood sticks or rolled newspapers are useful for making reinforcing bars for shoulder and hip spica casts. An indelible pencil for writing the diagnosis, drawing the fracture, or entering other useful information on the cast is handy (Fig. 10.21).

Figure 10.21. An indelible pencil is useful for writing on casts. When using an oscillating saw, be sure that the blade is sharp and does not overheat. Use one finger as a fulcrum on the cast to stabilize the blade and cut by pushing downward (arrow) and pulling upward (arrow) when the cast saw is moved along. Avoid bony prominences. Never draw the saw longitudinally, as it can cut skin.

Equipment essential to a well-furnished cast room includes hooks in the ceiling for suspension, broad stainless-steel or synthetic work surfaces on which to spread plaster, mechanical or hydraulic tables that can be elevated for plaster application, special orthopaedic tables for the application of spica casts, bandage scissors, disposable #10 and #20 blades, an electric cast saw with an attached vacuum (Fig. 10.21), and special tools for cutting, bending, and splitting casts (Fig. 10.22). Various types of foam-rubber bolsters and stands or devices for supporting the limb during plaster application are available and are quite useful, particularly when the surgeon must work unassisted.
GENERAL PRINCIPLES OF APPLICATION OF PLASTER OF PARIS CASTS

The application of a standard below-knee cast will be used to demonstrate the general principles of plaster cast application.

APPLICATION OF A SHORT LEG AND SARMIENTO CAST

Positioning

If you are working with an assistant, have him support the leg with one hand in the popliteal fossa and support the ankle in a neutral position with the other hand. If the forefoot is grasped with the extended fingers and thumb through the first toe web space, it is easily held without fatigue, and the cast can be applied over the assistant's fingers with ease. The additional width produced by the assistant's hand also leaves more room for the toes to move once the cast is completed (Fig. 10.23).

If you are working alone, several different techniques are possible. In Fig. 10.24, the patient holds a muslin bandage to maintain the foot in a steady position with the ankle at 90°. In unstable tibial fractures, the thigh can be supported on a well-padded arm board, using an ankle traction bandage with a pail attached; water can be poured into the pail to provide some traction for stabilization of the limb. Placing the forefoot on the knee (Fig. 10.25) helps stabilize the limb, holds the ankle at 90°, and allows the surgeon to control rotation. This technique is described in more detail in Chapter 24 on fractures of the tibia and fibula, where the removable ankle-traction bandage is illustrated in some detail.

Padding

Apply end pieces (Fig. 10.14) or a full-length stockinet (Fig. 10.15), or if desired start with Webril. As mentioned, full-length tubular stockinet is generally not
recommended on acute fractures. The general rule in the use of Webri is to use the smallest width practical for the limb and to hold the Webri off the limb, keeping it under constant tension. The smaller-diameter roll allows the Webri to contour to the limb more easily. The tension helps apply it smoothly and allows the Webri to tear when it needs to go around sharp corners such as the heel.

- Begin at the metatarsal heads. Cover the toes so that adequate Webri is present to protect the toes from plaster and so that a turnback of Webri can be done at the completion of the cast for padding the end.
- After applying five layers around the metatarsal heads, begin to progress up the foot, overlapping the Webri to produce at least two layers of thickness and, depending on the application, a maximum of four; for most cast applications, two layers is sufficient. Note that the surgeon has skipped the heel with the Webri (Fig. 10.26).

**Figure 10.26.** Application of Webri. Hold the Webri off the extremity and apply it with tension to achieve a smooth wrap two to four layers thick.

- Winding figure-eight Webri around the heel and instep results in inadequate padding of the heel and too much Webri in the instep. The former will result in a heel sore, and the latter will make cutting of the Webri very difficult if the cast needs to be split.
- Pad the heel with separate, independent strips of Webri that are torn so that they do not overlap the anterior aspect of the cast.
- Apply five layers of Webri over bony prominences and the heel if felt is not used (Fig. 10.27). If the Webri does not conform well, simply pull away the loose border, leaving a smooth layer of Webri behind (Fig. 10.28).

**Figure 10.27.** Pad the heel with separate strips of Webri. Do not use a figure-eight wrap, which places too much Webri over the instep.

**Figure 10.28.** When applying Webri, loose edges can be smoothed by simply pulling them away.

- Carry the initial short-leg section as high as the tibial tubercle, wrapping the Webri well above the patella. The padding shown in Fig. 10.29 is also suitable for application of a Sarmiento short-leg walking cast.

**Figure 10.29.** The Webri padding has been completed.

### Plaster Application

- Fill a plaster bucket with clean tepid water (70° to 75°F). If considerable molding is necessary, or if a fracture must be reduced within the plaster, use cold water. If a fast setting time is desired, water up to 95°F can be used. Avoid water over this temperature, as the hot water combined with the exothermic reaction of the plaster may be hot enough to injure the skin.
- Assemble all the plaster needed to apply the cast before dipping any plaster in the water. For a short-leg cast on an average 70 kg male, one 4-inch roll for the foot and three 6-inch rolls for the leg usually suffice. To reinforce the bottom of the cast or to add a walker, 10 to 15 thicknesses of a 5 × 15-inch splint, overwrapped with a portion of a 4-inch roll, suffice.
- If the water temperature is cool and the surgeon applying the cast is skilled, all the plaster rolls can be dipped simultaneously. All the rolls will set nearly simultaneously, providing ideal bonding between the layers of plaster. If warmer water is used or if the applier is less skilled, dip the rolls in sequence; preferably, have an assistant dip them.
- Move rapidly to allow adequate time for rubbing in the plaster and molding.
- Turn back a tail on the plaster gauze to help identify it after the plaster is wet. Dip the roll vertically into the water. The water must be deep enough to cover the plaster rolls even after the several rolls are dipped. Be sure the water is clean: water that is cloudy with plaster of Paris from previously applied casts will accelerate the setting of the plaster.
- Let the rolls stand in the water until no more bubbles rise from the roll (Fig. 10.30). If several rolls were dipped simultaneously, lift them all out at once and,
without squeezing, allow them to drain vertically on the tabletop.

**Figure 10.30.** Dip the plaster rolls vertically in a bucket of clean water at 70° to 75°F; allow the roll to soak until all bubbles finish rising from it.

- Take the first roll to be used, grasp it at both ends, and squeeze it between your palms like an accordion. This technique will express excess water out of the plaster without distorting the roll and without losing excess plaster from the gauze (Fig. 10.31).

**Figure 10.31.** Gently squeeze the water out of the roll by accordioning it from either end. Twisting or manipulating the roll will result in excessive loss of plaster.

- Do not twist or overmanipulate the rolls; twisting them makes them more difficult to work with and it squeezes excess plaster out of the outer layers of the roll. The assistant, if present, should hand the roll to the surgeon with the free end exposed and readily available.
- The general principle in applying plaster is to use the widest roll that can be applied to the extremity in a practical manner. In this way, the plaster is applied rapidly with a minimum of seams.
- Begin with the 4-inch roll around the metatarsal heads. Apply it distally to the middle of the toes. Use the 4-inch roll entirely on the foot. As much as possible, allow the plaster to roll on the surface of the extremity.
- Push the roll; rarely if ever pull it. Usually it is possible to change the direction of the plaster not by picking up the roll but simply by taking a tuck. For extreme direction changes, it may be necessary to pick up the roll, but avoid pulling the plaster (Fig. 10.32). Once the plaster is started in a figure-eight wrap around the foot and up around the lower ankle, it will usually seek its own course and nicely cover the foot without any special effort to change its direction.

**Figure 10.32.** A: Begin with a 4-inch roll at the metatarsal heads; use this roll on the foot and ankle. Notice that the plaster roll is pushed, not pulled. B: To change the direction of the roll, place the leading edge in the direction you want the roll to go. This maneuver produces a loose corner of plaster, seen here in the surgeon's left hand. Take a tuck with the left hand and smooth it down on the posterior aspect of the leg. For sharp changes of directions, pick up the roll with the right hand, but in general leave the roll on the extremity.

- Next, take a 6-inch roll, begin on the foot, and move rapidly up the leg. Apply a single layer of plaster all the way to the knee. The art of rolling plaster smoothly and skillfully now comes into play. If the plaster roll begins to progress upward on the extremity at too sharp an angle, it must be brought back to a transverse direction around the limb by taking a tuck. Do so by sliding the fingers of the assisting hand underneath the edge of the roll closest to you and gently sliding the plaster back to a horizontal relationship to the longitudinal axis of the limb and then smoothing out the tuck produced. It is best to place tucks over soft tissue rather than bone (Fig. 10.33). When crossing joints on their concave surface, slide the roll so that it passes smoothly over the concavity.

**Figure 10.33.** On the midportion of the limb, take tucks by slipping the hand under the near edge of the plaster and sliding it until it is transverse to the long axis of the limb. Smooth out the tuck posteriorly and continue rolling.

- Avoid pulling the edge of the roll into the angle of the instep, popliteal fossa, antecubital fossa, or other, similar areas. After each roll is applied, thoroughly rub in the plaster until the gauze pattern can no longer be seen. Rubbing ensures that the layers will unite into one solid, strong layer of plaster, rather than be laminated. This difference is illustrated in Figure 10.34.
Figure 10.34. A: These cross sections from well-molded splints show no evidence of lamination. The layers of plaster have consolidated into one solid piece. B: In this inadequately molded cast, the layers have laminated and are peeling apart, producing a very weak cast.

- Once enough plaster has been applied, thoroughly rub the cast in and mold the plaster. Special three-point molding may be necessary to maintain fracture position. Do this type of molding with the flat of the palm so that the areas of molding are broad, with the compression distributed over a broad area of soft tissue.
- Try to avoid any direct pressure on bony prominences unless the area is well padded.
- Do not use your fingers or fingertips; they dent the plaster, producing areas of high pressure. Molding pressures must be gentle; hard molding nearly always results in skin problems and pain.
- Plaster applied to the foot will set first (because it was applied there first). Begin molding distally. Mold to match the arch of the foot, restoring both the longitudinal and transverse arches (Fig. 10.35). Then gently mold the plaster with your palms from anterior to posterior to bring out the relief of the malleoli. This molding provides a snug fit to the anterior aspect of the leg, which provides support for the tibia. It pushes more plaster to the posterior aspect of the cast, creating a channel for the Achilles tendon and posterior muscles to function, making a more functional cast (Fig. 10.36).

Figure 10.35. Once all the plaster has been applied and rubbed in, begin molding at the foot. Restore the longitudinal and transverse arches of the foot.

Figure 10.36. In the region of the ankle and shaft of the tibia, gently pull the plaster with the palms of the hands from anterior to posterior to mold it carefully about the malleoli and secure a snug fit to the shaft of the tibia.

- Stop the molding as soon as the plaster begins to set—you will feel it stiffen—to avoid cracking the plaster or producing buckles in the cast. Let the plaster come to a firm set. If splints are to be used to reinforce the cast, apply them between the next-to-last and the last roll of plaster, thereby incorporating them into the cast. The use of splints is discussed in detail later in this chapter.

Trimming the Cast

As soon as the plaster has set well enough that it will not break when handled or set on a padded surface (usually 7–10 min after dipping of the plaster), trim the ends of the cast.

- I prefer to use a disposable #10 or #20 blade. It is quick, produces a very smooth edge, and is much more effective than a cast saw on a “green” cast. If the cast is allowed to dry, then a cast saw must be used. Take care to avoid cutting the patient or yourself when using a knife. A cast of appropriate thickness is easy to trim, is not too heavy, and does not give off too much heat during setting. In casts for the lower extremity, the average thickness should be about ¼ inch on nonreinforced surfaces and no more than \( \frac{5}{16} \) inch or so on reinforced surfaces.
- The trick to trimming with a knife is to make a cut in the edge of the plaster and produce a corner that the fingers can grasp easily. Set the blade into the cut and pull the plaster against the knife blade while gently pushing down with the blade; the plaster will usually cut quite easily. If you find that you must push considerably with the knife, get a new blade or change to a cast saw to avoid injuring yourself or the patient (Fig. 10.37).

Figure 10.37. A green cast is easily trimmed with a disposable #10 or #20 blade, following the instructions in the text.

- In standard short-leg casts, trim the cast to the base of the toes, leaving the metatarsal heads covered. If necessary, spread the cast at the end to allow full range of motion for the toes. Toe plates are generally contraindicated as they restrict motion of the toes. Use them only if the cast is being applied for toe pathology.

Trimming the Cast Ends

There are two easy methods for producing a neat, well-padded end to the cast.

- Turn a cuff of Webril to cover the plaster and then turn back the tubular stockinet (Fig. 10.38). If stockinet is not used, cut the plaster and Webril on the lateral aspect of the fifth toe and medial aspect of the great toe, turning back the cuff to an appropriate level.
When tubular stockinet is used, trim the edge of the cast just distal to the metatarsal heads, turn back a layer of Webril to pad the end of the cast, and turn back the tubular stockinet, securing it in place with a few wraps of circumferential plaster.

Then incorporate either the stockinet or the Webril with a few turns of a fresh roll of plaster (Fig. 10.39).

If tubular stockinet is not used, cut the Webril and plaster on the lateral and medial aspects and turn it back to produce a soft cuff, which is then secured with a few turns of fresh plaster.

When trimming surfaces such as the abdominal hole in a spica cast where it is not easy to use a roll, the Webril or stockinet can be adhered to the cast by first stapling it in position (using a staple short enough that it will not penetrate the full thickness of the cast). Then trim with two layers of splints cut to fit the area, or take a sloppy, wet roll of plaster and coat the raw Webril, thus incorporating it into the surface of the cast.

A completed and trimmed Sarmiento short-leg, weight-bearing cast is shown in Fig. 10.40 (described in detail in Chapter 24). I have modified the trimming of the upper end of Sarmiento’s cast: I begin the trim proximal to the patella and carry it directly posteriorly to the hamstrings. A channel for the hamstrings is then created sufficiently deep to allow the flexion desired. Notice that the cast is molded above and extends almost horizontally posteriorly over the femoral epicondyles (Fig. 10.40C). The upper edges are bent away to allow full extension of the knee. On the front view, notice that the cast is molded in well over the epicondyles of the femur, and around the epicondyles of the femur, is more important to obtain good rotational control proximally. Note that the cast is trimmed out posteriorly to allow good knee flexion without impingement on the hamstring tendons. Avoid pressure over the common peroneal nerve at the fibular head. I prefer this molding and trimming of the Sarmiento cast to that more traditionally described because it is technically simpler to do and resembles the configuration of a patellar tendon suspension (PTS) below-knee prosthesis, which provides better molding at the knee.

A long-leg cast can be made from a short-leg cast whether the initial cast was applied at the standard short-leg level at the tibial tubercle or was extended to a Sarmiento-type cast for a better hold. As long as Webril has been applied well proximal to the plaster, then the next plaster rolls can simply be applied over the upper end of the short-leg cast and then extended up the thigh.

Some surgeons prefer to petal the upper end of the cast and turn the plaster back, placing an additional roll of Webril beneath it to ensure that padding is adequate at the upper end of the cast (Fig. 10.41). The petals are then turned down and the plaster for the thigh portion is applied.

Three or four 6-inch rolls are usually sufficient for the average-size man, and a 10-layered 5 x 30-inch splint is often useful to reinforce the knee. I prefer to apply the splints as a V, with the point of the V placed in the region of the tibial tubercle and the vertical arms carried up the medial and lateral aspects of the knee. The
splints are thus at right angles to the plane of flexion and extension of the knee and provide maximum reinforcement. Carry the average long-leg cast proximally over the prominence of the greater trochanter and leave at least a handbreadth below the groin to facilitate perineal care. This space makes it simpler for the patient to sit on a toilet, yet the cast still provides good support proximally. The molding for this cast is well described in Chapter 24 on fractures of the tibia and fibula. A well-molded, completed cast for weight-bearing is shown in Figure 10.42.

Figure 10.42. Long-leg weight-bearing cast. A: Notice that the below-knee portion of the cast is molded exactly as described for the Sarmiento cast. Just above the femoral epicondyles and patella, mold the plaster on the medial and lateral sides to provide good rotational hold about the distal femoral condyles. Molding pushes plaster anteriorly and posteriorly, creating channels for the hamstring and patellar tendons. Mold the plaster proximally like a quadrilateral socket. Notice the oblique angle that carries the plaster up to the level of the greater trochanter. B: Notice the anatomic molding of this cast. The knee is in about 5° to 7° more flexion than necessary.

- Apply walking casts with the knee nearly in full extension. Avoid hyperextension or full extension, which may result in knee discomfort. Usually 5° of flexion is appropriate.

Walking Shoes and Heels

Most surgeons today use commercially available walking shoes (Fig. 10.43). The walking shoe is removable; the patient can take it off at night to make the cast lighter and to avoid getting the bed linens dirty. A walking shoe also provides some protection for the foot portion of the cast.

Figure 10.43. Commercial-type walking shoe.

For the agile, physically active patient, a walking heel is an excellent alternative. Its smaller surface area allows the foot to twist on the floor more easily than with cast shoes (Fig. 10.44). Because it places the patient’s foot somewhat higher off the floor, the walking heel gives a wider range of motion for the knee during gait.

Figure 10.44. Applying a walking heel. A: Before trimming the cast, apply a 10- to 15-layer splint along the plantar aspect of the foot and up the back of the heel. Place the walking heel at the mid foot and pack plaster underneath it to place it at right angles to the foot in both the longitudinal and frontal planes. B: Secure the walking heel to the cast with a 4-inch roll of plaster, thoroughly incorporating the heel. C: The completed walking heel is at right angles to the longitudinal axis of the leg. D: The walking heel is in the middle of the foot. If the heel is placed too far anteriorly, the patient will back-knee; if placed too far back on the heel, the patient will contact on the forefoot and break down the cast.

DELBET CAST

The Delbet cast is a short-leg walking cast that leaves the foot free—in essence, a cylinder cast of the leg. It is useful when full foot and ankle motion is desired and a mid-shaft fracture of the tibia and fibula is fairly stable. Because these casts tend to slip down and cause pressure on the foot, a heel cup and ankle hinge are usually attached for suspension (Fig. 10.45).

Figure 10.45. A: A Delbet walking cast is applied in exactly the same manner as a Sarmiento cast. Distally, the foot is left free, and the cast is molded carefully over both malleoli and left high enough above the instep and heel to allow full ankle motion. Suspension usually requires application of an ankle hinge with a heel cup. B:
This side view shows the molding over the malleoli.

**CYLINDER CAST**

The cylinder cast is used to treat ligament injuries of the knee and stable fractures about the knee joint where rotational control is not of great concern. Generally, it is used as a weight-bearing cast; therefore, the foot is left free.

Application is simplified by supporting the foot on a second table or stool with the lateral or medial side of the knee downward, depending on which side has the ligament injury. In a medial collateral ligament injury, place the lateral side downward. Gravity automatically reduces the knee joint (Fig. 10.46A). This is also a good position for control of cruciate ligament instability.

**Figure 10.46.** Cylinder cast. A: For a medial collateral ligament injury, place the foot on a supporting surface and rotate the limb so that the lateral side is downward. Gravity therefore closes the medial joint line. Use the opposite position for a lateral collateral ligament injury. In this case, a skintight cast is used by rolling a snug stockinet over the leg. Use Webril to pad around the bony prominences at the ankle and the knee, and trim the cast at the hip. Place two layers of Webril down the anterior aspect of the cast for removal with a cast saw. The plaster is now applied directly over this padding and the stockinet. B: The completed cylinder cast has been carefully molded to the leg, particularly above the femoral condyles to provide suspension. Note that the cast stops well above the malleoli so that if it drifts downward, it will not touch the malleoli and cause pressure sores.

Suspension of these casts can be challenging. Adhesive ointments such as Ace adherent or tincture of benzoin can be applied to the extremity and then a snug tubular stockinet rolled over it to adhere the cast to the leg. Strips of adhesive tape on the leg turned up into the cast from the lower end serve the same purpose. All of these methods have the disadvantage of placing a chemical adherent beneath the cast, which may elicit an allergic response. In the lean athletic leg, good molding of the cast (Fig. 10.46B) will result in adequate suspension. In obese patients, suspenders may be necessary to keep the cast up.

**LONG-LEG CAST-BRACE**

The long-leg cast-brace always incorporates hinges at the knee, either polycentric metal hinges or plastic hinges. The ankle can be hinged as well. Rotational control, particularly for treatment of fractures of the middle to proximal femur, can be facilitated by adding a hip hinge. The cast-brace was developed during the Vietnam War for the treatment of fractures of the shaft of the femur. It can also be used for treatment of tibial plateau fractures. It is most useful for treatment of supracondylar fractures of the femur. Shaft fractures can also be treated, but the incidence of shortening and malunion is significant. It has even been extended to the treatment of subtrochanteric fractures of the femur.

**Figure 10.47.** Long-leg cast-brace with hip hinge. A: The specialized equipment needed for application of a long-leg cast-brace: two types of hinges, a polycentric steel one and a polycentric plastic one; a quadrilateral plastic socket for the upper thigh and plastic heel cup with plastic ankle hinge; a cast-brace stocking (extra heavy and specially padded); adhesive synthetic pads and an elastic wrap for the knee; corset-bending irons for adjusting the knee hinges; and a jig and hose clamps for holding the hinges in proper position.

- Apply the special heavy stockinet over the limb and the elastic sleeve over the knee (Fig. 10.47B).
- Place synthetic adherent pads over the tibial head and malleoli. A plastic quadrilateral socket at the upper brim may or may not be used.
- Apply a well-molded long-leg cast as already described, or apply the cast in a leg and thigh section (Fig. 10.47C).
- Carefully locate the lateral and medial epicondyles of the femur and mark them with a pen. The center of a metal polycentric knee hinge will be placed directly over the epicondyles.
- Carefully mold the hinges to fit the lateral and medial sides of the leg, avoiding impingement of the metal on bony prominences. Both hinges must be located symmetrically and parallel to each other, in line with the knee's axis of bending.
- Apply the hinges to the cast with the jig and hose clamps and incorporate them well into the cast (Fig. 10.47D).

In the completed cast-brace shown (Fig. 10.47E), the ankle is incorporated into the cast and a hip hinge and wristband are added to increase proximal control.

With the advent of closed intramedullary, interlocking nailing, cast-braces are little used today in North America for the treatment of fractures of the shaft of the femur. Interested readers will find the articles of Mooney (61,62) and others (20,36,46,55,58) worth reading, particularly for details of the technique of application. Many fractures in the lower extremity cannot be treated by internal fixation, so we use cast-bracing with reasonable frequency. It should be part of the repertoire of every orthopaedic surgeon treating lower-extremity fractures.

**HIP SPICA CASTS**

A spica is a bandage that is applied in successive V-shaped crossings, resembling a spike of grain (the meaning of the Latin word spica); this configuration is produced by a figure-eight wrap around the torso and then around the limb. With the advent of internal fixation, spica casts are little used in adults, but they are commonly used in children for the treatment of hip dysplasia, for postoperative immobilization, and for the treatment of fractures.
**Children's Single-leg Hip Spica**

A pediatric, tabletop adjustable orthopaedic table (Fig. 10.48A) greatly facilitates the application of the single-leg hip spica cast in children. Sometimes spica casts can be applied with just heavy sedation, but usually an anesthetic is required.

**Figure 10.48.** Pediatric hip spica cast. See text for details.

- Support the child's shoulders and upper thorax on the table and the pelvis on the perineal post, which should be well padded.
- A single assistant can support the legs and apply any traction necessary (Fig. 10.48B).
- Trimming of the cast is greatly facilitated by first applying tubular stockinet. One size of stockinet will be necessary for the torso and another for the lower extremity.
- Thoroughly pad with Webril. Felt is usually unnecessary in children, but small ¼-inch-thick pads can be placed over the anterior superior iliac spines, around the rib cage, and over the sacrum if necessary.
- If only one surgeon is available, it is usually easiest to apply the long-leg cast first as a cylinder from the ankle to the hip, carefully molding it and allowing it to set. The direction of the spica wrap used to move up onto the torso is illustrated in Figure 10.49A.
- Then the cast can progress up onto the torso. If two sets of hands are available, the torso and long-leg portion can be applied simultaneously, which provides better integration between the long-leg cast and torso portion. Extra padding around the upper edge of the cast at the ribs makes it more comfortable.

The specifics of how the plaster is best applied are outlined as follows. In general, the cast should extend from the xiphoid process to the metatarsal heads.

- The initial rolls of plaster should be fairly thin (usually three or four layers) (Fig. 10.48C).
- To avoid a cast that is too heavy and to reinforce it where the stress is greatest, apply five-thickness splints on the lateral aspect of the extremity, extending up onto the torso. Also, wrap a splint around the upper chest cage and around the pelvis to reinforce the edge of the cast, which will become the border for the perineum and buttocks.
- Thoroughly wrap these in with another series of rolls of plaster, taking care to not make the cast too thick.
- Create a generous hole over the abdomen to make breathing easy and to ventilate the cast. To facilitate the abdominal hole, cut a star with the cast saw (Fig. 10.48D). It is then easy to bend the flaps upward and cut them off with either the cast saw or a sharp scalpel.
- Trim the cast well above the perineum to avoid soiling. Over the buttocks, allow adequate room for bowel movements; do not trim the cast above the prominence of the sacrum, however, as the patient's buttocks will protrude out of the cast posteriorly and develop pressure sores on the upper sacrum.
- In a single-leg hip spica cast, trim the opposite hip to allow flexion to 90°. Carefully trim the cast to make it comfortable. Softening the upper edge of the cast with a cast bender after the plaster has set makes it more comfortable.
- When the cast has been completed, apply 2- to 3-inch-wide plaster splints to trim and seal the tubular stockinet down to the cast. (The cast in Fig. 10.48E is about 2–3 inches below the xiphoid, which is somewhat too low. Most patients are more comfortable if it is at the level of the xiphoid.)

**Adult Double or 1½ Hip Spica Cast**

The principles for application of an adult double or 1½ hip spica cast are the same as those for the children's. In adults, a fracture table is essential. Figure 10.45A shows an anesthetized patient on the fracture table with a long-leg cast already applied to the left lower extremity to stabilize an unstable knee.

**Figure 10.49.** Adult double-hip spica cast. See text for details.

- Place the patient supine on a fracture table (Fig. 10.49A). Note the padded perineal post and special foot plates. Plaster can be applied directly over the foot plates, and they can then be slid out of the plaster; this is a very convenient feature. The knees are held in 10° or so of flexion by knee supports, which are also slid out of the cast after application.
- In adults, use felt to pad all bony prominences. A single sheet of ¼-inch-thick felt around the pelvis provides good padding over the sacrum and anterior superior iliac spines (Fig. 10.49B). Rubbing the felt over the end of a smooth-ended pole or stick will produce a small bulge in the felt that fits nicely over the anterior superior iliac spine or other bony prominences. Run a similar sheet of felt about 3 inches wide up the entire length of the spine, and apply another sheet around the upper edge of the cast.
- The nearly completed cast before application of the feet is shown in Fig. 10.49C. Trimming has yet to be completed, although the abdominal hole has been cut out. Shown in the photograph are the locations of the splints used to reinforce the cast. The cast should consist of an initial layer of plaster of about four thicknesses, overlaid by splints, and then thoroughly incorporated with rolls. The reinforced regions should be about ½ inch thick and the nonreinforced portions about ¼ inch thick.

**Adult Weight-bearing Single Hip Spica Cast**

The weight-bearing single-hip spica cast is useful for adults. Sometimes it is necessary to immobilize the hip and femur in a hip spica cast that will be used for walking. These casts fit much better if they are applied with the patient in the weight-bearing position (Fig. 10.50A).
Figure 10.50. Adult single-leg weight-bearing hip spica. See text for details.

- I find it easiest to have the patient stand between two chairs, using the chairs for support.
- Apply a tubular stockinet of the appropriate diameter.
- Pad with Webril and felt as previously described. Notice that the cast will stop well above the ankle to avoid ankle impingement if it settles.
- Make the upper edge of the cast oblique, high on the side opposite the extremity to be immobilized, and low on the rib cage on the immobilized side. The midportion should cross the xiphoid. Keeping the cast high on the chest wall opposite the immobilized extremity counterbalances the weight of the leg and makes the cast more comfortable. The oblique angle makes it easier for the patient to sit.
- Allow plenty of room for the perineum and the function of the opposite hip.
- First apply rolls of plaster to a thickness of about four layers; then apply reinforcing splints and more rolls to incorporate them (as described previously). Notice the direction of the splints (Fig. 10.50B).

The completed cast is illustrated in Figure 10.50C.

FLEXION BODY JACKET

A flexion body jacket is most commonly used to treat low back pain, although it is used less often today because of the increasing sophistication and effectiveness of orthotic appliances. The purpose of the cast is to provide three-point fixation, straightening hyperlordosis of the lumbar spine and increasing intra-abdominal pressure by compression on the abdomen. Generally, the patient should remain fairly active and do both abdominal and spinal muscle-strengthening exercises while in the cast.

- Stand the patient about 18 inches from a table and have him lean over, rest his hands on the table, and suck in his abdomen, rounding up his back (Fig. 10.51A).

Figure 10.51. Flexion body jacket. See text for details.

- Apply a tubular stockinet tied over his shoulders and extending down onto his legs.
- Wrap the torso thoroughly with Webril; felt is usually not needed.
- Apply circumferential rolls of 6- or 8-inch plaster from well below the hips to the xiphoid and well up onto the back. Splints up the spine and across the back are useful in reinforcing the high posterior portion of the cast.
- Apply the cast rapidly so that three-point molding can be applied, as illustrated in Fig. 10.51A. The direction of the molding is indicated by the arrows.
- The completed flexion body jacket (Fig. 10.51B) extends well down over the buttocks to the gluteal crease and extends to about T-4. The abdominal portion is narrower but well molded to produce abdominal compression over the mid abdomen.

HYPEREXTENSION BODY JACKET

Hyperextension body jackets are commonly used for the treatment of compression fractures of the spine in the region of the thoracolumbar junction. Most surgeons apply them by placing the patient on a fracture table in the supine position on Goldthwait irons, steel bands that can be adjusted to produce a desired degree of hyperextension of the spine. This is the simplest and most controlled method for applying this cast.

Another method is to place the patient prone on the canvas strap of a Bell orthopaedic table with the feet suspended from the overhead frame (Fig. 10.52). The fracture is placed directly over the middle of the canvas strap, and the strap is slowly loosened until the desired reduction is obtained. The cast is then applied and the canvas strap pulled out of the cast.

Figure 10.52. Use of a bell table and canvas strap for reduction of a thoracolumbar junction fracture and application of a hyperextension body jacket.

The classic method of Watson-Jones, suspending the patient between two tables, is described here.

- Suspend the patient between two tabletops and allow her back to hyperextend to a comfortable position.
- Apply the cast as previously described. The plaster must be brought down over the pubic symphysis and high on the chest just short of the sternal notch. As the cast sets, these two areas must be molded as illustrated in Fig. 10.53A.
shoulder and proximal humerus. It is used to treat humerus fractures, to protect soft-tissue injuries about the shoulder, and in surgical repairs of the shoulder.

SHOULDER SPICA CAST

With the advent of sophisticated orthotic braces, the spica cast is less commonly used for the shoulder. A spica cast is more versatile, however, and often more comfortable than an abduction shoulder brace. It is used to treat humerus fractures, to protect soft-tissue injuries about the shoulder, and in surgical repairs of the shoulder.

MINERVA CAST

With the sophistication of current halo jackets, Minerva casts are now rarely used, but they may provide better immobilization for unstable injuries at C-1–C-2. A loose halo jacket allows for some motion of the upper cervical spine when it is connected to a halo; the Minerva avoids this situation. In most situations, the Minerva is applied with the patient supine on an orthopaedic table in gentle head-halter traction. If the cervical or upper thoracic spine is stable (for example, after internal fixation) and protection until healing is desired, a better-fitting cast can be obtained by applying the cast with the patient in the upright position. Do it only after the patient has been mobilized somewhat, to avoid postural hypotension.

SHOULDER SPICA CAST

With the advent of sophisticated orthotic braces, the spica cast is less commonly used for the shoulder. A spica cast is more versatile, however, and often more comfortable than an abduction shoulder brace. It is used to treat humerus fractures, to protect soft-tissue injuries about the shoulder, and in surgical repairs of the shoulder and proximal humerus.

SHOULDER SPICA CAST

The completed cast extends well down over the iliac crest (Fig. 10.55F). The proper length is important for stability. If the cast is left too high, the weight of the arm will cause it to swing, and the edge of the cast will dig into the rib cage or the top of the iliac crest, causing pain. Note that the side of the cast opposite the immobilized arm is kept high to provide support for the arm.

Spica casts can break easily at the junction of the extremity and the body portions of the cast; therefore, a reinforcing rod, as used here, is useful. It can be made by rolling up newspaper and covering it with plaster; a wood stick covered with plaster can be used as well. A similar stick should be used between the legs on a double hip spica or a 1½ hip spica.
PLASTER BOLERO

The plaster bolero (Fig. 10.56) is useful for treating unstable fractures of the clavicle that require hyperextension of the two shoulders to maintain position. It can also be applied to one shoulder, incorporating the upper arm if necessary.

Figure 10.56. The plaster bolero is applied using splints across the top of the shoulders and a circumferential wrap around the chest. This bolero has not yet been trimmed.

- The bolero is best applied with the patient sitting on a chair, facing the back of the chair. An assistant holds the arms in extension to reduce the fracture.
- Apply the bolero with felt and good Webril padding over the fracture site.
- Mold it carefully and then trim it to allow as much shoulder motion as desired.

PLASTER VELPEAU

The shoulder Velpeau dressing is generally used only as a soft-tissue dressing to immobilize the shoulder or humerus. When combined with a sugar-tong splint on the humerus, it is very effective for immobilizing fractures of the shaft of the humerus. Otherwise, it is the utilitarian method for immobilizing the shoulder when secure fixation is desired. Overwrap the soft Velpeau with plaster if better immobilization is desired or if patient compliance might be a problem.

- Place abdominal pads or other padding into the axilla and over the skin of the arm and the chest wall to avoid skin irritation (Fig. 10.57A). Powder with baby powder or cornstarch to absorb moisture from perspiration.

Figure 10.57. Soft and hard shoulder Velpeau dressings. See text for details.

- Using a 6- or 8-inch-wide bias-cut stockinet, begin on the chest wall below the arm and bind the arm gently to the chest with a circumferential wrap (front view, Fig. 10.57B; back view, Fig. 10.57C). After a half-dozen wraps, pass it beneath the elbow and vertically over the ipsilateral shoulder to support the arm.
- Overwrap the bias-cut stockinet with Webril and then overwrap in the same manner with two 6- or 8-inch rolls of plaster (Fig. 10.57D).
- After application, check at the medial epicondyle of the elbow to be sure there is no pressure over the ulnar nerve. In acute fractures of the distal portion of the humerus, this amount of elbow flexion may not be possible initially due to swelling. In that case, use a sling and simply bind the arm to the chest wall in a sling-and-swatch technique.

SHORT-ARM CAST

The short-arm cast can be used to immobilize the wrist and the base of the finger metacarpals for a host of disorders. The application of a short-arm cast to maintain the reduction of a relatively stable Colles' fracture is shown in Figure 10.58.

Figure 10.58. Short-arm cast for immobilization of a stable distal radius fracture. See text for details.

- In stable fractures, place the patient supine on the treatment table, rest the elbow on the tabletop, and form the hand as if holding a soft-drink can.
- Apply a tubular stockinet at either end of the cast (Fig. 10.58A). On the hand, carry the tubular stockinet to the tip of the fingers. I prefer somewhat more stockinet around the base of the thumb and wrist than illustrated here.
- For the average-size adult, 3-inch Webril is best for padding (Fig. 10.58B). Obtaining smooth, adequate padding about the hand can be difficult. Use a figure-eight wrap; when you encounter the thumb, simply pull the Webril down over the tip of the thumb, as illustrated, allowing the thumb to poke through the Webril. This produces a nice layer of padding around the base of the thumb.
- Carry the Webril distally about 2 cm distal to the prominence of the metacarpal heads.
- Apply plaster using two or three 4-inch rolls, depending on the size of the limb (Fig. 10.58C). In small adults or older children, use a 3-inch roll. I do not find it necessary to use splints, although some surgeons prefer them. A nice trick for obtaining a smooth wrap around the thumb, palm, fingers, and wrist is to leave the 4-inch roll at its full width and apply it as a figure eight around the wrist, with the thumb in one hole of the eight and the fingers in the other, leaving the roll at full width as it passes through the palm. The result is a very smooth application of plaster with very nice coverage of the palm and wrist. The direction of this wrap is indicated by the dotted lines in the photograph.
- Carry the plaster proximally to the level desired. Apply it rapidly, and thoroughly rub it in (Fig. 10.58D). Try to keep the cast no more than ¼ inch thick.
Begin molding by reproducing the transverse arch of the palm, as illustrated.

Then mold the forearm to the normal oval shape of the forearm (Fig. 10.58E).

Do not stop the cast on the dorsal side more proximal than the metacarpal heads, as swelling will cause it to compress the dorsal veins, with resulting increased swelling of the digits. Placing the cast over the prominence of the metacarpal heads allows these veins to drain through the intermetacarpal spaces.

How the cast is molded and how far proximally it is carried at the elbow determine how much motion in supination and pronation will remain. The more the cast is made into an oval shape and the higher on the elbow it is carried, the less motion there will be.

Trim the completed cast at the elbow flexion crease to allow full elbow flexion without impingement of the plaster into the antebrachial fossa (Fig. 10.58F).

When trimming the cast around the hand, first cut the plaster to the desired level with a scalpel (Fig. 10.58G). Trim the cast on the dorsal side to the prominences of the metacarpal heads and cut the palmar side down to allow flexion of the fingers to 90° and good apposition of the thumb.

Turn a Webril cuff over the edge of the cast, and then cut a small hole in the stockinet for the thumb. Pull the entire tubular stockinet back over the thumb and palm of the cast and secure it about the wrist with a few rolls of plaster. This makes trimming the cast simple and eliminates the need for a bar of plaster in the first web space. The material on the palm also enhances the grip for objects.

Note that restoration of the normal transverse arch of the palm allows the patient to easily touch the thumb to the tips of the fourth and fifth fingers.

The trim around the fingers covers the top of the metacarpal heads and then inclines forward to allow flexion to 90° at the metacarpophalangeal joints (Fig. 10.58H).

### GAUNTLET CAST

The gauntlet cast is useful to immobilize fractures of the metacarpals of the hand and for minor wrist injuries. For fractures of the fourth and fifth metacarpals, I prefer to use an ulnar gutter splint (described below), but the gauntlet cast is quite useful for fractures at the base and in the mid shaft of the metacarpals. It also can be used for the typical boxer's fracture of the neck of the metacarpal. In the latter case, the cast must be carried distally enough to allow molding on the volar aspect of the

---

**Figure 10.58.** Muenster short-arm cast. A: The Muenster short-arm cast is applied in the same fashion as the short-arm cast just described, but the cast is carried up onto the distal arm and then subsequently trimmed down to the configuration seen here. Notice that the proximal end of the cast grips the epicondyles of the humerus as in the supracondylar portion of a Sarmiento cast. It is cut out well over the antecubital fossa to allow full flexion of the elbow.

B: In this side view, notice the extensions of the cast over the epicondyles and the grip on the back of the olecranon. Trim the posterior aspect of the cast to allow full extension.

---

**Figure 10.59.** Long-arm cast for Colles' fracture. See text for details.

---

**Figure 10.60.** Long-arm cast for Colles' fracture. See text for details.
metacarpal head. If rotational instability is of concern, it may be necessary to buddy-tape or splint the fingers.

- Apply this cast in a fashion identical to that of the forearm cast just described, but stop it at the junction of the middle and distal thirds of the forearm (Fig. 10.61).

**Figure 10.61.** Gauntlet cast. See text for details.

- Carry it distally over the affected metacarpals. It may need to be somewhat longer than the standard forearm cast, and in fact it may extend up to the midportion of the proximal phalanx, particularly for fractures of the third and fourth metacarpals.
- Place a felt pad over the dorsal aspect of the fractured metacarpal and over the palmar aspect of the metacarpal head.
- Use three-point molding to maintain the reduction of the fracture (Fig. 10.61B).

**THUMB SPICA CAST**

The thumb spica cast is used primarily for fractures of the scaphoid and other instabilities of the carpal bones amenable to cast treatment. It also is used for fractures involving all elements of the thumb itself. In scaphoid fractures, most surgeons use a long-arm thumb spica cast for the initial 6 weeks of immobilization and then convert to a short-arm spica cast (Fig. 10.62).

**Figure 10.62.** Short-arm thumb spica cast. See text for details.

Although I rarely use an unpadded cast, it is shown in Figure 10.62A for the purpose of illustration. When applied to acute injuries, the cast must be univalved.

- Apply a tubular stockinet over the forearm and hand as done for the forearm cast, and apply a second tubular stockinet over the thumb. Some custom shaping is necessary to obtain a snug fit.
- Carry the Webril distally to the end of the thumb. Apply Webril padding about the palm of the cast and around the proximal phalanx. Apply a double-thickness strip of Webril along the dorsal aspect of the thumb, wrist, and forearm for removing the cast, and secure it with a circumferential wrap of Webril.
- Position the hand as if holding a soft-drink can to maintain proper position of the thumb relative to the fingers.
- First apply a roll of plaster to the forearm about four layers thick (Fig. 10.62B). Then use a 3 × 15-inch splint, five to seven layers thick, and apply it around the thumb as a splint, as illustrated. This will lap around the thumb enough that it will not be necessary to actually wrap plaster circumferentially around the thumb. If a 3-inch roll is not wide enough, use a 4-inch roll.
- Incorporate this splint and the rest of the hand using the technique already described for a forearm cast.
- The completed cast is carried well up on the forearm, but not so far that it interferes with the antecubital fossa (Fig. 10.62C).
- Notice that the thumb is easily opposed to the first and second fingers. A common mistake with this cast is to get the thumb out into the ape-hand position, which makes it impossible for the patient to obtain three-jawed-chuck prehension. The patient will not be able to function with the cast on. Notice that on the thumb the cast is carried distally to the middle of the fingernail. This length provides adequate immobilization yet leaves the tip of the thumb available for prehension. Making the cast shorter allows the patient to jack the hand up in the cast by flexing the distal phalanx over the end of the cast, introducing significant motion into wrist injuries, which should be avoided.
- The line for univalving the cast and for removal has been indicated by writing on the completed cast (Fig. 10.62D). This must always be done on casts applied with minimal padding, as in this case. When the cast is univalved, split the underlying stockinet as well.

**HANGING-ARM CAST**

The hanging-arm cast is used to treat fractures of the humerus in all areas, including those of the surgical neck. The principle of the hanging-arm cast is that it relies on traction for fracture reduction rather than molding of the cast, although molding is useful in supracondylar fractures. In shaft fractures, the angle of varus and valgus can be changed by the location of the suspension hook and the length of the sling that hangs the cast from the neck.

For this cast to be effective, the patient must be able to remain upright most of the time during the first few weeks after the fracture and must not rest the cast on any surface. Sleeping at night with the head and upper thorax at a 45° angle usually suffices. Once the fracture becomes fairly sticky, the cast can be removed and other methods of immobilization used. The difficulties inherent in using this cast have limited its use. The best indication today is a fracture of the surgical neck of the humerus that requires traction for treatment.

- Apply a standard long-arm cast (Fig. 10.63A).

**Figure 10.63.** Hanging-arm cast. See text for details.

- Prepare a suspension sling. Determine the length of sling and location of the suspension point appropriate for the fracture. Shortening the suspension sling will
Short-leg Splint

The strongest and best-conforming splints are made by first applying a full cast. After drying, bivalve the cast and trim the edges.

Well-applied plaster splints can be used for nearly all the smaller tasks performed by casts, except for the spica casts. The primary advantages of splints are that they are lighter in weight than casts, allow for swelling of the limb, and are removable. They are, however, much weaker, and the fact that they are removable may pose a problem in noncompliant patients.

For correction of fracture alignment, wedges can be uniplanar or biplanar. If a fracture has angulation in both the anteroposterior and lateral planes, it is theoretically possible to place the axis of the hinge in the plane of maximum deformity and correct both angulations with a single wedge. This technique is tricky but perhaps worth a try; the alternative, changing the entire cast, may ultimately be necessary. Another option is to simply remove a 1- to 2-inch segment of cast, align it properly, and resheat the cast. This technique is more hazardous than wedging, as it is possible to offset the longitudinal alignment of the cast, producing pressure sores.

A useful technique is a combination of the preceding two methods that hinges the cast directly over the fracture site and introduces neither lengthening nor shortening.

Three wedges are commonly used—the opening wedge, the closing wedge, and the central-hinging wedge. The opening wedge is most common, as it is simple and produces distraction. Almost all angulation in fractures is accompanied by some shortening, so distraction is an advantage.

**Opening Wedges**
- Make a transverse cut in the cast, leaving the cast intact for a width of about 1 inch on the convex side of the deformity. Gently straighten the cast to the desired position.
- Place a wedge in the opening to hold it in position, and take a radiograph to confirm proper position.
- Seal the cast after removing the wedge.

**Closing Wedges**

The closing wedge is used when compression or shortening at the fracture site is desired; indications for it are rare. The procedure is opposite that of the opening wedge.
- Remove a wedge of plaster and close the cast on the convex side.
- Avoid pinching the skin in the closing wedge.

**Central Hinging Wedge**

A useful technique is a combination of the preceding two methods that hinges the cast directly over the fracture site and introduces neither lengthening nor shortening.

**SPLINTS**

Well-applied plaster splints can be used for nearly all the smaller tasks performed by casts, except for the spica casts. The primary advantages of splints are that they are lighter in weight than casts, allow for swelling of the limb, and are removable. They are, however, much weaker, and the fact that they are removable may pose a problem in noncompliant patients.

The strongest and best-conforming splints are made by first applying a full cast. After drying, bivalve the cast and trim the edges.

**LOWER EXTREMITY SPLINTS**

**Short-leg Splint**
- On a tabletop, lay out a length of Webril, three layers thick, that is about 4 inches longer than the splint desired and somewhat wider than the plaster to be used (Fig. 10.65A).
Figure 10.65. Short-leg splint. See text for details.

- Make a splint of appropriate length and width, either using commercially available splints or by unrolling a roll of plaster. For most lower extremities, a splint 10 layers thick with reinforcement to 15 layers around the foot and ankle is usually sufficient.
- Take the 10 to 15 layers of plaster splints as a unit, fold them in half without creasing the plaster at the fold, and grasp the two ends between the fingers of one hand.
- Dip the splints into water and let them soak thoroughly. Since little molding time is required for splints and fast setting is an advantage, use warmer water or extra fast setting plaster.
- Remove the splints from the water, bunch them into a ball while maintaining good control of the ends of the splints, and express excess water from the splints. Then unfold the splint out to full length and strip the splint between two fingers, as illustrated, to remove excess water.
- Lay the splint on the prepared Webril and thoroughly rub the splint in to ensure that all the layers are amalgamated (Fig. 10.65B).
- Place over it a layer of Webril similar to the one used for the bottom of the splint.
- Apply the splint to the leg, holding the foot in the appropriate position (Fig. 10.65C).
- Now wrap the splint into place with bias-cut stockinet, maintaining good position until the splint hardens (Fig. 10.65D). If not wrapped too tightly, elastic bandages can be used as well.
- Figure 10.65E shows the completed short-leg splint. Notice that the Webril has been turned down over the edges for trimming and padding.

Long-leg Splint

- A snug-fitting long-leg posterior splint applied by multilayering produces a very strong and smoothly conformed splint with a thin, smooth edge (Fig. 10.66A).

Figure 10.66. Long-leg splint using multilayered technique and reinforcing ridge. See text for details.

- Position the extremity in the desired position.
- Pad as desired. In this case, the splint is being applied directly to tubular stockinet. Padding or protection should be placed over the heel, malleoli, and fibular head.
- Take thin splints (only two or three layers thick) and apply them in a series of sequential layers, thoroughly rubbing in the plaster with each layer.
- A trick for reinforcing the cast at weak points such as the heel is to draw up the last splint with the fingers into a reinforcing ridge (Fig. 10.66B).
- Once set, the splint can be removed and is ready for trimming (Fig. 10.66C).

UPPER EXTREMITY SPLINTS

Sugar-tong Splint for the Humerus

The sugar-tong splint is the most useful immobilization device for the management of fractures of the shaft of the humerus. Critical to its success is three-point molding. I have not found it useful to carry the splint any higher than the tuberosities of the humerus. Avoid pressure over the ulnar nerve.

- Loop a single long splint padded with Webril on both sides around the elbow and along the medial and lateral sides of the arm (Fig. 10.67A).

Figure 10.67. Sugar-tong splint for fractures of the shaft of the humerus. See text for details.

- Overwrap it with bias-cut stockinet, keeping the splint snug around the elbow. Do not impinge on the axilla. Carry the splint up to the greater tuberosity of the humerus.
- The vast majority of shaft fractures require three-point molding into valgus or varus, depending on configuration. Overmolding is necessary to obtain and maintain the correct position.
- Molding into valgus is necessary for most supracondylar fractures. The torso is used as the molding point over the lateral aspect of the elbow (Fig. 10.67B).

Long-arm Splint

The long-arm splint is particularly useful when it is necessary to immobilize the elbow and forearm or if a circumferential cast is undesirable, as in supracondylar fractures of the humerus. With the long-arm splint shown in Figure 10.68, the antecubital fossa is left completely open to check the pulse and allow for swelling.
Long-arm splint. See text for details.

Apply this splint to the dorsal side of the arm and forearm, extending to the base of the metacarpal heads (Fig. 10.68A). These splints often break at the elbow. An excellent method of reinforcement is to apply a splint at a 45° angle along the medial and lateral sides of the elbow, although this leaves the antecubital fossa and volar side of the arm and forearm completely open. The splint can be applied with a roll of plaster, as illustrated.

The splint is wrinkled on the lateral side of the elbow from having been molded around the elbow joint (Fig. 10.68B). This wrinkling can sometimes produce irregularities in the cast that are uncomfortable or that can impinge on the ulnar nerve.

To produce a smooth fit of splints around joints, cut the splint as illustrated and allow it to overlap. The overlap also reinforces the splint on its two sides.

Short-arm Double Splint for a Colles’ Fracture

For Colles’ fractures, many surgeons prefer splints to casts because splints easily accommodate swelling, are lightweight, and in some cases are easier to mold than a circumferential plaster. In addition, they can be tightened by overwrapping as swelling decreases.

Precut the splints to conform to the palm of the hand and to fit around the thumb (Fig. 10.69A).

Produce a snug-fitting splint by reducing the fracture in fingertraps and padding with tubular stockinet and some Webril (Fig. 10.69B).

Apply the volar and dorsal splints in the multilayered technique (Fig. 10.67). Overwrap the splints directly with a roll of gauze. This gauze will stick to the plaster.

Apply these splints rapidly so there will be plenty of time for molding.

After the splint sets, cut the gauze along either the ulnar or the radial border, depending on the fracture being treated. Then overwrap with a gauze or other wrap to obtain the desired fit (Fig. 10.69C).

HAND SPLINTS

Splinting of the hand can be accomplished in many ways, some of which are quite complicated. Hand splints are often combined with wire splints, padded aluminum splints, and outriggers with elastic bands. Splints of metal or polymers are commercially available and are often custom-fabricated by occupational or hand therapists.

In this chapter, we focus on splints for the treatment of acute hand injuries. Splints are often used to treat nerve injuries, paralysis, and burns and are otherwise used to position the disabled hand. The use of splints for the treatment of traumatic and nontraumatic disorders of the hand and wrist is discussed in some detail throughout the many chapters in the section on the hand. Please refer to a chapter on a specific disorder to find recommendations on splinting, if applicable.

Thumb Spica Splint

The thumb spica splint is a convenient, lightweight method for immobilizing nearly all soft-tissue and bony injuries of the thumb, metacarpal, phalanges, and associated joints. It can be used as a temporary splint for the wrist and carpal bones. It is very useful as the first stage of a thumb spica cast, as it minimizes the need to wrap rolls of plaster around the thumb. Once hardened, it can be removed for exercise or examination of the limb and replaced.

Use seven to ten layers of 3 × 15-inch plaster splints overlaid on both sides with Webril to construct the splint (Fig. 10.70A).

Turn the Webril over the edges of the splint to give it a smooth edge.

Apply the splint along the radial aspect of the forearm, extending onto the thumb as far distally as the middle of the thumbnail. The splint should fit circumferentially around the thumb. The splint width will vary according to the size of the patient.

Molding around the thumb with the thumb in a position of three-jawed-chuck prehension is usually preferred.

The completed splint (Fig. 10.70B) has been overwrapped with an elastic bandage; this is ideal for molding it to the arm while it sets. If there is any concern about having an elastic wrap on the extremity, replace it with bias-cut stockinet or other nonelastic wrap after the splint has set.

Notice how nicely this splint can be removed from the thumb (Fig. 10.70C), leaving the circumferential thumb portion intact. It can be slid back onto the thumb and gently pushed proximally to obtain a snug fit, and rewrapped into place.

Ulnar Gutter Splint

Application of the ulnar gutter splint is identical to that of the thumb spica splint. If extended out to the tip of the digit, it can serve to immobilize injuries of the ulnar
fingers and ulnar metacarpals, or it can immobilize the wrist with the fingers free, depending on its distal extent. Splints that are 3 × 15 inches will just cover the fifth finger in medium-size adults and children; wider splints are necessary to incorporate the ring finger. A very wide splint, such as a 6-inch splint, can be used to incorporate the entire hand. It is my favorite splint for immobilizing boxer fractures of the neck of the fifth metacarpal (Fig. 10.71).

Figure 10.71. Ulnar gutter splint.

- Select the appropriate length and width of splint for the immobilization. Use the ulnar gutter splint to immobilize a boxer fracture of the fifth metacarpal after it has been reduced.
- Use a 3 × 15-inch splint as described for the thumb spica splint. For large hands, a 4 × 15-inch splint may be necessary.
- Carry the splint to the midportion of the middle phalanx of the little finger, allowing the more distal joints free to flex.
- Use three-point molding to reduce the fracture in place, with one point over the palmar aspect of the head of the fifth metatarsal and a broader area of molding over the dorsal shaft of the metacarpal. Rotation is usually not a problem in these fractures.
- If there is more proximal shaft comminution, then buddy-tape the little finger to the ring finger.
- In more unstable injuries, outrigger splints may be indicated, which can be incorporated into the ulnar gutter splint.
- Take care when molding this splint to avoid excessive pressure, as pain or skin injury could occur. Placing a \( \frac{1}{8} \)-inch piece of felt over the molding points is helpful in distributing pressure.

SPLINTING FINGERS

Several general principles are useful to remember in splinting the fingers.

- Splint only the joints that must be splinted; allow free movement of the other joints to prevent stiffness in the hand.
- The primary problems in the immobilization of major fractures of the fingers are malrotation, dorsal angulation at the fracture site in metacarpal fractures, and palmar angulation in fractures of the phalanges. These problems are usually avoidable by proper splinting, but severe instability, recurrent deformity, or the presence of other soft-tissue injuries may necessitate internal or external fixation.
- When splinting fingers, check carefully for proper rotation. As each digit is fully flexed to the distal palm, it reaches a specific contact point on the thenar eminence; these points differ from person to person (Fig. 10.72). Good rotation can usually be ensured by taping the injured digit to an adjacent noninjured digit. The index and little fingers have only one neighboring finger to be taped to. Tape the long finger to the ring finger, leaving the index free for function. Tape the ring to the long finger, because the long finger gives the proper rotation more reliably than the little finger (in some patients, the little finger is internally rotated and would splint the ring finger in malrotation).

Figure 10.72. Notice the contact points produced by contact of each of the fingers with the thenar eminence. This rotational alignment must be reproduced when unstable fractures in the fingers are immobilized.

Various polymeric and metal splints are available that can be used with or without casts or plaster splints on the wrist (Fig. 10.73). Many newer plastic splints are available as well.

Figure 10.73. Splints for the fingers. From top to bottom, an aluminum gutter splint for the finger designed to be used on the palmar side, a straight four-sided aluminum finger splint (generally not recommended because it splints the digit in full extension), a wire finger splint; strips of aluminum with adherent foam, and foam-padded mallet-finger splints.

Splinting to Allow Finger Flexion

Motion can be preserved by leaving the distal joints free or by allowing limited motion of the digit while splinting it to prevent recurrence of deformity or dislocation. For example, a dorsal finger splint can be incorporated into a short-arm cast or volar wrist splint to immobilize injuries that are stable in flexion but unstable in extension. The splint in Figure 10.74 blocks extension of the finger but allows nearly full flexion.
Figure 10.74. Finger splint allows limited motion.

- Fashion a 3 × 5-inch Webril-padded plaster splint of about 10 thicknesses for the wrist.
- Incorporate the foam-padded aluminum splint into the splint on the palmar side and into a second splint on the dorsal side.
- To achieve good incorporation and to reduce bulk, peel the foam from the portions of the splint inserted into the plaster. Notice that the splint has been bent to maintain the index finger in flexion, thus stabilizing an injury that is unstable in extension.

The splint, while protecting the finger, allows excellent flexion for early motion. A similar splint could be used if the index and long fingers were taped together.

**Padded Aluminum Splint for More Immobilization**

To splint more unstable injuries of the fingers, complete immobilization except for the distal interphalangeal joint may be necessary. For splinting the index and/or long fingers, a foam-padded aluminum splint can be bent into a complete loop and incorporated into a palmar wrist splint (Fig. 10.75).

Figure 10.75. Padded aluminum splint of the index finger incorporated into a wrist splint.

- Splint the metacarpophalangeal joint as close to 90° of flexion as feasible. Note that the proximal interphalangeal joint has also been immobilized at 90°.
- Bend the splint into a full loop with your hand. Bend the splint down until the loop is sufficiently tight that you can bring your fingers into the appropriate position.
- Strip the foam off the aluminum where the splint will be incorporated into the cast. Tape the ends of the splint together. This produces a nice, stable loop on which the finger will be set.
- Position the volar wrist splint no more distal than the proximal flexion crease of the palm, as this position is necessary to achieve the desired flexion of the fingers. The splint illustrated here is slightly too distal.
- Leave the fingertips free. Encourage early motion to avoid flexor tendon tie-down and stiffness.
- To avoid maceration between the fingers, place Webril or gauze between the digits. The tape fastening the fingers to the splint must be snug but not tight.

**Splinting a Proximal Interphalangeal Joint Injury**

A padded aluminum splint can be applied dorsally for injuries of the proximal interphalangeal joint (Fig. 10.76). The technique can also be used for mallet finger.

Figure 10.76. Use of padded aluminum splints for finger injuries. See text for details.

- Cut the splint to size with a large bandage scissors.
- Smooth the cut edges of the splint. Allow the foam to extend somewhat beyond the ends of the splint to protect the finger.
- Figure 10.76B shows the splint on the palmar aspect of the finger.
- To splint a mallet finger (Fig. 10.76C), fashion a splint to reach from the tip of the finger to the middle of the middle phalanx.
- Smooth the ends of the splint and leave plenty of foam over the edge of the splint to pad its edge. Notice the bend in the splint that will place the digit in slight hyperextension at the distal interphalangeal joint.
- Apply the splint to the palmar aspect of the digit and tape it into position over the distal interphalangeal joint (Fig. 10.76D). Sometimes this procedure is painful because of the injury, and a more indirect means of taping must be used. Usually the tape must be applied somewhat loosely initially and then gradually tightened over a couple of days as the tenderness and swelling subside. Because these splints get wet, the patient must replace them frequently, taking care not to allow the joint to drift into flexion. Off-the-shelf plastic splints are available for this application, but I prefer to use custom-molded splints. Generally, immobilization of the proximal interphalangeal joint is unnecessary in a mallet finger.

**COMPLICATIONS OF CASTS AND SPLINTS**

**PRESSURE SORES**

Pressure sores are most common over bony prominences, at the edges of the cast, or over flexion surfaces such as the instep and antecubital fossa. With good plaster
technique, pressure sores should be extremely rare in patients with normal sensation. They are most common in patients with sensory loss such as paraplegics, and in those with peripheral nerve disorders, including peripheral neuropathy from diabetes and other disorders. Head-injured patients who cannot communicate, small children, and the very elderly are also at risk. Try to avoid circumferential casts in these patients, particularly in paraplegics. On the other hand, short-leg antiequinus casts are often used to prevent heel-cord contractures in head-injured patients who are comatose and spastic. I have been very successful in avoiding pressure sores by appropriate padding and careful cast application.

Figure 10.77 shows a common source of pressure. Note that the cast is very thin over the olecranon and very thick over the antecubital fossa because of inappropriate cast application. Avoid excessive plaster over the flexor surface of joints. In addition, in this case the forearm portion of the cast was too long, so when the forearm was flexed at the elbow to 90°, the forearm part of the cast impinged on the antecubital fossa, producing a potential site for pressure necrosis of skin. Solve this problem by removing the antecubital part of the cast with a window, and reapply the plaster in this area; it may be easier to apply a new cast.

Figure 10.77. Cast sores. Notice the inappropriate application of this long-arm cast with impingement of the forearm portion of the cast into the antecubital fossa, which could well cause a pressure sore or neurovascular injury.

The lower extremity is particularly susceptible to cast sores, especially over the heel and instep (Fig. 10.78 and Fig. 10.79). The patient with an impending cast sore initially complains of discomfort in the cast, usually in a region where pressure would be expected, such as over the heel, instep, patella, olecranon, or antecubital fossa. This discomfort quickly becomes an unrelenting, severe, burning pain. It may last for several hours up to several days, depending on the severity of the pressure and whether or not the patient can gain temporary relief by shifting in the cast or repositioning. Eventually, the pain usually subsides in part and the patient becomes more comfortable; at this point a full-thickness ulceration has usually occurred. Subsequently, staining on the cast, a foul smell, or systemic evidence of infection will call attention to this neglected problem.

Figure 10.78. These pressure sores over the instep and heel of the foot were caused by a long-leg cast applied to a patient with a fracture of the proximal tibia who was multiply injured and unconscious for 3 days. Although the initial cast was probably applied in an appropriate manner, subsequent swelling in the cast, about which the patient could not complain, led to these pressure ulcers. These full-thickness ulcers resulted in exposure of the Achilles tendon and calcaneus, and full exposure of the extensor tendons of the ankle; major plastic reconstructive surgery was required. These problems could have been avoided by univalving the cast and spreading it widely initially, or by using splints with frequent inspection of the skin.

Figure 10.79. This pressure sore in the groin occurred at the upper edge of a cast-brace used to treat a lower extremity injury in a paraplegic. Even though the cast was well applied and appropriately padded, it was inadequate in this patient with impaired sensation.

Pressure sores can be quite severe, resulting in total loss of coverage over bony prominences or full exposure and loss of tendons, ligaments, and nerves. They can require major reconstructive surgery and result in permanent, major, long-term deficits. Avoid pressure sores by observing indications, by using appropriate technique, and by using immediate decompression of circumferential casts or snugly applied splints in patients complaining of pain or discomfort. In almost all cases, keep the offending area visible by placing a large window in the cast, by splitting the cast and spreading it, by bivalving the cast, or by removing the cast completely.

Pressure sores can also be caused by failure to trim the cast and pad it appropriately at its ends (Fig. 10.79) or by holding the cast inappropriately when it is wet, causing dents with the fingers or hand.

BURNS

As the exothermic reaction of setting takes place in plaster and fiberglass materials, enough heat can be generated to cause a severe burn, particularly if there is no way for the heat to dissipate. This is a greater problem in patients with impaired sensation. To avoid burns, try not to apply casts thicker than ¼ to 3/8 inch in a single layer. For a thicker cast, it is wiser to apply a thin cast initially, reinforcing it after it has set. This is commonly done by overlaying plaster casts with a thin layer of fiberglass.

Plastic-covered pillows present a problem for the unwary. Fresh casts are often laid on pillows as they set. Burns can occur because the setting plaster can not dissipate heat while lying against the plastic. Avoid setting fresh casts down on any impervious surface, and do not cover freshly set casts.

ALLERGIC DERMATITIS
In my experience, allergy to cast materials is exceedingly rare. Skin irritation under the cast is most likely to be caused by exudate from wounds soaking the cast padding, or from particles of plaster dust getting into the cast and abrading the skin. I do not believe I have ever seen a true allergy to either the padding materials or to plaster of Paris, although it has been reported. An occasional reaction to the tubular stockinet occurs; in patients with a history of allergy or dermatitis, do not use tubular stockinet directly against the skin. Synthetic materials are more likely to cause allergies, so be alert to this possibility. Change materials if allergy is a problem.

**CAST WINDOW BLISTERS**

When casts are windowed or split, part of the extremity is exposed while most of the limb is incorporated in the cast. Any swelling that occurs will bulge into the window or split and may create excessive pressure against the skin along the edges of the split or window. The result is a pressure sore or more commonly a blister in the window or split. Fill any windows or splits with soft compressible material, such as felt or multiple layers of Webril or dressings, and overlap with bias-cut stockinet or plaster to keep firm compression.

**VASCULAR COMPROMISE, COMPARTMENT SYNDROME, AND NERVE INJURY**

Direct impairment of vascular function due to casts or splints rarely occurs; the vessels are buried deeply enough that direct compression is almost never a problem. Excessive swelling, however, can cause compartment syndrome; avoid it by using splints. In any type of acute injury, or if there is any possibility of swelling, I always split longitudinally and univalve circumferential casts. Bivalving casts does not decompress the limb nearly as well as spreading a cast that has been univalved, as the bivalved cast can open only in one plane. See Chapter 27 on compartment syndrome for more details.

Direct compression injury can occur in the ulnar nerve at the elbow, the radial nerve at the lateral epicondyle, and the median nerve at the wrist. In the lower extremity, the most common and serious problem is paralysis of the foot and toe dorsiflexors due to paralysis involving the common peroneal nerve at the fibular neck. This paralysis may produce a permanent drop foot and must be avoided. Any neurologic complaints—pain, burning, dysesthesia, weakness, or paresthesias—demand immediate attention. Window, remove, or adjust the cast or splint. In some cases, such as carpal tunnel syndrome at the wrist, repositioning to decrease intracompartmental pressure may be necessary.

**MALPOSITION**

Malposition can influence the alignment of fractures and the positioning of joints. The measures necessary to mold fractures appropriately to maintain position have been described. When treating fracture–dislocations and dislocations, remember the positions of stability for the joint, and position the extremity appropriately. Keep in mind that very unstable injuries of the elbow and knee may not be adequately immobilized by a long-arm or long-leg cast and may require extension into spica casts. Joint fractures may be so critical that when splints and casts are applied by technical personnel to potentially unstable injuries, physician supervision is usually necessary to ensure that appropriate position is maintained.

Inappropriate positioning of the extremity during cast application may result in annoying problems, if not prolonged disability. When applying a long-leg cast, for example, do not hold the extremity by the heel with the patient in the supine position, as gravity will cause the knee to drop into hyperextension, which is very uncomfortable for the patient. Other common positions to avoid are toe hyperextension, excessive flexion of the knee when it is unnecessary, excessive flexion of the hip, or any varus or equinus of the foot when not indicated.

**STIFFNESS, DISUSE, AND REFLEX SYMPATHETIC DYSTROPHY**

Once the discomfort of the injury passes, it is important to immediately embark on a rehabilitation program. All joints not immobilized should be carried through active range-of-motion exercises daily, and passive exercise is generally indicated for joints or digits that cannot be moved actively. Generally, it is safe to begin immediate isometric exercises of the immobilized muscles.

In the upper extremity, encourage immediate functional use of the extremity when feasible. Avoid slings when possible. In Colles’ fractures, for example, use of a sling may produce a stiff shoulder due to disuse. To avoid swelling in the first few days, the patient is better encouraged to carry the extremity resting on the head and thereafter to use it as much as possible as if it were normal.

In the lower extremity, weight bearing should begin as soon as possible and should be actively encouraged when indicated. In general, tibial fractures should be treated with weight-bearing functional plaster casts and braces rather than non-weight-bearing, long-leg, bent-knee casts. Convert from casts to functional braces as soon as practical and safe. Early involvement of a physical therapist or hand therapist is often indicated.

Patient education is very helpful for avoiding complications. Every orthopaedic office, clinic, and emergency room should have a standard handout to educate patients about the care of casts and splints and to warn about the symptoms that must be brought to the physician’s attention.

**TRACTION**

Continuous traction is indicated in the treatment of fractures when reduction of the fracture or proper length of the limb cannot be maintained by the static immobilization provided by casts and splints. It is necessary in the presence of deforming forces caused by soft-tissue tension in the muscles, tendons, and ligaments, and by hydraulic forces generated by bleeding into and swelling in the soft-tissue envelope surrounding the fracture. Traction may also be necessary to treat unstable dislocations, particularly of the hip, where static methods are inadequate or impractical. Because of the sophistication of modern methods of internal and external fixation, it is uncommon to treat fractures or dislocations definitively in traction. Disadvantages include the need for prolonged bed rest and prolonged and expensive hospitalization. Additionally, the return to function is slow; the patient is recumbent in traction for so long that muscle atrophy, joint stiffness, and general cardiovascular deconditioning result.

Traction is almost never used for upper extremity problems, as current methods of internal and external fixation are usually superior. At the University of California, Davis, Medical Center, a busy level 1 trauma center with more than 3,000 trauma admissions per year, I have not used traction since the 1960s for even the temporary treatment of a disorder in the upper extremities, but olecranon pin traction is described below because it is a very useful method that I used frequently in the 1960s and early 1970s.

Musculoskeletal surgeons should be familiar with the use of traction, as it is a good backup method for situations where internal and external fixation are impossible. In particular, it may be useful in the management of major soft-tissue injuries in the upper extremity because the overhead suspension provides ready access for wound care. With the advent of percutaneous pin fixation for supracondylar fractures of the humerus in children, traction treatment has virtually disappeared and in most Western countries is not indicated.

Traction is still commonly used in the lower extremity, however. Common indications are Malgaigne injuries of the pelvis with vertical instability, fractures of the hip and shaft of the femur, and fractures of theibia and fibula. Unstable posterior dislocations of the hip are often immobilized in skeletal traction until soft-tissue healing occurs. Skin traction is commonly used to immobilize elderly patients with fractures of the hip as an emergency measure before performing internal fixation. Skeletal traction through either the distal femur or the proximal tibia is used for the temporary and early treatment of unstable fractures of the pelvic ring and acetabulum, the hip in younger patients, and femoral shaft and supracondylar fractures of the femur. Where traction is used for vertically unstable fractures of the pelvic ring, fixation is often supplemented by an external fixator on the pelvic ring.

In the vast majority of the injuries mentioned, internal or external fixation is the definitive method of treatment; however, local soft-tissue and systemic conditions may contraindicate surgery and necessitate prolonged definitive treatment in traction. Since external fixator and intramedullary nailing have not been tested in the face of the major mass casualties produced by war, skeletal traction remains the only proven treatment for high-velocity gunshot wounds of the femur in a military situation. It is highly likely that external fixation is a better treatment method, but its efficacy in this specialized situation has not been proven.

**INDICATIONS**

Common indications for skeletal traction in the lower extremity in our institution are the following.

- Vertically unstable fractures of the pelvic ring where external fixation cannot maintain vertical stability, and where internal fixation of the posterior portions of the pelvic ring is impossible
- Fractures of the acetabulum with minimal displacement where internal fixation is not indicated, the fracture is potentially unstable, and the patient is a good
candidate for treatment in traction (i.e., young, with isolated injuries)

- Unstable fractures of the acetabulum where either local bone or soft-tissue conditions or systemic factors contraindicate internal fixation
- Fractures of the hip (basilar neck, intertrochanteric, or subtrochanteric) where local soft-tissue or bone conditions or systemic conditions contraindicate surgery
- Fractures of the shaft and supracondylar area of the femur for which internal or external fixation is contraindicated
- Comminuted fractures of the tibial plateau where traction is necessary to maintain alignment and facilitate early motion, and where internal or external fixation is not possible or feasible. (Sometimes, traction may be supplemented with closed reduction, or limited open reduction of the articular surfaces with percutaneous fixation with wires or cannulated screws, with the metaphyseal portion being managed in traction.)
- Fractures of the shaft of the tibia and fibula where delay in initial treatment or unacceptable shortening in a plaster cast requires correction. (In such cases, it is desirable to regain length before internal or external fixation, or where severe soft-tissue problems preclude cast immobilization or any type of fixation.)
- Comminuted pylon fractures of the distal tibia and fibula and ankle joint, where early motion of the ankle joint is desired and internal or external fixation is contraindicated.

**HISTORY OF TRACTION**

Those interested in the history of traction should read Peltier's excellent article (70). In it he states that Malgaigne credited Guy de Chauliac with the first use of continuous isotonic traction for the treatment of fractures of the femur; this was 600 years ago, and traction remains today an effective and safe treatment for fractures (49). Initial efforts at traction treatment were frustrated by the surgeons' inability to obtain a firm grasp on the extremity to apply traction. Skin traction had obvious limitations. In addition, skin traction meant that the limb had to be treated in full extension, resulting in frequent shortening and malalignment.

The first really effective method for continuous longitudinal traction for femur fractures was introduced by Sir Hugh Owen Thomas in 1890 (93). The full-ring Thomas splint used today is identical to the one Thomas developed. His original method used skin traction and treated the fracture in full extension (Fig. 10.80).

**Figure 10.80.** This long splint, designed by Sir Hugh Owen Thomas for the treatment of fractures of the shaft of the femur, was described by him in 1890. Note the use of skin traction and treatment of the fracture in full extension. The wheels at the end of the splint were used to facilitate traction. The full-ring Thomas splint itself remains unchanged today. (From Peltier LF. A Brief History of Traction. *J Bone Joint Surg Am* 1968;50:1603.)

Percival Pott in 1773 recognized the need to flex the hip and knee to reduce the tension in the muscles and soft tissues that caused deforming forces on the fragments of the femoral shaft. Most surgeons endorsed his ideas, and traction treatment was modified thereafter to incorporate flexion of the joints above and below the injury (70). Pott used his method with the limb lying on its side, a position that was hardly practical. Mayor (61) and Sauter (85) developed the concept of balanced suspension of splints, which enabled the limb to be suspended in a flexed position. Suspension and traction in combination were first introduced by Nathan Smith prior to the American Civil War and published in 1867 (Fig. 10.81) (88,89 and 90). During the Civil War, Hodgen further refined Smith's splint and provided a mechanism for providing both suspension and traction through the splint (39). The Hodgen splint saw considerable use during World War I (64). Hodgen splints were still available at San Francisco General Hospital when I did my residency there in the early 1960s; they were used in combination with skeletal traction (Fig. 10.82).

**Figure 10.81.** Nathan Smith introduced suspension in the treatment of fractures of the femur with this suspended traction splint. No effort was made to incorporate traction. (From Peltier LF. A Brief History of Traction. *J Bone Joint Surg Am* 1968;50:1603.)

Up to this point, traction was applied most commonly through the splint itself. The concept of applying adhesive plaster directly to the skin of the leg for traction was introduced somewhat before the Civil War and is used today with only slight modifications. Although Crosby initially proved its effectiveness, Gurdon Buck's 1861 publication describing his experience using skin traction for the treatment of 21 patients with fractures of the shaft of the femur led to the method being known as Buck's traction (Fig. 10.83) (16). A modification of Buck's original method is still the standard method of applying skin traction today.
Buck, in 1883, improved the ability to apply traction to the skin by his method of isotonic skin traction with treatment of the fracture in extension. (From Peltier LF. A Brief History of Traction. J Bone Joint Surg Am 1968;50:1603.)

Thomas Bryant of Guy’s Hospital in London was quick to adapt Buck’s method to the treatment of fractures of the shaft of the femur in young children (Fig. 10.84) (15). Although much care is required to avoid complications from the traction, Bryant’s traction remains a useful method for treating subtrochanteric fractures of the femur in infants and young children.

Bryant, in 1879, modified Buck’s method for the treatment of fractures of the femur in children. This method is still occasionally used today for infants and small children with subtrochanteric fractures of the femur when initial traction at 90° of flexion of the hip is necessary to obtain a satisfactory reduction. Most young children’s femur fractures are treated today with closed reduction and immediate spica cast. Care must be taken in the application of the skin traction to avoid skin problems and decubitus ulcers about the knee and ankle. Although Bryant’s original illustration shows only one leg in traction, most surgeons put both legs in traction. This method is suitable for small children under 2 years of age. It should not be used in children older than 2 years of age because of the risk of ischemia and compartment syndrome caused by the overhead position of the extremities. Enough weight is applied to lift the buttocks slightly off the bed. Subtrochanteric fractures in this age group quickly become stable; therefore, Bryant’s traction is rarely used for more than 3 weeks. (From Peltier LF. A Brief History of Traction. J Bone Joint Surg Am 1968;50:1603.)

Australian surgeon R. Hamilton Russell further refined treatment with skin traction by combining Buck’s traction method with a sling system that allowed the limb to be treated in flexion (Fig. 10.85) (83). Russell described his method in 1921 and it is still used today when skeletal traction is not required.

In 1924, Russell introduced his flexion method for the treatment of fractures of the shaft and the femur, which used skin traction; see Fig. 10.90. (From Peltier LF. A Brief History of Traction. J Bone Joint Surg Am 1968;50:1603.)

Although it is almost never used today, this is an illustration of Russell’s traction as used with modern traction materials. Skin traction is applied as demonstrated in the previous figure.

With the discovery of x-rays in 1895, surgeons quickly realized that malunions of fractures of the femoral shaft were quite common when treated with these methods. Although methods of skeletal fixation and traction had been described several years before, Pearson in 1919 introduced the first popular method of skeletal traction, using a type of ice tong to grasp the distal femur (69). At the same time, he popularized an attachment to the Thomas splint that allowed the knee and hip to be flexed (Fig. 10.86). Tongs did not provide secure attachment to bone, and skin problems were common.
Pearson, in 1919, introduced the successful use of skeletal traction on the femur. He combined this with attachment to the Thomas splint, which allowed the knee to be flexed, improving the reduction of fractures of the femur and making the traction practical. (From Peltier LF. A Brief History of Traction. J Bone Joint Surg Am 1968;50:1603.)

Traction by skeletal pins was introduced by Fritz Steinmann of Switzerland in 1907. Two years later, Martin Kirschner introduced the use of small-diameter tensioned wires. Both of these methods are used today, little changed from the original introduced nearly a century ago. Lorenz Böhler, the well-known surgeon from Vienna, modified and improved these methods and popularized them throughout the world.

Modern methods of traction use new materials and manufacturing methods to refine these basic techniques, but they remain much the same. The principles established by our ancestors centuries ago remain valid.

**BASIC KNOTS**

Knots tied in traction ropes must be guaranteed not to slip, must be easy to tie, and most important must be easy to untie for adjustment of traction. Three basic knots are very useful and should be known by all who use traction: the square knot, bowline, and clove hitch. Frayed rope ends are unsightly and can be unsafe if the unraveling of the rope gets caught in the traction apparatus or causes failure of a knot. Wrap the rope end circumferentially with tape and then cut across the tape to produce a neatly trimmed end.

The square knot is the most common and useful knot for tying a rope to itself or to other objects. Note the direction of the strands of the rope in this illustration. At either end of the knot, the free strands must pass on the same side of the loop to avoid a granny knot. Take care: If the two overhand knots are not laid flat, a series of slip knots can be produced, and they will slip.

The bowline knot is used to attach the rope to itself around an object, or to join two ropes. Make a loop in the rope. In the illustration, the loop is being held by the left hand. Notice that the vertical portion of the rope (“the tree”) comes from beneath the horizontal component of the loop (“the ground with a hole in it”). The direction of the free end of the rope is easy to remember using this mnemonic: The upright strand represents a tree with its roots under ground, and the loop is a hole in the ground adjacent to it. Think of the end of the rope as a rabbit. The rabbit jumps out of its hole, runs around the tree, and dives back into its hole. Grasp the two free ends and pull the knot snugly together.

The clove hitch, a common knot used in sailing and horseback riding, is used to attach the rope to a fixed object such as a post or a splint. It is two half-hitches reversed on each other and tied around the splint. In the completed clove hitch, tape the free end of the line to the rope to ensure that the clove hitch will not unwrap. Notice that the end of the tape is folded back on itself and left free so that the knot can be easily adjusted. This versatile knot can be loosened and slid along the splint and retightened to adjust the line of pull.

**SKIN TRACTION**

The principles for application of skin traction are the same for the upper and lower extremities. Avoid pressure over bony prominences and superficial nerves and vessels. The material used to apply the traction should be adhered to the limb over as wide an area as possible to avoid concentrated areas of traction and shear lines where blisters might occur. Commercial off-the-shelf devices for skin traction for the lower extremity use a soft foam liner and Velcro straps; often, a support for the foot is included. These are quite useful and work well for temporary traction in patients who will be going to surgery shortly for stabilization of femur fractures. Generally, longitudinal pull of more than 5 pounds is impractical with these devices. For stronger traction and for prolonged traction, I recommend application of skin traction using one of the two following methods.

**Buck’s Skin Traction**

- Wrap four layers of Webril around the foot and ankle to protect the bony prominences and neurovascular structures.
- Next, wrap a 4-inch elastic bandage gently around the foot and ankle.

**Apply a traction strip and then incorporate it with the elastic wrap.**

**Incorporate the traction strip with the elastic bandages to just below the common peroneal nerve.**
Insertion of a Steinmann Traction Pin into the Proximal Tibia

- Place the traction loop or block through the traction strip at the bottom of the foot and apply the traction rope. The traction loop or block is important to prevent traction from causing excessive pressure over the malleoli. This simple method allows application of traction for up to 5 pounds for short periods of time. If the traction is used for more than 24–36 hours, it should be unwrapped daily for skin inspection and then replaced.

**Modified Buck’s Skin Traction**

- Apply Webril around the foot and ankle to protect neurovascular structures and bony prominences (Fig. 10.89A).

**Figure 10.89.** Modified Buck’s skin traction. See text for details.

- Coat the leg circumferentially with tincture of benzoin or other commercial skin adherent. Be sure the patient is not allergic to these adhesives, as serious blistering or rash can occur. Here, the adherent is applied to the skin below the knee. If traction heavier than 5 pounds is to be used, extend the coverage to the upper thigh.
- In children, the traction is routinely adhered to the mid thigh or upper thigh to increase the area of pull.
- Roll a snug tubular stockinet up the leg as high as necessary. Use one long enough that it can be doubled back down over the traction strip (Fig. 10.89B).
- Now apply the traction strip with the elastic wrap.
- Finally, pull the tubular stockinet back down over the elastic wrap and traction strip and secure it in place with some tape at the foot (Fig. 10.89C). This method of traction may allow skin traction up to 7 pounds, but care must be taken over 5 pounds to avoid skin problems or ischemia.
- With this method, the traction can be left in place for substantial periods of time without having to be removed, assuming that the patient is asymptomatic and comfortable.
- In an alternative method used on our pediatric service, Elastoplast strips are initially applied longitudinally and then held in place with a continuous row of circumferential strips. This works extremely well but must be used with caution to avoid skin problems.

**RUSSELL’S TRACTION**

Classic Russell's traction with skin traction is little used today, as this more complicated method is unnecessary for short-term preoperative traction, and skeletal traction is much more effective for long-term treatment. In Russell's traction (Fig. 10.90), a sling is placed beneath the knee and distal femur to help eliminate the posterior angulation common in distal fractures of the shaft of the femur. The pulley system combined with the suspension pulley provides a vector of pull along the axis of the femur, and the effective traction is roughly double the weight that is hung, excluding the effect of friction in the pulley system.

A fleece-lined sling is placed under the knee and distal femur. The traction–suspension rope inclines distalward from the knee sling and then passes through two pulleys on the frame and one mounted to the bottom of the foot, producing a combination of suspension and traction roughly in the axis of the femur. I no longer use this method, as modified Russell's traction with a skeletal pin is much safer and more effective.

**SKELETAL TRACTION**

Skeletal traction can be applied with smooth or threaded Steinmann pins, smooth Kirschner (K-) wires, or specialized screws or bolts designed for the greater trochanter of the femur or olecranon of the ulna. Smooth pins, which tend to slide back and forth in the bone, can become loose in the bone and damage the skin. For this reason, threaded pins are useful. Specialized traction pins, threaded only in the midportion, are ideal. Steinmann pins are larger, and tension is unnecessary to provide rigidity. For that reason, larger pins are necessary to avoid bending. Do not use those with diameters less than ¼ inch. K-wires are designed to be tensioned: They gain their rigidity from the tension and are quite effective. Because of their small diameter, avoid threaded wires, as they break often. Most K-wires are 1–2 mm in diameter; larger diameters cannot be effectively tensioned and are usually not used.

The typical sites for transverse traction pins are the olecranon, distal femur at the level of the epicondyles, proximal tibia at or below the tibial tubercle, distal tibia just proximal to the ankle joint, or calcaneus. I do not use threaded pins in the olecranon because of the risk of injuring the ulnar nerve. Knowledge of the location of the neurovascular bundles in the lower extremity is necessary for proper pin placement.

For femur fractures, I prefer traction through the proximal tibia using a large-threaded Steinmann pin (Fig. 10.91). I find it more comfortable for the patient and it interferes less with knee motion than do femoral pins. This is the best location and type of pin for the technique of closed intramedullary nailing that I use (see Chapter 20).

**Figure 10.91.** Insertion of a tibial traction pin. See text for details.

To prevent K-wires from slipping, stack 2 x 2-inch gauze pads on the pin between the skin and the traction bow. This must be a snug stack that prevents the bow from moving in relation to the leg (illustrated in Chapter 24).

**Insertion of a Steinmann Traction Pin into the Proximal Tibia**

- Figure 10.91A shows a patient in whom a previous traction pin became loose and is being replaced. The entry and exit wounds for the pin are somewhat more distal to the tibial tubercle than I prefer.
- Use sterile technique with gloves. Prepare the skin with an iodophor or equivalent disinfectant. Square off the knee and proximal tibia with sterile towels.
- Always insert the pin from lateral to medial, to minimize the risk to the common peroneal nerve. Additionally, this technique allows the pin to be started on a bone surface at right angles to the penetration angle of the pin. In adults, I prefer to locate the pin at the tibial tubercle about one and one-half finger breadths posterior to the anterior border of the fibula.
- Anesthetize the skin and deep tissues down to the periosteum with a local anesthetic.
- Use a #11 blade to make the initial skin incision. Here, the incision is being made transversely, but it is best to make it vertically in the longitudinal axis of the leg. Make the skin incision slightly smaller than the diameter of pin to be used to produce a snug fit of the skin around the pin and to prevent sliding of the skin on the bone.
pin, which increases the risk of infection. At the same time, accurate location of the skin entry point to the bone portal is essential to avoid gathering of the skin on the pin. If the latter occurs, the skin must be incised to relieve the tension. Close the excessive length of wound with an appropriate suture to maintain the snug fit around the pin.

- Always insert traction pins with hand drills, as power will produce excessive heat and kill the bone unless the bone is predrilled (Fig. 10.91B). Predrilling is usually not necessary and is inconvenient in the emergency-room setting. Be certain that the tip of the pin is sharp. Two-sided points are preferable to four-sided points.
- Push the pin down to bone and drill the pin through the tibia.
- When the pin tents the skin on the medial side, make a nick with the knife blade. An assistant can provide resistance to facilitate piercing the skin with the pin.
- In Fig. 10.91C, notice the location of the pin and the snug fit of the skin around the pin in the absence of tension. Remember that hip and femur fractures often lie in external rotation. Be certain to hold the leg rotationally straight while the pin is inserted, or it will be malpositioned for traction.
- Dress the pin with circumferential Kerlix or similar dressing (Fig. 10.91D). Antiseptic or antibiotic solutions on the pin at the skin interface are unnecessary. As long as the pin is properly inserted and does not loosen, daily skin care is unnecessary. Keeping a clean sterile occlusive dressing in place as illustrated here suffices.

**Skeletal Traction with a Western Boot**

The “Western boot” is a versatile method of skeletal traction (Fig. 10.92). It is very comfortable for the patient, as the foot is fully supported, the traction pin is protected, the thigh is suspended independently, and there is no traction splint or apparatus near the buttocks or groin to interfere with personal hygiene. This modification of Charnley's modification of Russell's traction (18) is called the Western boot because it was developed at San Francisco General Hospital, where the staff often decorated the cast to look like a cowboy boot. In addition to being comfortable and versatile, this method allows early motion of all joints and permits the patient to do resistive exercises against the pull of the traction, and a continuous passive motion motor can be attached to the thigh suspension rope to produce continuous passive motion of the hip and knee.

![Figure 10.92. "Western boot" traction. See text for details.](D) from Charnley J. The Closed Treatment of Common Fractures, 3rd ed. Baltimore: Williams & Wilkins, 1963.

- Insert a ¼- or ⅜-inch threaded Steinhmann pin (Fig. 10.91). Place sterile 4 × 4-inch gauze pads over the Steinhmann pin.
- Prepare the extremity for application of a short-leg cast. Use tubular stocking and Webril as needed. The heel and bottom of the foot are at risk for pressure sores, so place a piece of felt over the bony prominences.
- Tie a traction rope to either side of the Steinhmann pin, long enough to extend about 2–3 inches beyond the bottom of the foot. Tie this to the overhead bed frame to help hold the leg up while the cast is applied.
- Now apply a short-leg cast. Begin by incorporating the leg with a roll of plaster two layers thick.
- Once the initial two layers of circumferential plaster have been applied, place a 10- to 15-layer splint along the posterior aspect of the leg and foot (Fig. 10.92B).
- Place a second splint around the upper end of the cast, incorporating the Steinhmann pin.
- Bring the rope that was attached to the Steinhmann pin down alongside the cast and hold it in place opposite the heel of the cast.
- Now thoroughly incorporate the rope and the splints into the cast. Keep the rope sufficiently posterior that the anterior third of the cast can be removed.
- Once the cast has been completed, slip a small pulley onto the traction rope.
- When the cast is dry, remove the anterior half to avoid putting pressure on the foot and ankle if the cast should slip (Fig. 10.92C). The foot can be lifted out of the cast for skin care. The bottom of the cast supports the ankle and prevents an equinus contracture. The open top permits active motion of the toes and ankle into dorsiflexion and plantar flexion.
- The cast is usually not dry enough to window for several hours. Normally, I window the day after application.
- The importance of the cast's incorporating the Steinhmann pin and surrounding the leg is illustrated in Fig. 10.92D.
- In Fig. 10.92D, on the left, the leg is allowed to lie on the slings on a Thomas splint. The result is compression of the soft tissues of the leg, which can be uncomfortable and can produce a common peroneal nerve palsy. Distortion of the skin around the pin can cause pressure sores. In Fig. 10.92D, on the right, the calf is suspended within the rigid cast. Suspension prevents skin problems and minimizes the risk of common peroneal nerve palsy. It also reduces the risk of pin-track infection by immobilizing the pin and reducing the motion between the pin and skin.
- The completed Western boot incorporated into Russell's traction is shown in Fig. 10.92E. Notice that the rope and pulley configuration is identical to that described by Russell, except the suspension rope from the Steinhmann pin inclines backward, toward the head of the patient. This inclination is necessary to prevent the knee from dropping into full extension. This is convenient for the patient, as there is nothing on the thigh or buttck and groin.

The amount of traction needed to pull the femur out to length and maintain position is quite variable, depending on the size and muscle mass of the patient, and on the hydraulic forces at the fracture site. A good general rule is to apply 1 pound of traction for every 7 pounds of body weight. Prolonged skeletal traction over 35 pounds is uncomfortable and not well tolerated. In this patient, where about 25 pounds of traction were desired, a 15-pound weight was placed on the end of the rope. The additional weight compensates somewhat for the friction in the pulley system. This type of traction is ideal for the pelvis, acetabulum, and proximal femur, but it does not offer adequate stability for fractures of the femoral shaft or supracondylar fractures.

For fractures of the shaft or supracondylar area of the femur, and for additional stability under other circumstances, add an independent thigh sling (Fig. 10.92F). Antiseptic or antibiotic solutions on the pin at the skin interface are unnecessary. Keeping a clean sterile occlusive dressing in place as illustrated here suffices.

For fractures of the shaft or supracondylar area of the femur, and for additional stability under other circumstances, add an independent thigh sling (Fig. 10.92F), which may offer sufficient stability that a shaft fracture can be treated definitively. Additional stability may require the use of a Thomas splint.

Another advantage of the Western boot is that it is easily adapted for fixed traction or for fixed traction combined with longitudinal traction (Fig. 10.92G). In this case, the suspension ropes have been removed and a half-ring Thomas splint has been slipped under the limb. The traction rope is tied to the end of the splint and a windlass used to apply traction. To avoid excessive pressure in the groin, a traction rope has been tied to the end of the splint and a rope with a weight hung off the end of the stoo.

This arrangement can be used to transport the patient to another hospital or ancillary diagnostic facilities. This method can be used to get patients with multiple injuries out of bed early. For mobilization of the patient with multiple injuries who is in traction, I prefer roller traction.

**TRACTION TREATMENT OF FEMORAL SHAFT FRACTURES**

In his classic work The Closed Treatment of Common Fractures, Charnley includes a beautiful discussion of the mechanics of conservative treatment of femoral shaft fractures (18). The discussion here is based on his principles, and Figure 10.93, Figure 10.94 and Figure 10.95 are from his text.
the extremity as far as the first pulley. In Varus deformity is prevented by abducting the leg at the hip (below (posterior to) the longitudinal axis of the femur as viewed from the side). The Thomas splint position is achieved by aligning the Thomas splint posterior to the axis of the femur, placing a pad beneath the fracture site, and adjusting the pull of the traction line to ensure maintenance of position. The most effective method of controlling position, however, is Charnley's modification of the Thomas splint method. Although most fractures reduce well with the simple application of longitudinal traction in a properly applied splint, it is more humane to do the initial application of traction, particularly if a Western boot is to be used, in the operating room under regional or general anesthesia. If traction alone does not result in adequate alignment, then manipulate the fracture under anesthesia to achieve a good reduction and make the necessary adjustments in the traction lines to ensure maintenance of position.

In general, the Thomas splint with traction is used to maintain reduction rather than actually achieve reduction. Femoral shaft fractures tend to heal with recurvatum (posterior angulation of the fracture), varus of the distal fragment, and external rotation. External rotation is easily managed by placing the tibial pin in proper position and applying longitudinal traction. The anterior superior iliac spine, mid patella, and first web space of the toes should be longitudinally aligned. Any tendency for excessive external rotation can be managed by attaching a small traction rope to the lateral side of the traction pin and hanging on it a 1-pound weight, but it is rarely necessary to do so.

Posterior angulation at the fracture site is avoided by using gravity as an assistant. Charnley emphasizes that a pad must be placed below the fracture site, and the angle of the traction line must be adjusted downward to impart a forward thrust at the fracture site and a posterior thrust at the distal femur to correct the deformity. This position is achieved by aligning the Thomas splint posterior to the axis of the femur, placing a pad beneath the fracture site, and adjusting the pull of the traction line to be below (posterior to) the longitudinal axis of the femur as viewed from the side.

Varus deformity is prevented by abducting the leg at the hip (Fig. 10.93). To maintain this position, all traction and suspension lines should be in the longitudinal axis of the extremity as far as the first pulley. In Figure 10.95E, for example, the pulleys at the foot would need to be on long bars beyond the side of the bed, and the pulley at

---

**Figure 10.94.** Charnley's modification of Thomas's traction for fractures of the femur. Top: The line of traction is in the line of the femur, and the pad is low. Gravity causes the fracture to sag into posterior angulation. Bottom: In Charnley's modification, the Thomas splint is placed posterior to the femur, a pad is placed under the fracture site, and the line of traction is adjusted to pull below the longitudinal axis of the femur. This results in correction of the deformity. (From Charnley J. The Closed Treatment of Common Fractures, 3rd ed. Baltimore: Williams & Wilkins, 1963.)

**Figure 10.95.** Control of varus angulation. A: If the Thomas splint is placed in direct line with the body, varus angulation commonly occurs due to the pull of the hip abductors and iliopsoas, which pull the proximal fragment into abduction. B: This is nicely corrected by abducting the splint to bring the distal fragment into line with the proximal fragment, relaxing the muscle forces about the hip. To maintain this position, all traction and suspension lines should be in the longitudinal axis of the extremity as far as the first pulley. A continuous passive motion machine can be attached to the handpiece line. In 90-90 traction, useful for subtrochanteric fractures of the femur, the iliopsoas pulls the proximal fragment into flexion. Because a tibial traction pin tends to straighten out the knee, most surgeons prefer a femoral pin for 90-90 traction. A simple sling is used to suspend the calf and foot.

Various methods of traction have been described for skeletal traction of the femur (Fig. 10.93). The Thomas splint with Pearson attachment (Fig. 10.93A) is the most commonly used. The Thomas splint simply cradles the femur and plays no active role in controlling deformity.

The Braun frame (Fig. 10.93B) is almost never used today for the femur because of its many disadvantages. The frame is heavy and interferes with nursing care. The angles of the frame and the pulley positions cannot be adjusted. Deformity is quite common because no dynamic forces can be built into this frame for management of the alignment of the fracture.

Russell's traction (Fig. 10.93C) has already been discussed. Skeletal traction methods are superior.

With Perkin's traction (Fig. 10.93D), no splintage is used at all. The limb is placed on a pillow and there is a single traction line. Although simple, there is a major disadvantage: When the patient lifts to get on a bed pan, the fracture commonly angulates. We use Perkin's traction in our intensive care units for multiply injured patients when we want to keep the method of treatment as simple as possible. Commonly, we combine it with a cast-brace, which allows the nursing staff to mobilize the patient by rolling or moving him to a bedside chair. The cast-brace provides good stability, and a single traction line is easy for the nursing staff to manage.

Fisk's traction (Fig. 10.93E), a modification of Thomas's method, allows 90° of knee movement for early rehabilitation. A continuous passive motion machine can be attached to the handpiece line (Fig. 10.90).

In 90-90 traction, useful for subtrochanteric fractures of the femur, the iliopsoas pulls the proximal fragment into flexion. Because a tibial traction pin tends to straighten out the knee, most surgeons prefer a femoral pin for 90-90 traction. A simple sling is used to suspend the calf and foot.

In general, the Thomas splint with traction is used to maintain reduction rather than actually achieve reduction. Femoral shaft fractures tend to heal with recurvatum (posterior angulation of the fracture), varus of the distal fragment, and external rotation. External rotation is easily managed by placing the tibial pin in proper position and applying longitudinal traction. The anterior superior iliac spine, mid patella, and first web space of the toes should be longitudinally aligned. Any tendency for excessive external rotation can be managed by attaching a small traction rope to the lateral side of the traction pin and hanging on it a 1-pound weight, but it is rarely necessary to do so.

Posterior angulation at the fracture site is avoided by using gravity as an assistant. Charnley emphasizes that a pad must be placed below the fracture site, and the angle of the traction line must be adjusted downward to impart a forward thrust at the fracture site and a posterior thrust at the distal femur to correct the deformity. This position is achieved by aligning the Thomas splint posterior to the axis of the femur, placing a pad beneath the fracture site, and adjusting the pull of the traction line to be below (posterior to) the longitudinal axis of the femur as viewed from the side.

Varus deformity is prevented by abducting the leg at the hip (Fig. 10.93). To maintain this position, all traction and suspension lines should be in the longitudinal axis of the extremity as far as the first pulley. In Figure 10.95E, for example, the pulleys at the foot would need to be on long bars beyond the side of the bed, and the pulley at
Unstable supracondylar fractures of the humerus in children are rarely treated in traction because closed reduction with percutaneous pin fixation gives far superior results. Dunlop traction is popularized by placing the attachment of the Pearson splint at the fracture site. Use a commercially available single synthetic fleece suspension sling, attached to the splints with plastic clips, to support the limb. A pad has been placed beneath the fracture site in Figure 10.96: note that a Western boot is in place, which provides the advantages already discussed. Wrap the suspension rope around the ring of the Thomas splint twice to prevent the rope from slipping on the ring and to allow control of rotation of the splint. In this case, the weight has been hung at the head of the bed. I recommend hanging all weights at the foot of the bed, because traction bars at the head of the bed can damage the wall. Having the weights at the foot of the bed makes them easy to adjust, as well.

Use a single line of rope to suspend the Pearson attachment from the Thomas splint and to suspend the Thomas splint from the overhead frame. A clove hitch is used on the end of the Thomas splint, which allows the angle of knee flexion to be easily adjusted without untying any knots. In this case, a fixed line is used. Use pulleys and weights at the lower end if desired to provide suspension, but they add to the complexity of the arrangement and are usually unnecessary. The traction line in this case passes only slightly below the longitudinal axis of the femur, as the fracture is in the upper mid shaft.

Place sufficient weight on the balanced suspension so that when the patient lifts to get on a bedpan, the limb rises easily with the torso.

### Cast-Brace Traction

Before the development of cast-braces, femur fractures needed to be maintained in traction until bridging callus was evident on both the anteroposterior and lateral views and the fracture was clinically stable. In the average adult, callus formation requires 6–12 weeks. At that point, we would leave the patient in balanced suspension but remove the traction; if no shift in the fracture was noted after several days, a single leg or 1½ spica cast would be applied and maintained until union occurred. Because this approach requires prolonged hospitalization and excessively long bed rest and immobilization, cast-brace traction became popular. A combination of cast-bracing with traction has been described by Connolly and King (20), Hardy (37), Lesin et al. (46), McIvor et al. (58), and Mooney et al. (61,62), as well as others. The method is called roller traction when the cast-brace is combined with traction through a single overhead line connected to a pulley that rolls on the overhead bar of the traction frame (60). With this method of treatment, the patient is much more mobile in bed and the fracture is more securely supported. As soon as the patient is comfortable and there is early soft-tissue stability of the fracture site (usually in 3–6 weeks), the patient can begin to get up on crutches or a walker and begin non-weight-bearing crutch walking a few times a day.

Since the tibial traction pin is incorporated into the cast-brace, the cast-brace provides traction by virtue of gravity while the patient is upright, producing “ambulatory traction.” Frequent radiographic monitoring of the fracture is necessary during this mobilization to ensure that good alignment is maintained, as angulation is common with this technique. As soon as the patient is getting out of bed with a physical therapist twice daily and radiographs show no further shift in the fracture site, traction can usually be discontinued and treatment thereafter continued in the cast-brace. When sufficient consolidation of the fracture has occurred that shortening can no longer occur, the traction pin can be removed and weight bearing begun.

This method, popularized by the military during the Vietnam War, enables the average young healthy patient to be out of traction and discharged from the hospital by 6–8 weeks after fracture. The cast-brace must be maintained until solid union has occurred, which usually requires at least 10–12 weeks.

### Traction for Fractures of the Tibia

The usual indication for traction treatment of fractures of the tibia is soft-tissue problems precluding external or internal fixation. In addition, severe comminution, especially in the presence of poor-quality bone, may necessitate treatment in traction to initiate early motion of the knee or ankle. Use a traction pin through the calcaneus or distal tibial metaphysis, as indicated. The leg can be placed on a Braun frame, or for more convenient nursing in a Thomas splint with a Pearson attachment for balanced suspension. In most cases, traction is maintained for only a short time, until the soft-tissue problems resolve and a cast or cast-brace can be applied. The basic principles already described apply.

### Upper Extremity Traction

**Dunlop Traction**

Unstable supracondylar fractures of the humerus in children are rarely treated in traction because closed reduction with percutaneous pin fixation gives far superior results (Fig. 10.97). Rarely, operative fixation is contraindicated and treatment in traction may be necessary.

**Figure 10.97.** Dunlop traction for supracondylar fractures in children, as modified by Allen and Gramse. (From W. P. Blount's classic textbook, Fractures in Children. Baltimore: Williams & Wilkins, 1955.279.)

- First, apply skin traction to the forearm using the techniques described for modified Buck’s traction.
- Leave the hand and fingers free for neurovascular examination. The radial pulse should be accessible.
- It is usually best to place the patient in the orthopaedic bed (Fig. 10.97) in which she will be immobilized and to perform the closed reduction in that bed to prevent...
loss of reduction when she is moved from the operating table to the ward bed.

- Reduce the fracture, then apply sufficient traction from the forearm to hold the arm level with the floor.
- Fashion a sling for the arm from a commercial fleece sling or from felt inserted into tubular stockinet. It must be sufficiently wide that at least the lower third of the arm is covered.
- Attach to it sufficient weight to maintain reduction (rarely more than 1–2 pounds).
- To avoid malrotation and varus or valgus alignment, the patient’s torso must be maintained in correct relationship to the line of traction.
- Note the sheet doubled around the torso. It is quite difficult to keep the average child in this position for very long. Despite these disadvantages, I managed dozens of these fractures with this method in the 1960s and early 1970s with reasonably good success.

Overhead Olecranon Pin Traction

Like Dunlop traction, olecranon pin traction is rarely indicated today; I have not used it since the early 1980s. Most fractures of the humerus are now better managed with external or internal fixation. Rarely, a particular combination of systemic disease and soft-tissue and bone problems may necessitate treatment in overhead traction. An example might be a fracture of the humerus associated with burns, in which overhead traction may be the optimal method.

- Using sterile techniques, place an appropriate-size K-wire transversely through the olecranon. Always insert this pin from medial to lateral, taking care to avoid injury to the ulnar nerve. In Figure 10.98 the pin is not dressed, but I advise placing sterile 2 × 2-inch gauze pads between the skin and the K-wire bow to protect the pin entry site, and to prevent the bow from sliding back and forth. If the bow slides toward the medial side of the forearm and impinges on the ulnar nerve, ulnar nerve palsy and erosion of skin and nerve can occur.

Figure 10.98. Overhead olecranon pin traction.

- Apply sufficient traction to maintain appropriate length and the reduction.
- Suspend the forearm with a sling. The sling here is rather large. Rather smaller slings that can be more easily removed may facilitate physical therapy and hand function.

COMPLICATIONS OF TRACTION

Table 10.2 lists general recommendations for avoiding complications of traction, which follow the principles of those for casts and splints. Generalized cardiovascular deconditioning and atrophy of muscle occur very rapidly in patients on complete bed rest and traction. The physical therapist should visit all patients in traction within the first few days of treatment to initiate a physical therapy program for maintenance of cardiovascular conditioning and joint range of motion and strength. Stretching exercises, particularly of the Achilles tendon, are necessary to avoid contractures. Splinting may be necessary.

Table 10.2. Avoiding Complications of Traction

A program of progressive resistance exercises using light weights or elastic bands will help maintain muscle strength. All joints that can be moved through a full range of motion passively or actively without interfering with the treatment of the fracture or dislocation should be exercised vigorously throughout the day. Cardiovascular conditioning is very difficult to maintain while in traction, but a general exercise program is very helpful. It is usually possible to move the joints to some extent and to do isometric exercises of the muscles above and below the fractured bone; encourage the patient to do so as soon as possible.

Pressure sores and injuries to the nerves are avoided by careful attention to the techniques described. Remember that excessive traction on a swollen limb can precipitate compartment syndrome. If symptoms develop, reduction of the traction may be necessary.

Make every attempt to avoid decubitus ulcers. The key factor is an active, vigorous patient who frequently does pull-ups on the overhead frame to allow good circulation to the skin. Good nursing care to maintain a clean perineum and dry sheets is imperative. An egg-crate foam mattress or similar device should routinely be used, and alternated with an air mattress if necessary. The more complicated beds used for the care of quadriplegics are rarely practical with traction.

Thrombophlebitis is common in patients on prolonged bed rest, and secondary pulmonary embolism can be fatal. Some type of prophylaxis is indicated in nearly all patients (see Chapter 5 for more details).

Remember that traction rarely remains as initially adjusted. It requires constant attention to maintain optimal alignment and position, ensure patient comfort, optimize nursing care, and prevent complications.

CHAPTER 11

PRINCIPLES OF INTERNAL AND EXTERNAL FIXATION

This chapter combines five chapters from the second edition of Operative Orthopaedics, written by Timothy J. Bray and David C. Templeman (screw fixation), Fred Behrens (external fixation), David H. Gershuni (wire and pin fixation), Thomas P. Rüedi (plate fixation), Harry B. Skinner (materials), and myself. Much of the original material by these authors has been retained in this chapter, and I wish to acknowledge and thank them for their contributions.

A. INTRODUCTION

Orthopaedics is a highly technical specialty that employs an incredibly broad range of techniques, from fine microvascular surgery to bone fixation implants, to large metallic and polymeric composite implants for joint replacement, to sophisticated methods of external fixation involving all regions of the skeleton. Successful use of these implants and devices requires sophisticated knowledge on the part of the surgeon, as well as respect for the biology of the tissues being handled, for the best chance of a successful result. The surgeon must be certain that the indications for surgery are appropriate and that the patient is suitable for the operation: Even the best-performed procedure will fail if the indications are not correct and if the patient cannot benefit.

The technical aspects of applying internal and external fixation implants are critical to achieving bone union in the appropriate position and to avoiding implant failure. It is essential that resident and neophyte surgeons master the general principles and that mature surgeons constantly remind themselves of them, particularly when they are employing fixation techniques that they do not perform often.

METALLIC ALLOYS

The biocompatibility of metallic alloys is based on the presence of a constituent element that has the ability to form an adherent oxide coating that is stable and chemically inert. Materials that do not form stable oxides or that permit the oxide to become detached from the underlying metal, such as common carbon steel, are not biocompatible and continue to undergo degradation in the body. The common metallic alloys [e.g., cobalt chromium (ASTM F75-82, ASTM 799-82), titanium alloy (ASTM F136-79), and stainless steel (ASTM F55, F56)] have at least one element that forms an adherent oxide coating. The composition of these alloys is shown in Table 11.1. Detailed specifications of the composition are given in the American Society for Testing and Materials (ASTM) standards.

Composition varies somewhat depending on the intended use of the material. For example, if ductility is not a requirement, carbon is used to strengthen cobalt-chromium alloy (F75-62), although carbon reduces the alloy’s ductility. Other phases present in each alloy tend to stabilize the crystal structure. Forged cobalt-chromium alloy is strengthened by nitrogen as a minor impurity. Certain elements are deleterious to the properties, such as oxygen in a titanium alloy, which tends to make it brittle. Similarly, carbon in stainless steel decreases ductility unless it is allowed to precipitate in the grain boundaries as chromium carbide, where it decreases resistance to corrosion.

Implant alloys are manufactured by melting the appropriate elements together to produce a liquid solution that subsequently becomes a solid solution of each element in the matrix after cooling. This material is shipped as a bar, rod, or plate for further processing by the implant manufacturer. Titanium alloy can be shaped by machining from bar stock or sheet stock; stainless steel implants can be produced the same way. After initial forming of the more ductile version of the cobalt-chromium alloys, forging significantly strengthens the alloy and brings it to its final shape by applying mechanical work. The casting process can be used for titanium alloy or cobalt-chromium alloy to produce intricate shapes. A wax mold of the prosthesis is coated with ceramic and fired. The wax melts out of the ceramic mold (i.e., lost wax process); after cooling, liquid metal is poured into the ceramic shape and allowed to solidify. Final shaping is done by machining and grinding. Machining and forging done under appropriate conditions do not diminish the mechanical properties of the alloy. However, investment casting typically weakens the material by causing an increase in the grain size. This mostly affects the fatigue life, because for most materials the fatigue strength is inversely proportional to grain size.

MECHANICAL PROPERTIES OF IMPLANT MATERIALS

The yield stress is the transition point between elastic deformation and plastic or permanent deformation. Deformation at strains lower than this level obey Hook's law, which states that the elastic modulus (Young's modulus) is the proportionality constant in the linear portion of the stress-strain curve below the yield point. Fatigue strength refers to the ability of a material to resist repetitive loading. Typical yield and fatigue strengths and elastic moduli are presented in Table 11.2.
The elastic modulus is an intrinsic property of a material generated by the attraction of atoms within the material, and it has essentially no variation with thermal or mechanical history. Fatigue strength, however, can be significantly improved or diminished by heat treatment. Cast cobalt-chromium alloy has a fatigue strength of about 255 megapascals (MPa), which is only about twice that of the cast stainless steel used in total hip prostheses in the early 1970s that failed in fatigue. Titanium alloy, although quite strong in fatigue strength in the "as received" or forged condition, can undergo significant deterioration of its fatigue properties as a result of applying a porous coating. Failure is caused by the creation of stress concentration sites by the porous coating, and the grain growth caused by the heat treatment used to apply the porous coating. Much of the deterioration in properties of titanium alloy can be alleviated by the use of a diffusion bonding process that lowers the temperature of sintering. The notch sensitivity problem is managed by design modifications that remove the porous material from areas subjected to tensile loading. These concerns regarding the effect of porous coating do not apply to implants for internal fixation.

Surface hardness is tested by indentation tests, such as the Rockwell test or the Vickers test, in which the material is indented by a very hard object. The resistance to this plastic deformation indicates the tensile strength of the material and its wear properties. These tests are suitable for metallic alloys.

**STAINLESS STEEL VERSUS TITANIUM FOR BONE FIXATION IMPLANTS**

For decades, stainless steel has been the most widely used material for bone fixation implants. The 3.16L alloy is still used most commonly; however, other stainless steel alloys are also in use and provide useful characteristics such as increased strength in hip fixation implants, which can be subjected to high bending loads and fatigue stress because of delayed healing (Table 11.1). A major concern about stainless steel implants has been their stiffness, which is approximately seven times that of human bone. Uhthoff and Dubus (103) and others (16,27,63) have demonstrated in animal experiments that when rigid internal fixation is applied with stainless steel implants, prolonged exposure of the bone can lead to porosis and weakening of the bone due to stress protection. This is also seen in total joint arthroplasty, particularly about the proximal portions of the stem in the femoral components of total hip arthroplasty. Perren et al. (81,82) have shown that the porosity and weakening observed is in part due to the revascularization response resulting from the surgical procedure itself. In spite of this, however, stress protection remains a significant problem, particularly where the size and stiffness of the implant is significant compared to that of the bone. Chapman et al. (27), in a review of 174 forearm fractures, found no refractures of the radius or ulna after removal of AO 3.5 mm dynamic compression (DC) plates, whereas in all three patients in whom the larger narrow DC plates and 4.5 mm screws were used, refractures occurred either through the screw holes or the fracture site.

Therefore, orthopaedic surgeons have sought a material for plates and nails that is closer to bone in its mechanical characteristics, yet would be stiff enough to permit fracture healing and strong enough to avoid fatigue failure prior to fracture union. Titanium and its alloys, widely used in military aircraft and submarines, have proven, in part, to meet this need. Most manufacturers have used a titanium alloy containing 6% aluminum and 4% vanadium (6-4 titanium). The mechanical characteristics of commercially pure (CP) titanium were not suitable for internal fixation implants until recently; however, the AO group has used plates and screws of CP titanium, which have proven to be clinically useful. By utilizing particular forging and other techniques, they have been able to render the CP titanium sufficiently strong. Other alloys of titanium, particularly beta alloys, offer even better mechanical properties for internal fixation implants than the 6-4 titanium, and some of these are listed in Table 11.1. Overall, titanium alloys are approximately twice as flexible as stainless steel and at least one-third stronger. A primary disadvantage of titanium is that it is difficult to manufacture, which increases costs. Also, it is more brittle than stainless steel: Cracks occurring from notches in the metal tend to propagate much more easily than in stainless steel, which influences implant design and how the surgeon uses the implants. Titanium alloys become particularly useful in smaller implants, such as nonreamed intramedullary nails, and in smaller plates, which employ smaller-diameter screws, where the superior strength of the titanium results in much less screw and nail breakage compared with stainless steel. In spite of the increased cost, most major implant manufacturers today offer bone fixation implants composed of titanium. Some entire implant systems, both plates and intermedullary nails, are offered in titanium.

In addition, titanium is more resistant to corrosion than stainless steel, which has a tendency to experience crevice corrosion at the contact point between screw heads and plates. Plate failure can take place through these corrosion pits. Titanium aggressively forms an oxide, which provides superior passivation of the implants. I have removed numerous titanium plates and screws and have never seen any visible evidence of crevice corrosion.

All metallic implants release a small quantity of metallic ions into the local soft tissues and general circulation. Although concerns have been raised about the potential toxic or carcinogenic effects of these minute amounts of ions, and sarcomas have been described in association with implants, no evidence has been presented that implants are a significant health risk to patients. On the other hand, current implant materials have been used for approximately 60 years. Whether exposure to these ions for up to 50 or 90 years in our long-lived population will produce diseases is not yet known. When placing these implants in children and young adults, a concern is the weakening observed is in part due to the bone and its mechanical characteristics, yet would be stiff enough to permit fracture healing and strong enough to avoid fatigue failure prior to fracture union. Titanium and its alloys, widely used in military aircraft and submarines, have proven, in part, to meet this need. Most manufacturers have used a titanium alloy containing 6% aluminum and 4% vanadium (6-4 titanium). The mechanical characteristics of commercially pure (CP) titanium were not suitable for internal fixation implants until recently; however, the AO group has used plates and screws of CP titanium, which have proven to be clinically useful. By utilizing particular forging and other techniques, they have been able to render the CP titanium sufficiently strong. Other alloys of titanium, particularly beta alloys, offer even better mechanical properties for internal fixation implants than the 6-4 titanium, and some of these are listed in Table 11.1. Overall, titanium alloys are approximately twice as flexible as stainless steel and at least one-third stronger. A primary disadvantage of titanium is that it is difficult to manufacture, which increases costs. Also, it is more brittle than stainless steel: Cracks occurring from notches in the metal tend to propagate much more easily than in stainless steel, which influences implant design and how the surgeon uses the implants. Titanium alloys become particularly useful in smaller implants, such as nonreamed intramedullary nails, and in smaller plates, which employ smaller-diameter screws, where the superior strength of the titanium results in much less screw and nail breakage compared with stainless steel. In spite of the increased cost, most major implant manufacturers today offer bone fixation implants composed of titanium. Some entire implant systems, both plates and intermedullary nails, are offered in titanium.

In addition, titanium is more resistant to corrosion than stainless steel, which has a tendency to experience crevice corrosion at the contact point between screw heads and plates. Plate failure can take place through these corrosion pits. Titanium aggressively forms an oxide, which provides superior passivation of the implants. I have removed numerous titanium plates and screws and have never seen any visible evidence of crevice corrosion.

**IMPLANT POLYMERS**

Four polymers find application in orthopaedic surgery on a routine basis. These are ultrahigh-molecular-weight polyethylene (UHMWPE), polypropylene, polytetrafluoroethylene (PTFE, Teflon), and poly(methylmethacrylate). Other polymers show promise as matrix materials for composite biomaterials, including polysulfone (UDEL), polyethersulfone, and polyetherketone (PEEK). Their chemical structures are shown in Fig. 11.1.

**Figure 11.1.** Chemical structures of implant polymers.

Polymers are manufactured under heat and pressure to produce addition or condensation reactions. Condensation reactions produce polymers by a combination of an organic acid and an organic base to produce water or an alternative third compound (Fig. 11.2). Reactive moieties on both ends of each type of molecule permit the reaction to grow long chains. Additional polymerization produces the polymer chains by adding one more link to a chain that was begun by an initiator molecule reacting with a carbon double bond, such as found in ethylene. Most implant polymers are thermoplastic, because they can be melted and cooled until solid again with no composition change.
Although injection molding of polymers from the melt is possible, molding of granules of a polymer under heat and pressure, called compression molding, is more common for production of polyethylene components. Machining of implants from stock is another technique that can be used. Both methods produce acceptable articular surfaces for implants.

The uses for polymeric materials are more diverse than for metallic implants, but their interchangeability is not as great. Polypropylene is used as a ligament augmentation device for knee reconstructive surgery, UHMWPE is used as the bearing surface in total joint arthroplasty, and Teflon is expanded to form a Gore-tex material used in knee reconstructive surgery. Polyethylene is partially crystallized, provided as granules, and combined with monomer and an initiator to form a final polymerized mass (e.g., Zimmer bone cement). When copolymerized with polyethylene, polylethylene methacrylate is used in a similar manner to form Simplex-P (Howmedica, Rutherford, NJ).

Polyactic and polyglycolic acids, polyaclatin (copolymers of the two acids), and polydioxanone find their main uses as resorbable suture materials under the brand names Dexon (Davis and Geck; US Surgical, Norwalk, CT), Vicryl, and PDS (both manufactured by Ethicon, Johnson and Johnson, Somerville, NJ). These materials are also available as resorbable pins, primarily for fracture fixation in the hand, foot, ankle, and skull. These materials can be made relatively stiff and are slow to resorb. Polyactic acid is now available as screws and pins because its slow rate of resorption may reduce the level of inflammatory response. Attempts at improving the stiffness of polyactic acid have included mixture with hydroxyapatite fibers.

CERAMICS

A ceramic is a nonmetallic, nonorganic material, usually produced by high-temperature processing. Typically, ceramics have high thermal and electrical resistance and high elastic modulus, low ductility, and low tensile strength. Excellent biocompatibility results from chemical inertness.

Carbon (Pyrolite) is produced by deposition of carbon from a gas-phase breakdown of gases such as methane (\( \text{CH}_4 \)) or methyltrichlorosilane (\( \text{CH}_3\text{SiCl}_3 \)) to produce carbon-silicon compounds with various proportions of silicon, typically 10% to 20%.

Ceramic materials are characterized by very high strengths, but brittle failure occurs after minor plastic deformation. Although the failure strength is quite high in many cases, relatively low failure stresses can occur occasionally.

Attempts have been made to form plates from ceramics, but they have not proven practical because of the inability to conform them to the bone, and because of their high failure rate caused by the brittle nature. Because of the unique characteristics of ceramics, they enjoy much more practical application in the bearing surfaces of total joint replacement prostheses and in the coatings of prosthetic implants where direct bone–implant ingrowth is desired.

COMPOSITE MATERIALS

A composite is a combination of two or more materials in which the mechanical performance of the composite is superior to that of either component alone. In man-made composites, usually one component is a fiber and the other is a matrix material. Bone itself achieves most of its mechanical properties as a natural composite material composed of calcium phosphate ceramics in a highly organized collagen matrix.

The first composite to come into general use, initially made by an orthopaedic surgeon, was the plaster of Paris bandage. This has been refined to fiberglass with a polymeric matrix in the current synthetic casting materials. A composite for internal prosthetic applications is based on the addition of chopped carbon fiber to improve the mechanical properties of polyethylene components.

Materials used in composites intended for implantation must be biocompatible. Three potential matrix materials that have undergone at least preliminary biocompatibility studies are thermoplastic and have similar structures (Fig. 11.1). These are UDEL, polyethersulfone, and PEEK, discussed above. The fiber materials strengthen and stiffen the matrix and can be used as chopped fibers or as long fibers. The chopped fiber material usually produces a composite that is isotropic, having stiffness and strength properties that do not vary with direction. The long fibers can be woven, wound, or formed in many geometric orientations to provide desirable mechanical properties. Only carbon fiber is being studied for orthopaedic applications.

Composite structures are typically produced from laminates. A laminate is a thin sheet of composite material in which all the fibers run in one direction and are held together by a thin coating of the polymer matrix material. It is produced by passing the fibers through the polymer, allowing it to be coated, and subsequently sticking the layers together and pressing them. This laminate is combined with other laminates to form a bulk composite; the properties of this composite vary depending on the orientation of each layer of the laminate. The primary direction of the fibers is called the zero direction, and other layers, or laminae, are oriented in relation to this (e.g., 0°, 45°, -45°, 90°, +30°, and -30°) to vary the properties of the polymer. A polymer that has equal numbers of layers in the 0°, 45°, -45°, and 90° orientations is called a pseudoisotropic polymer because the mechanical properties in any direction in the fiber plane are the same. An alternative means of producing a composite structure is to wind one or more continuous fibers in a particular orientation to provide desirable mechanical properties. Composite for internal prosthetic applications is based on the addition of chopped carbon fiber to improve the mechanical properties of polyethylene components.

Composite structures are typically produced from laminates. A laminate is a thin sheet of composite material in which all the fibers run in one direction and are held together by a thin coating of the polymer matrix material. It is produced by passing the fibers through the polymer, allowing it to be coated, and subsequently sticking the layers together and pressing them. This laminate is combined with other laminates to form a bulk composite; the properties of this composite vary depending on the orientation of each layer of the laminate. The primary direction of the fibers is called the zero direction, and other layers, or laminae, are oriented in relation to this (e.g., 0°, 45°, -45°, 90°, +30°, and -30°) to vary the properties of the polymer. A polymer that has equal numbers of layers in the 0°, 45°, -45°, and 90° orientations is called a pseudoisotropic polymer because the mechanical properties in any direction in the fiber plane are the same. An alternative means of producing a composite structure is to wind one or more continuous fibers in a particular orientation to provide the desired prosthetic shape.

The mechanical properties of primary concern are the strength and the modulus. The strength generally mirrors the modulus, and both of these depend on the orientation of each layer of the laminate. The primary direction of the fibers is called the zero direction, and other layers, or laminae, are oriented in relation to this (e.g., 0°, 45°, -45°, 90°, +30°, and -30°). These are the moduli of the fiber and matrix, respectively, and \( V_f \) and \( V_m \) are the volume fractions of the fiber and matrix, respectively. In the range of typical polymer fiber used in a laminate of 0.4–0.7 volume fraction fiber, the elastic modulus varies linearly in that range parallel to the fibers. The modulus relationship parallel to the fibers is more complicated and less applicable to all composites:

\[
E_{\text{parallel}} = E_f V_f + E_m V_m
\]

in which \( E_f \) and \( E_m \) are the moduli of the fiber and matrix, respectively, and \( V_f \) and \( V_m \) are the volume fractions of the fiber and matrix, respectively. In the range of typical polymer fiber used in a laminate of 0.4–0.7 volume fraction fiber, the elastic modulus varies linearly in that range parallel to the fibers. The modulus relationship perpendicular to the fibers is more complicated and less applicable to all composites:

\[
E_{\text{perpendicular}} = \frac{E_f V_m}{E_f V_m + E_m V_f}
\]

Because carbon fiber polymeric materials are strong and radiolucent, roentgenographic examination of fractures fixed with external fixation devices made of these materials can be performed with relative ease. Similarly, halo rings made of these materials are compatible with magnetic resonance imaging, allowing studies of the brain and cervical cord to be performed.

Plates and intermedullary nails manufactured from carbon composites have been used experimentally for internal fixation. Their potential advantages include radioluency (making observation of fracture healing easier), the ability to vary the modulus of the material, and the potential for using an absorbable polymer. None of these materials are currently in clinical use because of the inability to modify the shapes of the implants intraoperatively to fit the bone; because of liberation of carbon fibers into the adjacent tissues; and because the difficulties of predicting the resorption of polymers in larger load-bearing implants, as opposed to screws and pins, has
thus far precluded their use for these larger implants. No doubt, implants in this category will be available in the future, perhaps even containing bone inductive proteins.

B. PRINCIPLES OF WIRE, CABLE, AND PIN FIXATION

In France in the late 18th century, brass and iron wires were used for fracture fixation. Later, silver wire was introduced by Lister to treat a patellar fracture. Parham and Martin described steel bands used around the shaft of fractured long bones in 1913, and in 1922 Johnson developed stainless steel, which is the material still used for most types of wire and pin fixation. This form of fixation includes fine Kirschner wires, larger Steinmann pins, and flexible wire used for provisional and definitive fracture stabilization, osteotomy fixation, and skeletal traction.

KIRSCHNER WIRES

MATERIAL FEATURES

Martin Kirschner (1879–1942), a surgeon from Heidelberg, Germany, was the first to use thin wire pins for fracture management, in 1909. Kirschner, or K-wires are manufactured in lengths from 7 to 31 cm and in diameters from 0.6 to 3.0 mm. They may be smooth or threaded, but threaded wires have poorer bending strengths for a given pin diameter and may be difficult to remove at a later date. The wire may be pointed at one or both ends. In the latter case, the pin can be inserted antegrade from the fracture site to exit from the distal fragment and then retrograde back into the proximal fragment. K-wires may be trocar or diamond pointed (Fig. 11.3). The trocar point is somewhat easier to insert into dense cortical bone and there is less of a tendency to overheat.

Figure 11.3. Ends of Kirschner wires or Steinmann pins with trocar points on right and diamond points on left.

Because of their flexibility, K-wires are normally introduced with a power drill and a pin stabilization system, which may be a telescopic guide attached to the end of the drill chuck, or an external guide with a handle. The drill itself may have the capability of rapid locking and release of the wire; advancement therefore can be made from the barrel of the drill, which acts as the guide. Small-diameter pins can be inserted through large bore needles. An alternative is to introduce a gentle bow into the wire while drilling. This prevents oscillation of the wire. Two disadvantages of this technique are that the direction of the wire may be more difficult to control and the wire will overheat more rapidly. When K-wires are used, wire cutters and instruments for wire bending are required. The wire benders may be simple metal tubes into which part of the wire is inserted before being manipulated, or special pliers can be used (Fig. 11.4).

Figure 11.4. Instruments for wire bending. A: A metal tube with a flanged end. B: Special pliers.

INDICATIONS FOR USE

Traction

K-wires, even those with 3 mm diameters, are quite flexible, but the wire may be stiffened by applying tension with a traction bow. The construct is thus made strong enough to apply a load of approximately 20 kg, providing the bone is able to sustain this weight (Fig. 11.5).

Figure 11.5. Kirschner wire tensioner and traction bow.

K-wires are frequently used for the application of skeletal traction, particularly in children, in whom smaller traction loads are required and the cosmetic advantages of a smaller skin entry point pertain. K-wires can be used in any of the common sites for skeletal traction in the treatment of extremity fractures such as the upper end of the tibia, the lower end of the femur, the olecranon, and the digits. In children, passage of traction pins across the upper tibia risks damage to the physis, resulting in its partial closure and a subsequent growth deformity. If the proximal tibia must be used, the wire must be inserted posterior and distal to the physeseal line.

For a given load on the traction system, the force per unit area directed against the bone by the K-wire is greater than that exerted by a larger-diameter pin. Osteopenic
bone is therefore a relative contraindication to use of a K-wire for traction. See Chapter 10 for additional details.

Provisional Fixation

An important principle of internal fixation of fractures, especially in the presence of comminution, in which the definitive fixation of two fragments may impede the subsequent reduction of the rest of the fracture, is that the fracture be initially provisionally fixed. K-wires are particularly useful, and many of them may be used in combination, with little damage to the bone or its vascularity. They may be used alone or in combination with bone-holding forceps or cerclage wires. A complicated fracture can be fully and accurately reduced and temporarily fixed with K-wires. Radiographs may then be taken on the operating room table to demonstrate the anticipated result or to demonstrate any defects in the reduction and facilitate their correction (Fig. 11.6).

![Figure 11.6. Tibial plafond fracture. A: Lateral radiograph shows provisional Kirschner wire fixation. B: AP radiograph shows provisional Kirschner wire fixation. C: Lateral radiograph after definitive screw fixation. D: AP radiograph shows definitive screw fixation.](image)

Careful planning is required during insertion of provisional K-wire fixation to prevent the wires from interfering with the later exchange to the definitive fixation with, for example, plates and screws. Where K-wires are to be replaced by lag screws, introduce the wires in the same direction that will be used later for the screw fixation. Nonparallel K-wires will interfere with production of satisfactory compression by lag screws across the fracture site (Fig. 11.6). If crossed wires must be placed, remove them after the screw is in place and before final compression. A simple trick to facilitate plate application in the presence of multiple K-wires is, first, to place the plate on the bone and mark the location of the holes on the bone with a marking pen. Then, insert all the K-wires through the location of the holes.

Definitive Fixation

K-wire fixation can be employed successfully where the subsequent loading on a fractured bone is anticipated to be small because the fracture is close to a joint or if the overall length of the bone is not great. Thus, intra- and extraarticular fractures of the phalanges, metacarpals, and metatarsals, and other bones of the carpus, tarsus, and distal radius, may be stabilized with crossed Kirschner wires.

- Insert the first K-wire at right angles to the fracture plane.
- Compress the fracture fragments and place a second K-wire obliquely to lock and maintain the compression (Fig. 11.7). In the fixation of transverse phalangeal fractures, it has been found that four crossed wires provide the strongest fixation; and in oblique phalangeal fractures, three wires at right angles to the fracture provide the best stabilization (106). Stabilization with K-wires in these cases must almost always be supplemented and protected by plaster-cast fixation, but early motion is important.

![Figure 11.7. Kirschner wire fixation of an intraarticular phalangeal fracture. One wire is inserted at right angles to the fracture line, and the second wire locks the reduction by its oblique insertion.](image)

Another common use for K-wire fixation is in supracondylar fractures of the humerus in children. After closed or open reduction, two K-wires inserted from the lateral side can maintain good reduction when combined with external cast immobilization (see Chapter 164).

If K-wires are used for definitive fixation and the proximal end of the wire is left straight, there is a significant likelihood of migration of the wire into or from the bone. Therefore, the exposed end of the wire should always be bent with an appropriate instrument if it will be left buried. If only a very small segment of the wire is left exposed above the surface of the bone, it may be very difficult to find later when metal removal is required. Another alternative is to leave the end of the wire longer and just under the skin to facilitate removal. Pressure on the skin from within (and possibly from without due to dressings or plaster casts) may produce skin necrosis and infection around the wire tip. It is therefore recommended that either the wires be left buried with a bent end to facilitate removal, or the tip of the wire be left protruding by a centimeter or so from the skin. Prevent tension on the skin around the wire and protect it from unwanted blows. Either cap the wire with a commercially available wire cap or bend the end of the wire over. The former is preferable as it prevents catching the end of the wire on clothing. Reaction of the skin around the thin wire is minimal and infection unusual as long as it is stable in the bone. Subsequent removal of the pin is almost always easy and relatively pain free. In situations where K-wires are used in a tension band construct and functional postoperative therapy will be instituted, bend the ends of the wires into a U shape and impact them into the bone.

The special use of tensioned wires used in ring fixation and distraction techniques is described in Chapter 32.

STEINMANN PINS

MATERIAL FEATURES

In 1911, Fritz Steinmann (1870–1933), a surgeon in Bern, Switzerland, introduced pins that were thicker than those of Kirschner but otherwise very similar.

Steinmann pins are made in diameters of 3 to 6 mm and in lengths of 150 to 300 mm. The pointed end is usually of the trocar or diamond-pointed design (Fig. 11.3), but cove points are also available (Fig. 11.8). The cove point has a positive rake angle, which cuts bone rather than scraping it as occurs with the trocar and diamond tips. Flutes facilitate removal of chips from the hole made in the bone. Heat generated when using the cove point is probably less than with the trocar or diamond-tip Steinmann pin. In general, however, predrilling with the appropriate drill bit is recommended before pin placement into cortical bone. Predrilling is usually not necessary in cancellous bone.
Steinmann pins can be smooth or threaded. The threading of the pin facilitates fixation within the bone so that infection, which is facilitated by metal–bone motion, is prevented. Steinmann pins that are threaded only in the central region are easier to introduce and are as effective as fully threaded pins (Fig. 11.9). The thread diameter is 0.5 mm larger than the pin, so that the threaded segment is no weaker than the remainder of the pin.

**INDICATIONS FOR USE**

Steinmann pins are used mainly for traction through the femur, the tibia (proximal or distal end), or the os calcis. Traction is best applied with the use of a Böhler stirrup or bow, which fits over the ends of the pin. The design of the clamps holding the pin is such that movement of the stirrup does not rotate the Steinmann pin and cause it to loosen, because the bearings on the stirrup clamps allow free rotary movement on the pin (Fig. 11.10). See Chapter 10 for technical details.

**PINS INCORPORATED IN CASTS**

The incorporation of one or two transverse Steinmann pins into each end of a long bone fracture and then, after reduction, incorporation of the pins into a cast (i.e., “pins-and-plaster” technique) was used for many years. The stability of this construct is not very satisfactory, however. There is always a tendency for the plaster cast to loosen, because the bearings on the stirrup clamps allow free rotary movement on the pin (Fig. 11.10). The use of pins-and-plaster techniques has largely been replaced by the more efficient and advantageous external skeletal fixators, which are discussed later in this chapter and in the various sections on fractures.

**TECHNIQUE OF PIN INTRODUCTION**

Steinmann pins can be introduced with a Jacob's chuck and T-handle or hand drill into soft bone, but this technique tends to lead to inaccurate pin placement. Particularly in hard cortical bone, such as the upper end of the tibia in young people, free-hand introduction of a Steinmann pin is very difficult and inaccurate; in this situation, always predrill the pin tract with a drill bit having a cutting tip that does not generate heat. The use of a power drill to insert the Steinmann pin directly into dense bone may generate sufficient heat to cause bone necrosis; infection frequently ensues with loss of fixation and development of a ring sequestrum and osteomyelitis.

Similar considerations for the introduction of Schanz pins, which are partially threaded at their pointed tips and are used in the external fixation of bones, are discussed later in this chapter.

- Make an initial skin stab incision with its long axis in the line of subsequent traction pull.
- Use a soft-tissue guide over the appropriate drill bit and drill a pin tract at right angles to the subsequent traction pull.
- Then introduce the Steinmann pin by hand into the bone with a Jacobs chuck and T-handle, making the skin incision at the exit site of the pin tip. Little heat is generated with a sharp drill, so bone necrosis does not occur; infection, loosening, and sequestrum formation are much less likely, and greater accuracy of pin placement is achieved.
- Apply a Böhler traction bow or stirrup to the pin and apply traction.
- Release any skin compression developed on applying the traction by incising the skin next to the pin; this is necessary to prevent skin necrosis and subsequent infection. Keeping a snug fit of the skin on the pin in the absence of tension on the skin minimizes motion of the skin on the pin and helps to prevent infection, so close any excessive incision. Keep the pin sites dressed in a sterile fashion and cap the pointed tip of the Steinmann pin to prevent injuries.

**TENSION BAND WIRES**

**PRINCIPLES OF USE**

In regions such as the olecranon and patella, an understanding of active and passive muscle forces allows the use of a minimal amount of fixation material to obtain
excellent fracture stability and immediate functional movements of the contiguous joints. The principle of the tension band wire is that tensile fracture distracting forces, which the wire can easily absorb, are converted into stabilizing compression forces passing through the bone. It is essential that the cortex distant from the tension band side be strong enough to bear the applied compressive load. Loss of bone stock or poor bone quality will allow development of bending stresses, leading to wire fatigue and failure of the fixation. Tightening of the tension band wire produces static compression, particularly through the cortex under the wire. On active joint flexion, dynamic compression results across the whole of the fracture surface.

The wire used for this technique should have considerable ductility, combined with a high yield point and ultimate tensile strength. The wire is usually available in diameters from 0.4 to 1.5 mm made from type 316 stainless steel or Vitallium. The modulus of elasticity of Vitallium is higher than that of steel and for the same strain should support higher loads than stainless steel of equal diameter. Wire is weakened by cold working (e.g., kinking, bending, twisting), so care must be taken to avoid damage during implantation.

**TECHNIQUE OF APPLICATION**

The tension band method can occasionally be used with wire alone, as in a transverse fracture of the patella in which an irregular fracture line allows perfect reduction by interdigitation of the fracture surfaces (Fig. 11.11). In most situations, however, axial rotational stability cannot be obtained without the addition of two parallel, longitudinally placed K-wires (Fig. 11.12). In comminuted fractures, the K-wires also assist in providing some interfragmentary stability, which is completed by the tension band wire. The K-wires must be inserted in a parallel fashion. Crossed wires provide much less rotational stability and interfere with interfragmental compression. The K-wires also provide anchorage points around which the tension band wire can be placed.

---

**Figure 11.11.** Transverse patellar fracture stabilized by two tension band wires.

**Figure 11.12.** Transverse patellar fracture stabilized with two parallel, longitudinally placed K-wires and tension band wire.

Tension band wiring of a fractured olecranon is described to illustrate the principles of the technique (Fig. 11.13).

**Figure 11.13.** Transverse olecranon fracture stabilized with two parallel, longitudinally placed K-wires and a figure-eight tension band wire.

- After exposure of the fracture, place a 2 mm drill hole 2–3 cm distal to the fracture in a transverse fashion, passing just ventral to the dorsal cortex (Fig. 11.13). Then pass a 1.0 mm (18-gauge) or a 1.2 mm (16-gauge) diameter wire through the hole and displace the wire distally out of the proximal fracture field.
- To control fragment rotation, insert two 1.6 mm diameter K-wires parallel from the tip of the olecranon into the distal fragment (Fig. 11.13). This can be achieved using a 2 mm triple guide, or the wires can be inserted retrograde from the fracture site to exit the tip of the olecranon.
- After fracture reduction, advance the 2 K-wires 3 or 4 cm into the distal fragment. Alternatively, the wires can be inserted in an antegrade manner from the tip of the olecranon before fracture reduction, allowing their accurate placement within the medullary canal to be confirmed before reduction and driving of the wires across the fracture site. With more experience, after anatomic reduction of the fracture, the K-wires can be inserted from the tip of the olecranon across the fracture site and into the distal fragment. More secure fixation is obtained by drilling the wires through the anterior cortex rather than placing them in the medullary canal.
- Place the ductile wire around the protruding proximal tips of the K-wires in a figure-eight fashion. Be certain that they are against bone. Throw a simple loop in the midpoint of one limb of the figure eight, and complete the opposite limb by twisting the two ends of the wire (Fig. 11.13). Twisting the loop and two ends of the wire alternately allows well-controlled and equal tension in the whole figure-eight wire. Achieve wire tightening with bullet-nosed pliers, being careful that the wire ends are arranged in a helical fashion one around the other and that the pliers do not score the tensed wire. Shorten the twisted wire ends and the twisted loop to about three helical twists, and bend the wire ends away from the subcutaneous region to lie alongside the bone. Bend the proximal protruding K-wires twice, shorten them appropriately, and then impact them, like a staple, into the bony tip of the olecranon (Fig. 11.13): this prevents migration of the pins. Even with some comminution of the olecranon, the tension band wire technique can still be used after reduction and fixation of the minor fracture fragments with lag screws; thus, excision of the olecranon can usually be avoided.
- Commence immediate postoperative active flexion exercises for the elbow; extension exercises should proceed with more care because the bone–fixation complex is less stable in extension. If the proximal ends of the K-wires are not sufficiently impacted into bone, they can back out and protrude under and even through the skin (68). Another occasional complication is for the tension band wire to cut out of the distal fragment if it has not been inserted deeply enough below the dorsal cortical surface. After fracture union, the tension band wires tend to be uncomfortable. Removal is often necessary. The tension band wiring technique can similarly be employed for transverse and comminuted patellar fractures, fractures of the femoral greater trochanter, fractures of the malleoli (particularly where small or osteoporotic fragments are involved), and fractures of the distal end of the clavicle (Fig. 11.12 and Fig. 11.14).
Figure 11.14. Tension band wiring techniques employed to stabilize greater trochanteric, comminuted medial malleolar, and distal clavicular fractures.

CERCLAGE WIRING

PRINCIPLES OF USE

Cerclage wiring techniques have some utility for provisional fixation of long-bone fractures or for definitive fixation, usually in combination with other fixation devices.

The wire applicable for cerclage is of the same type as that described for use in tension band wiring. Wire diameters of 0.8 to 1.25 mm are commonly used, and the strength varies directly with the square of the diameter. Two wires may be twisted to form a double strand, which may have greater flexibility than a single wire and is less likely to slip on the bone. Some cerclage wires are manufactured with a loop in one end, so that after passage around the bone the other end can be threaded through the loop and kinked backward to quickly achieve temporary fixation (Fig. 11.15). Regular wire can be tightened around the bone by twisting the two ends one around the other in a helical fashion with the aid of bullet-nosed pliers or one of the many available wiretighteners, while maintaining adequate tension on the wire (Fig. 11.15). A minimum of two full twists is necessary for maximum strength with 1.0 or 1.2 mm diameter wire, and the pitch of the twists should be as high as possible (60).

Figure 11.15. Methods of joining ends of wire. A: One end of the wire is passed through a loop in the other end and kinked backward for temporary fixation. B: Helical twisting at a high pitch at the ends of the wire for temporary or definitive fixation. C: Technique like (A) but with one end of the wire passed under itself and against the underlying bone.

Any method of securing the wire ends that is stronger than the yield strength of the wire is satisfactory. For definitive cerclage wiring, it has been suggested that tying a formal square knot between the wire ends produces a fixation least likely to disengage (50). After the first throw of the knot and subsequent tightening, however, it is very difficult to maintain wire tension during the second throw of the knot (47,86). Although it is unlikely to completely unfold, with time the knot will commonly relax and precipitate failure of fixation. Knots therefore are suitable only for wire securing soft tissues. Helical twisting of the wire ends is easily applied, maintains the initial fixation tension, and will untwist only at tension loads beyond an acceptable limit. Anchoring the twisted wire tips by folding them down into a predrilled hole has been shown to produce the least slippage compared with other methods (68). The AO loop with bending of the free end under the wire also produces a satisfactory fixation strength, but the passing of the free end of the wire between bone and the tightly opposed cerclage can be very difficult (Fig. 11.15) (50,111).

Wire of insufficient strength can fail during clinical use by yielding, elongating, or fatiguing due to repetitive loading. This is especially true if the wire has in any way been scored before or during application (29).

Permanent cerclage wire fixation has sometimes been condemned as interfering with the periosteal circulation and thus producing bone necrosis. However, it has clearly been shown that the bone cortex receives most of its vascular supply in a centrifugal fashion from the medullary cavity, and even complete loss of periosteal blood supply may not lead to cortical necrosis. The periosteal vessels also tend to pass vertically into the cortex and not run along the cortical surface. Therefore, thin cerclage wires placed circumferentially at intervals are unlikely to severely damage periosteal blood supply in mature or immature bone (46,85,112). This contrasts with previously used wide Parham bands, which did eliminate periosteal blood supply from relatively wide segments of underlying bone (77,85). Recent modifications of Parham bands, as described by Partridge, are made of nylon and have elevations on the underside of the band that prevent wide contact and constriction on the bone by the band (79). This modified form of cerclage fixation may be useful in situations in which severely osteoporotic bone prevents other forms of stable internal fixation.

The method, however, has been condemned when used to control butterfly fragments in femoral shaft fractures, in which erosion of the bands into the cortical bone has sometimes been found (84).

The use of cerclage wire placed like a purse string circumferentially around the bone in the treatment of patellar fractures is now considered obsolete. This technique is not efficient and permits fracture fragment separation and mobility (108). Tension band wiring techniques described in this chapter are much more applicable to the problem.

TEMPORARY WIRING

During fixation of diaphyseal fractures in which a butterfly fragment is diametrically opposite the line of approach to the bone, the judicious application of a temporary cerclage wire may hold the butterfly fragment reduced so that lag screws may be inserted into it (Fig. 11.16). After stable screw fixation, remove the cerclage wire.

Figure 11.16. Temporary cerclage wiring to facilitate lag screw fixation.
Connecting rods or ring elements connect the pins in the same or in different bony fragments. Complex rods have in addition a built-in capability to compress or adjustab
distract, provide axial loading across the fracture at specific loads and excursions, and provide articulations for angular adjustments.

Simple articulation components connect two isolated pins, two rods, or a pin and a rod. Modular articulations hold two or more pins in one clamp, which is connected by a universal joint to a longitudinal rod.

Instrumentation usually includes wrenches, some with quantitative torque-measuring capabilities, to tighten the articulations; hand-held devices to insert and remove pins; drill bits; drill guides; depth gauges; pin caps; removable compression devices; and pin cutters.

**FIXATOR FRAMES**

The three-dimensional structure that is built with the components of a device is called a fixator frame or fixation configuration. In accordance with a frame's space requirements, we differentiate between unilateral and bilateral frames (11) and multiaxial devices. Each of the former two frame types can be applied in a one- or two-plane configuration. One-plane configurations are less cumbersome, and two-plane configurations are more effective in neutralizing bending and torsional moments (Fig. 11.19).

![Figure 11.19. The four basic configurations of external fixation frames. (From Behrens F, Sears K. External Fixation of the Tibia: Basic Concepts and Prospective Evaluation. J Bone Joint Surg Br 1985;68:246, with permission.)](image)

One-plane unilateral or half-frames are versatile (11,14,37). In the past, however, they were afflicted by a high rate of pin tract infections, malunions, nonunions, and component failures (25,86,105). Weight bearing was often possible only after advanced consolidation of the fracture callus. Most of the mechanical disadvantages of these configurations have been resolved through the introduction of stiffer components or a combination of stiffer components and mechanical optimization of frame designs (10,37,41). Two-plane unilateral frames (e.g., Delta frame, tent frame, triangular frame) can provide increased frame stiffness even with the use of relatively weak components, but they are more cumbersome and may interfere with wound access and secondary operative procedures (6,11).

One-plane bilateral configurations (e.g., quadrilateral frame, bilateral frame) were frequently used during the 1970s, when it was felt that the transfixion pins and the bilateral longitudinal support system would render them considerably stiffer than the traditional unilateral designs (56,105). Subsequent mechanical studies showed that these frames are rather weak in resisting sagittal bending moments (12,19). The insertion of multiple closely spaced transfixion pins caused compartment syndromes, neurovascular injuries, and impairment of musculotendinous units with resulting joint stiffness (11). One-plane bilateral frames are therefore considered unsafe in most locations and have been largely abandoned. The stiffest configurations, two-frame bilateral frames, have been advocated for the management of infected and unstable fractures, in particular pylon fractures of the ankle, or to provide optimal conditions for bone healing. Although mechanically better balanced than one-plane bilateral frames, they are not commonly used today; new unilateral fixators work as well and are not afflicted with all the disadvantages and complications caused by transfixion pins and bilateral rods.

**BASIC CONCEPTS**

To be safe and effective, the application of a fixator frame must avoid iatrogenic injuries (11,14,48). The frame must minimize obstruction to other operative procedures, be adaptable to a wide variety of injury patterns, and be stiff enough to maintain alignment under various loading conditions. Its use should facilitate full weight bearing yet produce a low rate of serious complications. These goals are best achieved by adhering to three basic principles (6,11,14). In decreasing order of importance, these principles demand that an applied frame minimize the risk of injury to the vital limb anatomy, provide ready access for wound debridement and secondary procedures, and meet the mechanical demands of the patient and the injury.

**LIMB ANATOMY**

The shape and size of the soft-tissue corridor through which pins can be safely inserted is primarily determined by the location of the main vessels, nerves, and musculotendinous units. Of the two limb segments that make up the lower extremity, the distal segment is much better suited for the application of an external fixator, because the principal bone lies eccentrically and the pins can be inserted through a subcutaneous bony corridor (14,42).

Sequential cross sections of the lower leg (Fig. 11.20) show that in the proximal third of the tibia, pin placement is safe within an arc of 220°, which extends from the posteromedial border of the tibial plateau to the proximal tibiofibular joint (42). Excluded is a small rectangular area overlying the patellar tendon. This safe anteromedial corridor decreases to 140° just below the tibial tubercle and to 120° at the ankle joint. Therefore, half-pins are safest distal to the tibial tubercle. Full transverse pins lie down the muscles of the anterior compartment; in certain locations neurovascular structures are threatened by injury from a pin, so their use should be minimized and their insertion should be done judiciously.

![Figure 11.20. The "safe corridor" for pin insertion in the lower leg. A: Proximal to the tibial tubercle, pins can be safely inserted within an arc of 220°. B: Just below the tibial tubercle, the safe arc decreases to 140°. C: In the distal third of the leg, the safe arc remains 140°, but the anterior tibial vessels and deep peroneal nerves become vulnerable as they cross the lateral tibial cortex. D: Above the ankle joint, the safe arc is 120°. E,F: Pins in the tarsal or metatarsal bones may be used to splint the ankle joint if neurologic or soft-tissue injuries prevent the application of an external support. (From Behrens F, Sears K. External Fixation of the Tibia: Basic Concepts and Prospective Evaluation. J Bone Joint Surg Br 1985;68:246, with permission.)](image)

Two potentially dangerous pin exit areas deserve special attention. Proximaly, a pin can pierce the protective posterior muscle layer and injure the posterior neurovascular structures. This is prevented if the pin exit area is limited to the medial third of the posterior tibial cortex. In the distal third, the anterior tibial vessels are vulnerable along the lateral tibial cortex, which therefore should be avoided. Whenever possible, pin placement should be limited to areas where the tibia lies subcutaneously.
In the proximal segment of the lower extremity, the femur is circumferentially covered with soft tissues. There is no ideal corridor available as all pins pierce the thigh musculature before they are seated in the bone (3). Preferred pin placement is from the lateral side, just anterior to the intermuscular septum. Half-pins are essential because they transfix only the vastus lateralis. Sometimes the pins can be inserted anterior to the lateral intermuscular septum and posterior to the vastus lateralis, but they still limit the excursion of the iliotibial band and thus restrict knee motion while the fixator is in place (3,9). Medial-pin exit sites that are between the midfemur and the distal fifth are in a danger zone, because in this region the superficial femoral vessels and the saphenous nerve are tightly held in the adductor canal and are vulnerable to pin injury. If pins in these locations are essential, place them using open technique and avoiding the neurovascular bundles. These same considerations apply to the upper extremity. Only the subcutaneous borders of the long bones are reasonably safe, but even there tendons and cutaneous nerves are still at risk of injury. In general, place upper-extremity fixation pins with open technique.

The regional anatomy in the lower leg limits the choice of safe frame types to one- or two-plane unilateral configurations. Within the safe soft-tissue corridor, the best pin location, frame geometry, and frame placement are determined by the size and severity of soft-tissue lesions, and by the comminution and stability of the bone injury. Adapt each frame to the injury at hand to permit the best possible wound access for initial care, repeated debridements, and secondary soft-tissue procedures such as the transfer of local and distant soft-tissue flaps and the placement of bone grafts. Within the safe corridor, place pins and frames away from the injured area and the principal access routes. If an injury involves mainly the medial side of the leg, apply the frame anteriorly or anterolaterally; a lateral injury may call for a medial or anteromedial frame (Fig. 11.21).

**Figure 11.21.** A gunshot wound involving the lateral aspect of the proximal tibia with severe loss of soft tissue and bone. **A:** Initial appearance from the lateral side. **B:** Stabilization by an external fixator placed on the medial side. **C:** The soft-tissue defect covered by a lateral gastrocnemius flap; there is no interference from the fixator frame. A split-skin graft was used to cover the muscle flap. **D:** Radiographs at this stage. **E:** Elevation of the healed gastrocnemius flap to allow the skeletal defect to be bone grafted. **F:** At 5 months, the fracture has healed, and the patient has borne full weight for 4 weeks. **G:** Radiographs 1 year after the injury. (From Behrens F, Sears K. External Fixation of the Tibia: Basic Concepts and Prospective Evaluation. *J Bone Joint Surg* Br 1985;68:246, with permission.)

**MECHANICAL DEMANDS**

To be mechanically effective, the stiffness of a fixator frame should control the prevailing forces and moments at the fracture site. Information based on the size and weight of the principal lower extremity segments and the distribution of the muscles surrounding the femur and tibia indicate that, in the supine position, sagittal bending moments are two to five times larger than the moments acting in the frontal plane. After a patient is weight bearing, compressive loads and torsional moments around the longitudinal axis gain in importance (11). However, there is little change in the ratio of anteroposterior-to-frontal bending moments. This suggests that regardless of other mechanical properties, a fixator frame in the lower extremity should be about two to five times stiffer in the sagittal than in the frontal plane (12). For tibial fixators, this stiffness ratio is most easily achieved if the principal pin plane is oriented in an anteroposterior (AP) direction. Although clinically appropriate, lateral femoral frames are not ideal mechanically because they are relatively inefficient in resisting fragment motion in the sagittal plane. To counteract this tendency, spread the pins in each principal bony fragment as far apart as possible. Use stiff longitudinal rods and double-stack them if necessary (5).

The size of the fixator components and the frame geometry are other factors that influence the application of a mechanically effective frame. Assuming that stainless steel components are used, the pins should have a diameter of at least 5 mm, and the longitudinal rods should have a diameter of 8 mm or more. The articulations must not slip within the range of clinically applied torques. Experimental work has shown that the following methods increase frame stiffness in one or more loading modes (12,13):

- Increasing the pin spread within each main bony fragment (14)
- Reducing the distance between the bone and the longitudinal rods (13)
- Attaching a second longitudinal rod to the same pin plane (13)
- Erecting a second half-frame at an angle to the first (i.e., creating a two-plane unilateral frame)

These mechanical measures alone or in combination can accommodate most tibial and femoral injury patterns without the need for bilateral frames. Unilateral frames suffice for most upper-extremity injuries.

**PREOPERATIVE CONSIDERATIONS**

The successful and effective use of external fixation devices rests on thorough preoperative planning (14). Although much of this planning process occurs before the fixator is applied, it must anticipate the most likely time course of healing and the principal variations and potential complications that might be encountered.

In the initial assessment, note the patient's age, size, premorbid condition, socioeconomic circumstances, and the cause, severity, and extent of the injuries. Determine whether external fixation is the best method for treating the patient's injuries, what is the best device and in what configuration, whether the fixator will be used alone or in conjunction with internal fixation (Fig. 11.22), what equipment is available, and what surgical skills are needed. Determine also if the full frame should be applied immediately or completed at a later time, and whether the fixator will remain in place until the fracture is healed or will be replaced with a cast or internal fixation as soon as the soft-tissue conditions permit (14).

![Figure 11.22.](image-url)

**Figure 11.22.** A: Comminuted proximal tibial fracture in an elderly patient, showing a combination of external and internal fixation to stabilize the comminuted periarticular fracture pattern in an osteopenic patient. B: Radiotranslucent carbon fiber rods facilitate assessment of the fracture site and proper timing of secondary intervention, yet provide sufficient stability to allow for soft-tissue consolidation.

If there is a choice of several devices, the sturdier designs are preferred for patients who are heavy or who have an unstable fracture pattern. For the younger child, a wrist or upper extremity device may be sufficient. When rapid application is essential or proper radiographic control unavailable, fixators with full universal joints at both
ends are ideal, because they facilitate alignment and length adjustments at a later time (88,89).

When dealing with complex fracture patterns that require repeated assessment of healing, devices composed of radiolucent carbon fiber components are advantageous.

CONFIGURATIONS

The factors that determine location and configuration of a particular fixator frame depend on the extent of the soft-tissue injury within the safe corridor, the stability and location of the fracture, the size of the patient, the presence of associated lesions, the size of the fixator components, and the designs of the fixator articulations (13).

When using simple fixators that allow for free pin spread and provide moderately stiff components, 80% to 90% of the applied frames are of a one-plane unilateral design (13). For devices that provide universal articulations but lack the mechanical advantage of maximal pin spread (e.g., Hoffmann apparatus, Orthofix), the risk of slippage at the articulations is considerable. With these fixators, take care to use undamaged functioning articulations and possibly double-stacked one- or two-plane unilateral frames (95). These configurations are preferred for fractures with segmental bone loss or extensive comminution (Fig. 11.23, item 2, lower drawing).

One-plane frames with double rods (Fig. 11.19, upper drawing) have a rigidity pattern similar to that of two-plane unilateral frames, but they are less cumbersome and allow better wound access (10). Due to their greater rotational rigidity, two-plane unilateral frames may be still preferable for the management of infected nonunions and lesions that are accompanied by substantial bone loss.

**Figure 11.23.** The recommended configuration of fixator frames for different bone and soft-tissue injuries. The location and extent of the lesion is indicated, on the left, by the crosshatched area. The preferred frame is shown, with solid bars representing the pins; on the right are the indications for the use of the configuration. (From Behrens F, Sears K. External Fixation of the Tibia: Basic Concepts and Prospective Evaluation. J Bone Joint Surg Br 1985;68:246, with permission.)

One-plane unilateral frames are ineffective in stabilizing comminuted proximal and distal periarticular fractures, which often provide only short metaphyseal or epiphysyal fragments for pin insertion. With simple frame modifications (Fig. 11.21B; Fig. 11.23, items 3 and 4), however, these fractures are easily managed. Proximally, where the safe corridor opens wide, subchondral pin placement affords anchorage for two or more half or full pins (Fig. 11.21B, Fig. 11.21C and Fig. 11.24D). Over two or more longitudinal rods, these pins are then rigidly connected to several distal pins, which in the tibia are placed close to the sagittal plane. After the application of these frames, the knee is moved through a full range of motion to ensure free mobility of joint capsule, pes anserinus, and iliotibial band. Distal tibial fragments as short as 2 or 3 cm long can be stabilized by inserting two or more pins on either side of a longitudinal rod (Fig. 11.23, item 4). For the immobilization of distal intraarticular fractures, a talar or calcaneal pin is connected with two rods to two or more anterior half-pins in the proximal tibia (Fig. 11.23, item 5). Hybrid frames work well and to some extent have replaced these frames. These are presented in more detail in Chapter 23 and Chapter 25.

**Figure 11.24.** A grade 3 open tibial fracture with bone loss in a patient with other open fractures. A: Clinical appearance on admission. B: Radiographic appearance on admission. C,D: Stabilization of the fracture with two-plane bilateral pin configuration proximally and three anterior pins distally. Bone graft had been delayed for 3 months because of adult respiratory distress syndrome. E: At 8 months, after the patient had started full weight bearing, the frame was gradually reduced. As a last step before removal, the proximal pin was loosened. F: Radiographs 1 year after injury.

**COMBINED INTERNAL AND EXTERNAL FIXATION**

Additional internal fixation is occasionally employed in the management of type II or IIIA open tibial fractures with two or three comminuted fragments. After anatomic reduction and interfragmental compression with screws, a relatively rigid external frame is applied instead of a neutralization plate. This approach has been quite successful in metaphyseal fractures, which generally heal within 2 to 3 months. In the diaphysis, however, high complication rates, mainly in the form of refractures, have been common. This is not surprising, because in cases of avascular diaphyseal fragments bony union is often delayed for more than a year. Additional detail on this issue is provided in Chapter 24.

**SURGICAL TECHNIQUES**

- Drape the limb to keep the injury zone and the adjacent joints accessible in the operating field. Avoid adhesive plastic drapes where pins will be inserted, as they tend to wind up on drill points and pins and may be inadvertently transported deep into the wound. An image intensifier helps to assess proper pin location, pin depth, and fragment alignment, and it is particularly valuable in dealing with closed fractures that do not allow direct manipulation of the fracture fragments.

**PIN INSERTION**

- Make a skin incision just large enough to accommodate the drill point and pin sleeves to be used. Most manufacturers provide matched protective sleeves for drilling, depth measurement, and pin placement.

The following technique applies to pins that require predrilling, which make up the majority of pins used today.

- Insert the protective sleeves down to the bone.
Gently impact the teeth of the sleeve or trochar into the bone, if called for by the manufacturer.

Drill the initial hole with the size called for by the manufacturer for the pin diameter to be used. Use power, cool the drill, and avoid overheating the bone.

Usually one drill size suffices. In some cases, the near cortex must be drilled with a larger diameter to accommodate a larger smooth shank on the pin.

Select the appropriate pin and the thread length: in some systems, a depth gauge is required, or the drill may be calibrated.

Insert the pin until at least one full thread penetrates through the opposite cortex. Carefully monitor this with the fluoroscope, as in some systems the pin cannot be reversed without loosening.

Many half-pin systems allow selection of a total thread length that is 5 mm less than the overall diameter of the bone at the site where the pin is inserted. This permits the wider nonthreaded shaft of the pin to fit tightly into the proximal drill hole and places a smooth shank at the level of skin. This reduces skin irritation and doubles the bending stiffness of the pin (Fig. 11.25).

Figure 11.25. Seating of half-pins. A: Threaded pin portion protrudes beyond the skin. This tends to cause skin irritation and pin-tract infection. Pin stiffness is determined by the core diameter. B: Threaded pin portion is limited to the distal cortex. The smooth shaft rarely irritates the skin. Pin stiffness is determined by the larger thread diameter. (From Behrens F. General Theory and Principles of External Fixation. Clin Orthop 1989;241:15, with permission.)

Once the entire frame has been assembled and the fracture reduced, check the skin around each pin to be certain that tension on one side of the pin is not present. This is indicated by gathering of the skin. If there is tension, incise skin where it is gathered until it lies tensionless around the pin.

Differential motion of skin on the pin can result in bacterial contamination of deeper tissues; therefore, gently close any excessive incision about the pin with a fine nylon suture that can be removed when the skin is healed.

The sequence of subsequent pin insertion depends on the type of fixator used. Many frames allow independent pin insertion, in which case be certain that the limb or the fracture is aligned and insert the next pin most distant from the initial pin. The initial pin should have been the most extreme pin at the other end of the bone. Insert the second pin using either a template guide or the preassembled fixator as a guide.

In some frames, the pins are applied in clusters in the proximal and distal fragments. With these fixators, independent arrangement of the pins anywhere along a fixator bar, such as in the unilateral frame, is not possible as the pins are inserted through a clamp or ring that holds the cluster of pins in one fragment in a more-or-less fixed arrangement relative to the others. The exceptions are Ilizarov type ring fixators, where pins can be placed anywhere along the 360° arc of the ring, and pin clamps that allow a limited range of placing the pins longitudinally on the bone. With these fixators, maintenance of overall alignment of the limb is less crucial, as universal adjustment clamps permit reduction of the fracture after the fixator has been applied; however, each fixator has a limited range of adjustment. It is possible to apply pin clusters so out of alignment with each other that reduction cannot be achieved. Therefore, it is always prudent to maintain general overall alignment of the limb, particularly rotation, as any type of fixator is applied. The following steps describe the technique for a typical fixator of this type.

Using the manufacturer’s guide or the fixator itself, insert the pins in one fragment and then the other. A wide spread of the pins within the range allowed by the clamp increases stability. Always apply the two outer pins on a given clamp first, to be certain that all pins will be anchored in bone.

Now reduce the fracture; with the universal joints loose, obtain anatomic reduction. Tighten the universal joints or adjustments once reduction is achieved.

If fracture-fragment alignment is not satisfactory on subsequent fluoroscopic examination or x-rays, loosen the universal joints and repeat the reduction maneuver.

FRAME APPLICATION

The design of the clamps largely determines the sequence of steps for the application of a fixator frame (9). With simple fixators, each pin is independently connected to the longitudinal rod in several steps as follows (2).

Insert one pin into each main fragment, generally starting with the pins close to the joints (i.e., farthest from the fracture). Maintain gross alignment of the limb (13).

Reduce the fracture. Apply adjustable clamps to each pin and connect them by a longitudinal rod. Then manually reduce the fragments and tighten the two clamps to achieve temporary reduction. Proper rotational alignment is crucial (13).

Insert the remaining pins (10).

Adjust the fixator. Adjustments in the plane of pin insertion are easily achieved by loosening the pins. For angular adjustments in another plane, replace the longitudinal rod by two shorter ones that are connected over a central universal joint. For the correction of significant rotational malalignment, all pins except one in each fragment must be exchanged.

HINTS AND TRICKS

Whenever possible, achieve an anatomic reduction. For simple transverse or interdigitating fractures, axial compression of the fracture site provides additional stability. When axial compression is attempted with unilateral frames, the fracture fragments have a tendency to angulate away from the longitudinal rods. It is advantageous to start with the fracture fragments angulated toward the rod(s). With increasing compression, the fracture fragments tend to straighten into anatomic alignment.

Proper rotational alignment and length is ensured by comparing the injured to the opposite limb, if it is uninjured; for assessment of alignment, however, obtain AP and lateral radiographs that include the joints above and below.

POSTOPERATIVE CARE

In the early postoperative period, elevate the injured extremity, for example in balanced suspension with the calf muscles supported with a sling (Fig. 11.26). Support the ankle joint in 5° to 10° of dorsiflexion with a prefabricated splint. If the patient has sustained a severe soft-tissue injury (in particular, compartment syndrome requiring fasciotomy, or palsy or paresis of the common peroneal or posterior tibial nerves) or bony injury distal to the ankle joint, replace the ankle splint with a transtarsal pin (Fig. 11.26E) or two metatarsal pins that are connected to the external fixator frame (Fig. 11.26F).

Figure 11.26. The early postoperative management of an open tibial fracture. The limb is suspended, the calf is supported, and the ankle joint is splinted in 5° to 10° of dorsiflexion.
As soon as the leg wounds permit, begin twice-daily, passive, active-assisted, and active range of motion exercises of knee and ankle joints. Follow with isometric muscle strengthening exercises across both joints and mobilization with crutches or a walker. As soon as tolerated, encourage the patient to partially bear weight on the injured extremity, progressing to full weight bearing as the fracture consolidates, if the fracture type and external fixator permit. If this course is conscientiously followed, approximately 70% of all patients with tibial fractures can advance to full, unsupported weight bearing before the fixator is removed or replaced by a different method of immobilization. Weight bearing has little to do with pin tract infection or pin loosening. Patients with segmental bony defects must be limited to bearing with only the weight of the limb.

CARE OF THE PIN SITES AND FRAME

After the initial operative procedure and any subsequent debridements, or additional soft-tissue or bony reconstructive procedures, the limb will generally be encased in a bulky postoperative dressing, which precludes access to the pin sites. Because the patient returns often to the operating room for wound debridement and subsequent reconstruction, there is no necessity for pin care by the nursing staff on the ward. In fact, exposing an open fracture wound on the ward unnecessarily invites contamination with nosocomial organisms. When the wound has stabilized and repeat operations are no longer necessary or are infrequent, it is appropriate for the nursing staff to begin pin care, particularly since the patient must be educated in this important aspect of care of the external fixator in an outpatient setting. Unless the patient is hospitalized for a prolonged period of time and is nonambulatory, pin care in the hospital offers little from what I prefer to have patients do at home. There is little in the literature to prove that one pin-care regimen is superior to another (88). I have found the following program to be effective and simple for nursing staff and patient. Using this regimen, I have had external fixator pins located in cortical bone in place as long as 1 year with no complications.

- In the hospital setting, because the soft tissues are still edematous, serum and hematoma ooze from the pin sites and dries as a crust around the pins. This can be a source of bacterial colonization and skin irritation. Once a day, the nursing staff should expose the entire external fixator and all of the pin sites, and wipe down the pins and frame.
- The dried exudate can be removed by any method that is gentle, comfortable for the patient, and effective. Cleaning with a 50% hydrogen peroxide solution, or simply washing the pin sites with saline gauze and soap water are equally effective. (Although many surgeons apply antibiotic or antiseptic ointment to the pin sites, I have not found these to be of any value, and this risks sensitizing the patient to the material used.)
- Dress the pin sites with a 2×2 or 4×4 gauze cut to fit snugly around the pin. (There are commercial sponges available for this purpose, but I have found these to be less effective than simple gauze bandages.) Wrap these into place to stabilize the skin and prevent vertical motion of the skin on the pin. This helps reduce bacterial contamination of the pin site caused by movement of the skin along the pin, and it makes the patient more comfortable. Once bulky dressings are no longer needed for the wound, these small gauze bandages can be held in place by plastic clips placed on wires or half-pins and slid down against the dressing to stabilize the skin. These were an innovation of Ilizarov and have proven to be very useful.

After discharge from the hospital, daily showers are simple for the patient and provide the easiest method for pin-site and frame care. As soon as the wound allows, have the patient take a daily shower, thoroughly scrubbing the external fixation frame and all of the pins and wires with ordinary soap and water (avoid strong soaps and those heavily perfumed) using a clean, fresh washcloth. Removal of tough crust is facilitated by a soft gical brush and a child’s toothbrush. After the shower, the patient should dry the apparatus and pin area with a freshly laundered towel different from the one used for the rest of the body, and dress the pin sites as described above. For the second pin-care episode each day, it is necessary only to clean the pin sites themselves using similar techniques.

Pin-site irritation or inflammation occurs at one time or another in most patients, but, if good technique is used, pin-traction infection should be uncommon (this is discussed below in the Pitfalls and Complications section).

Educate all patients about the mechanics of their frame, in particular how to keep the frame and pin clamps tight. If they are incapable of understanding, or of maintaining the frame, a relative or caregiver who will take this responsibility must be involved. Provide the patient with a wrench, or other appropriate tools, so that the components of the frame can be checked at least weekly to be certain that they remain tight.

Once the patient’s condition has stabilized it is evident that good care is being taken of the pin sites and frame, reliable patients may be able to go up to 6 weeks between follow-up visits. Less reliable patients may need to be seen by the surgeon weekly, and they may need frequent visits by a home health nurse to do pin-site and frame care.

GETTING FRACUTES TO HEAL IN EXTERNAL FIXATION

Many closed and open fractures treated with external fixation are of such severity that they will not heal readily without additional biologic or mechanical measures.

SOFT-TISSUE COVERAGE

Severe open fractures heal faster if they are covered with adequate soft tissue, in particular muscle, which is a source of neovascularization (116). If coverage is not possible locally, free muscle or composite flaps should be placed early, because this tends to prevent the development of local wound colonization and subsequent osteomyelitis. This is a prerequisite for the success of later bone reconstructive procedures (88-105) (see Chapter 8 on soft-tissue management and Chapter 12 on open fractures for more detail).

BONE GRAFTS

Many adult patients with severe open tibial fractures need bone grafts to get the fracture to unite. When dealing with a Gustillo type IIIA or lower grade clean open wound that allows osseous closure after appropriate debridement, I may place an autogenous cancellous bone graft at the time of soft-tissue closure. After massive wound infection, contamination, infection, or delayed closure with a flap, as in type IIIb or IV open fractures, wait until the soft tissues are fully recovered and there is no evidence of infection. This often requires 6 or more weeks. Reckling and Waters (83) place a cancellous or corticocancellous bone graft, often in conjunction with osteoperiosteal elevation through an anterior or medial incision. At the University of California, Davis, Trauma Center, we prefer the posterolateral approach applying a large cancellous autologous iliac graft, and we usually perform a Tibiofibular synostosis (see Chapter 26 and Chapter 31).

CHANGING FIXATOR STIFFNESS AND AXIAL MICRO McMOTION

Many surgeons elect to replace the external fixator with a patellar tendon-bear ing or long-leg cast as soon as soft-tissue coverage has been obtained (68,96). This is often successful in patients with stable fractures. However, unstable fractures and even stable fracture patterns often angulate after fixation removal, even if immobilized in a long-leg cast. I prefer to hold these fractures in the external fixator until they are healed. After advancing the patient to full, unsupported weight bearing, gradually dismantle the more complex configurations (e.g., two-plane unilateral, one-plane unilateral with double rods) to one-plane configurations with a single anterior or anterior and posterior rod (Figs 11.24, 11.25). Then, sequentially loosen the pin clamps, starting with the pins closest to the fracture site, until the load is held only by the most proximal and most distal pins.

Another option is to loosen all the pins in the proximal or distal main fragment. This permits free axial loading while preserving angular and rotatory alignment (13), and most proximal and distal pins.

Although attractive and logical, there is no evidence that this approach leads to an increased rate of fracture healing. Easier to use are tube-type and other fixators that can be dynamized, some with very specific control over the excursion and amount of loading.

Early induction of axial micromovement at the fracture site has been shown to increase the rate of fracture healing (43,58). This is achieved with the help of a pneumatic actuator temporarily connected to the fixator. The actuator induces a loading regimen of 1 mm displacement at 0.5 Hz for 30 minutes each day. With this approach, a 20% reduction in the average healing time was achieved in a controlled trial of complex tibial fractures (59).

SECONDARY INTERNAL FIXATION

Delayed union or progressive malunion after a tibial fracture often is best handled by replacing the external fixator with an intramedullary rod or a plate. Internal fixation following removal of external fixator pins where infection has occurred, particularly osteomyelitis, is generally contraindicated until the infection has been eradicated. Although there is little information about results and complications after plating, indurmiticramic secondary intramedullary nailing has been shown to have a high infection rate (70). However, secondary nailing can be performed with only a slightly increased infection rate if the procedure is carried out very early or within 4-6 weeks of fixator application (15). Even with these restricted indications, it is safest to place the limb in a cast for 2-4 weeks before proceeding with intramedullary nailing to allow the pin tracks to heal. Unless extraordinary circumstances prevail, avoid intramedullary nailing after local soft-tissue or bony infection or in a patient who once had a pin.
influences the frictional force developed between the screw and the bone, and thus the tendency of the screw to back out. Because bone is either cortical or surface area of thread in contact with the bone and the configuration of the thread relative to the structure of the bone. Whether the hole is tapped or untapped maintains, but does not itself exert, compression.

If the patient is midway in the course of fixator treatment, removal of the loose pin is necessary; it may be either left out or replaced with another pin in a sound location at least 15 mm or more from the original site. If the patient is nearing the end of treatment (e.g., the fixator needs to be left on for only an additional 1–2 weeks) and there is a lack of evidence of infection, then shifting the pin clamp location on the fixator, slightly bending the pin to bring it against one cortex of its hole, will occasionally stabilize the pin and allow the patient to complete treatment. This is a temporizing measure that does not solve the underlying problem of pin loosening and should be used only in these special circumstances.

Pin loosening that results in pain is particularly a problem in ring and hybrid external fixators using tensioned wires in metaphyseal bone. Continuation of tensioned wire fixation where loosening of the wires has occurred guarantees persistent pain for the patient and eventually further pin complications of more severity. In the case of tensioned wires in metaphyseal bone, detection of loosening usually requires detaching the ring from the rest of the external fixator and manipulation of the ring to detect motion of the pin in the bone.

PIN-SITE DRAINAGE AND INFECTION

Pin-site problems manifest themselves as a progression of symptoms from slight pin-site tenderness, swelling, and erythema, to substantial serous exudate, to evidence of frank infection with purulent exudate at the pin site with or without evidence of abscess formation. If the patient has clinical evidence of infection and a radiolucent zone around the pin on a radiograph, then bone infection is usually present. In my experience, the most common cause of pin-site complications is loosening of the pin in the bone. In metaphyseal bone, this is most commonly the result of simple mechanical loosening due to the weak structure of the cancellous bone. In cortical bone, it is most commonly due to improper surgical technique producing necrosis of the bone as a result of overheating drill points or fixation pins. In the latter case, a remodeling response is precipitated in the bone immediately surrounding the pin, which rapidly leads to pin loosening and in some cases formation of a ring sequestrum around the pin, seen after pin removal when the central beam of the x-ray is directed along the axis of the pin hole. Management of pin-site irritation and infection is illustrated in Table 11.3. The pin must be removed, the soft tissues and bone thoroughly debrided, and appropriate antibiotics prescribed.

**Table 11.3. Management of External Fixator Pin Site Problems**

Note that oral antibiotics have only a small role to play in managing pin-site irritation. The typical situation in which a patient requires oral antibiotics occurs when the pins pass through a thick soft-tissue envelope, which, because of the patient's activities and rehabilitation, are moving on the pin, resulting in contamination and a low-grade cellulitis in the absence of any evidence of pin loosening or infection. This is most common in limb-lengthening and deformity-correction procedures where tensioned wire ring fixators or hybrid frames are being utilized. In these cases, I have found that a few patients do well on oral cephalosporins for 10 days or more if episodes of cellulitis occur. Always be alert for pin loosening and evidence of deeper infection.

Superficial cultures of pin tracts, regardless of clinical appearance, have no place in the management of pin-site complications. These cultures are nearly always positive, usually represent normal skin flora, and are of no help in prescribing appropriate treatment. I take cultures only when formal deep debridement of an infected or potentially infected pin site is carried out. These cultures are taken at the level of bone, preferably from a curetting of the pin tract.

DEFORMITY, DELAYED UNION, AND NONUNION

Progressive deformity in the fixator is usually caused by either pin loosening, loosening of components on the frame, or both. If deformity is noticed prior to consolidation of the fracture, then usually it is correctable by addressing pin or frame problems. Because of the nature of the fractures treated with external fixators, delayed union and nonunion are common and are best approached by manipulation of the frame or by bone grafting, as described previously. Conversion to some type of internal fixation is much less common unless done very early, as has been discussed. These issues are addressed in much more detail in chapters on each specific bone and on nonunions in this section of the book.

D. PRINCIPLES OF SCREW FIXATION

GENERAL PRINCIPLES

Screws can be used to attach implants such as plates and prosthetic devices to bone, to fix bone to bone, and to fix soft tissues such as ligaments and tendons to bone. Perhaps the most important use of screw fixation is interfragmentary compression, which improves the mechanical stability of internal fixation by increasing the friction between bone fragments. This minimizes micromotion between the fragments by minimizing the effects of torsion, shear, and bending forces.

As described by Müller et al., interfragmentary compression can be static or dynamic (71). Interfragmentary compression with a lag screw is the best example of static compression. A screw function as a lag screw when the threads obtain purchase only in the far cortex, and the thread of the screw or a nontouched portion of the screw passes freely through the cortex immediately beneath the screw head. Screws can be made to function as lag screws either by overdrilling the near cortex to prevent the threads from gripping, or by having smooth shanks in the portion adjacent to the screw head. Clearly, interfragmentary compression cannot occur if the screw threads cross the fracture site, unless compression is achieved by a bone-holding forceps at the time the screw threads cross the fracture. The screw then maintains, but does not itself exert, compression.

The holding power of a screw in bone is most dependent on the density and quality of the bone. Other factors related to the strength of screw fixation are the overall surface area of thread in contact with the bone and the configuration of the thread relative to the structure of the bone. Whether the hole is tapped or untapped influences the frictional force developed between the screw and the bone, and thus the tendency of the screw to back out. Because bone is either cortical or
cancellous, and each type has very different structural characteristics, two types of specialized screws have been developed—cortical and cancellous (Fig. 11.27 and Fig. 11.28).

**Figure 11.27.** Cortical screws. **Top:** A 4.5 mm cortical screw with a core diameter of 3 mm, outside thread diameter of 4.5 mm, and thread pitch of 1.75 mm. Notice that the underside of the screw head is hemispherical in cross section. A 3.2 mm drill bit is used for the threaded hole and a 4.5 mm drill bit for the gliding hole. **Center:** A 3.5 mm cortical screw. In the AO system, two varieties of this screw are now available—one with threads like those on a machine screw, known as the 3.5 mm cortical screw, and the one here, the 3.5 mm cancellous screw. The screw illustrated has a core diameter of 1.9 mm, an outside diameter of 3.5 mm, and a thread pitch of 1.75 mm. A 2 mm drill bit is used for the threaded hole, and a 3.5 mm drill bit for the gliding hole. **Bottom:** The 2.7 mm cortical screw is used for fixation of small fragments, as in the hand and foot. The thread has a core diameter of 1.9 mm and an outside diameter of 2.7 mm. The threads have a 1 mm pitch. A 2 mm drill bit is used for the threaded hole and a 2.7 mm bit for the gliding hole. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979:33, with permission.)

**Figure 11.28.** Cancellous bone screws. **Top:** The two upper screws are standard AO 6.5 mm cancellous screws with spherical heads. The shafts are 4.5 mm in diameter, with 16 mm and 32 mm thread lengths. The screw threads have a core diameter of 3 mm, an outside diameter of 6.5 mm, and a thread pitch of 2.75 mm. For most applications, a 3.2 mm drill tip is used. If the shaft must pass through thick cortical bone, drill the cortex with a 4.5 mm drill. **Center:** A 4 mm cancellous screw with a core diameter of 1.9 mm, an outside diameter of 4 mm, and a thread pitch of 1.75 mm. A 2 mm drill bit is used. **Bottom:** Malleolar screw. The screw thread has the same profile as the 4.5 mm cortical screw, but a portion of the shank is unthreaded. The drill bit is 3.2 mm. Note the cutting tip, which allows the screw to be self-tapping in cancellous bone. In the ankle, this screw is used less often than the 4 mm cancellous screw. Various washers are available for both the 6.5 mm and the 4 mm screws. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979:28, with permission.)

**CORTICAL SCREWS**

Typical stainless-steel cortical screws used for large-fragment and small-fragment fixation are shown in Figure 11.27 (3). These screws have spherical heads and are threaded for the full length of the shafts. A hexagonal screwdriver is used. Because there are no flutes on the tips of these screws, the bone must first be tapped to create threads for the screw. The advantage of tapping is that more engagement of the screw threads into bone is possible (Fig. 11.29). Because taps provide four cutting flutes, microfracture of the bone is less likely to occur. Theoretically, this produces better hold of the screw in bone. Disadvantages of tapping are that it requires an extra step in the operative procedure and, because a rather smooth track is established, the screw is more likely to loosen by backing out when it is subjected to cyclical stress.

**Figure 11.29.** Tap for the 6.5 mm cancellous screw (a); short- and long-threaded taps for the 4.5 mm cortical screw (b); key handle for the 4.5 mm and 3.5 mm taps (c); 3.5 mm tap (d); handle for the 3.5 mm and 2.7 mm taps (e); and 2.7 mm tap (f). (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979:35, with permission.)

Self-tapping screws using a four-flute tap-like cutting tip are also used. They are manufactured from a titanium alloy, and variations are available from several manufacturers (Fig. 11.30). These new screw designs surpass the holding power of non-self-tapping screws and are stronger due to their larger diameter and the use of titanium alloy. The major advantages are that the extra step of tapping is eliminated, and the screw is less likely to back out because of better frictional hold between the screw threads and bone. The only disadvantage is that 3–5 mm of screw tip must protrude from the bone to achieve maximum thread surface in contact with bone in the opposite cortex.
CANCELLOUS SCREWS

Compared with cortical screws, cancellous screws (Fig. 11.28 and Fig. 11.31) have larger threads with a higher pitch and usually a smaller core diameter, providing more surface area for purchase on bone. Because cancellous bone is fairly soft and easily deformed, tapping usually is not required. If the screw is inserted through cortical bone first, however, it is usually necessary to tap the cortex; for this reason, taps are provided for cancellous screws.

To obtain the best hold when placing a screw in cancellous bone, do not tap. As the screw penetrates, it compresses the bone to either side, thereby increasing the bone density in the immediate vicinity of the screw thread; this improves the holding power. Typically, cancellous screws have smooth shanks in the portion immediately adjacent to the screw head so that an automatic lag effect occurs without having to overdrill the near cortex. This is significant in the larger 6.5 mm screws, where a very large hole would need to be drilled in the near cortex to produce a lag effect. Varying thread lengths are available (16 and 32 mm). Fully threaded cancellous screws are available as well.

Today, many surgeons use cortical screws for internal fixation of the pelvis and fixation in the cancellous bone of juxtaarticular fractures such as those of the tibial plateau. These screws are inserted without tapping and take advantage of the compressive effect of the bone around the screw, as described above. Sometimes, a tap must be used to initiate penetration of the screw through the thin cortical cortex. If the opposite cortex is to be penetrated and it is more than one or two thread widths in diameter, pressure must be maintained against the screw to penetrate the cortex and to prevent stripping of the screw. This is the major disadvantage of this technique. The major advantage is that taps and the aggressive threads of cancellous screws do not need to be used in areas where excessive penetration of these sharp cutting surfaces may threaten neurovascular structures, and, in addition, a larger surface area of purchase of the screw threads on bone results in more holding power. This is a particularly good technique with self-tapping screws.

SPECIAL FEATURES

Most screws today have a spherical head that allows the screw to be angulated in all directions within a washer or plate while maintaining concentric contact between the screw and the side of the plate. The only disadvantage of the spherical head is that it is more prominent when used without a plate. This necessitates countersinking to avoid prominence of the head and to avoid the stress created by asymmetric contact of the underside of the head with the edge of the predrilled screw hole. Washers (Fig. 11.28) often must be used with cancellous screws because the screw head tends to bury into the thin cortex overlying cancellous bone.

A specialized use for the spherical screw head (Fig. 11.32) is in achieving interfragmentary compression. The screw head is driven asymmetrically in the specially designed screw hole of the dynamic compression plate, which was pioneered by the AO Group (71). This design eliminates the need for an external compression device but has the disadvantage of limiting the angulation with which the screw can be driven. Extreme angulation of the screws may reverse the compression force to some extent. The amount of compression achievable is less than that possible with an outboard compression device, described below in the General Principles of Plate Fixation section.

Specialized washers for fixing tendons and ligaments to bone have spiked undersurfaces. Also available are nuts with attached washers and screws. These improve fixation when the screw threads fail to gain purchase because of poor bone quality or technical error. A unique asymmetric nut is available in the Alta system (Fig. 11.33).

Specialized washers for fixing tendons and ligaments to bone have spiked undersurfaces. Also available are nuts with attached washers and screws. These improve fixation when the screw threads fail to gain purchase because of poor bone quality or technical error. A unique asymmetric nut is available in the Alta system (Fig. 11.33).
failure. In healthy young cortical bone, it is generally recommended that about 25 inch-pounds be applied to the screw. This can be learned by using a torque wrench. Make screws snug but avoid overtightening, which can result in fracture of the bone or failure of the screws. Overtightening also predisposes the screw to premature loosening.

When driving screws, maintain axial alignment to the hole drilled. Once the medullary canal is entered, it is possible to miss the opposite drill hole. Inexperienced surgeons should always drive screws by hand; hand-driving is also necessary when the bone quality is poor. A power driver with a screwdriver tip is useful when multiple screws are being inserted into cortical bone, but this technique requires experience.

Instruments and Techniques for Screw Insertion

Drill Points

Drill points (Fig. 11.27 and Fig. 11.29) must be sharp and straight. Dull drill points will overheat and “kill” bone. This can lead to premature mechanical failure of fixation and also predisposes to infection. Bent drill tips wobble, producing a hole larger than that required for the screw and thereby compromising fixation. When a dozen or more drill holes are made during a fixation procedure, drill points become dull and usually need to be replaced for the next procedure. If a drill point is inadvertently run against a metal surface such as a retractor, replace it, as dulling of the tip compromises its cutting power and can overheat bone. Use the proper-diameter drill point for each size of screw used. For cortical screws, use a drill point equal to or slightly larger than the core diameter of the screw. To produce a lag effect with cortical screws, use a drill point equal to or slightly larger than the outside diameter of the threads in the near cortex. For the screws used in the AO systems, the appropriate sizes of drill points are shown in Fig. 11.27 and Fig. 11.28.

Power Source

For screw fixation, hand drills are not as effective as power drills, primarily because the wobble introduced by hand drilling produces a slightly larger hole than desired. Power drills offer more precision and are preferred. The major danger with both hand and power drills is overheating due to excessive drilling speeds, particularly if drill points are dull. High-speed drills designed for inserting wires or for use with high-speed burrs are not suitable for inserting screws. The usual drilling speed for drill points is 600 to 700 rpm. To avoid bone necrosis, continually cool the drill point during drilling by irrigation with sterile saline. If drilling is prolonged, withdraw the drill point and frequently clean its flutes of bone.

The soft tissues around bone, particularly neurovascular structures, must be protected during drilling. In addition, avoid scratching fixation devices such as plates. To protect soft tissues and plates, use drill sleeves over the drill point. Drill sleeves also give better purchase on bone and increase the accuracy of drilling.

Proper drilling depth is established through practice. As a drill point begins to exit a cortical bone surface, it slows slightly and the pitch of the drilling sound changes. Use this as a signal to ease pressure on the drill, and prepare to arrest the forward motion of the drill to avoid overpenetration.

Measuring Screw Depth

Some drilling systems provide measurements on the drill shaft to determine screw length, but for the most part separate depth gauges are used (Fig. 11.34). Incorrect measuring can occur if you accidentally hook only the near cortex, or hook soft tissues or a bone surface other than the one desired, on the far side. In addition, improper mounting of the measuring tip in the depth gauge can produce erroneous measurements. After insertion of screws, always verify appropriate screw lengths either by palpation or by intraoperative radiographs, and check the depth gauge if lengths are inappropriate. In most situations, the appropriate screw length is such that one full thread exits the far cortex. This is unnecessary with cancellous screws in most applications and in fact may be inadvisable where the sharp tip of the screw threatens soft tissues on the opposite side of the bone.

![Figure 11.34. Alta depth gauge. Insert the hook into the screw hole, hook the far cortex and read the screw length off the shank. This gauge automatically adds 3 mm to compensate for the self-tapping tip of the screw.](image)

There are other nuances affecting screw length to be aware of. In the AO and similar systems, cortical screws are generally available in 2 mm increments. The depth gauge measurement is designed to place just one thread of the tip of the screw through the opposite cortex when the screw head is fully seated. If measurement indicates an odd number, such as 21 mm, then the next larger screw is used, in this case 22 mm. This ensures that the maximum number of threads is always engaging the far cortex.

In self-tapping screw systems, such as the Alta system, 3 mm or so of the tip of the screw is made up of the flutes, which are a part of the self-tapping feature. To be certain that a maximum number of screw threads engage the far cortex, depth gauges in these systems usually compensate for this and provide a measurement that allows approximately 3 mm of the screw tip to protrude beyond the far cortex. In addition, self-tapping screws are more frequently available in titanium systems where the plates being used are quite flexible and conform much more closely to the bone than steel. This may result in the screw tip protruding through the opposite cortex 5 mm or more, particularly in the first several screws used to fix the plate to the bone. Therefore, it is important to check the screw lengths by either palpation or radiographic visualization after completion of insertion of all screws in the plate, as it may be necessary to replace them if excessive length of the tip beyond the opposite cortex poses a problem. Penetration of 5 mm or so in many locations where the screw tip is well buried and not in the vicinity of neurovascular structures presents no problem, if the screw tips are on a subcutaneous border beneath skin, however, they can be quite bothersome to the patient and must be adjusted. If an in-between-size screw is needed in these systems, choose the next smaller screw, rather than the next longer screw as in AO system.

Tapping

If a self-tapping screw is used and excessive torque is required to insert it, back it out, clean the flutes, and readvance the screw. This avoids microfractures of the bone. Very dense cortical bone may require tapping of the near cortex. The screws most commonly used require tapping (Fig. 11.29). The correct tap for a given screw diameter must be used. In the AO system, a short tap is provided where lag screw fixation with cortical screws makes tapping of the near drill hole undesirable. Tapping can be done by hand or with power. To avoid microfracture of the bone and breakage of the tap, reverse the tap for a half turn every several terms to clear bone chips. Use low rpm settings and frequent reversals if tapping with power.

Screwdrivers

Many different screwdriver bits and heads are available, but the most commonly used are hex-socket-type heads and modified cruciate heads, in which the tines are rounded at the corners. Many names are applied to the latter tips, but they are most often referred to as Woodruff tips. A standard industrial screwdriver tip recently introduced is the Torx used in the Alta system. It provides superior driving torque, particularly in titanium alloy screws. It fits snugly into the screw, providing a self-retaining feature that is helpful in screw placement.

When driving screws, maintain axial alignment to the hole drilled. Once the medullary canal is entered, it is possible to miss the opposite drill hole. Inexperienced surgeons should always drive screws by hand; hand-driving is also necessary when the bone quality is poor. A power driver with a screwdriver tip is useful when multiple screws are being inserted into cortical bone, but this technique requires experience.

Make screws snug but avoid overtightening, which can result in fracture of the bone or failure of the screws. Overtightening also predisposes the screw to premature loosening.
screwdriver; experienced surgeons can sense the appropriate tightening of a screw.

**SURGICAL TECHNIQUES**

**LAG SCREW FIXATION**

Whenever a screw crosses two bone surfaces, as in a fracture or osteotomy, use the principles of lag screw fixation (Fig. 11.35):

- For effective interfragmentary compression, overdrill the cortex adjacent to the screw head, so thread purchase is achieved only in the opposite fragment.
- Notice that threading both fragments produces persistent distraction between the fragments.

When fixing a plate to bone where the screw does not cross a fracture or osteotomy interface, better purchase is obtained by bicortical fixation. In rare circumstances, it is undesirable to reduce the distance between two bone surfaces; the classic example is in fixation of the distal tibiofibular syndesmosis. In this situation, it is undesirable to overcompress the joint between the tibia and the fibula after reduction has been achieved. Instead, use a fully threaded cortical screw in each of the four cortices of the tibia and fibula, engaging all cortices with threads. To achieve lag screw fixation with cortical screws, two techniques are available, depending on which screw hole is drilled first: the gliding hole or the threaded hole.

**Gliding-Hole-First Technique**

- In simple fractures where most of the fracture line is visible, reduce the fracture anatomically and hold it with bone-holding forceps.
- To provide optimal alignment between the screw holes and to prevent displacement of the fracture as the screw is tightened, insert one or more interfragmentary lag screws, drilling the gliding hole first, then placing a drill sleeve and drilling the threaded hole (Fig. 11.36).

When the fracture site is not well visualized, or when the configuration of the fracture or osteotomy will make accurate screw placement difficult, drill the gliding hole first either from the outside or inside in the near bone fragment before reducing the fracture. This permits precise placement of the drill hole, which ensures that the screw does not enter the fracture line and that adequate bone stock is available for purchase (Fig. 11.37).

- Protect the soft tissues by using a 4.5 mm tap sleeve as a drill guide. Drill the gliding hole in the near cortex with a 4.5 mm drill bit (Fig. 11.36A).
- Insert a drill sleeve into the hole until it makes contact with the opposite cortex. This sleeve has an outer diameter of 4.5 mm and an inner diameter of 3.2 mm (Fig. 11.36B).
- Drill the opposite cortex with a 3.2 mm drill bit (Fig. 11.36C).
- Use a countersink to create a recess for the screw head in the near cortex (Fig. 11.36D).
- Use the large depth gauge to measure screw length (Fig. 11.36E).
- Tap the drill hole in the opposite cortex with the short 4.5 mm tap (Fig. 11.36F).
- Insert the correct-length 4.5 mm cortical screw until the fracture site is snugly approximated. If more than one screw is to be placed across a fracture, do not completely tighten the screws until they are all in place (Fig. 11.36G).

**Figure 11.35.** Lag screw fixation. A: Overdrilling the near cortex produces a “lag” effect and interfragmentary compression. B: Threading both cortices leaves a gap between the two bone fragments. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. *Manual of Internal Fixation.* New York: Springer-Verlag, 1979:37, with permission.)

**Figure 11.36.** Fixation with a lag screw after reduction of the fracture using the gliding-hole-first technique. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. *Manual of Internal Fixation.* New York: Springer-Verlag, 1979:37, with permission.)

**Figure 11.37.** Screw fixation prior to reduction of the fracture, using the gliding-hole-first technique. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. *Manual of Internal Fixation.* New York: Springer-Verlag, 1979:39, with permission.)

- Locate the appropriate site in one bone fragment for the gliding hole. Drill the hole using the 4.5 mm drill through a tap sleeve (Fig. 11.37A, Fig. 11.37B).
- More accuracy can sometimes be obtained by drilling from inside to outside (Fig. 11.37B).
Reduce the fracture, insert the drill sleeve, drill the threaded hole, and complete the screw fixation (Fig. 11.37C).

**Threaded-Hole-First Technique**

- Where it is not convenient to make the gliding hole first, drill the threaded hole with the 3.2 mm drill bit inside to outside first (Fig. 11.37D).
- Insert the pointed drill guide into this hole (Fig. 11.37E).
- Reduce the fracture, place a 4.5 mm tap sleeve through the sleeve of the pointed drill guide, and drill the gliding hole with a 4.5 mm drill, taking care to maintain appropriate alignment. While maintaining reduction, insert a screw and complete the fixation (Fig. 11.37C, Fig. 11.37D and Fig. 11.37E).

**Lag Screw Fixation of a Spiral Fracture**

Figure 11.38 illustrates the principles applied to the fixation of a long, spiral fracture. In general, lag screw fixation of an oblique or spiral fracture requires neutralization by a plate if sufficient stability is to be achieved to allow immediate rehabilitation without external protection. In very long or oblique diaphyseal fractures, and in some similar fracture configurations in the epiphysis and metaphysis, it may be possible to achieve good fixation with lag screws alone. When only lag screws are used, however, external protection with a functional brace and delayed weight bearing are advised. For fixation of a noncomminuted diaphyseal fracture with lag screws alone, the fracture length must be at least three times the diameter of the shaft at the site of the fracture.

**FIGURE 11.38.** Interfragmentary screw fixation of a long spiral fracture, showing the appropriate orientation of the screws along the fracture. Note that they are approximately at right angles to the long axis of the bone, yet spiral about the bone to maintain optimal alignment to the plane of the fracture lines. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979:41, with permission.)

Place screws at right angles to the fracture lines in each section of the fracture to obtain maximum interfragmentary compression. Proper placement avoids shear stresses that will cause the fracture to slide on itself. In spiral fractures, this requires the screws to spiral down the fracture site. In addition, in most fracture configurations, the screws are best placed at right angles to the long axis of the shaft of the bone, because longitudinal compressive forces will cause the screws to tighten rather than loosen.

**FIXATION OF ARTICULAR FRACTURES**

Internally fix fractures in the epiphyseal and metaphyseal regions with cancellous screws and washers, using lag screw fixation. At least two (often three) screws are required to prevent the fragments from rotating. Unless the bone is osteoporotic, cancellous screws need not exit the opposite cortex. In fact, in articular locations this is usually inadvisable because the sharp tip of the screw may impinge on neurovascular structures or present an uncomfortable prominence under the thin skin over joints. A typical configuration is shown in Fig. 11.39.

**FIGURE 11.39.** Lag screw fixation of an intraarticular fracture of the femoral condyles using two 6.5 mm cancellous screws with washers. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979:31, with permission.)

**FIGURE 11.40.** Displaced fracture of the body of the talus in an immature ankle has been internally fixed with two 4.5 mm cancellous screws.
Figure 11.41. Fixation of a displaced fracture of the malleolus with two 4 mm cancellous screws.

Figure 11.42. Internal fixation of a complex fracture of the acetabulum using only cancellous lag screws. Although these were sufficient in this patient, in some fractures plate fixation would be required as well.

When intraarticular fractures in cancellous bone, such as a vertical split fracture of a lateral tibial plateau, are fixed with interfragmentary screws alone, vertical shear forces tend to displace the condyle inferiorly. This can be neutralized by placing a buttress screw to support the fragment. Either a cancellous or a cortical screw can be used, depending on the location of the fracture and the quality of the bone.

- Place a drill hole immediately adjacent to the inferior tip of the proximal fragment, and drill in a bicortical fashion at right angles to the longitudinal axis of the tibia.
- Then place a screw with a washer. Be certain that the screw shaft contacts the tip of the fragment and the washer is brought snugly against the inferior spike of bone. This will prevent inferior shift of the fragment (Fig. 11.43).

Figure 11.43. Buttress screw (antiglide screw). Insert at the tip of the condylar fragment with the washer overlapping the proximal fragment, to prevent inferior subsidence of the condyle.

SPECIALIZED SCREWS

DOUBLE-THREADED SCREWS

The Herbert screw is another implant used for interfragmentary compression. Threads are present at both ends of the screw, with a pitch differential between the leading and trailing threads. Interfragmentary compression is achieved by the difference in thread pitch, so a screw head is not required. The absence of a screw head makes it possible to insert Herbert screws through articular surfaces without the head being prominent. Originally designed for scaphoid fractures, current indications include osteochondral fractures, osteochondritis dissecans, capitellar fractures, radial head fractures, and small joint arthrodesis. A disadvantage is that the Herbert screw can be difficult to remove. The Herbert screw used in an illustrative case is shown in Fig. 11.44.

Figure 11.44. Internal fixation of osteochondritis dissecans by Herbert screws. The trailing thread is countersunk beneath the articular surface of the medial femoral condyle.

CROSSLOCKING SCREWS

Strong screws are required for interlocking of intramedullary nails. Most systems use a smooth-shanked screw with special features to ease removal (Fig. 11.45).
CANNULATED SCREWS

Cannulated screws have a hollow core that allows screw insertion over a previously placed guide wire (Fig. 11.46). Potential benefits of this system are less soft-tissue dissection and the presence of a guide wire for provisional fixation and for accurate screw placement (Fig. 11.47). These screws are most often used for percutaneous fixation or femoral neck fractures, where fluoroscopic imaging of guide-wire placement helps to ensure appropriate screw length and screw position. Placement requires initial placement of a guide wire. A hollow drill is used over the guide wire and a cannulated tap is used if required. Cannulated screws are best inserted under fluoroscopic control. A depth gauge or measurement from a calibrated drill bit determines the length of screw to be used.

The disadvantages are that the screws are weaker than noncannulated screws, particularly in the small fragment size, and they break more easily when removal is attempted (Fig. 11.48).

ABSORBABLE SCREWS

Polylactic acid and other polymers are now used to manufacture absorbable screws. Indications include children when hardware removal can be avoided, and in the internal fixation of juxtaarticular fractures such as those of the medial malleolus, where high strength is not required and removal of hardware is often required because of the subcutaneous location of the screw. Bucholz et al. (23) have described good success with absorbable screws.

FIXATION OF TENDONS AND LIGAMENTS

Ligaments and occasionally tendons can be attached to bone for repair or reconstruction using a cancellous bone screw driven through the soft-tissue structure, with a spiked washer to obtain purchase on the ligament or tendon. Although this works well, one disadvantage is that the area of soft tissue fixed with the screw and washer becomes avascular due to the pressure. Sometimes this avascularity will lead to failure of fixation before adequate soft-tissue healing.

Other ingenious techniques have been devised to secure ligaments and tendons to bone, either by bone blocks or by indirect fixation. Daniel et al. described a step-cut tibial channel to capture the tendon preparation (35). Sutures are passed through the tendon preparation using a double-loop technique and are then tied to the head of...
a cancellous screw (Fig. 11.49). The interference screw technique (Fig. 11.50) described by Lambert is easier to perform and in my opinion provides better fixation.

**Figure 11.49.** Step-cut tibial channel for fixation of a bone ligament preparation for reconstruction of the anterior cruciate ligament. Sutures placed through the bone–tendon preparation by double-loop technique are tied to the head of a cancellous screw. (From Daniel DM, Robertson DB, Flood DL, Biden EN. Fixation of Soft Tissue. In: Jackson DW, Drez D Jr, eds. The Anterior Cruciate Deficient Knee. St. Louis: CV Mosby, 1987, with permission.)

**Figure 11.50.** Interference-fit fixation of the bone plug on a bone–tendon preparation for reconstruction of the anterior cruciate ligament using a 30-mm-long, 6.5-mm-wide cancellous screw. Fixation depends on a snug fit of the bone plug in the drill hole. (From Lambert KL. Vascularized Patellar Tendon Graft with Rigid Internal Fixation for Anterior Cruciate Ligament Insufficiency. Clin Orthop 1983;172:885, with permission.)

**SUTURE ANCHORS**

Since the previous edition of this book, a large number of suture anchors have become available that are based on the molly bolt principle or that are screws. Sutures of various sizes and materials are attached to these devices. When needing to attach ligament, tendon, or capsule to bone, these devices are inserted into the cancellous bone at the attachment site, securing the suture to the bone, which is then used to attach the soft tissue (Fig. 11.51). These have offered significant improvements, particularly where arthroscopic repairs are performed.

**Figure 11.51.** Mitek suture anchor (magnified).

**E. PRINCIPLES OF PLATE FIXATION**

Except for simple lag screw fixation, plates are probably the oldest means of fracture stabilization. Many types of plates have been applied to bone, some by screws, others with the help of wire loops. However, not until Danis in 1949 were plates applied with axial loading (compression) of the bone and fracture underneath (96). It was observed that this type of compression fixation leads to fracture healing without visible external callus (soudure autogène, or direct bone healing). From this observation, in the late 1950s, Müller developed the original AO round-hole compression plate with the removable compression device. Bagby and Janes developed a similar plate (7, 8). Since that time, plating has become a well-established means for fixation of a large variety of fractures and nonunions, and many different plate designs, forms of application, and plate functions have been described. For a review of the literature, see The Dynamic Compression Plate by Allgöwer et al. (2).

Although there is virtually no fracture that could not in principle be fixed with a plate, other devices for fracture fixation, such as the interlocking nail and the external fixator, have advantages over plates in certain situations, especially in diaphyseal fractures of the femur and tibia.

Plates may be classified according to either type (shape and size) or function. Both type and function often correspond to a specific application (for example, the L-shaped buttress plate for fractures of the tibial plateau). On the other hand, a given plate may have different functions, depending on (a) the mechanical configuration of the bone–plate conjunction, resulting in static compression, dynamic compression (tension band), neutralization, and buttressing; (b) which part of the bone is stabilized (metaphysis or diaphysis); and (c) the specific fracture configuration.

**DEVELOPMENT OF PLATE FUNCTIONS**

The original AO round-hole compression plate was thought to provide static compression of a diaphyseal fracture, thereby leading to rapid bony union, as was shown experimentally in sheep (82). After fracture reduction, compression or axial loading was applied with the help of the removable compression device. Today, it is known that in most cases the originally instituted compression force of up to 80–90 kilopascals (kp) was lost after the remaining screws were introduced into the round holes of the plate. The reason for the success of the so-called compression plate, therefore, was most probably not compression in the first place, but rather the better method of fracture fixation with newly designed implants that were also applied differently (e.g., by power drilling, pretapping). In hypertrophic nonunions, the primary achievement of the compression plate was better approximation of the nonunited fragments and optimal stabilization, allowing calcification of the interposed tissues. If properly placed on the tension side (convexity) of the nonunion, the compression plate acts as a tension band, which actually provides dynamic rather than static compression.

With increasing knowledge about the physiology of fracture healing, it became evident that to stimulate bone remodeling by creeping substitution, a signal was needed. The best way to transmit or generate this signal appeared to be physiologic loading of bone by controlled weight-bearing. For this purpose, the original AO/ASIF
round-hole plates were probably somewhat less forgiving when not ideally applied. Too much axial loading could lead to fatigue failure of the plate or loosening of the screws rather than to bony union.

In 1965, the dynamic compression plate (AO/ASIF DCP) was introduced. The self-compressing effect by eccentric screw placement, combined with the possibility of a gliding or sliding effect (Fig. 11.52) between the screw head and the plate hole, allowed a more physiologic force transmission within bone during weight bearing. Furthermore, thanks to the spherical configuration of both screw head and plate holes, the compression instituted initially was maintained throughout the procedure, even if the screws were not placed at a right angle to the plate.

**Figure 11.52.** A: Dynamic compression plates of different dimensions. From top to bottom: broad, 4.5 mm; narrow, 4.5, 3.5, 2.7 mm. B: Schematic representation of the spherical gliding principle of the DCP. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979:235, with permission.)

**STATIC COMPRESSION**

Static compression is best demonstrated on the model of a transverse fracture (Fig. 11.53). Tensile pre-stressing of a straight plate produces axial compression in the fracture. The area underneath the plate is compressed, while the opposite cortex shows a gap. To increase the amount of bone surface being compressed (including the opposite cortex), it is advisable to contour the plate to approximate the cortex opposite the plate. Another possibility to prevent a slight gapping of the osteotomy or fracture line in the far cortex is to place a lag screw across the fracture or osteotomy plane (Fig. 11.54).

**Figure 11.53.** Static compression in a transverse fracture (humerus) fixed with a slightly overcontoured plate. Axial compression is obtained via the removable tension device. A: Plate application with the tension device. B: Equal distribution of compressive forces. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979:223, with permission.)

**Figure 11.54.** Fracture fixation is improved by placing an interfragmentary lag screw through the plate. A: Placement of interfragmentary lag screw across a 3.5 plate; drilling of a gliding hole with a 3.5 mm drill bit. B: Drilling of a threaded hole with a 2.5 mm drill bit and corresponding drill guide. C: Interfragmentary compression across plate and fracture is achieved by tightening the lag screw. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979, with permission.)

Most transverse diaphyseal fractures are best treated by a medullary nail. The indications for a static compression plate, therefore, are less common; these include transverse fractures of the humerus and forearm bones.

**DYNAMIC COMPRESSION (TENSION BAND PLATE)**

From his experience in mechanics, Pauwels borrowed the principle of tension band fixation and demonstrated its application in operative fracture treatment (79). Every eccentrically loaded bone is subjected to bending stresses and deforms in a typical manner, with a gap on the convex or tension side and compression on the concave side of the bone (Fig. 11.55A). To restore the load-bearing capacity of an eccentrically loaded bone, the tensile forces on the convex side must be absorbed by a tension band (wire or plate) (Fig. 11.55B). The bone itself—especially the cortex opposite the tension band—must be able to withstand axial compression; this requires a medial buttress, usually supplied by the intact cortex. Thus, the implant absorbs the tension forces, and the underlying bone the forces resulting from compression. Loading (e.g., by partial weight-bearing) results in a dynamic increase of the axial interfragmental compression. In the absence of a medial buttress, which absorbs the compression forces, the plate is subjected to repeated bending stresses, which inevitably lead to fatigue failure and implant breakage (Fig. 11.55C).
Figure 11.55. Tension band plate in femur. A: Eccentric loading of the femur results in tensile forces on the lateral side and compression on the medial aspect of the bone. B: In the presence of a good bony buttress, the lateral plate acts as a tension band. The plate is therefore stressed only in tension, the bone in compression. C: In the absence of a bony buttress—due to a cortical defect—the plate undergoes cyclic bending, leading rapidly to fatigue breakage.

Except for the femur, olecranon, and patella, it is difficult to identify the tension or compression side of a fresh fracture, but in a malunion the aspect (lateral, medial, or posterior) on which the tensile forces are most active is usually clearly visible (Fig. 11.56). The best indications for a tension band plate, therefore, are fractures in the subtrochanteric area of the femur (requiring a 95° blade plate or broad DCP), certain olecranon fractures (one-third tubular or 3.5 mm plate), and nonunions.

Figure 11.56. Tension band plate in nonunions. To act as a tension band, the plate must always be placed on the tension or convex side of the bone. A: Lateral position. B: Medial position. C: Posterior position. (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979:731, with permission.)

NEUTRALIZATION

By far the most common function of a plate is neutralizing or protecting an interfragmentary lag screw fixation (Fig. 11.57). Most fractures can be reduced by interfragmentary lag screw fixation alone (Fig. 11.57B), but in many instances this fixation will not suffice for early active movement or partial weight bearing. To protect the lag screw fixation from bending, torsion, and shearing forces, a neutralization or protection plate is added (Fig. 11.57C).

Figure 11.57. Neutralization plate in the tibia. A: Comminuted, multfragment fracture. B: After anatomic reduction and preliminary fixation with two lag screws and a cerclage wire. C: A neutralization or protection plate has been added on the medial aspect of the tibia, with two additional lag screws through the plate (arrows). (From Müller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979:33;581, with permission.)

After screw fixation, carefully contour the plate and fix to the bone with all screws in a neutral position. Place a lag screw across the fracture through the plate whenever possible, as this greatly improves the neutralizing bone/plate system (Fig. 11.57C).

BUTTRESS FUNCTION

In the metaphyseal area of most bones, one encounters intraarticular fractures that are a combination of cleavage (T or Y), with or without impaction of cartilage and subchondral cancellous bone. After reconstruction of the articular surface and grafting of the bone defect, one or two buttress plates will fix the articular fragments to the shaft and support or buttress the metaphyseal area (Fig. 11.58). Typical indications for buttress plating are fractures of the distal humerus, the tibial plateau, and the tibial pylon, and compression fractures of the distal radius. Accordingly, all T and L-shaped plates are designed for buttress functions. If a DCP with gliding holes is applied for buttressing, the screws must be introduced at the end of the gliding slope to prevent further collapse.

Weber described a special kind of buttress plate, an antiglide plate (107). For this purpose Weber usually applies semi- or one-third-tubular plates in such a way as to prevent the tip of an oblique fracture from displacing due to muscle pull. For example, in a type B fracture of the lateral malleolus (Fig. 11.59), the three-hole, one-third-tubular plate is placed posteriorly and thereby locks the tip of the distal fragment into an anatomically correct position.

**PHYSIOLOGY OF PLATE FIXATION**

Before the revolution in plate fixation was started by the AO Group in the late 1950s, the major problems encountered in plate fixation of fractures, other than the usual surgical complications, were early plate failure, screw breakage, and screw pullout. Plates were relatively weak, and the principles of obtaining a biomechanically stable reconstruction through improvements in interfragmentary contact were not yet well known. Screws were still based on designs from the woodworking and metal industries, and their thread designs were not ideal for fixation in bone. In addition, most screws were self-tapping; this self-tapping feature was not well designed and led to microracks, which hindered the hold of the screw in bone.

The introduction of the much more rigid fixation obtainable with AO implants led to a new set of clinically significant problems: bone loss under the plate, fracture at the ends of the plates, or refracture through the fracture site or screw holes after plate removal. Anderson et al. (5) and Hida and Gustilo (52) had a 22% incidence of refracture after plate removal using the standard, narrow 4.5 mm AO plate on fractures of the radius and ulna. Chapman et al. (57) were able to eliminate refractures in plate fixation of the radius and ulna by using the AO/ASIF 3.5 mm system.

Laboratory investigation of this problem has shown two possible causes: stress protection, and devascularization followed by revascularization. Studies by Woo et al. (115), Coutts et al. (32), Uhthoff and Dubus (103), and others demonstrate that stiff plates, when applied to healing fractures, result in weaker fracture callus and, when left in place for prolonged periods, weakening of the bone under the plate due to bone resorption. These authors felt that this effect was due to “stress shielding.” In accordance with Wolff’s law, introducing a rigid member across a fracture site alters the signals influencing the homeostatic mechanisms controlling bone apposition and resorption, so that the fracture heals with weaker callus and bone resorption occurs under the plate and in the surrounding cortex.

Swiontkowski and Senft (102) and others have demonstrated devascularization of the cortex secondary to soft-tissue stripping and disturbance of the intrinsic blood supply to bone by the application of the plate and insertion of screws. Revascularization of the bone results in bone resorption. The hypervascularity associated with that is most evident under the plate.

Both of these factors are important, and newer plate designs have addressed both issues by producing more flexible plates from materials with a lower modulus of elasticity, such as titanium, titanium alloys, carbon fiber, or polymer, and by newer configurations. Only titanium is currently in use clinically, however.

**NEWER PLATE SYSTEMS**

Many plating systems are now available that use CP titanium, 6-4 titanium alloy (described above, in the section on Implant Materials), or other alloys. Titanium is more flexible than surgical steel, yet stronger. Howmedica (Rutherford, NJ) produces a modular bone fixation system from 6-4 titanium in an attempt to optimize the environment for fracture healing. The modular system allows plates of different lengths and types to be interconnected by dovetailing (Fig. 11.60). This modular feature reduces the need for soft-tissue stripping to place the plates. The use of larger oval holes in the plate, which will accommodate two screws, permits fixation with shorter plates and increases the range of angles through which screws can be placed; this enhances fixation. The railed design of the plate limits plate contact with the bone to the minimal area, thereby reducing soft-tissue stripping and allowing the plate to be inserted without disturbing the fracture callus. The use of larger oval holes in the plate, which will accommodate two screws, permits fixation with shorter plates. The use of larger oval holes in the plate, which will accommodate two screws, permits fixation with shorter plates.

![Alta modular titanium plating system. A: The Alta channel plate (extension plate) features a railed undersurface, holes for single or double 5.0 mm screws, and a rounded configuration for insertion into a dovetail. B: The underside of an Alta distal femoral fracture plate, showing the dovetail connection between the two plates. If needed, they can be preassembled and fixed together with a screw and nut. C: Alta compression hip screw with the side plate dovetail holding a four-hole channel plate. Note the double screw hole configuration. The channel plate is available in three lengths. D: The channel plates can be connected with this double dovetail. This modularity drastically reduces the implant inventory and increases versatility. E: The distal femoral fracture plate seen from its top surface. The notch in the end of the plate permits insertion of two interfragmentary screws. The three double screw holes permit multiple screw fixation into the condyles. F: The dovetail is also featured in the Alta 3.7 mm small reconstruction plate, which has oval holes to accommodate two 3.7 mm screws or a 5.0 mm cortical screw (enlarged photograph). G: Specialized L, T, and U plates can be interlocked with the dovetail of the 3.7 mm plates. (Illustrations courtesy of Howmedica, Rutherford, NJ.)](image)

CONSIDERABLE EXPERIMENTAL AND CLINICAL WORK HAS BEEN DONE WITH POLYMERIC AND CARBON FIBER PLATES AS WELL (103). THEIR MODULUS OF ELASTICITY IS EVEN CLOSER TO THAT OF BONE, BUT THEY CANNOT BE MOLDED DURING SURGERY AND SOME TEND TO BE QUITE BRITTLE. THUS FAR, THEY HAVE NOT BEEN FOUND TO BE PRACTICAL IN CLINICAL APPLICATIONS. OTHER EFFORTS TO MAKE PLATE AND SCREW FIXATION MORE COMPATIBLE WITH NORMAL BONE PHYSIOLOGY HAVE BEEN DIRECTED TOWARD THE DEVELOPMENT OF RESORBABLE PLATES AND SCREWS, OR PLACING RESORBABLE SURFACES ON THE PLATE–BONE OR PLATE–SCREW INTERFACE. RESORPTION RESULTS IN EVENTUAL LOOSENING OF THE CONSTRUCT, THEREBY ALLOWING MORE PHYSIOLOGIC TRANSMISSION OF STRESSES. ALL OF THESE ARE EXPERIMENTAL AT PRESENT AND HAVE NOT ENTERED CLINICAL PRACTICE.

GENERAL PRINCIPLES OF PLATE FIXATION

LOCATION

Earlier in this chapter, I emphasized that plates should be used as tension bands if possible and therefore placed on the convex surface of bones. This is particularly true for the radius, where plates are usually placed on the dorsal lateral surface, and for the femur, where they are placed anterolaterally. In the humerus, plate location is dictated more by the anatomy of the surgical exposure, and generally the plate is placed laterally or dorsally. The bending forces about the tibia are less predictable, but generally plates are best placed on the lateral surface because of the excellent soft-tissue coverage provided. In general, try not to place plates in subcutaneous locations, as skin slough or infection may result in plate exposure. In addition, plates in subcutaneous locations are more likely to produce symptoms. However, the practical aspects of fixation demand placement of plates in subcutaneous locations in some circumstances, such as plating of the olecranon and the lateral malleolus.

SURGICAL TECHNIQUES

EXPOSURE

The following principles apply to fixation of most diaphyseal fractures with plates:

- When exposing the fracture, limit soft-tissue stripping to just the surface on which you expect to place the plate. Avoid the use of retractors and bone-holding forceps, which require circumferential stripping of bone. Fine-pointed tenaculum-type bone-holding forceps are best.
- There seems to be no advantage to leaving the periosteum intact beneath the plate. For most plates in common use today, application of the plate on the periosteum results in complete loss of blood supply to the periosteum. In addition, the fixation of the plate to bone is less secure, due to the intervening soft tissue. It is more difficult to obtain an anatomic reduction, particularly in comminuted fractures. On the other hand, maintaining soft-tissue attachments to bone is important. Newer “point contact” plates may change this advice.
- If very small butterfly fragments are involved, maintaining soft-tissue attachments to the butterfly may make the fixation of the fracture exceedingly difficult and may result in less-than-optimal reduction. In such cases, I do not hesitate to detach small bone fragments from soft tissues to enhance the ability to obtain fixation. These small fragments usually revascularize very quickly.
- To ensure that bone union occurs in the presence of such comminution, however, apply a cancellous bone graft across the comminuted zone.
- Accurate reduction and apposition of butterfly fragments is particularly important when their absence would leave a gap opposite the plate. This dramatically increases the bending stresses on the plate and could lead to early fatigue failure of the plate.
- After exposing the fracture site, clean the fracture ends of all organized hematoma and soft tissue. Strip the periosteum from the fracture ends 1–2 mm, just enough to delineate the fracture surface.

REDUCTION AND PLATE APPLICATION

Transverse fractures that are inherently stable can be reduced before plate application, and this simplifies fixation. Unstable fractures pose a challenge, particularly if excessive soft-tissue stripping is to be avoided. In simple oblique or spiral fractures, or those with small butterfly fragments where there is good cortical contact, often the fracture can be reduced with a small tenaculum forceps and preliminary fixation obtained with an interfragmentary lag screw. Application of the plate then is simplified. In more unstable and comminuted patterns, a different approach may be necessary. If a major butterfly is present, the best approach may be to fix the butterfly to one fragment with an interfragmentary lag screw, which then may produce a stable pattern that can be reduced and easily plated. If this is impossible, I advise using the plate to provide the mechanism for reduction of the fracture:

- Precontour the plate, select the approximate location for the plate, and choose the point for the first screw hole on one side of the fracture. If necessary, lay the plate on the surface of the bone on one side of the fracture and mark the site for the screw with a methylene blue marking pen.
- Drill for the screw without the plate in place, and then secure the plate to one fragment with one screw.
- Tighten the screw to achieve reasonable stability, but do not overtighten it, as this may interfere with the reduction. Then reduce the fracture and stabilize it using a tenaculum or small plate-holding forceps on the side of the plate not attached to bone.

Fixation of the plate to one side of the fracture before reduction is immensely helpful. This avoids the common struggle in which the fracture is reduced and held with multiple bone forceps, but then the surgeon finds that the plate cannot be placed. Removing the forceps to place the plate then results in loss of stability, and a prolonged struggle ensues to hold the reduction while applying the plate.

INDIRECT REDUCTION TECHNIQUES

For very comminuted fractures, such as in the supracondylar region of the femur and in pylon fractures, use indirect reduction techniques as popularized by Mast to avoid devascularization of the many bone fragments (71). To achieve length, apply a femoral distractor and then use it to pull the fracture out to length; or, fix the plate to one fragment and use the plate itself to distract the fracture out to length, using the outboard plate compression device or a lamina spreader between the end of the plate and an outboard screw.

- With distraction, nudge the intercalary comminuted fragments into reasonably good position.
- With severe comminution, achieve good plate fixation above and below the fracture, but do not attempt fixation of the multiple small fragments. Application of a bone graft to the comminuted section through the fracture site, prior to reduction, to accelerate union may be wise.
- In small, good-quality bones, apply screws through five or six cortices (up to three bicortical screws) for fixation on either side of the fracture. In the humerus, tibia, and femur, use solid bicortical fixation through the cortex, with four screws on each side of the fracture. In long spiral or oblique fractures, some of these screws should be interfragmentary lag screws.
WAVE PLATES

Another interesting method for plate fixation popularized by the AO group and recently used successfully by Jupiter et al. (33,55) is the wave plate. Although this is potentially applicable to acute comminuted fractures in a technique similar to that described previously as an indirect reduction technique, for the most part it has been limited to the treatment of nonunions of the diaphysis of large bones such as the humerus and femur.

- Contour a large broad plate to fit the bone proximally and distally to the nonunion site, producing a wave in the plate that lies free of the cortex and bypasses the nonunion site and fracture callous (e.g., in hypertrophic nonunions). Solidly fix this to the proximal and distal fragments with at least four bicortical screws above and four below. Then pack bone graft around the nonunion site, including the area beneath the plate.

The principle of this technique is that it requires minimal stripping of soft tissues around the nonunion site and, therefore, maximally protects vascularity. In addition, it makes available the largest surface area for revascularization. The major disadvantage of the technique is that it does not provide nearly as secure fixation as more rigid techniques such as the double plates described below. If the patient bears excessive weight on an unstable nonunion site, premature fracture of the plate through one of the empty screw holes in the wave section can occur.

DOUBLE PLATES

For simple fractures, I do not use double plates: Their application requires too much soft-tissue stripping, and the rigid fixation produced may cause stress protection osteopenia. Indications for double plates are difficult nonunions, particularly where bone quality is less than optimal, and fracture configurations where solid bone contact on the cortex opposite a single plate is impossible. Typical examples are subtrochanteric and supracondylar fractures of the femur. A second plate should always be smaller, both in overall size and length, than the major fixation plate, and it should be substantially shorter to avoid a stress riser at the end of two plates of similar length. The strongest construct is when the plates are placed at right angles to each other. For example, in the subtrochanteric region, after fixation with a hip screw with a side plate, use a four- or six-hole narrow 4.5 mm plate. In the supracondylar region, a similar principle applies, and even a small fragment plate can be used (Fig. 11.62 and Fig. 11.63).

Figure 11.62. Double plate fixation of an intertrochanteric fracture.

Figure 11.63. Reconstruction of a supracondylar fracture of the femur with double plate fixation using a 95° condylar screw with an extension plate laterally and a broad plate anteromedially. Note that the anteromedial plate is shorter than the lateral plate to minimize the stress at the upper ends of the plates.

After fixation of a fracture with a single plate, always stress the fracture to see if micromotion occurs through the fracture site. If it does, either interfragmentary screw fixation or a second plate is usually required.

SPECIALTY PLATES

Specialty plates are usually designed for fixation in the metaphyseal or epiphyseal portions of the long bones, or they are designed for the spine or pelvis (Fig. 11.64). Reconstruction plates have become quite popular since the early 1990s for the fixation of fractures where bending of the plates in three planes is necessary to achieve adequate conformity to bone. The most common sites for this are the distal humerus and the acetabulum and pelvis.

Figure 11.64. A: The 3.5 mm AO reconstruction plate is used for fibula, radius, ulna, pelvis, and other metaphyseal fractures. B: AO tibial lateral buttress plate for fixation of fractures of the tibial plateaus. The plate is thick in the diaphyseal portion and thin in the metaphyseal section. C: An AO miniplate for small bones. (Courtesy of Synthes, Paoli, PA.)

The notched reconstruction plates bend easily in all three planes. Make bends in the plane of the plate before twisting or bending vertically to the plane of the plate. Apply a malleable template to the bone first. Use the template to determine the bends on the plate. Bending is less injurious to the plate and easier with the use of special bending presses. Bending is more accurate and safer if the plate is held by an assistant while the surgeon bends the plate. Bend in small increments to avoid overbending. Reverse bending of the plate substantially weakens it and is not recommended. Avoid kinking the plate. Bends are best distributed throughout the length...
F. PRINCIPLES OF INTRAMEDULLARY NAILING

ADVANTAGES AND DISADVANTAGES

For the diabetes of weight-bearing bones, intramedullary nailing is a fixation method superior to plates or external fixation, because the location of the rod in the intramedullary canal virtually guarantees proper axial alignment. Rotational alignment can be ensured with interlocking screws. In stable fractures, weight bearing is not only feasible but preferable; in an intramedullary location, nails, unlike plates and external fixation methods, are load-sharing devices, being subjected to small, bending loads. Bracing of intramedullary implants is thus minimized. Intramedullary nails can be placed using percutaneous closed techniques that minimize soft-tissue dissection, thereby decreasing the risk of infection. An additional advantage of intramedullary nails is that removal is often unnecessary. When needed, removal can usually be done from one end of the nail, using a small incision. Refracture after removal is uncommon, as no significant stress riser is left in the bone.

One disadvantage of intramedullary nailing is the fact that the size of the intramedullary canal may limit the size of nail that can be used; this limits the bending strength of the nail unless extensive reaming is performed. Intramedullary nails without cross-locking screws do not provide as good rotational control as do plates or external fixation. Intramedullary nails, particularly reamed nails, interfere with the endosteal blood supply, which makes up to 90% of the vascular supply to the diaphysis of long bones. This disadvantage may be minimized by using nonreamed and fluted nails. In closed fractures, the clinical significance of this disadvantage is limited, since revascularization from the surrounding muscle takes place rapidly (84,85 and 86). In open fractures, particularly of the tibia, in which stripping of the periosteum and muscle and bacterial contamination occur, the risk of infection in devascularized bone subjected to intramedullary nailing is significant. In addition, the techniques for inserting intramedullary nails by closed technique can be technically demanding.

EFFECTS OF NAILING AND REAMING ON BONE AND SYSTEMIC PHYSIOLOGY

Reaming of the medullary canal and intramedullary nailing embolizes marrow contents into the general circulation and results in microembolization to many solid organs including the lung. In addition, there are dramatic acute effects on the diaphyseal blood flow (87).

Embolization of fat and marrow elements into the general circulation through the copious venous channels in the bone marrow has been demonstrated in animals (88-101), and embolization has been demonstrated in humans by transesophageal echocardiography and other measures (80-109). The degree of embolization is influenced by various factors (38,51). Nearly all manipulations of the intramedullary cavity cause some increase in pressure; however, Duwelius et al. (39) have shown the highest pressures with insertion of an axel into the medullary canal to open it. Reamer design can greatly influence pressurization of the canal. The lowest pressures can be obtained by using reamers with a small shaft diameter relative to the diameter of the cutting flutes, and where the design of the flutes optimizes depressurization of the canal. The presence of a fracture, slowing the rate of progression of the reamer down the canal, and increasing the rotational speed of the reamer have been found to reduce the intramedullary pressure and amount of embolization. Vent holes in the distal femur have not been shown to reduce reaming pressures reliably.

Whether this embolization is of clinical significance is controversial. Pape et al. (75) and Kröpf et al. (82) have expressed the view that embolization of marrow contents to the lungs in patients with severe multiple injuries in whom there is pulmonary compromise or where there has been direct lung trauma is of concern; therefore, they recommend the use of nonreamed nails in patients with severe multiple injuries and/or pulmonary compromise. Many other investigators, however, have shown only transitory changes in pulmonary function in animals (92-114). Other investigators in well-designed prospective randomized and multi-institutional studies have not been able to demonstrate any significant adverse effects of reamed nailing in multiply injured patients with and without pulmonary compromise (17,109).

In view of this concern, surgeons should use instrumentation and techniques to minimize the amount of marrow and fat embolization. In addition, using caution in patients with severe pulmonary trauma or preexisting compromise of pulmonary dysfunction is wise.

The blood flow to the diaphysis of long bones can be reduced to one third of normal by reaming initially; however, this stimulates a strong hyperemic reaction that in experimental animals can reach several times normal by 2 to 4 weeks after fracture (49,76). Revascularization of the cortex occurs by reversal of the normal centrifugal blood supply to a centripetal supply coming from the surrounding muscle and periosteum. Nails that fit the cortex tightly interfere with this revascularization, so the use of smaller or fluted nails enhances reestablishment of blood supply to the marrow cavity and cortex (44,45,114). In reamed intermedullary nailing, the fracture healing process is dependent on revascularization of the diaphysis from the surrounding soft tissues; therefore, reamed nailing is potentially more dangerous to bone, particularly if infection intervenes and the soft-tissue envelope is compromised. The hyperemic response in the bone is echoed by increase in the blood flow to all the soft tissues of not only the injured leg but the contralateral extremity as well (4,6). In open fractures of the tibia with exposed bone, muscle flap coverage of a devascularized cortex has been shown to be important to revascularization and bone union (89,89,95). The hyperemic response to reaming, however, leads to high rates of union in the tibia and femur reported up to 98% (16,72). This has led to arguments about whether reamed or unreamed nailing is the best procedure for diaphyseal fractures. Schmitz et al. (93,94) showed no difference between these two types of nailing in an animal model, from the standpoint of the vascular profusion of the bony callus formed at the fracture site at up to 12 weeks and in the strength of union of the callus. On the other hand, studies by this same research group showed that, in a canine fracture model, overall tibial blood flow was reduced by 63% with limited reaming and 83% with full reaming. These data suggest that in severe open fractures, in particular of the tibia, the best of all worlds may be achieved by gentle, limited reaming to provide maximum protection to the blood supply but still allow the use of a 10 mm or larger nail, which provides adequate mechanical strength for union in the vast majority of cases.

TYPES OF NAILS

REAMED NAILS

The classic reamed nail is the hollow, open-section nail of Küntscher (45,49). Most other reamed nails are variations of the Küntscher nail, such as the AO nail, and the various interlocking nails, such as the Grosse-Kempf (Howmedica, Rutherford, NJ), Klemm (Richards, Memphis, TN), Alta (Howmedica), Russell-Taylor (Richards), Uniflex (Biomet, Warsaw, IN), AO Universal (Synthes, Wayne, PA), and others (Fig. 11.65) (46,57,71). Fluted nails, such as the Sampson (Zimmer, Warsaw, IN), are little used since the introduction of more advanced locking nails (1). Reaming provides a precise fit for the nail in the intramedullary canal, thereby reducing the incidence of nail incarceration and improving the stability of fixation. Reaming permits the use of larger nails, which are stronger than smaller ones. A nail with a 12 mm diameter is 1.25 times stronger in bending than one with an 11 mm diameter.

Figure 11.65. A: Intramedullary nails that require reaming. (1) A Küntscher nail, designed for open nailing, which is straight, nontapered, and slotted throughout. (2) A Grosse-Kempf nail, designed for closed nailing, which has a curved, tapered tip, and is slotted throughout. (Courtesy of Howmedica, Rutherford, NJ.) (3) A Grosse-Kempf nail with a curved, tapered tip, a closed section at the upper end, an oblique cross-locking screw proximally, and two transverse cross-locking screws distally. (Courtesy of Howmedica, Rutherford, NJ.) B: Alta intramedullary locking nail for the femur. This is a solid-section, cannulated nail with a hexagonal cross section with smooth flutes to enhance revascularization. It is made of a titanium alloy. Two transverse 5.0 mm diameter cross-locking screws are used distally and proximally, eliminating the need for right and left nails. (Courtesy of Howmedica, Rutherford, NJ.)

NONREAMED NAILS

Single, nonreamed, nonlocking nails have been designed for most of the long bones, including the femur (the Schneider nail (97) and the Hansen-Street nail (100), both
The greater trochanter (cortex at its entry hole. This permits the surgeon to set the nail more proximally to secure fixation in the femoral neck without having the nail protrude above the tip of the greater trochanter.

Alta nail is designed to have its two proximal cross-locking screws located just distal and proximal to the lesser trochanter when the top of the nail is flush with the femoral head, as in the Russell-Taylor nail (Smith Nephew Richards, Memphis, TN) or the Alta CFX nail (Howmedica, Rutherford, NJ) (Fig. 11.65B). Proximal fixation includes inclined screws, as in the Grosse-Kempf nail (Fig. 11.65B); two transverse screws, as in the Alta (Fig. 11.65B); and specialized screws through the nail designed to secure fixation in the femoral head, as in the Russell-Taylor nail (Smith Nephew Richards, Memphis, TN) or the Alta CFX nail (Howmedica, Rutherford, NJ) (Fig. 11.65B). The Alta nail is designed to have its two proximal cross-locking screws located just distal and proximal to the lesser trochanter when the top of the nail is flush with the cortex at its entry hole. This permits the surgeon to set the nail more proximally to secure fixation in the femoral neck without having the nail protrude above the tip of the greater trochanter (Fig. 11.71). This allows fixation of subtrochanteric fractures that include even the lesser trochanter.

Nearly every fracture combination in the femur can be addressed by percutaneous fixation techniques. Except for the Brooker-Wills nail (Biomet, Inc., Warsaw, IN) (Fig. 11.68), the tibia (the Lottes nail (Howmedica, Rutherford, NJ) (90)), the humerus (the Sampson nail (13)), and the forearm (the Sage nail (Smith Nephew Richards, Memphis, TN) (81)) (Fig. 11.66). Single, nonreamed nails are simple to insert and are associated with improved preservation of the endosteal blood supply and rapid revascularization (71,73,84). Their disadvantages include an increased likelihood of impaction during driving and, because smaller nails must be used, their relative weakness, particularly in bending.

Some nonreamed intramedullary nails are designed to be used in groups. The best example is Rush rods, which have been designed for all the long bones of the body (Fig. 11.67) (90). Ender pins have a similar design (Fig. 11.68) (39,40,73,74). Multiple Steinmann pins and Kirschner wires can also be used as intramedullary nails. These devices have all the advantages of nonreamed single nails, but provide better rotational control; as a cluster, they are generally stronger than single nails. However, they are technically more difficult to use and provide relatively poor axial stability.

Several intramedullary nails, particularly for the tibia, are designed to be used reamed or nonreamed. Some of these newer nails are made of titanium alloys. Titanium nails drive more easily due to their flexibility and are stronger than stainless-steel nails.

LOCKING NAILS

Since 1988, when the first edition of this book was published, locking intramedullary nails have gained wide acceptance and have revolutionized fracture care. The Grosse-Kempf (Howmedica Rutherford, NJ) (57) and Klemm (no longer manufactured) (60) nails were the first generation of locking nails. Many new second-generation designs are available, and they address a wide range of problems in the femur, tibia, and humerus. Although available, locking nails for the forearm have not yet gained wide use.

Locking nails have made single nonlocking nails obsolete. The only advantages of nonlocking single nails are their simplicity and low cost.

Intramedullary nails designed to be used as single nails without reaming. (Note: illustrations are not proportional.) A: A Schneider nail with a solid, four-fluted cross section and self-broaching ends. (Courtesy of Howmedica, Rutherford, NJ.) B: A Harris condylocephalic nail that is made from a titanium alloy (Ti-6Al-4V), curved in two planes, and designed for percutaneous, retrograde fixation of extracapsular hip fractures. (Courtesy of Zimmer, Warsaw, IN.) C: A Lottes tibial nail, which is solid, specially curved to fit the tibia, and has a triflanged cross section. These nails are available in $\frac{5}{16}$-inch (8 mm) and $\frac{3}{16}$-inch (9.5 mm) diameters. (Courtesy of Howmedica, Rutherford, NJ.)

Rush rods are available in four diameters—$\frac{1}{4}$ inch (6.4 mm), $\frac{5}{16}$ inch (4.8 mm), $\frac{1}{8}$ inch (3.2 mm), and $\frac{5}{32}$ inch (2.4 mm)—and in a variety of lengths that are proportional to all the major long bones. Rush rods are solid, with an oblique tip and hooked end that are designed to be inserted percutaneously. These rods must be prebent by the surgeon to obtain three-point fixation in the canal. (Courtesy of Howmedica, Rutherford, NJ.)

Ender pins, which are sold with an oblique tip and an eye in a flange at the other end, were originally designed for percutaneous, closed treatment of extracapsular hip fractures. Special sizes are available for the humerus and tibia. They are used in groups. (Courtesy of Howmedica, Rutherford, NJ.)

Several intramedullary nails, particularly for the tibia, are designed to be used reamed or nonreamed. Some of these newer nails are made of titanium alloys. Titanium nails drive more easily due to their flexibility and are stronger than stainless-steel nails.
Since the initiation of early locking nail designs, many specialized nails for particular problems have been developed based on the locking principle. The Zickel nail (117,118) for subtrochanteric and supracondylar fractures of the femur is now obsolete because it is not a fully cross-locked nail, and the Sage nail (91) for fractures of the radius and ulna has been replaced by plates, again because cross locking is not available.

An early specialized nail was the gamma nail (Howmedica, Rutherford, NJ) (Fig. 11.73), developed initially in a short design for fixation of intertrochanteric and some intersubtrochanteric fractures. This nail has been extremely successful in Europe but has not gained much popularity in North America. When it was introduced, the principle of overreaming and sliding the nail in by hand was not appreciated by early users in North America and this led to an unacceptable incidence of additional subtrochanteric fractures of the femur. The gamma nail is now available in a long device that functions like most reconstruction nails, except that a single locking screw is used in the femoral head and neck. Nearly every manufacturer now offers a third-generation, so-called reconstruction nail; in this system, different types of screws are inserted through the reinforced larger proximal section of the nail up into the head neck fragment of the femur. When combined with distal cross-locking screws, these devices enable the surgeon to stabilize single or combination fractures from the femoral neck to the supracondylar area of the femur. Similar design concepts have now been applied to the humerus as well.
INDICATIONS

CLOSED FRACTURES

The use of intramedullary nails is most appropriate in patients with displaced, closed fractures of the lower extremity, who have unstable fracture patterns and in whom early weight-bearing and rehabilitation is advantageous. Fracture patterns (Fig. 11.75) are important to consider in making therapeutic decisions (21,22,26,113). Unless some type of supplemental external protection is used, simple oblique or spiral fractures are the only fractures that are nearly always stable after reamed or nonreamed intramedullary nailing without locking (Fig. 11.74A, Fig. 11.74B). The fracture configurations in Fig. 11.74C, Fig. 11.74D, Fig. 11.74E, Fig. 11.74F and Fig. 11.74G generally remain unstable with the use of routine reamed or nonreamed nails, and interlocking nails are required. Noninterlocking nails must not be used in the latter group of fractures unless special precautions are taken to prevent shortening and malrotation. Protection for 6 to 12 weeks is often necessary, depending on the fracture configuration.

Even simple transverse fractures can easily malvolve. Fractures often have unseen cracks that can progress and lead to instability. I look nearly all nails at both ends now. Even in transverse fractures, I prefer to distally lock the rod first, impact the fracture with the slap hammer driver, and then lock proximally. With such good bone contact, immediate weight-bearing is almost always possible.

The treatment of choice for most closed fractures of the femoral shaft in adults and older adolescents is closed intramedullary nailing (30,113). A review of the literature comparing closed intramedullary nailing to open intramedullary nailing, plate fixation, and cast-brace treatment confirms this view (110).

In the tibia, most closed fractures are best treated by nonoperative means, using a weight-bearing cast or cast-braces (see Chapter 24). Closed nailing is reserved for fractures that develop unacceptable malposition with routine closed treatment or are obviously unstable at the outset.

Indications for intramedullary nailing of the humerus are rare. Most of these fractures are nicely managed by closed technique. The few fractures that do require surgical intervention are usually best treated by plates and screws, but selected indications for reamed and nonreamed intramedullary nails are discussed in Chapter 15. In displaced fractures of the forearm, the best results in adults have been reported with plate fixation; indeed, the use of intramedullary nails has been associated with an increased incidence of nonunion and angulation (5). Locked forearm nails have not proven to be superior to plates.

OPEN FRACTURES

Intramedullary nailing of open fractures remains controversial. However, Brumback et al. (20) and Lhove and Hansen (65) have shown that nailing of open fractures of the femur can be done with an acceptable complication rate, provided the benefits of the procedure outweigh the risks. Although Hansen et al. recommend immediate nailing of all open fractures of the femur, the infection rate may be lower if nailing is delayed in type IIIB open fractures. Immediate stabilization of all femur fractures is important for victims of multiple trauma to salvage life. Intramedullary nailing is the procedure of choice for most of these patients.

For isolated open fractures of the femoral shaft, perform a meticulous irrigation and debridement, including thorough irrigation of the bone and medullary canal at the fracture site, and initiate appropriate intravenous therapy as described in detail in Chapter 12 on Open Fractures. In Gustillo grades 1, 2, and 3A fractures, I almost always carry out locked intramedullary nailing. Since the fracture site is open, nailing is simplified and the majority of these cases can be stabilized on a regular operating table with the patient in the lateral decubitus position using an antegrade approach. I leave the traumatic wound open and perform delayed primary closure at approximately 5 days. It is important to protect the vascularity of the femur in open fractures, so I use gentle, minimal reaming and usually an 11 mm nail. In large men, this nail can often be implanted without reaming. Although the risk of infection is low, this makes recovery more likely if infection does ensue, as the diaphysis will be better vascularized and less likely to become a sequestrum. In isolated high-grade 3B or C open fractures of the femur, which are exceedingly rare, I also consider immediate intramedullary nailing using a nonreamed or minimally reamed small nail, as long as the wound is not highly contaminated and the delay from time of injury to surgery is not more than 6 hours. Brumback et al. (20) had an exceedingly low rate of infection after immediate-reamed nailing of open fractures of the femur and encountered an unacceptable infection rate only when debridement and nailing was delayed for more than 24 hours. In the presence of exceedingly severe soft-tissue wounds, high levels of contamination, and delay in treatment, my treatment of choice is external fixation with conversion to reamed intramedullary nailing when the soft tissues have recovered, the wounds are closed, and there is no evidence of infection. The procedure for conversion from external fixation to nailing is described above, in the section on external fixation.

My approach to open fractures of the tibia is similar to that of the femur. Early studies comparing nonreamed intramedullary fixation with Lottes nails with external fixation showed comparable results (67,104). As a result, when locking nails became available, nonreamed locking nails quickly became the stabilization method of choice for the vast majority of open fractures of the tibia as reflected in discussion in Chapter 24 (note the results listed in Table 24.7). External fixation is reserved for those fractures that are unsuitable for nailing because of their configuration, or in those that are highly contaminated and irrigation and debridement has been excessively delayed, as discussed for the femur. Because of their small size, nonreamed nails have experienced significant failure rates, with fracture of screws reported up to 30%, and delayed and nonunion rates reported up to 20%; therefore, some centers have studied minimally reamed and fully reamed nails for the fixation of open fractures. This is discussed in detail in Chapter 24. Recent reports, particularly those from Court-Brown et al. (131), have shown complication rates in reamed
nailing of open fractures to be comparable to those with nonreamed nails with improved union rates, less hardware breakage, and fewer malunions.

My approach to this issue is to now always try to place 10-mm-diameter titanium nails, which permits the use of the strongest 5-mm-diameter cross-locking screws (Fig. 11.75). With this device, fixation is secure and hardware failure exceedingly rare. A nail this size can be passed unreamed in about 40% of men, and with the passage of only one or two reamers in the remainder. Women require somewhat more reaming, so in the smallest I will use a 9 mm nail.

I have nearly abandoned nailing of the humerus, because if the fracture is open I much prefer plate and screw fixation as it better preserves the blood supply to the diaphysis, and injury to the rotator cuff is avoided.

TECHNICAL CONSIDERATIONS

TIMING

When using a closed technique to treat closed fractures, nailing can be done as soon as practical after injury. However, evidence suggests that if nailing is done with an open technique, a delay in nailing of 7 to 10 days may increase the union rate by taking advantage of the secondary injury phenomenon (27-29, 89).

ENTRY SITES

With reamed rods, which are generally fairly rigid, the entry site must be directly above the intramedullary canal. Eccentric entry sites, particularly in the femur and tibia, can result in incarceration of the nail or comminution. At the proximal end of the femur, the entry site for reamed nails is in the thin cortex at the base of the greater trochanter, at the site of its junction with the superior aspect of the femoral neck (see Chapter 20 (Fig. 11.76}). The entry site on the femur for retrograde nailing is centralized on the intramedullary canal on both AP and lateral views with the fluoroscope and distally in the intercondylar notch just posterior to the articular cartilage and anterior to the origin of the anterior cruciate ligament (see Chapter 20).

For entry into the femur, most surgeons now use a guide pin and cannulated reamer rather than an awl; this offers better control and facilitates the use of the fluoroscope to identify the proper entry site. In the tibia, the most direct route is to split the patellar tendon and enter the bone just proximal to the tibial tubercle. To avoid injury to the patellar tendon, some surgeons enter just medial or lateral to it.

Because of the obvious advantages of not splitting the patellar tendon, I used the medial parapatellar approach for a year or so at the University of California, Davis, Medical Center. Although nailing can be successfully carried out through this portal, I found that in the hands of less experienced surgeons it was difficult to obtain an entry site directly over the intramedullary canal, resulting in unacceptable angulation of the nail relative to the longitudinal axis of the medullary canal. In addition, I have not seen any significant long-term consequences from splitting the patellar tendon. For that reason, I now always split the patellar tendon. In the tibia, flexible nails such as the Ender are usually inserted on the flares of the metaphysis of the proximal tibia. This technique is discussed in more detail in Chapter 24.

In the humerus, reamed nails are introduced at the proximal end. To avoid injury to the rotator cuff, try to locate the entry site just distal to the insertion of the rotator cuff tendons on the lateral aspect of the humerus, just below the prominence of the greater tuberosity, if the nail design permits. Many nails must be inserted through the cuff. Unfortunately, these result in residual shoulder symptoms in many patients. The entry sites for the radius and ulna are discussed in Chapter 16.

For nonreamed, flexible nails, an eccentric entry site is usually used to take advantage of three-point fixation of the curved nail within the medullary canal. Generally, these nails are inserted distally through the supracondylar flares of the long bones. Because of the limited space in the epicondyles of the humerus, the entry site for the Ender nails is centrally posterior, just proximal to the olecranon fossa. At entry sites, avoid impingement on neurovascular structures; to avoid stress risers, do not make the holes too big. The nails should not be prominent enough to produce bursae or skin problems.

FRACTURE REDUCTION

Generally, the earlier a fracture is nailed, the easier it is to reduce the fracture. Shortly after injury, the hydraulic effects of edema fluid can cause shortening and rigidity of the limb segment, which may make fracture reduction extremely difficult. If nailing is not done before this degree of edema occurs, gentle traction may be necessary to regain length and alignment gradually as the edema subsides. If intramedullary nailing is absolutely indicated, it may even be advantageous to distract the fracture slightly before surgery to facilitate reduction. With maintenance of length and early nailing, reduction is usually easy.

In fractures of the femur, reduction is most easily achieved by placing the distal fragment in a neutral position, avoiding tightness of the iliotibial band, which could otherwise result in shortening and a fixed valgus deformity (Fig. 11.77). The neutral position is achieved with 15° to 20° of hip flexion, and with the distal fragment level with the floor in the lateral decubitus position. It can also be achieved in the supine position. The proximal fragment is then aligned with the distal one by manipulating it with an intramedullary nail placed temporarily in the proximal fragment (Fig. 11.78). The Alfa system has a fracture manipulation tool that enhances fracture reduction.
and guide-pin placement, and it can also be used to measure nail length (Fig. 11.79).

Figure 11.77. A: In the adducted position, the iliotibial band is tight, shortening the fracture and causing a fixed valgus deformity. B: A “neutral” position relaxes the iliotibial band, facilitating reduction. (From Chapman MW. Closed Intramedullary Nailing of Femoral-Shaft Fractures: Technique and Rationale. Contemp Orthop 1982;4:213, with permission.)

Figure 11.78. In manipulating the proximal fragment, lateral pressure at point A brings the distal end of the proximal fragment to point B. Downward pressure at point C then moves the proximal fragment into alignment with the distal fragment. Careful, methodical, and thoughtful technique usually permits quick passage of the guide pin. (Illustration by Beverly A. Kessler, courtesy of LTI Medica, New Scotland, NY, and the Upjohn Co., Kalamazoo, MI, copyright LTI.)

Figure 11.79. Alta fracture manipulation tool. This device is used to manipulate the proximal fragment to reduce the fracture, enhance driving the guide pin, and measure the length of the nail. (Courtesy of Howmedica, Rutherford, NJ.)

When the supine position is used for femoral nailing, the torso may obstruct manipulation of the proximal fragment. Direct manipulation of the fracture site is often necessary. To avoid radiation exposure of the surgeon, use manipulation devices such as the crutch and strap advocated by Küntscher. Use the fracture table for fractures of the femur and tibia to facilitate reduction. As the tibia is subcutaneous, direct manual manipulation results in reduction in most cases.

In the upper extremity, fracture tables are rarely used. Reduction is achieved by a combination of manipulation of the proximal fragment with the nail and direct manual manipulation of the distal fragment and fracture site.

In open nailing, the key to reduction is to angulate the fracture. Approximate the corners of the cortices of the proximal and distal fragments at an acute angle and then straighten the fracture into appropriate alignment. If nonreamed nails are used, this manipulation is facilitated by placing the nail in the proximal fragment before manipulation. In reamed nailing, use an incision just large enough to achieve manipulation; after the reaming guide pin is placed, close the wound and proceed as for closed nailing. These techniques are described in more detail in the chapters devoted to fractures of each long bone.

REAMING

Reamers must be sharp, and the surgeon must consider the relationship between the size of the reamers and the nail. A 12 mm reamer is not necessarily equal in diameter to a 12 mm nail. Because flexible reamers follow a curvilinear pathway, overreaming is usually necessary for most nails. Most nails require overreaming from 0.5 to 2 mm over the size of the nail, depending on the type of nail, the configuration of the fracture, and the canal of the bone.

Reaming Technique for the Femur, Tibia, and Humerus

- Insert a ball-tipped reaming guide pin across the fracture to the subchondral bone in the distal fragment.
- Begin with an end-cutting reamer, generally 8.5 to 9.0 mm in diameter. To avoid overheating and excessive pressure in the intramedullary canal, push the reamer slowly.
- Pay attention to the sound and speed of the reamer. Slowing of the reamer and intermittent catching are signs of impending jamming. In this situation, maintain full power, withdraw the reamer, clean it, and then readvance.
- When substantial cortical bone is being reamed, clean the reamer frequently to maintain effective cutting action. On the first pass of the reamer past the fracture site, visualize it on the fluoroscope to ensure that reaming is progressing appropriately; thereafter, it is not usually necessary to visualize the reamer.
- To avoid eccentric reaming and to allow the reamer head to pass the fracture site, an assistant may need to manipulate the fracture site gently.
- On withdrawal of the reamer, have an assistant hold a surgical towel or pad on the end of the guide pin to prevent its withdrawal along with the reamer. Driving the guide pin into the solid cancellous bone near the subchondral plate helps to stabilize the pin. Avoid grasping the guide pin with a bare surgical glove, as sudden turning of the guide pin will wrap up and rupture the glove.
- On withdrawal, the reamer will occasionally “hang up” at the fracture site or at the entrance to the bone because of the slight shoulder in the design of some reamer heads. Overcome this by advancing the reamer with full power, then retract it vigorously. If this is unsuccessful, try pulling the reamer eccentrically with an Army/Navy retractor while the power is on.
- It is safest to ream progressively in 0.5 mm increments. If the canal is large, after passing the end-cutting reamer, progress in 1 mm increments until firm contact of the reamer with cortical bone is established. Thereafter, progress in 0.5 mm increments.
- In general, avoid overreaming of the canal by more than 2 mm, as excessive thinning of the cortex may result in comminution during the drive of the nail. The exception is in reconstructive procedures and in young patients who have small canals, where considerable reaming may be required to accommodate a nail of adequate size.
Occasionally, the entry hole for the nail, particularly in femoral nailing, is eccentric and off-line in relation to the canal. Correct this with the last reamer by pulling it eccentrically in the direction of the central axis of the canal with an Army/Navy retractor while reaming the entry hole. This will produce an oval hole that will permit proper entry of the nail.

If a reamer breaks or jams, remove it by pulling it out with the ball-tipped guide pin. Reamers must be powered by high-torque, low-rpm power sources designed specifically for intramedullary reaming.

Avoid excessive pressurization of the canal by using reamers with large open cutting flutes and small-diameter shafts. Use a vent hole in the distal femur when indicated, and advance the reamers slowly using the highest rate of revolution provided by the power reamer.

**NAIL SIZE**

Obtain preoperative radiographs of the fractured long bone, including the proximal and distal joints. These help to rule out irregularities in the bone that might preclude nailing, and they also aid in the selection of an appropriately sized nail. If a full complement of intramedullary nails is available, it is usually unnecessary to measure patients for nail size before surgery unless they are of unusual stature. If there is any question, obtain AP and lateral radiographs of the opposite normal limb at a tube-distance of 1 m. Tape a nail of the appropriate size to the side of the limb for reference, or a radiographic ruler can be used; alternatively, a Kuntscher measuring device—the ossimeter—may be used to measure length and width (Fig. 11.80). The ossimeter has two scales, one of which takes into account the magnification caused by the x-ray at a 1-meter tube distance. In most cases, a nail reaching to within 1–2 cm of the subchondral bone distally is indicated. In reamed nailing, the width of nail is determined by the feel of the reamers rather than by radiographic measurements, although the approximate size to be used can be determined from preoperative radiographs. Diameter is critical in nonreamed nails, especially when a snug fit is anticipated. The radiograph is helpful in determining nail size before surgery, but, again, the feel of the nail as it is driven is most important.

In comminuted fractures, it may be difficult to determine the proper nail length. A radiograph of the opposite normal bone with an appropriate-size nail taped to the extremity is quite helpful.

**INTERLOCKING NAILS**

Numerous designs of interlocking nails for the femur, tibia, and humerus and forearm are now available. The most common types of interlocking nails use transverse screws distally and oblique, or transverse screws proximally (Fig. 11.70, Fig. 11.71, Fig. 11.73, Fig. 11.72, and Fig. 11.77). The guides for proximal cross locking are effective. Never subject nails to extremely hard driving, as distortion of the proximal end of the nail may interfere with both proximal and distal cross locking. Difficulties in passing the proximal cross-locking screw are almost always due to distortion of the proximal end of the rod or a loose connection between the nail and the guide. Before driving the rod, check all connections of the driver and guide.

**SURGICAL TECHNIQUES**

**CROSS LOCKING**

- To perform proximal cross locking, lock the proximal screw guide securely into place. Use the drill sleeve and an appropriate drill point for drilling. If the drill point contacts the rod, immediately withdraw it to avoid breakage.

- After drilling, measure the screw length with the depth gauge. Often this requires fluoroscopy, as it is difficult to feel the opposite cortex with the depth gauge. If the bone in the region where the cross-locking screws are being inserted is nearly round, then screw lengths can be determined by measuring directly on the fluoroscope monitor. The diameter of the rod is known (e.g., 12 mm). Have a nonsterile assistant or nurse mark the width of the rod on a piece of paper placed on the bone in the region where the cross-locking screws are being inserted. Use a special scale to measure width from roentgenograms taken at a 1 m tube distance. A “real” scale and a special exploded scale (to allow for radiographic magnification) are available.

- Insert the screw, taking care to avoid cross threading the rod in threaded designs. The heads of most cross screws are quite prominent. Insert them to bring the top of the screw head flush with the bone of the greater trochanter to avoid trochanteric bursitis and a snapping iliotibial band, and prominent screw heads in other locations.

Guiding devices for distal cross locking do not work as well as those for proximal cross locking due to the flexibility of these long guides and distortion of the nail. The Alta system offers a rod-mounted distal cross-locking guide for the femoral, tibial, and humerus nails. The fluted design of the Alta nails minimizes nail distortion in rotation and varus and valgus. The rod will bend in the anteroposterior plane, and this is adjusted for by the guide. It can be used with percutaneous technique, minimizing exposure to x-rays (Fig. 11.81).

- Other manufacturers offer guides, some of which are based on a stabilizer probe placed at right angles to the cross-locking screws, which must be inserted down to articulate with the rod through a separate stab wound and hole drilled in the femur. These have met with mixed success. Laser light guides that mount on the C-arm head are used to facilitate free-hand targeting but are not in wide use as they do not eliminate the need to use x-ray. Guides using detection of a magnetic field can eliminate the need for x-ray except to verify screw position and length. They are just now in clinical trials.
FREE-HAND TARGETING

Free-hand methods for placing distal cross screws work well with all current designs.

- Position the heads of the C-arm fluoroscope for a lateral view of the distal end of the rod. Provide maximal clearance between the lateral side of the limb and the head of the C-arm. Align the C-arm with the first of the two distal cross holes. The cross hole to be targeted must be located directly in the center of the fluoroscope screen, must be perfectly superimposed, and must be round (Fig. 11.82). Achieving this alignment can be difficult. It may save time for the surgeon to break scrub to align the fluoroscope head while the radiology technician operates the controls of the C-arm. It saves considerable operating time if all controls on the C-arm are loosened and if the head is moved into position under direct fluoroscopy. Spot images can also be used but are much more time-consuming.

- Use a long, very sharp 1/4-inch (0.3 mm) Steinmann pin or a sharp drill point mounted on a radiolucent targeting handle, or held in a Kocher clamp to pinpoint the area of penetration of the bone and to avoid exposing the surgeon's hands to the central beam of the fluoroscope. Bring the tip of the pin or drill point into the fluoroscope image, placing it on the skin directly over the screw-hole image. Mark the location for the skin incision.

- Make a 1 cm longitudinal incision directly over the screw hole down to bone. In the pin percutaneously to the cortex of the bone. Again, bring the tip of the pin into the fluoroscopic image at an angle to the fluoroscope beam and locate the tip of the pin directly in the middle of the screw hole (Fig. 11.83). Once located, carefully tip the pin to place it vertical to the cortex and directly in line with the fluoroscope head in all planes.

- Maintaining this alignment, mallet the pin into the cortex. It is often possible to insert the pin directly into the near hole on the rod.

- Once this hole is made, insert the appropriate-size drill point and, while maintaining alignment with the fluoroscope head, drill the hole through the rod and the opposite cortex.

- Remove the power source, leaving the drill point in place. Verify with the C-arm that the drill point is directly in the center of the hole. Verify its position on the AP view. If you plan to insert two screws, leave the first drill point in place as it is a useful guide to the proper drilling angle for the second hole. Insert the second drill point with the same technique. Some systems have a hand-held guide that can be slipped over the first drill point to provide guidance for the second hole. Repeat the procedure just described.

- Now insert the appropriate-size screw. Once the initial pin or drill is through the rod and bone, I prefer to place a drill sleeve over the pin and then do subsequent drilling and screw insertion through the guide as this avoids getting lost in the soft tissues. With this technique, radiation exposure is minimized and only 5 minutes or so are needed to insert each screw.

Partially radiolucent power units that use a gunsight principle for targeting are available but are not widely used, as the drill points tend to “walk” on the cortex, and the power units are large and cumbersome.

POSTOPERATIVE CARE

The postoperative regimen used depends on the bone nailed, the quality of the bone, the stability of the fracture, and whether an interlocking nail has been used. If a noninterlocking nail has been used, the patient must be protected against shortening, angulation, and malrotation until early bone union has occurred. Because interlocking nails are used in the vast majority of cases, this discussion will be focused on locked nails.

In the femur, if the fracture pattern is stable and there is good bone contact over at least a 50% diameter of the cortex with an adequate-size nail and cross screws for the patient, patients can be encouraged to bear weight as tolerated using crutches or a walker. In my experience, the average patient will not attain full weight bearing before 6 weeks. During this period, the supporting musculature is quite weak and quadriceps control is poor; therefore, the patient has little control of the knee. Begin isometric exercises, followed by progressive resistance exercises, as soon as practical to reeducate the quadriceps and hamstring and other muscles. In the meantime, use a knee immobilizer to protect the knee. This can be discontinued when the patient regains good quadriceps control. In unstable fracture patterns, particularly where there is extensive comminution or lack of good bone contact between the major proximal and distal fragments, limit weight bearing to the weight of the leg until periosteal callus is seen bridging the fracture site on two views. At that point, weight bearing can be progressed as the fracture consolidates.

This same philosophy can be applied to the tibia; however, it is usually easier because the patient normally have good control over their knee. A patellar-tendon-bearing brace or similar protective orthosis is often useful, particularly in unstable fractures of the tibia.

In the humerus, external protection is usually unnecessary and the patient can begin immediate gentle range-of-motion exercises of the shoulder and elbow. Resistive muscle rehabilitation can usually begin as soon as bridging callus is seen, or earlier in stable patterns.

PITFALLS AND COMPLICATIONS

MALPOSITION

Although malposition of the fracture with subsequent malunion is unusual in intramedullary nailing, the surgeon must pay close attention to avoid it. In simple fracture patterns, establishing overall alignment of the bone and matching the fracture pattern usually results in good alignment, particularly since the bone automatically aligns itself on the rod. In simple fracture patterns, the most common problem of alignment is malrotation. Verify that the patient's position has not shifted on the operating table prior to driving the rod, and be certain that rotation is comparable to the opposite uninjured extremity. In bilateral cases, align the first web space of the toes with the patella and the center line of the hip.

In complex comminuted fractures, particularly those extending into the metaphysis, angular malalignment of the distal or proximal metaphyseal fragments can occur, particularly since it is difficult to ascertain overall alignment on the fluoroscope. Inspect the limb clinically after insertion of the nail. It is occasionally prudent to get long
AP and lateral radiographs immediately after insertion of the nail to be certain that proper alignment is present prior to placement of cross-locking screws. Once the nailing has been completed and the patient is lying in the supine position on the operating table, carefully examine the operated extremity. It is better to detect and correct malalignment now than to have to return the patient to the operating room or to allow malalignment to persist.

Another source of unexpected malalignment is when cross-locking screws appear to have gone through the nail on an AP view, but have actually missed the nail. Careful examination with the fluoroscope after completion of insertion of each screw is essential to be certain that the screw has in fact passed through both the bone and the locking holes in the nail. Take final plain films in the operating room to confirm the fluoroscopic visualization.

DELAYED UNION

Delayed union is most common in fractures of the tibia due to their increased severity. Delayed union and nonunion in the femur and humerus is unusual with intramedullary nailing because of the copious blood supply available from the surrounding muscular envelope. Other than the deleterious effects of the initial trauma, the most common cause of delayed or nonunion is distraction in the operative site. Brumback et al. have shown that dynamization of locked nails or removal of cross-locking screws before nail removal is unnecessary to achieve union (23). On the other hand, where the fracture pattern is stable and union is delayed (no evident callus bridging the fracture site by 12 weeks after nailing), dynamization may sometimes be indicated. For dynamization to be effective, it is necessary to remove screws from the end of the nail farthest from the fracture site. It is important that, when the fracture site impacts with weight bearing, it becomes rotationally stable. Dynamization of a straight transverse fracture may lead to increased rotational instability and progression to nonunion.

NONUNION

The incidence of nonunion after closed intramedullary nailing of fractures of the femur is less than 1% to 2%, and only slightly higher in the tibia. The risk of nonunion can be minimized by utilizing closed techniques, and by ensuring good bone contact, preferably impaction, and stable cross locking with nails of sufficient size. If nonunion occurs, most cases are responsive to exchange nailing. Use closed-technique reaming to a larger nail and then provide compression across the fracture site with a compression device and lock the nail in compression. Of course, this is not applicable to fracture patterns that are axially unstable, where open bone grafting may be needed. This is discussed in detail in Chapter 26, Chapter 30, and Chapter 41.

NEUROLOGIC INJURY

In nailing of fractures of the humerus, the primary nerve at risk is the radial nerve. Although closed nailing techniques have been advocated for the humerus and used successfully, I have seen one radial nerve transected by an intramedullary nail or reamers using closed technique. For that reason, unless there are special circumstances precluding open nailing, I prefer to expose the fracture site to ensure that the radial nerve is not in danger, and then to perform nailing using open technique.

In the femur, the most common palsy is that of the pudendal nerve, which is usually due to inadequate padding or use of too small a perineal post, plus excessive traction for a prolonged period of time. If femur fractures are nailed early, within 24 hours, strong traction is rarely required. If traction is required to reduce a transverse fracture, apply it only long enough to reduce the fracture, and then release. Proper technique should prevent the vast majority of pudendal nerve palsies. Fortunately, nearly all recover without residual effects.

Paresis of the sciatic nerve or its components is usually due to excessive traction with the hip in a flexed position and the knee straight. For that reason, I always keep the knee flexed about 45°, and more if possible, during closed intramedullary nailing of the femur on a fracture table. The methods described above to avoid pudendal palsy are also applicable to avoid sciatic nerve palsy. Direct surgical injury to the nerve is also possible. The exposure used for closed intramedullary nailing is usually not large enough to allow formal exploration of the sciatic nerve, but look for the nerve in the surgical field. In small women with dysplasia of the hip, and in some Asians, the sciatic nerve rests very close to the greater trochanter when the hip is flexed 15° to 20° for nailing.

Transient paresis of the lateral femoral cutaneous nerve can also occur due to pressure from the traction post on the fracture table. To avoid this, use a well-padded post of adequate size and avoid excessive traction.

In closed nailing of the tibia, the nerve at risk is the common peroneal. Paresis can be caused by placing the popliteal bar against the common perineal nerve and then applying excessive traction for prolonged periods of time. To avoid problems, use a thigh bolster that is at least 4 in. in diameter and well padded. Place it under the distal thigh rather than in the popliteal fossa. The region of the common perineal nerve near the head of the fibula should always be free of impingement.

Fortunately, most peripheral nerve palsies secondary to intramedullary nailing are neuropathies, which recover nicely within a reasonably short period of time.

G. PRINCIPLES OF HARDWARE REMOVAL

In adults, I do not feel that routine removal of plates, screws, wires, or intramedullary nails is indicated. The primary indication for removal is pain due to the implants, or a request by the patient for removal for reasons important to her. Another possible indication is a plate or screw on the diaphysis of a long bone, which is a stress riser in a patient involved in sports or in an occupation carrying increased risk for fracture, or increased risk for a fracture of worse severity because of the presence of the hardware.

In children, unless removal poses unacceptable morbidity, we advise routine removal of implants, particularly if they are composed of titanium. The rational is that implants in children tend to become very tightly integrated to bone and are commonly overgrown by bone, making subsequent removal exceedingly difficult if not impossible. There do not appear to be any adverse effects of leaving current stainless-steel and titanium implants for up to 40 years. However, the long-term effects of leaving these implants in place for 60–70 or more years is not known; therefore, removal in children seems advisable.

In addition, high-performance athletes may complain that their limb feels not as lively as before they received the implant. This is usually caused by stiffening of the bone, and in cases of delayed or nonunion, removal may be indicated. For the patient involved in sports or in an occupation carrying increased risk for fracture, or increased risk for a fracture of worse severity because of the presence of the hardware, removal of the implant may be necessary to allow the bone to heal properly.

SURGICAL TECHNIQUES

REMOVAL OF PLATES AND SCREWS

Almost always, implants can be removed through the original surgical incision. To obtain a nice scar, unless contraindicated, I usually excise the old wound and use closed techniques to ensure good cosmesis. Superficial cutaneous nerves and other structures are more at risk in hardware removal than at the time of initial surgery, as they are frequently bound down in scar. Look for these to avoid injury. Occasionally, the pain associated with hardware is due to nerve entrapment or a neuropathy.

In removing plates and screws, remove only the bone covering the screw head or plate that interferes with its removal.

It is easy to strip screws, making their removal very difficult. Be certain that the head of the screw is completely cleaned of bone and that a good-quality screwdriver without a worn tip is firmly engaged into the screw head.

When removing plates and screws, avoid creating a stress riser in the bone that might lead to refracture. If the plate is totally uncovered and does not easily lift off the bone, place an osteotome beneath the plate and drive along the underside of the plate parallel to the bone and plate. This usually results in fairly easy removal. The sharp instruments used for hardware removal should be from a special set reserved for that purpose, to avoid damaging high-quality instruments used for initial surgery.

Once the screws and plates have been removed, resist the temptation to curet the screw holes. This is not necessary for healing and simply makes the screw hole wider, thus increasing the risk of refracture.

In most cases, the plate will be surrounded by a ridge of bone that has grown up around the edges of the plate. Never remove these ridges, as they serve to reinforce the bone in the early remodeling phase after hardware removal. Nubbins of bone sticking up from the screw holes can be removed if necessary for patient comfort.
POSTOPERATIVE CARE

In the case of intramedullary nails, as soon as the patient is comfortable, he or she can be weaned off crutches to bear full weight, assuming that the fracture is solidly healed and does not have a defect in it. Once full muscle rehabilitation has been achieved, patients can return to sports and occupational activities without limitations.

In the case of plates and screws, however, more caution needs to be taken because removal of the plate and screws leaves the bone in a weakened condition with holes that are stress risers. If the fixation device is confined to the metaphyseal or epiphyseal regions of the bone, then generally the same guidelines as applied to nails can be used. In the mid diaphysis, however, assuming that the fracture is solidly healed, patients can return to functional use of the limb as tolerated, but they must avoid any activity that would predispose them to fracture until the diaphysis remodels and the screw holes fill in. The timing on this depends on the bone, the age of the patient, and the particular fracture and implant involved.

The highest-risk situation is in the athlete competing in a contact sport. I recommend the following as a general protocol: Typically, the athlete sustains the fracture during the active season (let us assume the sport is football and the fracture occurred in October). If the fracture heals within the expected time and the callus is adequate to support stress, I permit the athlete to return to a general conditioning program, avoiding high-risk activities or contact sports, by 6–8 months after the initial injury. The football player could then engage in fall practice in August and return to competitive football in the fall, approximately 1 year after injury. If intramedullary nails are in place, no special precaution or protective device is necessary.

If the plates are on the upper extremity, then a protective brace is indicated. The athlete should recognize that if a second severe trauma occurs, a fracture at the end of the plates could result. If plates are in the lower extremity, on the mid diaphysis of the femur or tibia, I would not permit the athlete to play contact sports that season. When that season is over, the time would be opportune for the removal of the implant, as by then it would be approximately 18 months since the injury and the bone should be solidly healed. In the case of plates, I would conclude high-risk activity or contact sports in approximately 6 months after removal. Then the patient could gradually return to full-contact activities by approximately 9 months after implant removal, assuming that the appearance of bone is satisfactory on radiographs.

CHAPTER 12

OPEN FRACTURES

GOALS OF TREATMENT

The goals in the treatment of open fractures are to prevent infection, achieve bone union, avoid malunion, and restore the limb and patient to full function as early as possible. Of these, it is most important to avoid infection, as infection is the most common complication leading to nonunion and loss of function. The most important prognostic factor that determines the long-term result in open fractures is the amount of energy absorbed by the limb at the time of initial injury. This determines the amount of devitalized soft tissue and the level of contamination, which are more important than the configuration of the fracture (1,5,12,30,42). The latter, however, is a good indicator of whether a fracture is the result of high-energy or low-energy forces. Comminution and wide displacement are almost always associated with high-energy injuries. The classification of open fractures developed by Gustilo and Anderson is a good guide to the severity of injury and permits some prognostication and recommendations for treatment (32,35).

CLASSIFICATION

Although wound size plays a role in the classification of open fractures, it is a mistake to use this as the overriding factor in determining the classification. Extremely severe soft-tissue crushing is often associated with punctate wounds. The entire extent of the injury must be taken into account in applying this classification.

A type I open fracture (Fig. 12.1) has a wound that is usually less than 1 cm long and is caused by low-energy forces. Generally, it is caused by the bone piercing the skin rather than a penetrating object. It is not associated with significant crushing or muscle damage. Fractures of this type that occur in highly contaminated environments, such as a farmyard, are classified as type III fractures.

Figure 12.1. Type I open fracture of the tibia.

A type II open fracture (Fig. 12.2) has a wound that is more than 1 cm long and is associated with moderate deep muscle damage secondary to the high energy absorbed at the time of injury. A type II open fracture is considered to be transitional between type I and type III open fractures.

Figure 12.2. Type II open fracture of the tibia.

A type III open fracture (Fig. 12.3) is caused by high-energy forces, is usually associated with wounds more than 10 cm long, and involves extensive muscle damage. The fracture is often widely displaced or comminuted. Any open fracture with one or more of the following characteristics is classified as type III: high-velocity gunshot wounds, shotgun wounds, displaced segmental fractures, fractures with significant diaphyseal segmental loss, concomitant vascular injuries requiring repair, and fractures occurring in highly contaminated environments, such as farmyards. Fractures associated with crushing caused by high-velocity motor vehicle accidents are
The objectives of irrigation and debridement are delineated in Table 12.1.

**TREATMENT IN THE EMERGENCY ROOM**

In the emergency room, quickly assess the patient for vital body functions and resuscitate as necessary. During resuscitation and immediate evaluation, splint the patient's fractures and cover open wounds with sterile compression dressings. Soak the dressing immediately adjacent to the wound with a dilute povidone-iodine solution, particularly if the patient will not be undergoing immediate debridement. I no longer obtain cultures of open fracture wounds in the emergency room, as studies have not shown this to be useful in making therapeutic decisions. Use traction for femoral fractures. Immediately after resuscitation and stabilization, perform a complete history and physical examination. Evaluate the extremities for neurovascular function, possible compartment syndrome, and soft-tissue injury, and record the findings. Then obtain appropriate radiographs. Certain open fracture-dislocations and dislocations, such as widely displaced dislocations of the ankle, subtalar joint, knee, or elbow, are best reduced immediately in the emergency room. This usually can be accomplished with premedication and no anesthesia. Open fracture-dislocations of the hip and shoulder almost always require general or regional anesthesia. Fracture reduction under anesthesia is generally easier for both patient and surgeon.

**SYSTEMIC ANTIBiotics**

To prevent tetanus, administer tetanus immune globulin and tetanus toxoid. The globulin is not required if the patient has had toxoid in three or more doses within the last 10 years. Start intravenous bactericidal antibiotics as soon as possible. In types I and II open fractures, the antibiotic of choice is usually a cephalosporin; I prefer cefazolin sodium. For the average adult, a loading dose of 1 to 2 g, followed by 1 g every 8 h, is effective. For patients with farmyard injuries or other open fractures in which there is a risk of infection with Clostridium, give 4 to 5 million units of penicillin every 6 h as well. In type III open fractures, give an aminoglycoside intravenously—3 to 5 mg/kg of lean body weight per day—in divided doses at 8-h intervals. I begin with gentamicin. Monitor serum levels of the aminoglycosides to ensure therapeutic levels and to avoid toxicity. Obtain a complete blood count, urinalysis, blood urea nitrogen level, serum creatinine levels, liver function test, and audiometry test as soon as practical after the initiation of therapy and then at appropriate intervals.

Type III injuries are further broken down into three subgroups. In type IIIA open fractures, there is limited periosteal and muscle stripping from bone, and major plastic reconstructive procedures, such as flaps, are not required to achieve bone coverage. In type IIIB fractures, there is extensive soft-tissue stripping from bone. Soft-tissue defects that result in exposed bone require reconstructive procedures to restore soft tissue coverage. In a type IIIC open fracture, a major vascular injury requires repair to salvage the limb. The AO/ASIF group has a classification that grades the soft tissue injury incorporating the degree of injury to the skin, muscle, tendon, and neurovascular structures; it is used in conjunction with the AO/ASIF alphanumeric fracture classification system. Tscherne and associates have reported on an open fracture score that takes into account the AO/ASIF fracture classification and grades bone loss; skin, muscle, and soft tissue injury; neurovascular injury; compartment syndrome; time from injury to initial treatment; contamination; and results of cultures. Using a combination of these scores, they grade open fractures into types I to IV. They validated this score in a study of 651 open fractures. I find the latter two classifications to be too complex for day-to-day clinical use; instead, they are more suited to clinical research. We continue to use the Gustillo classification; however, the reader needs to be aware that even this simple system is subject to significant variation in interobserver agreement.

**ANTIBIOTIC-IMPREGNATED BEADS**

Almost any antibiotic available in a powder form can be added to beads made of polymethylmethacrylate. They are not commercially available in the United States but can be manufactured by the surgeon in the operating room by mixing 1 g of tobramycin powder into one batch of polymethylmethacrylate using a bead maker (available from Department of Orthopaedics, Hennepin County Hospital, Minneapolis, MN); this produces a string of 30 6-mm beads on a wire. Antibiotics leach from the surface of the beads to produce wound levels of antibiotics several times higher than that achieved by the intravenous route, and systemic absorption is negligible. They are not approved for sale by the Food and Drug Administration.

Seligson and associates placed beads in debrided open fracture wounds, which were left open and covered with a watertight, oxygen-permeable membrane (Opsite), the surface of the beads to produce wound levels of antibiotics several times higher than that achieved by the intravenous route, and systemic absorption is negligable. This not only produces high levels of local antibiotics but also protects soft tissue and bone from desiccation and further contamination. Antibiotics are then discontinued unless postdebridement cultures and the patient's clinical course suggest that infection has occurred. An advantage of discontinuing antibiotics after 3 days is that the patient will not be receiving antibiotics at the time of delayed primary closure, which takes place about 5 days after injury in uncomplicated open fractures. At the time of delayed closure, obtain repeat cultures and reinstitute a 3-day course of antibiotics. If the results of the cultures are negative, and the patient's clinical course is progressing satisfactorily, discontinue the antibiotics at the end of the second 3-day regimen. Detection of organisms on Gram stain of tissues from the wound at the time of delayed primary closure suggests that there are more than 10,000 organisms per cubic millimeter in the wound; this indicates heavy contamination or infection. With this finding, it may be necessary to continue antibiotics for at least 3 weeks, and closure may have to be delayed. If infection is evident, cultures and antibiotic sensitivity tests may indicate the need to change the antibiotic regimen to one that is specific for treatment of the infecting organism(s). In more extensive, severe type III open wounds, a continuous course of antibiotics is usually indicated until successful wound closure. For more information on this complex topic, see publications by Gustillo, Patzakis, and others.

**PRINCIPLES OF WOUND DEBRIDEMENT**

The objectives of irrigation and debridement are delineated in Table 12.1.
IRRIGATION

- Irrigate the wound with copious amounts of normal saline solution. Irrigation is most effective when a mechanical irrigator with a shower-head type is used. The pulsating lavage produced is very effective in loosening and washing away debris. Moreover, high volumes of solution can be run through the wound in a short period of time. The degree of contamination and the size of the wound determine the extent of initial irrigation. For an average type I wound of the tibia, begin irrigation within 2 h.
- Irrigate the wound at intervals throughout the debridement process to clear the wound of debris on a continuous basis. At the completion of debridement, topical antibiotics can be added to the last 2-L bag of irrigation solution. The type and concentration of topical antibiotic is the surgeon’s choice. I most commonly use 50,000 units of bacitracin per liter of solution.
- For large wounds, try to use 10-L irrigation by the time the debridement is completed. Anglen and associates compared bulb syringe irrigation to pulse lavage and found the latter to be 100 times more effective in reducing bacterial count (2). They also compared adding bacitracin or neomycin or soap detergent (castile soap) to the solution. They found no benefit from the antibiotics, but the detergent was very effective in reducing the bacterial count. Kelam and associates have shown that solutions of povidone-iodine or hydrogen peroxide decrease osteoblast function; therefore, they are not recommended as routine irrigation solution (47).

DEBRIDEMENT TECHNIQUE

- Extend the wound as large as necessary to irrigate and debride all contaminated and nonviable tissue using extensile incisions (Fig. 12.4).

- Remove all ragged, contaminated skin edges, establishing a surgical wound edge that is at right angles to the skin and suitable for closure. Be conservative in skin removal, as skin coverage can be a problem in certain areas such as in the lower extremity distal to the knee and in the hand. Skin flaps with a length-to-base ratio greater than 2:1, particularly those that are distally based, will often exhibit some necrosis at the tip of the flap. It is often difficult to predict flap viability at the time of initial debridement. Inflating the tourniquet for a brief period of time and then deflating it to produce hyperemia in the flap will often delineate devascularized portions, which can then be excised. Leave marginal skin, as it can be debrided later. If extensive, nonviable flaps are removed and skin coverage is a potential problem, split-thickness skin grafts can be removed from the debrided flaps in areas where the skin is in good condition. Use a Padgett dermatome. This skin can be banked for later use or placed immediately as a meshed split-thickness skin graft.
- Subcutaneous fat has a poor blood supply. Debride all contaminated or devascularized fat. The fascia is also relatively avascular and, if contaminated, should be excised.
- In type II or worse fractures, perform prophylactic fasciotomy at the time of debridement through the open fracture wound. If the wound is not large enough to perform the fasciotomy under direct vision, use a Metzenbaum scissors to split the fascia beneath the skin. Releasing the fascia of one major compartment, such as the anterior tibial compartment in the leg, is usually sufficient. If a significant compartment syndrome is present or expected, formal four-compartment fasciotomy is indicated.
- Debride all nonviable and contaminated muscle. Color and bleeding are not good determinants of muscle viability, as hematomas renders the muscle dark and arteriolar bleeding can persist in totally nonviable muscle. The best indicators of viability are the muscle’s response to a stimulus and its ability to rebound to normal appearance after being pinched gently with a pair of forceps. Viable muscle fibers contract in response to either the gentle pinch of a pair of toothed forceps or stimulation with a nerve-stimulating device or electrical coagulator on a low setting. Muscle that does not respond and in which a prominent forceps imprint is left is usually nonviable and should be debrided. In type II open fractures, entire compartments or muscle–tendon units may appear nonviable. It may be quite difficult to determine nonviability at the time of initial debridement. In major wounds, leave intact marginal muscle necessary to preserve muscle–tendon units that are important for future function. A tendon with only 10% of the muscle remaining produces surprisingly good function. If marginal muscle is left intact, repeat debridement within 24 to 36 h and then as frequently as necessary to remove all nonviable muscle.
- Exposed tendons and bone not covered by peritenon or periosteum will desiccate and die within several days, particularly if not kept moist. Therefore, irrigate peritenon and periosteum copiously rather than debriding it. Try to cover tendons without peritenon and bone without periosteum with soft tissue.
- Totally detached cortical fragments of bone that are contaminated are generally discarded. If internal fixation is performed, and the bone fragment is critical to the construct, and it can be adequately debrided, retain it. If infection occurs, the fragment must be discarded. When large nonviable fragments such as these are reimplanted, bone grafting is almost always advisable. Try to preserve all soft-tissue attachments to bone fragments. Free fragments of cancellous bone that can be debrided adequately are left in the fracture bed as bone graft. Swiontkowski has described criteria for bone debridement using laser Doppler flowmetry (83).

WOUND CLOSURE

After initial debridement, it is never an error to leave the traumatic wound open. The infection rates with type I open fractures are equal to those reported in elective orthopaedic surgery, however (18,35,61,72). Therefore, many surgeons do primary closure of type I open fractures and occasionally of mild type II wounds (24). The surgeon who elects to close these wounds must exercise caution: gas gangrene can be a complication of primary closure of type I or mild type II open fracture wounds if the surgeon has underestimated the degree of contamination. Most type I wounds are so small that closure will occur spontaneously, without surgical closure. Never close type III open fracture wounds primarily, and the same applies to most type II wounds. This is particularly true if primary internal fixation using plates has been done.

- Cover bone without periosteum, tendons without peritenon, and neurovascular structures with muscle, fascia, or subcutaneous fat. Perform this without formal wound closure. In wounds with large flaps, where retraction of skin edges may occur, place loose sutures to prevent flap retraction. In either of the latter two instances, if closed spaces are created, place a suction tube for drainage.
- With types I and II wounds, a return to surgery within less than 5 days after the initial operation is usually unnecessary. Type III wounds, as well as heavily contaminated wounds, however, require repeat debridement before 5 days, and usually within 36 h. Repeat the debridements at 36- to 48-h intervals until a clean completely viable wound is present.
- After 5 days, if the wound appears clean and little or no nonviable tissue is present, delayed primary closure can be performed after irrigation and minimal debridement. Delay closure of the wound for a few more days if significant debridement is required. Accomplish delayed closure without tension. Split-thickness skin grafting is often necessary. Wounds that can be closed to within 1 cm can be allowed to close by secondary intention, provided vital structures are not exposed and scarring is not a major consideration. Strive to achieve coverage of bone by 5 to 10 days. Wounds requiring local flaps or free microvascularized flaps are often ready for flap coverage within 5 to 10 days, sometimes earlier. In my opinion, applying flaps to close the wound before 5 days is usually not
indicated. When performing delayed closure, use as little suture material as possible; monofilament sutures are best.

FRACTURE STABILIZATION

Fracture stability is essential for initial wound care and for fracture union (10). Restoring normal length and alignment of the extremity minimizes dead space and reduces muscle–tendon units to their normal position. This reduces the space available for serum and toxins to their normal position. This reduces the space available for serum and toxins to pabulum for bacterial growth. Stabilizing the soft tissues may increase local wound resistance to infection by facilitating neutrophilic migration, white blood cell migration, and diffusion of nutrients. Bone fixation often eliminates the need for casts, splints, and skeletal traction, thereby allowing optimal access to the limb for wound care. Early stability provides an opportunity for early muscle and joint rehabilitation, which, in turn, reduces edema, facilitates lymphatic and venous return, lowers the incidence of deep vein thrombosis, and improves the overall physiology of the limb.

CASTS AND SKELETAL TRACTION

Use traditional casts for type I and low-grade type II fractures with stable configurations when external or internal fixation is unnecessary. This usually applies to fractures distal to the elbow and knee (10,23). Immobilize only the necessary muscle groups and joints. Encourage early joint and muscle rehabilitation. Administer isometric exercises to immobilized muscles.

Use skeletal traction for fractures of the femoral diaphysis in patients who do not have multiple injuries where delayed nailing is planned.

Nearly all open femur fractures can be nailed immediately. In type IIIA fractures, immediate skeletal stabilization is nearly always indicated. Although traction and cast bracing may constitute definitive treatment, skeletal traction is most often used for temporary immobilization until closed intramedullary nailing is done. Skeletal traction may also be useful for some fractures of the humerus and the tibia in which soft-tissue injuries mitigate against casts or splints and when subsequent early internal fixation is planned. Skeletal traction for definitive treatment of fractures of the tibia is not advisable because of the high incidence of nonunion. Although skeletal traction can be used for the definitive treatment of fractures of the humerus, the prolonged hospitalization required and high incidence of nonunion makes external or internal fixation the treatment of choice.

EXTERNAL FIXATION

External fixation provides excellent stability without the need for circumferential plaster dressings. Compared with internal fixation, external fixation has several advantages: external fixation devices are relatively easy to apply and are easily adjusted during healing; there are no metallic implants at the fracture site; and there is usually ready access to the wound. Its disadvantages include the awkwardness of the frame for patients; the potential for pins to injure neurovascular structures and to lie down muscle–tendon units, thereby interfering with joint motion and rehabilitation; possible interference by the pins in plastic reconstructive procedures; and pin loosening and secondary infection, which remain significant problems. In addition, external fixation has a higher incidence of delayed and nonunion, particularly in the tibia. The primary indication for external fixation is very severe, highly contaminated type III open fractures where plating or nailing is either contraindicated or not technically feasible. Open unstable fractures of the pelvis are usually best initially stabilized with external fixation (76). Intra-articular fractures require internal fixation; however, external fixation is useful for providing neutralization when more extensive internal fixation is impossible or contraindicated. Hybrid frames are commonly used today to treat high-energy fractures of the metaphysis such as bumper fractures of the proximal tibia and pylon fractures of the distal tibia (67). Ring, Ilizarov-type fixators are useful in similar problems, especially where there is segmental bone loss that may be amenable to bone segment transport (63,68).

Fractures less suitable for external fixation are those that are stable, as well as type I and mild type II open fractures for which casts and splints are adequate. The thick muscle coverage of the femur and the humerus makes external fixation less suitable and internal fixation safer. When fixation crosses a joint, external fixation can be used, but internal fixation may be preferable.

In some open fractures, particularly in the femur and tibia, the surgeon may choose to initially apply external fixation with a plan for early conversion to either an intramedullary nail or a plate. Superior results to primary nailing have been reported (6). This alternative is discussed in detail in Chapter 11 and Chapter 24.

INTERNAL FIXATION

The role of internal fixation in open fractures remains somewhat controversial (5,11,13,18,19,29,38,41,44,48,56,59,64,81,85,86,91). Over the past several years, however, many trauma centers have reported the use of primary internal fixation in open fractures with good results and an acceptable rate of complications (18,20,23,49,54,63,71,72). In the combined results of three earlier reports, 403 open fractures were treated with early internal fixation (18,20,72). The acute infection rate was 8.2%; most of the infections occurred in type III open fractures. The incidence of late, chronic osteomyelitis was only 0.5%, however. There was a 2.2% incidence of amputation, all in type III open fractures of the tibia.

Indications

Indications for primary internal fixation of open fractures include the following:

- Fractures in patients with multiple injuries in whom external fixation is impractical and stabilization is necessary to preserve life.
- Patients with severely mutilated or amputated limbs undergoing reimplantation in whom external fixation is impractical.
- Intra-articular fractures.
- Open fractures of the major long bones, in elderly patients, where external fixation is impractical and where immediate mobilization for the salvage of life and function justifies the risk of the procedure.
- Major vascular injuries requiring repair that accompany open fractures and where external fixation is not the best choice.
- Selected fractures of the hand, forearm, and foot (9,22,69,70,86).
- Open fractures of the shafts of the femur, tibia, humerus, radius, and ulna are now generally stabilized primarily using reamed or unreamed intramedullary nails in the femur, tibia, and occasionally the humerus; the forearm bones and humerus are generally plated, except where the fracture is not suitable for internal fixation or the severity of the soft tissue injury and level of contamination preclude immediate internal fixation.

In patients with multiple injuries, immediate internal fixation of open fractures of the femur and the humerus is usually necessary (27). Open fractures of the pelvis are generally stabilized with external fixation. If internal fixation is required to obtain a satisfactory functional result, it is delayed until the risk of infection is minimized and is usually done posteriorly using percutaneous techniques if possible (see Chapter 17).

For an optimal result in intra-articular fractures, anatomic reduction of the joint surface must be achieved with interfragmentary lag screw fixation, and early joint motion must be instituted (9). This requires rigid internal fixation. In type I open intraarticular fractures, primary internal fixation should be done, as the incidence of infection is the same as with elective orthopaedic surgery. Type II open fractures treated with primary internal fixation are associated with reported infection rates of 5% to 8%, and type III fractures in the recent past have been reported to have infection rates of 26% to 41% (18,20,49,72). Because of the risk of infection in more severe fractures, consider fixation of the joint surface fragments with screws and wires and stabilization of the metaphyseal portion of the fracture with external fixation. This can then be converted to plate fixation when the wound status permits, if necessary.

The most controversial open fracture is that of the shaft of the tibia. Although external fixation has been the fixation method of choice in the recent past, the more recent literature overwhelmingly supports primary intramedullary nailing as the stabilization method of choice (3,8,21,39,46,78,79,82). Most reports are on unreamed nailing; however, minimally reamed or fully reamed nails inserted acutely or on a delayed basis have received more attention recently because of the breakage rates in the smaller nails and screws required for nonreamed nailing as well as the significant incidence of delayed union. See Table 12.2 and Chapter 24 on fractures of the tibia for more detail.
Chapter 135

Please refer to the chapters on the fracture of concern and to the following chapters dealing with the management of complications: excellent results reflect compulsive adherence to the principles of treatment outlined in this chapter. For specific details on the management of these complications,

The most common complications include acute infection, osteomyelitis, nonunion, malunion, and loss of function. Remarkable progress has been made since the early 1970s in reducing the rate of these complications. A review of the recent pessimism in the literature regarding the outcomes in the salvage of severe open fractures, Hertel et al. (75), in an analysis of 39 type IIIB or IIIC open fractures, found the long-term functional outcomes to be better and costs less with limb salvage.

OPEN FRACTURES IN CHILDREN

Bone that is devitalized can be saved if it is not contaminated or left exposed.

In some injuries, immediate or early amputation may be the treatment of choice (51). Immediate amputation is usually indicated in the following situations:

- Severe open fractures with associated vascular injuries requiring repair (type IIIC) when the injury cannot be repaired or the warm ischemia time is over 8 h.
- The limb is so severely crushed that minimal viable tissue remains for revascularization.
- There is irreversible associated soft tissue injury and neurologic damage that will result in final function worse than that provided by a prosthesis.
- When limb salvage may be life-threatening in the presence of severe chronic disease such as diabetes mellitus with severe peripheral vascular disease and neuropathy.
- A mass casualty situation where salvage of life, transportation of the victim, or the need to direct scarce resources to more severely injured casualties is indicated.

Severe open fractures with associated vascular injuries requiring repair (type IIIC) when the injury cannot be repaired or the warm ischemia time is over 8 h.

The social and psychological impact of these severe injuries, particularly in terms of time lost from school, should not be underestimated (51). Johanson and associates developed the "mangled extremity severity score" (MESS) (43). Factors they graded include energy dissipation, hemodynamic status, age of the victim, and limb ischemia. A score of 7 or higher on their scale predicted amputation with a high degree of confidence. Amputation is most frequently an indicated.

PITFALLS AND COMPLICATIONS

The most common complications include acute infection, osteomyelitis, nonunion, malunion, and loss of function. Remarkable progress has been made since the early 1970s in reducing the rate of these complications. A review of Table 24.7 in Chapter 24 on tibial fractures and Table 12.2 in this chapter shows a drop in acute infection rates of up to three- to fourfold and similar trends in the other complications as well. Infection rates of 6% or less are now reported (6,8,21,46,78,79 and 80-83). These excellent results reflect compulsive adherence to the principles of treatment outlined in this chapter. For specific details on the management of these complications, please refer to the chapters on the fracture of concern and to the following chapters dealing with the management of complications: Chapter 132, Chapter 133, and Chapter 135 on infection and Chapter 26, Chapter 27, Chapter 28, Chapter 29, Chapter 30, Chapter 31 and Chapter 32 on nonunions and malunions. The general principles of care as outlined in this chapter apply except as noted above.

The healing capacity of the soft tissues is excellent.

The bone that is devitalized can be saved if it is not contaminated or left exposed.

Infection is rare if adequate irrigation and debridement are performed.

External fixation works well where the soft tissue injury requires ready access or the fracture is unstable. It can usually be left in place until union of the fracture.

The healing capacity of the soft tissues is excellent.

Infection is rare if adequate irrigation and debridement are performed.

External fixation works well where the soft tissue injury requires ready access or the fracture is unstable. It can usually be left in place until union of the fracture.

The social and psychological impact of these severe injuries, particularly in terms of time lost from school, should not be underestimated (53).
AUTHOR'S PERSPECTIVE

For the overall management of open fractures, I follow the principles outlined in this chapter. I use antibiotic bead pouches with tobramycin when the wound severity and level of contamination justify their use. I strive to close all wounds by 10 days after injury with full-thickness coverage. I work closely with my orthopaedic and plastic surgery colleagues, whose skills in local and free flaps are essential to achieving an optimal result (see Chapter 8, Chapter 35, and Chapter 36).

From the standpoint of fixation in adults, I have the following preferences. In type I and low-grade type II fractures, I usually perform primary internal fixation if indicated by the fracture, leaving the traumatic wound open and closing it on a delayed primary basis. In type III fractures, I use the following protocol:

- In intra-articular fractures, I use interfragmentary fixation of the articular portion with "biological" plate fixation of the metaphyseal portion in low-grade fractures and hybrid or other external fixation in high-grade open fractures. Occasionally I will convert the external fixation to internal fixation when the soft tissue envelope permits and the conversion is the best alternative for the patient.
- For fractures in the upper extremity, I use primary internal fixation with plates and screws in most cases (17), reserving external fixation for those where the bone is not amenable to internal fixation or where the wound makes primary internal fixation inadvisable.
- In hip fractures, I use primary internal fixation except where not fixable.
- For femoral shaft fractures, I favor reamed locked intramedullary nailing in most cases (15,20); I use nonreamed locked nailing in patients with multiple injuries, where the speed of surgery is important and compromised pulmonary status is a problem.
- For supracondylar femur fractures, see the item above on intra-articular fractures.
- For tibial plateau and pylon fractures, see the item above on intra-articular fractures.
- For tibial shaft fractures, I use locked intramedullary nailing, either nonreamed or with gentle reaming sufficient to place a nail (usually 10 mm in diameter) that permits the use of large cross locking screws (4.5 to 5.0 mm in diameter) (42-45,80). I use external fixation only when the fracture configuration or surgical situation does not permit nailing. I try to convert external fixation to a nail early if it is feasible (67,69).
- For foot fractures, I favor primary internal fixation using small fragment screws and plates and wires.

Definition and Classification

Compartment syndromes are a condition in which accumulating fluid and/or external compression creates high pressure within a closed fascial space, reducing perfusion of the tissues within that compartment below a level necessary for viability. Compartment syndromes develop in skeletal muscles enclosed by relatively noncompliant osseofascial boundaries. A buildup of pressure within these compartments is not easily dissipated because of the inelasticity of the muscle-investing fascia and surrounding bone. If pressure remains sufficiently high for several hours, normal function of the muscles and nerves is jeopardized, and necrosis eventually results. Permanent loss of function and a Volkmann's limb contracture may occur. Prompt diagnosis is therefore essential, with immediate treatment to reinstate capillary perfusion and prevent irreversible sequelae. Surgical decompression is accomplished by fasciotomy, which allows the muscles to increase in volume and reduces pressure within the fascial enclosure.

Compartment syndromes may be acute or chronic, based on cause and reversibility (33). An acute compartment syndrome (ACS) is a severe form, usually following trauma, in which intracompartmental pressure is elevated to a high level for long enough that capillary flow is impeded and decompression is necessary to prevent necrosis and preserve limb viability. Commonly used terms for ACS are anterior tibial syndrome, calf hypertension, compartmental syndrome, Volkmann's ischemia, and impending ischemic contracture (27). The terms Volkmann's ischemia and impending ischemic contracture should not be used, however, because they do not define the cause of the ischemic problem (e.g., compartment syndrome or arterial injury). Volkmann's contracture is the residual limb deformity that is the last stage of muscle and nerve necrosis after an ACS.

Chronic compartment syndrome (CCS) is mild and recurrent. It is most commonly associated with exercise and occurs when intracompartmental pressure is raised sufficiently to produce ischemia, pain, and/or neurologic deficit. The symptoms spontaneously resolve with rest; in the rare instance when exercise is continued despite pain and neuromuscular deficit, however, a CCS may evolve into a full-blown acute form that requires immediate decompression. Synonyms for CCS include chronic exertional compartment syndrome, exercise ischemia, exercise myopathy, and recurrent compartment syndrome.

Pathophysiology

Common to all compartment syndromes is elevated intracompartmental pressure with subsequent ischemia of muscle, nerve, and other compartment contents. In ACS the cause of the elevated pressure is fluid accumulation from hemorrhage, extracellular edema, and intracellular edema within the confines of a closed, noncompliant osseofascial compartment (41). Intracellular fluid accumulation is associated with membrane pump changes that lead to an increase in intracellular calcium concentration and subsequent shifts of water into the cell. Interstitial fluid accumulation results, at least in part, from elevated capillary permeability, which is caused by ischemia (41). The elevated intracompartmental pressure causes further muscle ischemia, which leads to further edema production. An edema–ischemia cycle is thus established; without decompression, muscle infarction and other irreversible damage will ensue (Fig. 13.1).

Figure 13.1. Pathophysiology of a compartment syndrome, which can be initiated by arterial injury, trauma, exercise, or prolonged limb compression associated with alcohol or drug overdose. Common to all compartment syndromes are elevated intracompartmental pressure and subsequent ischemia. The asterisk marks the point of entry of decompression (fasciotomy) into the cycle. Without decompression, a self-perpetuating ischemia–edema process occurs, and irreversible damage, including Volkmann's contracture, may ensue. (From Mubarak SJ, Hargens AR, Owen CA, and Akeson WH. Muscle Pressure Measurement with the Wick Catheter. In: Goldsmith HS, ed. Practice of Surgery. New York: Harper & Row, 1978.)

Starling's law describes fluid transport across the capillary wall. Variables included in this equation include hemodynamic factors (capillary pressures), colloid osmotic factors, and permeability factors (41). In tissues at heart level, capillary blood pressure normally ranges from 20 to 30 mm Hg; when compartment pressure rises above this level, muscle perfusion is jeopardized (3, 8). Hargens et al. confirmed that the capillary pressure in the anterolateral compartment, at heart level, of normotensive
An acute compartment syndrome can be caused by either an increase in compartment volume (e.g., postfracture swelling) or a decrease in compartment size (e.g., ETIOLOGY)

The pathophysiology of CCS is not well known. Styf et al. have shown that normal muscle contractions during exercise can generate very high pressures (100 to 200 mm Hg) and that the muscle is perfused during the periods of muscle relaxation (60). In cases of CCS, the compartment pressure during relaxation is significantly higher than normal (above 35 mm Hg), and muscle blood flow decreases. This presumably leads to ischemic pain, although this has not been proved. The primary cause of elevated relaxation pressures is also not known. Hypotheses include muscle hypertrophy, fascial thickening, aberrant anatomy, and vessel occlusion (10,32,57).

ANATOMY

The compartments of the leg and the forearm are involved most frequently in compartment syndrome and are discussed in detail in this chapter. Compartment syndromes of the hand and foot are discussed in Chapter 33, Chapter 45, Chapter 65, and Chapter 11. Compartment syndromes can also arise in the shoulder, arm, thigh, buttocks, and spine. It is essential to understand the compartmental anatomy of the extremities in order to diagnose and treat acute and chronic compartment syndromes effectively.

FOREARM

The forearm consists of three compartments: volar, dorsal, and mobile wad (Fig. 13.2). The volar compartment contains the flexors and pronators of the forearm and wrist. These muscles may be further subdivided into (a) a superficial group consisting of the pronator teres, flexor carpi radialis, palmaris longus, flexor carpi ulnaris, and flexor digitorum and (b) a deep group consisting of the flexor digitorum profundus, flexor pollicis longus, and pronator quadratus. It is essential to decompress adequately the entire course of the median nerve as it courses through this compartment. Proximally it enters the forearm between the two heads of the pronator teres muscle and then runs the length of the forearm between the flexor digitorum superficialis and profundus muscles before it enters the carpal tunnel.

The dorsal or extensor compartment of the forearm also contains two groups of muscles. The superficial layer consists of the extensor digitorum communis, extensor digitorum minimi, and extensor carpi ulnaris. The deep layer consists of the supinator, abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus.

The third compartment of the forearm, the mobile wad, consists of three muscles: the extensor carpi radialis longus, extensor carpi radialis brevis, and brachioradialis.

LEG

The leg is the most common part of the extremities to be involved in compartment syndrome. There are four compartments in the leg, with the anterior compartment the one most commonly involved in both ACS and CCS (Fig. 13.3). The anterior compartment contains the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius muscles as well as the deep peroneal nerve, which supplies all of them. The deep peroneal nerve also supplies the extensor digitorum brevis and supplies sensation to the first dorsal web space in the foot.

The lateral compartment of the leg contains the peroneus longus and brevis muscles. The common peroneal nerve runs in this compartment as it winds around the neck of the fibula, and after the deep peroneal branch enters the anterior compartment, the superficial peroneal nerve continues down the leg in the lateral compartment. In the lower third of the leg it pierces the fascia and runs in the subcutaneous tissues to the foot, where its two terminal branches, the medial and intermediate dorsal cutaneous nerves, supply sensation to the dorsum of the foot.

The deep posterior compartment of the leg can be troublesome because it is not as accessible to palpation as are the other compartments. This compartment contains the popliteus, flexor hallucis longus, flexor digitorum longus, and tibialis posterior muscles as well as the tibial nerve, which supplies them. The tibial nerve runs between the soleus and tibialis posterior muscles proximally and between the flexor digitorum longus and flexor hallucis longus muscles distally before it enters the foot to supply the plantar muscles and provide sensation to the sole of the foot. Clawing of the toes after a tibial fracture suggests previous compartment syndrome of the deep posterior compartment of the leg or the deep calcaneal compartment of the foot.

The least involved compartment of the leg is the superficial posterior compartment, whose surrounding fascia is less constrained. Contained in this compartment are the plantaris, gastrocnemius, and soleus muscles, as well as the sural nerve, which pierces the fascia in the lower third of the leg and supplies sensation to the lateral aspect of the foot.

ETIOLOGY

An acute compartment syndrome can be caused by either an increase in compartment volume (e.g., postfracture swelling) or a decrease in compartment size (e.g.,...

Acute Compartment Syndrome

The first and most important symptom of an impending acute compartment syndrome is pain that is greater than expected from the primary clinical problem, such as a

fracture or contusion. Frequently, the patient has been observed for a period of time with minimal or stable pain and then rapidly develops pain out of proportion to what

is expected. This may be associated with a need for larger and larger doses of narcotic analgesia. The pain is usually described as a deep, throbbing feeling of

unrelenting pressure and is not responsive to change in position of the extremity. The absence of pain in ACS is almost always related to a superimposed central or

peripheral sensory deficit.

Figure 13.5. Early findings of a compartment syndrome. Increased pressure leading to a palpably tense compartment is the earliest sign. (Redrawn from Mubarak SJ, Hargens AR, Owen CA, and Akesson WH. Muscle Pressure Measurement with the Wick Catheter. In: Goldsmith HS, ed. Practice of Surgery. New York: Harper & Row, 1976.)

Figure 13.4. Leading causes of compartment syndrome. (From Mubarak SJ, Hargens AR. Compartment Syndromes and Volkmann’s Contracture. Philadelphia: WB Saunders, 1981.)

When a decrease in compartment size leads to an ACS, the constriction may be extrinsic or intrinsic. Extrinsic compartment constrictions may be caused by a tight

bandage or cast or by the noncompliant eschar that forms in severe burns. Intrinsic constrictions may be iatrogenic in nature by the surgical closure of fascial defects.

These fascial defects may represent autofasciectomy from increased intracompartmental pressure or may be the result of fascial incisions used in the operative

treatment of fractures (e.g., tibial plateau).

Another possible intrinsic cause of decreased compartment size is stretching of a relaxed compartment. Gershuni et al. showed that passive ankle and knee position

significantly affected intracompartmental pressures of the leg (16). Pressures as high as 40 mm Hg were noted in the deep posterior compartment of normal volunteers

with full passive ankle dorsiflexion.

Compartment stretching can also occur in the operative treatment of fractures. For example, late treatment of a shortened long bone fracture by open reduction and

internal fixation, such as in a nonunion and/or malunion, can stretch the compartments back to their original length. This effect reduces the compartment size and

can significantly increase intracompartmental pressure. Similarly, in the operative treatment of acute femur or tibia fractures, compartment syndrome is occasionally

seen following intramedullary nailing. In such cases, there is considerable swelling of the thigh or leg with resultant shortening of the fracture. When the limb is placed

in traction and the fracture is reduced, the size of the compartments is decreased; this can lead to a sudden increase in intracompartmental pressure.

Although it is usually not difficult to identify the cause of an ACS, less is known about the etiology of CCS. As mentioned above, there are several hypotheses, all

related to anatomic. Styf suggested that CCS of the anterior compartment of the leg may be related to vessel occlusion by local muscle herniations (57). Chronic

exercise may lead to significant muscular hypertrophy, which essentially “outgrows” its noncompliant fascial covering. The fascia itself may be abnormally thick or tight. 

Marten and Moeyersons have hypothesized that the fascia in these patients is abnormally noncompliant and does not accommodate the increased muscle volume

seen during exercise (32). Detmer et al. reported increased fascial thickening in 25 of 36 samples from patients with CCS (10). Fascial scarring may also be present in

cases where a specific traumatic event is associated with CCS (30,45,61).

ASSESSMENT AND INDICATIONS

DIAGNOSIS

Acute Compartment Syndrome

The first and most important symptom of an impending acute compartment syndrome is pain that is greater than expected from the primary clinical problem, such as a

fracture or contusion. Frequently, the patient has been observed for a period of time with minimal or stable pain and then rapidly develops pain out of proportion to what

is expected. This may be associated with a need for larger and larger doses of narcotic analgesia. The pain is usually described as a deep, throbbing feeling of

unrelenting pressure and is not responsive to change in position of the extremity. The absence of pain in ACS is almost always related to a superimposed central or

peripheral sensory deficit.

The earliest and only objective finding of a compartment syndrome is a swollen, palpably tense compartment that is a direct manifestation of increased

intracompartmental pressure (Fig. 13.5). Subcutaneous edema can mask the underlying swelling and increased pressure of the compartment. Despite its relative

specificity for compartment syndrome, the tenseness of a compartment is difficult to quantify and remains a crude indicator of increased intracompartmental pressure.

In addition, the deep posterior compartment is difficult to palpate, and an isolated syndrome of this compartment can be missed if the examiner feels a sense of

security in the absence of palpably tense compartments.
sensory examination is extremely helpful in evaluating a patient with ACS. Each compartment of the forearm and leg has at least one peripheral nerve coursing through it, and careful sensory examination of the hand or foot can help confirm the compartment(s) involved. Initially, the sensory deficit may manifest itself as paresthesia only. With delay in treatment, hypoesthesia progressing to anesthesia is inevitable. In cooperative patients, any sensory deficit after an injury must be explained.

As mentioned above, unless there is an associated major arterial injury or disease, peripheral pulses are palpable and brisk capillary refill is found routinely in the patient with ACS. Although the compartment pressure may be high enough to cause muscle and nerve ischemia, only on rare occasions is it elevated sufficiently to occlude a major artery (Fig. 13.6). If palpation of distal pulses is difficult because of soft-tissue swelling, Doppler studies are used to confirm their presence. It is crucial that the treating physician be aware that the peripheral pulses are generally intact with compartment syndromes and avoid a false sense of security by palpating a pulse and deciding all is well. Moreover, the skin circulation is satisfactory and the hand and foot are pink and viable, unlike the ischemic appearance seen with an arterial injury.

Figure 13.6. Ischemia associated with compartment syndromes. A: At tissue fluid pressures below 30 mm Hg, blood flows normally from arteries to arterioles and into capillaries. B: When intracompartmental pressure rises above 30 mm Hg, blood flow is confined to large arteries, veins, and nonnutritional arteriovenous anastomoses. Typically, pulses are present distal to the region of the elevated tissue pressure. This may give the physician a false sense of security because he may assume that normal circulation exists in the muscle compartment. (From Mubarak SJ, Hargens AR. Compartment Syndromes and Volkmann’s Contracture. Philadelphia: WB Saunders, 1981.)

The differential diagnosis for patients with limb injuries and neurovascular deficits is primarily limited to compartment syndrome, arterial injury, and peripheral nerve injury (Table 13.1). Identification of these problems is important because the treatments are vastly different. A compartment syndrome must be treated by immediate fasciotomy. A major arterial injury requires immediate surgical restoration (e.g., repair of the artery or thrombectomy). A peripheral nerve injury associated with a fracture or severe soft-tissue injury is most commonly a neuropaxia, and the initial treatment of choice is usually observation.

Table 13.1. Clinical Findings of Compartment Syndrome, Arterial Occlusion, and Neuropaaxia

These three conditions frequently coexist, and their clinical findings can overlap (Table 13.1). All three may have an associated motor or sensory deficit and pain. An arterial injury usually results in absent pulses, poor skin color, and decreased skin temperature. Unfortunately, however, there can be a delay in diagnosis when poor blood flow is attributed to other factors such as hypovolemia, local compression, or “kinking” of the vessel from significant limb deformity. As mentioned, the patient with a compartment syndrome routinely presents with intact peripheral circulation. Isolated nerve injuries usually give little pain, and the diagnosis is often by exclusion of the other two entities. Doppler studies, arteriography, and intracompartmental pressure measurements are frequently required to aid in the differential diagnosis of these three conditions.

Chronic Compartment Syndrome

The hallmark symptom of CCS is extremity pain induced by exercise or other exertion. The treating physician must have a high index of suspicion to correctly identify patients with CCS.

The patient with CCS may range from a casual weekend jogger to an enthusiastic marathon runner. Nonrunners may also be at risk (e.g., weightlifters). The majority are young, active men, and the symptoms are frequently bilateral. In most cases, the patient reports recurrent pain that is initiated by exercise over the anterior or lateral compartment of the leg. Symptoms have usually been present for months by the time medical attention is sought. For runners, the onset of pain is reproducible for a specific speed and distance. It is usually necessary for the patient to discontinue his run and rest for a few minutes, similar to the situation in elderly patients with vascular claudication. This is variable, however, and some individuals may continue to run at a reduced speed. The pain may persist for hours.

Pain with CCS is described as a feeling of pressure or cramping in the compartment and may be achy, sharp, or dull. Occasionally, there may also be associated numbness or weakness. The most common compartments involved in CCS are the anterior and/or lateral compartments of the leg; however, it has also been reported in the posterior compartments of the leg (48), thigh (49), foot (51), back (52), forearm (50,52), and hand (53).

Few findings are gleaned from the physical examination before the patient exercises. Muscle hernias, occurring in 60% of Reneman’s patients, may be clinically more obvious after exercise (50,51). Pedowitz et al. summarized the physical examination findings in 45 patients with CCS (48). Muscle herniation through a fascial defect was present in 46% of these patients. Most of these defects are located in the lower third of the leg overlying the anterior intermuscular septum between the anterior and lateral compartments (Fig. 13.7). In this location, the fascial defect may represent an enlargement of the orifice through which a branch of the superficial peroneal nerve (e.g., medial dorsal cutaneous nerve) exits the lateral compartment. Muscle herniation may cause superficial peroneal nerve irritation and even neurona formation (52). After exercise, a sensation of increased fullness over the anterior compartment may be experienced, and occasionally hypoesthesia on the dorsum of the foot is documented. There should be no changes in the peripheral pulses after exercise.
Because the history and physical examination findings are usually inadequate for the definitive diagnosis of CCS, objective intracompartmental pressure measurements are needed. Unfortunately, there still exists significant controversy over the critical pressure criteria used for the diagnosis of CCS. In addition, different investigators have used different catheter systems to obtain their data. It is important to define abnormally high pressures in relation to normative data from a control population using the same pressure measurement system.

Based on the work by Styf et al., it is logical to obtain intracompartmental pressures during the period of muscle relaxation when microcirculatory perfusion occurs. In CCS, resting intracompartmental pressure is elevated. In our lab, objective criteria for the diagnosis of CCS were developed by Pedowitz et al. using slit catheter determinations of static pressures before and after exercise. Pressures are measured before exercise and 1 and 5 minutes after exercise. One or more of the following criteria are diagnostic of CCS: rest pressure $\geq$15 mm Hg, 1-minute postexercise pressure $\geq$30 mm Hg, and 5-minute postexercise pressure $\geq$20 mm Hg.

The measurement of intracompartmental pressure is invasive, and recently there have been studies using a noninvasive technique of near-infrared spectroscopy to diagnose CCS. This technique holds promise for future research and clinical diagnosis in patients with CCS and other skeletal muscle disorders.

The differential diagnosis for CCS includes other causes of exercise-induced extremity pain. These include stress fracture, periostitis, tendinitis, peripheral nerve entrapment, vascular claudication, venous stasis, and neurogenic claudication. Plain radiography, bone scintigraphy, ultrasound, magnetic resonance imaging, electromyography, and nerve conduction studies may be useful in determining the correct diagnosis other than CCS.

**PRINCIPLES AND TECHNIQUES OF PRESSURE MONITORING**

A variety of means exist for measuring compartmental pressure, including the needle techniques popularized by Reneman and Whitesides et al. and the infusion technique advocated by Matsen et al. We have employed the wick and slit catheter technique for measurement of tissue pressure in compartment syndromes. The wick technique was first described in 1968 by Scholander et al. The wick catheter used in our patients was based on the original design, but instead of cotton a piece of braided polyglycolic acid suture was employed as the wick in the end of the catheter. The development of the clinical wick catheter began in 1973, and the first human use studies began in 1974. Because the history and physical examination findings are usually inadequate for the definitive diagnosis of CCS, objective intracompartmental pressure measurements are needed. Unfortunately, there still exists significant controversy over the critical pressure criteria used for the diagnosis of CCS. In addition, different investigators have used different catheter systems to obtain their data. It is important to define abnormally high pressures in relation to normative data from a control population using the same pressure measurement system.

Based on the work by Styf et al., it is logical to obtain intracompartmental pressures during the period of muscle relaxation when microcirculatory perfusion occurs. In CCS, resting intracompartmental pressure is elevated. In our lab, objective criteria for the diagnosis of CCS were developed by Pedowitz et al. using slit catheter determinations of static pressures before and after exercise. Pressures are measured before exercise and 1 and 5 minutes after exercise. One or more of the following criteria are diagnostic of CCS: rest pressure $\geq$15 mm Hg, 1-minute postexercise pressure $\geq$30 mm Hg, and 5-minute postexercise pressure $\geq$20 mm Hg.

The measurement of intracompartmental pressure is invasive, and recently there have been studies using a noninvasive technique of near-infrared spectroscopy to diagnose CCS. This technique holds promise for future research and clinical diagnosis in patients with CCS and other skeletal muscle disorders.

The differential diagnosis for CCS includes other causes of exercise-induced extremity pain. These include stress fracture, periostitis, tendinitis, peripheral nerve entrapment, vascular claudication, venous stasis, and neurogenic claudication. Plain radiography, bone scintigraphy, ultrasound, magnetic resonance imaging, electromyography, and nerve conduction studies may be useful in determining the correct diagnosis other than CCS.

**PRINCIPLES AND TECHNIQUES OF PRESSURE MONITORING**

A variety of means exist for measuring compartmental pressure, including the needle techniques popularized by Reneman and Whitesides et al. and the infusion technique advocated by Matsen et al. We have employed the wick and slit catheter technique for measurement of tissue pressure in compartment syndromes. The wick technique was first described in 1968 by Scholander et al. The wick catheter used in our patients was based on the original design, but instead of cotton a piece of braided polyglycolic acid suture was employed as the wick in the end of the catheter. The development of the clinical wick catheter began in 1973, and the first human use studies began in 1974. Because the history and physical examination findings are usually inadequate for the definitive diagnosis of CCS, objective intracompartmental pressure measurements are needed. Unfortunately, there still exists significant controversy over the critical pressure criteria used for the diagnosis of CCS. In addition, different investigators have used different catheter systems to obtain their data. It is important to define abnormally high pressures in relation to normative data from a control population using the same pressure measurement system.

...circulation ceases and ischemia ensues, or whether this ischemic threshold is relative to the patient's systemic blood pressure.

Figure 13.10. Silt catheter technique for continuous measurement of intracompartmental pressure. Before inserting it into a muscle compartment, connect the sterile silt catheter to a pressure transducer and digital recorder and then fill it with saline using a 30-ml syringe. The catheter tip protrudes from the insertion needle during filling so that the tip can be checked for air bubbles (upper left). Before insertion into muscle, pull the catheter entirely within the needle. (From Mubarak SJ, Hargens AR. Compartment Syndromes and Volkman’s Contracture. Philadelphia: WB Saunders, 1981.)

The Camino catheter is a fiberoptic transducer-tipped pressure-monitoring catheter system (Camino Laboratories, San Diego, CA) that uses a unique method of obtaining pressure measurements without the disadvantages of the long fluid-filled catheters with external transducers (3). The Camino catheter operates by using a light-sending and receiving system that responds to movements of a mirror diaphragm when pressure is applied to the catheter tip. The movement is sensed by light signals emitted from a “sending” light fiber; the reflected light is sent to an amplifier through a “receiving” light fiber. The light sent and received is analyzed by a microcomputer and converted into digital and analog signals directly related to the applied pressure. This pressure-measuring instrument has its sensor near the catheter tip, which eliminates the need to make adjustments for hydrostatic pressure. The fiber optic cable has a relatively large diameter, however, and can be uncomfortable during long-term monitoring.

Small portable pressure-monitoring systems have also been developed. These work best, and are most accurate, when used with high-pressure tubing and a silt catheter at the end. Simple needles often plug with tissue and are much less accurate. An example of a portable unit commonly used is the Stryker Pressure Monitor System (Stryker, Kalamazoo, MI). The Stryker system is hand-held, with a prefilled, sterile, disposable syringe (Fig. 13.11). It can be used for intermittent measurement or continuous monitoring. When possible, it should be used with a silt-tip catheter rather than the fenestrated needle.

Figure 13.11. The Stryker system is a small portable monitoring system (Stryker, Kalamazoo, MI). It is most accurate if used with high-pressure tubing and a silt catheter.

In certain settings, the treating physician may not have immediate access to a wick catheter, silt catheter, or even a portable unit with a side-ported needle. In these situations, intracompartmental pressure measurements can be readily obtained with an existing arterial line setup and a catheter that has been cut at the tip. A simple 18-gauge needle and a mercury manometer (Whitesides technique) (63) can also be used, but it is important to recognize that this method is considered the least accurate. Moed et al. compared measurement of intracompartmental pressures using a silt catheter, a Stryker portable unit with a side-ported needle, and a simple 18-gauge needle with a mercury manometer (65). They found that the values obtained with the simple needle were consistently higher, by an average of 18 to 19 mm Hg, than those obtained with the other two methods. They found no statistical difference between the values obtained with the silt catheter compared with the side-ported needle unit.

In the evaluation of a patient with a possible compartment syndrome, obtain multiple pressure measurements throughout each compartment. This is particularly important in patients with a long bone fracture and suspected compartment syndrome. Heckman et al. showed that, in cases of closed tibia fractures, there exists a relationship between intracompartmental pressure and distance from the actual fracture site (23). The highest pressures were routinely found at or within 5 cm of the fracture site. On the basis of these data, the authors recommend using the highest recorded intracompartmental pressure as an indicator for fasciotomy.

Indications

Many compartment syndromes can be diagnosed clinically without the need for intracompartmental pressure measurements. In these cases, documentation of the elevated compartment pressures is confirmatory. However, patients are frequently encountered in whom there is difficulty in eliciting or interpreting the physical examination findings. In these patients, the measurement of intracompartmental pressure is particularly valuable in the diagnosis and as a criterion for decompression.

In the uncooperative or unreliable patient, a careful physical examination may be difficult, and measurement of intracompartmental pressures may be extremely valuable. Children with fractures and other severe soft-tissue injuries may be so frightened that examination is impossible. Polytrauma patients frequently have closed head injuries and may be intoxicated from drugs and/or alcohol, making examination difficult.

Intracompartmental pressure measurement is essential in unresponsive individuals. Obliterated patients, intubated and paralyzed patients, and comatose patients are unable to cooperate with a physical examination, and palpably tense compartments are the only finding they can demonstrate. It is essential in these patients to have a high index of suspicion.

Lastly, pressure measurements are valuable in patients in whom the diagnosis is inconclusive. A patient may have an evolving or early compartment syndrome in which their pain is clearly out of proportion to what is expected from their injury. On examination they may have palpably tense compartments but may not yet have developed other classical findings such as pain on passive muscle stretch and sensory deficits. A patient may also have a nerve deficit attributable to other causes. It is often difficult to differentiate neuropathia secondary to stretch or conus of a peripheral nerve from neurologic deficits resulting from increased intracompartmental pressure.

Pressure Threshold for Fasciotomy

Acute compartment syndrome has been recognized clinically for more than 100 years. Despite significant advances in the understanding of the etiology and pathophysiology of this syndrome, disagreement still remains on the pressure threshold for fasciotomy. One possible reason for the different published thresholds may be the technique of measurement. As discussed above, the needle techniques usually give higher pressure readings when compared with a silt catheter or side-ported needle. In addition, there remains disagreement on whether there exists an absolute critical closing pressure, that is, a tissue pressure beyond which capillary circulation ceases and ischemia ensues, or whether this ischemic threshold is relative to the patient’s systemic blood pressure.

Whitesides et al. initially recommended fasciotomy when intracompartmental tissue pressure rose to within 10 to 30 mm Hg of the patient’s diastolic blood pressure (64). This recommendation was then modified slightly by Heckman et al. to perform fasciotomy when the measured intracompartmental pressure rises to within 10 to 20 mm Hg of the patient’s diastolic blood pressure (23). For example, this would represent an absolute pressure of 50 to 60 mm Hg in a patient with a diastolic blood pressure of 70 mm Hg. This recommendation is based on their work in a canine model where histologic evidence of muscle regeneration did not occur until the 8-hour...
pressurization level was within 20 mm Hg of the dog's diastolic blood pressure. Necrosis and fibrosis of muscle did not occur until the 8-hour pressurization level was within 10 mm Hg of the dog's diastolic blood pressure.

Hepgenstall and colleagues, using phosphorus nuclear magnetic resonance spectroscopy to measure the metabolic activity of muscle, also concluded that the perfusion pressure gradient between systemic blood pressure and intracompartmental tissue pressure was important in determining the ischemic threshold for muscle (25-28). In their canine model, using a silt catheter to determine intracompartmental pressures, they determined that normal cellular metabolism can occur as long as the intracompartmental tissue pressure was no closer than 30 mm Hg to the mean arterial blood pressure (MAP). Hypertension would therefore have a "protective" effect on muscle perfusion and would raise the absolute pressure threshold for fasciotomy, whereas hypotension, as is frequently seen in the polytraumatized patient, would effectively lower the threshold. In addition, these authors noted that in traumatized muscle, cellular damage was noted when the tissue pressure was within 40 mm Hg of the animal's MAP.

Matsen et al., in a clinical study using their needle-infusion technique, reported that no patient with an absolute pressure less than 45 mm Hg developed a compartment syndrome (33). Almost all patients with intracompartmental pressures greater than 50 mm Hg, however, were noted to have true compartment syndromes. Matsen et al., using an external compression device to elevate intracompartmental pressure, and using themselves as volunteers, also demonstrated that elevating the limb to approximately 50 cm above the level of the heart lowered the tolerance of the leg to increased intracompartmental pressures by as much as 35 mm Hg (34). They attributed this to the relative hypotension of the limb and to decreased perfusion pressure.

Rorabeck and colleagues, using the silt catheter, recommend decompression for resting pressures in the range of 30 to 40 mm Hg (65). We have used similar pressure thresholds in our practice. Our clinical and animal studies support the conclusion that the threshold intracompartmental pressure at which fasciotomy is recommended is 30 mm Hg for 8-hour pressurization in an acute compartment syndrome (18,19 and 20,40). Using a similar dog model, our lab has also demonstrated that the pressure threshold is lowered during systemic hypotension (65). Because the total time of elevated tissue pressure and the absolute pressure levels before measurement are usually unknown in most cases of ACS, we recommend that intracompartmental pressure greater than 30 to 35 mm Hg, combined with other positive clinical findings, warrants fasciotomy (Figs. 13.12).

Despite continued disagreement on the pressure threshold for irreversible tissue damage, all authors agree that intracompartmental pressure measurement is only one of many factors that play a role in determining the need for fasciotomy. Any absolute pressure threshold is a relative indication for decompression that should be tempered by several patient factors, including overall condition, systemic blood pressure, peripheral perfusion, trend of symptoms and signs, trend of intracompartmental pressures, and the cooperation and reliability of the patient.

PREOPERATIVE MANAGEMENT

In evaluating a patient with a traumatized limb, carefully document the time of injury as well as the initial and subsequent examinations. Perform and record a sensory examination to include light touch, pin prick, and two-point discrimination. The nurses and treating physician must monitor these values frequently. Perform intracompartmental pressure measurements when indicated and carefully document them as well.

You must have a high index of suspicion in all cases of possible compartment syndrome. The consequences for a patient from a missed compartment syndrome can be devastating. The best way to ensure early diagnosis and treatment is to understand the pathophysiology of the syndrome, take all possible cases seriously, and deal with them on an emergency basis.

When the diagnosis of an acute compartment syndrome is considered, but the exam is equivocal and/or the intracompartmental pressure is not high enough to warrant a fasciotomy, take all measures possible to attempt to prevent a full-blown compartment syndrome from occurring. Initially, remove all constrictive dressings and split or remove any casts (Figs. 13.13). Garfin et al. used a canine model to show that a cast can restrict volume expansion of a compartment by 40% (13). In addition, univalving and spreading the cast decreased compartment pressure by as much as 65%.

The position of the limb in a patient at risk for developing a compartment syndrome is important. Frequently the limb is elevated to decrease swelling. Matsen and colleagues have shown, however, that elevation of the limb reduces mean arterial pressure as well as the arteriovenous gradient and thereby reduces capillary flow (34). Leaving the limb dependent may increase the mean arterial pressure, but significant swelling may occur and also increase the risk of developing a compartment syndrome. Therefore, place any extremity with an incipient compartment syndrome, or at risk of developing a compartment syndrome, at the level of the heart.

**SURGICAL TECHNIQUES**

Take the patient with an established acute compartment syndrome emergently to the operating room for decompressive fasciotomy.

- Place a tourniquet on the limb but do not elevate it unless absolutely necessary. Administer prophylactic antibiotics intravenously.
This approach was described by Mubarak et al. and is used routinely in our practice for fasciotomy of the four leg compartments (Double-incision Approach must be released in acute compartment syndrome of the leg. The leg is the most common area to be involved in compartment syndrome. As described above, there are four compartments in the leg. In general, all compartments need to be released if there is any question as to the need for decompression, proceed with fasciotomy. The dorsal incision is similar to that used in the Thompson approach and can extend for the entire skin incision is not needed, and with adequate undermining of the skin, the fascia of the dorsal and mobile wad compartments can be easily reached through this approach.

**Volar Curvilinear Approach**

The volar approach of Henry is an excellent incision for release of the volar compartment.

- Begin the skin incision proximal to the antecubital fossa on the ulnar aspect of the arm and cross the antecubital fossa horizontally in the flexion crease (Fig. 13.14). Extend the incision down the forearm in an S shape to the wrist flexion crease and then cross the crease into the palm to allow release of the carpal tunnel.

*Figure 13.14. The dorsal and volar incisions used for forearm decompression. Both volar incisions provide excellent exposure to the major neurovascular structures. The volar curvilinear incision also provides access to the mobile wad compartment. (Redrawn from Gelberman RH, Zakaib GS, Mubarak SJ, et al. Decompression of Forearm Compartment Syndromes. Clin Orthop 1978;134:225.)

- Incise the superficial fascia throughout the length of the forearm. Identify the median nerve proximally and release the lacertus fibrosus.
- Release the proximal edge of the pronator teres and the proximal edge of the flexor digitorum superficialis. Follow the median nerve into the forearm between the flexor digitorum superficialis and profundus and decompress it all the way to the carpal tunnel. Preserve the palmar cutaneous branch of the median nerve.
- Incise the transverse carpal ligament to release the carpal tunnel.
- Inspect the deep volar muscles (flexor digitorum profundus, flexor pollicis longus, and pronator quadratus) and release their respective fascial coverings as needed. With undermining of the skin, the mobile wad can also be reached through this approach.

**Volar Ulnar Approach**

- Begin the incision on the lateral aspect of the arm above the antecubital fossa. Extend it horizontally across the elbow flexion crease, down the ulnar border of the forearm, and then continue into the palm (Fig. 13.14).
- Carry out the remainder of the decompression as described above for the Henry approach.

Gelberman et al. compared the two volar approaches to the forearm and found no significant differences between the two in regard to adequate decompression (15). The mobile wad, however, cannot be easily reached through the volar ulnar approach, and a second dorsal incision is needed to release this compartment.

**Dorsal Approach**

After release of the volar compartment, pressures in the dorsal and mobile wad compartments can be measured to determine whether decompression is needed. If there is any question as to the need for decompression, proceed with fasciotomy. The dorsal incision is similar to that used in the Thompson approach and can extend from the lateral epicondyle to the midportion of the wrist (Fig. 13.14). Usually the entire skin incision is not needed, and with adequate undermining of the skin, the fascia of the dorsal and mobile wad compartments is readily released. As previously mentioned, the mobile wad can also be released from the volar curvilinear approach of Henry.

**LEG DECOMPRESSION**

The leg is the most common area to be involved in compartment syndrome. As described above, there are four compartments in the leg. In general, all compartments must be released in acute compartment syndrome of the leg.

**Double-incision Approach**

This approach was described by Mubarak et al. and is used routinely in our practice for fasciotomy of the four leg compartments (38).

- To approach the anterior and lateral compartments, make a longitudinal skin incision 20 to 25 cm long, halfway between the fibular shaft and tibial crest (Fig. 13.15). This lies approximately over the anterior intermuscular septum dividing the anterior and lateral compartments and allows easy access to both. Undermine the skin edges proximally and distally to provide wide exposure of the fascia.

*Figure 13.15. The two-incision technique for four-compartment release of the leg. Anterolateral incision, step 1. (Redrawn from Mubarak SJ, Hargens AR. Diagnosis and Management of Compartment Syndromes. In: AAOS: Symposium on Trauma to the Leg and Its Sequelae. St. Louis: CV Mosby, 1981.)

- Make a small transverse incision in the midportion of the leg, just through the fascia, to identify the anterior intermuscular septum that separates the anterior compartment from the lateral compartment (Fig. 13.16). Identification of this septum is necessary to identify the superficial peroneal nerve, which lies in the lateral compartment next to the septum.

- We recommend long extensile skin incisions, both to supplement the fascial decompression and to prevent iatrogenic injury to nearby vessels, tendons, and nerves. Carefully debride obvious areas of muscle necrosis at the initial operation, but areas of muscle with uncertain vascularity can be left until the patient is returned to the operating room in 24 to 72 hours, when muscle viability can be determined more accurately.
- At the completion of all fasciotomies, measure the pressure in several areas of each compartment to ensure adequate decompression.
Using a 12-in. (31-cm) Metzenbaum scissors, open the anterior compartment fascia. Visualization is aided by retraction with right-angle retractors. Push the scissors with the tips open slightly in the direction of the great toe distally and proximally toward the patella (Fig. 13.17). If there is any question whether the tip of the scissors has strayed from the fascia, lengthen the skin incision to ensure complete fascial release. Blind repeat attempts to complete the fasciotomy are dangerous and can injure vascular, nervous, and tendinous structures.

Make the lateral compartment fasciotomy in line with the fibular shaft. Direct the scissors proximally toward the fibular head and distally toward the lateral malleolus. In this way the fascial incision is posterior to the superficial peroneal nerve. Adequate visualization is essential, so do not hesitate to extend the skin incision if necessary.

Make a second longitudinal incision, 20 to 25 cm long, on the posteromedial side of the leg to approach the superficial and deep posterior compartments (Fig. 13.18). Place this incision 2 to 3 cm posterior to the posterior tibial margin. If the incision is too anterior, the tibia may be left exposed after the skin edges retract. An anterior incision also risks injury to the saphenous vein and nerve, which course along the posterior margin of the tibia.

It is usually easiest to decompress the superficial posterior compartment first by extending the fasciotomy proximally as far as possible and then distally behind the medial malleolus. Release the deep posterior compartment distally and then proximally under the soleus bridge (Fig. 13.20). Release the soleus if it attaches to the tibia distally more than halfway. In cases where both the deep and superficial compartments are anchored to the posteromedial edge of the tibia, there is no identifiable intermuscular septum and the deep posterior compartment should be released from within the superficial posterior compartment by retraction of the soleus off the tibia.
This completes a four-compartment decompression (Fig. 13.21). If intraoperative pressure monitoring was used during the procedure, or if there is any doubt as to the adequacy of the decompression, check final intracompartmental pressures.

**Single-incision Approach**

Matsen and colleagues described a single-incision approach to all four compartments of the leg (33,35). Centered over the lateral compartment, the incision must be extensile in order to allow easy decompression of all four compartments.

- Make an incision from the head of the fibula to the lateral malleolus. Undermine the skin at the level of the deep fascia both anteriorly and posteriorly in the middle third of the wound sufficiently to visualize the posterior edge of the anterior compartment, the lateral compartment, and the anterior edge of the superficial posterior compartment.
- Make a transverse incision with a knife through the deep fascia, beginning in the anterior compartment, crossing the lateral compartment, and extending into the posterior compartment. With careful inspection you can now identify the anterior intermuscular septum running longitudinally between the anterior and lateral compartments and the posterior intermuscular septum running between the lateral and posterior compartments. It is very important to take this step, because identification of the three compartments can be difficult in the traumatized, distorted, and swollen limb. This transverse incision is similar to that illustrated above for the two-incision technique (Figs. 13.19 and 13.20).
- Using a knife or Metzenbaum scissors, as described above for the two-incision technique, incise the deep fascia of the anterior, lateral, and superficial posterior compartments for the full length of each compartment. Be certain to decompress all muscle proximally. Distally, at the level of the musculotendinous junctions, further decompression is usually not necessary.
- Identify the deep posterior compartment. Dissect the soleus free from its origin on the posterior intermuscular septum in the middle or proximal third of the wound. In the nonswollen limb the deep compartment lies about 1 cm deep to the superficial posterior compartment, but in a limb with severe compartment syndrome this compartment may be as deep as 2.5 cm. Release the deep fascia of this compartment throughout its full length in a similar manner. As with any technique, take care to avoid injury to the neurovascular structures, particularly the common peroneal nerve proximally and its branches distally.

Decompression by fibulectomy was described by Patman and Thompson (44) and popularized by Kelly and Whitesides (29). We do not advise fibulectomy, as it destabilizes tibia fractures and removes an important structure for reconstruction of the leg. It is mentioned for historic interest only.

**FRACTURES AND COMPARTMENT SYNDROME**

When compartment syndrome is combined with fractures of any of the long bones, perform external or internal fixation of the fracture at the time of compartment decompression (17,33,53). The obvious advantage of immobilizing the fracture is that care of the fasciotomy wound is facilitated. The technique chosen for stabilization should minimize further soft tissue damage if possible, and in the lower extremity intramedullary nailing is an excellent choice. In some lower extremity fractures, particularly high-grade tibia fractures, intramedullary nailing may not be the optimal technique, and external fixation may be a more prudent choice. The major disadvantage of an external fixator is that mobilization of the skin for delayed primary closure is more difficult, and skin grafting is usually required. For forearm fractures, compression plates are the recommended choice for fixation.

In cases of long bone fractures, you should recognize the high risk that exists for the development of an acute compartment syndrome. Gershuni et al. have shown that, in the case of tibia fractures and acute compartment syndrome, a good functional result can be obtained if the compartment syndrome is readily identified and adequately treated before irreversible muscle and nerve damage occur (17). In cases where the compartment syndrome is missed, or treatment is delayed, the patient may have a poor functional outcome despite adequate treatment and healing of the tibia fracture.

In the operative treatment of long bone fractures, particularly in the treatment of femur and tibia fractures with intramedullary nailing, you should be aware of the possibility of inducing a compartment syndrome. This was discussed above in the etiology of acute compartment syndromes. In all cases of intramedullary nailing of the femur and tibia, carefully inspect the thigh and leg for tight compartments. If there is any evidence of increased intracompartmental pressure, measure the pressure in all compartments before the end of the procedure. If indicated, perform fasciotomies immediately.

**PROPHYLACTIC FASCIOTOMY**

Consider a prophylactic fasciotomy for any patient with a high probability of developing a compartment syndrome (33). Anterior and lateral compartment fasciotomies should be considered in patients undergoing tibia osteotomies or leg-lengthening procedures, or when the tibia is used as a donor bone graft site. When debriding an open tibial fracture, release those compartments accessible through the exposed wound.

Patients who have sustained an arterial injury or developed a thrombus or who have had a femoral artery bypass are especially prone to developing compartment syndromes. In our experience, patients with postischemic compartment syndrome have a poor prognosis because the period of ischemia caused by the arterial injury is added to the compartment syndrome that results after reinstitution of arterial flow. If the arterial ischemia has been present for more than 4 to 6 hours, prophylactic fasciotomy of the leg or forearm is warranted at the time of arterial repair.

**TREATMENT OF CHRONIC COMPARTMENT SYNDROME**

After the diagnosis of chronic compartment syndrome has been established by history, physical examination, and intraocular compartmental pressure measurement, fasciotomy is usually required. After the diagnosis and surgical treatment are outlined to patients, however, many prefer to limit their running or alter their exercise program. The patient choosing nonoperative treatment must also be counseled about the possibility of developing an acute compartment syndrome if the symptoms are ignored and the activity is not modified (39). In our experience, most patients who desire to maintain a given level of jogging or running require fasciotomy.

**Chronic Anterior Compartment Decompression**

The technique for decompression of the leg in CCS is the same as that used for ACS; however, the skin incisions can be much smaller, in the range of 5 to 6 cm (Fig. 13.22).
Place a small 5-cm incision between the tibial crest and fibular shaft, overlying the anterolateral intermuscular septum. In the absence of a fascial hernia, place the incision in the midportion of the leg.

Extensive undermining and a fasciotome aid limiting the skin incision while still performing a safe and satisfactory fasciotomy (Fig. 13.23).

Muscle hernias frequently occur in the lower third of the leg in the area overlying the anterior intermuscular septum. This is the site of emergence through the fascia of one or both sensory branches of the superficial peroneal nerve (Fig. 13.24). For this reason, make the skin incision over the hernia and perform the fasciotomy at the fascial defect. This allows easy decompression of both the anterior and lateral compartments and allows simultaneous decompression of the nerve.

Do not close the fascial defect associated with a muscle hernia because of the risk of precipitating an acute compartment syndrome.

After making the skin incision, carry out decompression of the anterior and lateral compartments as described earlier (Fig. 13.25).

With CCS of the anterior compartment, we usually recommend release of both the anterior and lateral compartments. In cases of posterior compartment decompression, perform fasciotomy of the posterior compartments as described above for ACS, but through a smaller incision.

GENERAL REHABILITATION AND POSTOPERATIVE PRINCIPLES

- Following adequate compartment decompression, pack the wounds loosely open with saline-dampened gauze and apply a bulky dressing.
- Never close the skin incisions immediately after fasciotomy. At 24 to 72 hours after fasciotomy, return the patient to the operating room for repeat debridement if necessary and partial or even complete skin closure. Frequently the compartment syndrome is associated with an open fracture, and the patient is returned to the operating room several times for repeat debridement related to the fracture and soft tissue injury.
- Most commonly, fasciotomy wounds are not amenable to delayed primary closure, and split-thickness skin grafting is necessary for wound closure. With the two-incision technique in the leg, one wound can usually be closed primarily on a delayed basis, and the other wound covered with a split-thickness skin graft. In the case of compartment syndrome associated with open fractures, quantitative cultures can be used to determine the appropriate time for skin grafting.
- Begin active and active-assisted range of motion of the adjacent joints on the second day after fasciotomy. After split-thickness skin grafting, immobilize the limb for 3 to 5 days to decrease shear forces across the graft and allow full incorporation. When the skin graft has incorporated, reinstitute range-of-motion exercises.
- In contrast to fasciotomy after ACS, close the wound with an interdermal running stitch after fasciotomy for CCS. Apply a light dressing and allow the patient to remain bed-bound.
weight bearing as tolerated with the use of crutches as needed. After suture removal at 2 to 3 weeks, initiate light running and progress exercises as tolerated over the next 3 to 6 weeks according to the patient's abilities and pain tolerance.

**PITFAILS AND COMPLICATIONS**

Most pitfalls and complications of compartment syndrome are related to a delay in diagnosis and treatment and/or to inadequate decompression. The sequelae in such cases can be devastating to the patient. Despite an abundance of clinical and basic science work on the subject, compartment syndromes remain poorly understood. Because of their relatively infrequent occurrence, they may be overlooked by a treating physician who does not deal often with patients at risk, namely the polytraumatized patient and the intravenous drug user. In addition, the clinical findings of a compartment syndrome are rather subjective and rely heavily on patient cooperation.

The classic sequela from an untreated or untimely treated compartment syndrome is Volkmann's ischemic contracture of the extremity (Fig. 13.26). This results in a limb with a varying amount of deformity and functional loss, depending on the severity of the muscle and nerve injury. Muscles, nerves, tendons, bone, vessels, and skin can all be affected by the ischemia from a compartment syndrome. Irreversible muscle damage has been shown to occur after 4 to 6 hours of complete ischemia (21). Hargens et al. showed in a canine model that, at a pressure of 30 mm Hg, irreversible muscle necrosis occurred at 8 hours (20). In addition, they noted that this 8-hour threshold can be shorter in cases of hypotension. Irreversible nerve damage occurs after 6 to 12 hours of ischemia at intra-compartmental pressures between 30 and 40 mm Hg (19,44).

![Figure 13.26](image)

*Figure 13.26. Volkmann's ischemic contracture in a child who suffered compartment syndrome of the forearm. Note the deformities of the wrist and hand. (From Mubarak SJ, Hargens AR. Compartment Syndromes and Volkmann’s Contracture. Philadelphia: WB Saunders, 1981.)*

A high index of suspicion, early diagnosis, and immediate institution of treatment will help prevent Volkmann's ischemic contracture and restore normal function to a limb that has suffered a compartment syndrome. In addition, if there is any question as to the adequacy of decompression, intra-compartmental pressure measurements should be obtained in the operating room after fasciotomy.

There also exists the potential for significant iatrogenic injury during the treatment of compartment syndrome. Nerves, blood vessels, and even tendons can be injured during compartment release if careful attention is not paid to compartmental anatomy and if there is inadequate visualization. In such cases, immediately repair the injured structure(s).

**AUTHORS' PERSPECTIVE**

**PREVENTION**

The best way to avoid an acute compartment syndrome and its possible sequelae is to understand its pathophysiology and focus on prevention of the disorder. We routinely univalve and spread all casts used in the treatment of closed fractures of the long bones or use splints in the acute postinjury period before placement of a potentially constricting cast. In patients undergoing surgical procedures that have an associated risk of compartment syndrome, such as tibial osteotomies and open treatment of tibial plateau fractures, we usually perform a prophylactic fasciotomy.

There have been reports in the literature on the development of compartment syndrome in the well leg from positioning on the fracture table (2,11). Similarly, there have been many reports in the urology and gynecology literature on the development of compartment syndrome in legs placed in the lithotomy position (1,42,68). Most commonly, these patients are in the lithotomy or hemilithotomy position for prolonged periods of time (>4 hours). Heavy patients and periods of intraoperative hypotension may also be risk factors, although this has not been studied.

We have experienced three such cases of compartment syndrome in the well leg from positioning on the fracture table. All cases involved heavy patients and prolonged time in the well-leg holder. These cases, along with those reported in the literature, prompted an investigation in our lab into the pathophysiology of this complication.

We studied eight healthy volunteers positioned in the hemilithotomy position on a fracture table and found that the well-leg holder caused a significant increase in calf intramuscular pressure and a significant decrease in ankle blood pressure. More importantly, the well-leg holder caused a significant decrease in P, the difference between ankle blood pressure and calf intramuscular pressure. In the lateral compartment P averaged only 31 mm Hg, a level very close to the ischemic threshold of muscle as reported by Heppenstall et al. (25).

We recommend the use of alternate patient positions for complicated fracture cases which may take several hours to complete. We frequently place both legs in traction boots and "scissors" the limbs (Fig. 13.27), or use the lateral position on the fracture table. Supine or lateral positioning on an image table without the use of traction are also good alternatives. If the hemilithotomy position is used, we recommend palpating the well-leg compartments and temporarily lowering the limb every 2 to 3 hours. After all fluoroscopic images have been obtained, the well leg should be immediately placed into a more relaxed, lowered position.

![Figure 13.27](image)

*Figure 13.27. Several cases have been reported in the literature of compartment syndrome of the leg from the use of a well-leg holder. This places the limb at 90° of flexion at both the hip and knee, and the elevated leg rests on a support (A). In complicated fracture cases, which may take several hours to complete, we recommend alternate limb positioning, such as the "scissors" position (B).*
EARLY RECOGNITION

Frequent patient rounds by the treating physicians and nurses to examine the peripheral neurovascular status are extremely important. We educate our nurses, medical students, and residents on the evaluation and early recognition of patients with compartment syndrome.

Having a high index of suspicion is the best way to recognize an early compartment syndrome. Often, the patient is unable or unwilling to cooperate with a physical exam, and the treating physician must rely on his or her knowledge of the disorder and use early intracompartmental pressure monitoring. The risk of measuring compartment pressures is nominal compared with the risk of missing a compartment syndrome. We generally teach residents and students that the time to measure intracompartmental pressures is when they first think about it.

PRESSURE MONITORING

We most commonly use the slit catheter connected to an arterial line pressure transducer and recorder to measure compartment pressures. These are readily available in intensive care units, recovery rooms, emergency rooms, and, of course, the operating room. We also use the hand-held Stryker unit with the slit catheter or the side-port needle alone. When measuring pressures, we take multiple readings throughout each compartment and immediately document them. In patients who are obtunded or comatose and who are in a monitored setting, we frequently employ continuous intracompartmental pressure monitoring when initial pressures are elevated but not above the threshold for fasciotomy.

EARLY TREATMENT

An acute compartment syndrome is a true surgical emergency. Although it may take 4 to 6 hours for irreversible muscle damage to occur, it is usually impossible to determine the length of time the compartment pressure has been elevated and at what pressure. Furthermore, delaying treatment usually leads to poor outcome.

OPERATIVE TECHNIQUES

For forearm compartment syndrome, we perform Henry’s curvilinear volar incision, as this allows access to the entire forearm, neurovascular structures, mobile wad, and radius if fixation is required. After volar release, the dorsal compartment is measured, and, if necessary, this compartment is released through a single dorsal incision.

For compartment syndrome of the leg, we routinely use the two-incision technique. This allows excellent visualization and easy release of all compartments. The deep posterior compartment is readily accessible through the medial incision, even in patients with severe swelling. Usually one of the incisions can be closed in a delayed fashion, and skin grafting is then required only for the second wound. A potential disadvantage to the two-incision technique is that it tempts the inexperienced surgeon to use short incisions in the midcalf. We use fairly extensive incisions, as the risks of “blind” fasciotomy are significant. Another potential disadvantage to this technique is uncovering of the posteriormedial edge of the tibia if the skin incision is not properly placed. It is very important to make the posteroomedial incision several centimeters below the posterior margin of the tibia in order to prevent this complication.

Other authors have advocated the use of the single lateral incision for fasciotomies of the leg (33,35). One advantage to this technique is that it is cosmetically more acceptable, as it is less visible from the front. It must be an extensile incision, and this minimizes the risk of injury to neurovascular structures. Although the wound could potentially be closed secondarily in its entirety, this is usually not the case; similar to the two-incision technique, a portion of the wound usually requires coverage with a split-thickness skin graft. A potential disadvantage to the single-incision technique is that the deep posterior compartment is more difficult to reach, particularly in a very swollen limb. The approach, however, is similar to the Harmon posterolateral approach to the tibia for bone grafting, an approach used commonly by many orthopaedic surgeons.

We routinely place a tourniquet on the limb but do not elevate it unless absolutely necessary. Inflation of the tourniquet during compartment release simply adds to the ischemia time. With careful dissection, blood loss can be kept to a minimum. Debridement of obviously necrotic and other nonviable muscle is done primarily at the time of compartment decompression. If, however, the viability of an area of muscle is in question, we do not debride this area but rather reevaluate the wound in 24 to 48 hours. In acute compartment syndrome, we never close the fasciotomy wounds primarily and always return the patient to the operating room in 24 to 48 hours for repeat debridement. Frequently, a patient may require multiple debridements before the wound is clean enough for delayed primary closure or split-thickness skin grafting.

After fasciotomy, we frequently place vessel loops through staples placed near the wound edges. This prevents the skin edges from retracting significantly, and they can also be intermittently tightened to help decrease the wound size, particularly in the sick patient who is too unstable to return to the operating room within the first few days after fasciotomy. It is very important not to place the vessel loops too tight initially. The dermotomy is an essential component to compartmental release, and tightening the skin could significantly increase the intracompartmental pressure.

Occasionally we have employed the use of a skin closure system, such as the Sure-Closure (Life Medical Sciences, Inc., Princeton, NJ), to help close fasciotomy wounds in a delayed fashion. There are several such devices on the market; when properly used, they can obviate the need for a skin graft or at least significantly decrease the size of the graft.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Injury to the musculoskeletal system is commonly associated with blunt trauma. An isolated injury rarely poses any threat to life, but, when associated with multiple injuries, a musculoskeletal injury assumes greater significance. Trauma is the leading cause of death in persons between the ages of 1 and 45 years. It is estimated that there are 150,000 deaths annually from accidents alone. The cost in lost years and dollars from death and disability exceeds that of heart disease, stroke, and cancer combined (1). Trauma remains a major social and economic affliction (2). Proper management can greatly reduce the mortality and morbidity associated with these injuries (3).

PREOPERATIVE MANAGEMENT

FIELD TRIAGE

Management of the multiply injured patient begins in the field with initial contact by the emergency medical technicians. Their job is to initially evaluate and, if necessary, resuscitate the patient; to extricate the patient; and to safely transport him or her to the appropriate facility. The emergency medical technicians should obtain a history of the accident to better understand the mechanism of injury and relate that information to the treating physician. They should assess the airway and, when properly trained, perform endotracheal intubation if needed. Although intravenous access is beneficial, it should not be obtained at the expense of time in transfer of the patient from the scene to the trauma center (Table 14.1).

<td>Patient is hypotensive secondary to their injuries are often placed in pneumatic antishock garments (PASG). When there is life-threatening hemorrhage and severe loss of blood pressure, these garments may be inflated to 100 mm Hg, and the patient is sent immediately to the trauma center for resuscitation and gradual release of the PASG. If prolonged use of the garments is necessary, do not inflate to more than 30 mm Hg because of the increased risk for compartment syndrome and soft-tissue loss with lower extremity injuries (7). The PASG has been a good device for initially stabilizing pelvic fractures, helping to tamponade hemorrhage with some reduction and stabilization of the pelvic fracture or separation (12).</td>

EMERGENCY ROOM MANAGEMENT

Initial management of the multiply injured patient in the emergency room has been well studied, and protocols have been developed by the Committee for Trauma of the American College of Surgeons (6). Their courses on advanced trauma life support (ATLS) have shown that assessment of the patient in an orderly fashion has improved the care and reduced the incidence of missed injuries. Patient management requires rapid primary evaluation, resuscitation of vital functions, a more detailed secondary assessment, and definitive care.

Primary Survey

Airway The primary concern for any injured patient is to establish an airway for adequate oxygenation. In establishing and maintaining an airway, it is important to control the cervical spine to avoidiatrogenic neurologic injuries if the cervical spine is unstable. Examine the trauma patient to be certain that the airway is cleared of any obstructions, such as foreign objects, loose teeth, blood, mucus, or vomitus. In the unconscious patient, protect the cervical spine with longitudinal traction. Keep the mandible elevated to clear the airway of the patient's tongue. Take a cross-table lateral radiograph of the cervical spine as soon as possible to rule out cervical injury that could be exacerbated with motion. Quickly assess the patient's ability to oxygenate by inspecting an arterial blood gas sample to see whether the arterial blood is red or dark, indicating the state of oxygenation.

Breathing Inspect the patient's chest for movement to assess air exchange. Airway patency does not necessarily mean that the patient is adequately exchanging oxygen; this can be determined through an arterial blood gas sample. Inspect for evidence of a flail segment in the chest with paradoxic movement. Cover and clean open chest wounds with a Vaseline gauze dressing. If the patient does not appear to be ventilating adequately (i.e., patient is using accessory muscles in the neck to help breathe), and the arterial blood gas is dark, perform endotracheal intubation. If you are not experienced in endotracheal intubation, use a mask and bag valve device with an oral airway first to oxygenate the patient. Endotracheal intubation in the trauma patient can be difficult and should be performed by the most experienced hands. Causes of inadequate oxygenation must be found. If no flail segments are visible, palpate the rib cage for tenderness or crepitus caused by rib fractures.

Auscultate the chest to listen for proper breath sounds bilaterally to help rule out a pneumothorax. If no cause is found for the patient's inadequate oxygenation, perform bilateral tube thoracostomy to decompress potential bilateral pneumothoraces.
Perform endotracheal intubation to obtain control of the airway and provide adequate oxygenation for any patient with inadequate or labored ventilation or flail chest and for patients who are unconscious and unable to control the airway, those with facial fractures, multiply injured patients, and those with deteriorating blood oxygenation. If a cervical spine injury is suspected or has not been ruled out, perform nasotracheal or fiberoptic intubation with proper longitudinal control of the head and cervical spine. Oral endotracheal intubation is preferred because a larger tube can be placed. Rarely, a surgical cricothyroidectomy may be needed to obtain access to the airway.

Circulation Hypotension is a result of hypovolemia in the trauma patient until proved otherwise. Shock is caused by and defined as inadequate oxygen delivery to soft tissues. Assess cardiac output by palpation of peripheral pulses and observe skin color and capillary refill. As a general rule, if the radial pulse is palpable, the systolic blood pressure is 80 mm Hg. The femoral pulse indicates a pressure of 70 mm Hg, and the carotid pulse a pressure of 60 mm Hg. Normally, capillary refill requires less than 2 s. A delay of longer than 2 s indicates hypotension. Additional indicators of hypovolemia are decreased bicarbonate and acidosis found in the arterial blood gas samples. Hemorrhagic shock requires rapid fluid resuscitation. Initially, insert two large-bore angiocaths and give a 2-L bolus of lactated Ringer's solution.

Occasionally, a trauma patient is hypotensive secondary to nonhypovolemic shock. Rule out causes of myocardial dysfunction such as cardiac contusion with arrhythmias or cardiac tamponade or myocardial infarction. A history of direct blow to the sternum from a deceleration injury suggests myocardial contusion. The combination of distended neck veins, decreased arterial pressure, and muffled heart sounds (Beck's triad) is diagnostic of a cardiac tamponade. Electrocardiographic changes may indicate an acute myocardial infarction. In the patient with a history of cardiac injury, perform cardiac monitoring and insert a Swan-Ganz catheter. In the patient with the clinical suggestion of a cardiac tamponade, decompress the tamponade emergently with pericardiocentesis. Monitor arrhythmias secondary to myocardial infarction or contusion and manage with appropriate medication.

The patient in hypovolemic shock is best monitored by pulse, blood pressure, and urine output. Repeat arterial blood gases as necessary. The effectiveness of oxygenation is reflected through the oxygen saturation (PO₂), and the effectiveness of fluid resuscitation through the pH and bicarbonate levels. Constantly reassess the patient to be certain adequate resuscitation and oxygenation are maintained. Prolonged shock contributes to pulmonary distress syndrome, hepatic dysfunction, renal failure, gut-origin septic state, and multisystem organ failure.

Evaluate the patient's level of consciousness with a brief neurologic examination. The Glasgow Coma Scale (Table 14.2) was developed as an easy and reproducible scale for evaluating the patient's level of consciousness (10). A score may range from 3 to 15, with a score of less than 8 signifying serious neurologic injury. Repeat determinations of the Glasgow Coma Scale are helpful in determining changes in the patient's mental status. In addition to the Glasgow Coma Scale, evaluate for focal signs such as unequal pupils and doll's eyes, which point to an expanding intracranial lesion.

Secondary Survey

**Extremity Injuries** Palpate and examine the extremities, looking for abnormal swelling, instability, or crepitus suggesting musculoskeletal injury. Perform a careful neurologic examination. Check pulses bilaterally for any decrease in peripheral blood flow. Perform arteriography in any patient with major skeletal injury in whom the distal pulses in the injured limb are weaker than those in the opposite extremity. Be alert for vascular injury in patients with supracondylar humerus fractures, supracondylar femur fractures, dislocations of the knee, and crush injuries of the tibia. Reduce dislocations as soon as possible, dress open fractures and extremity wounds, and splint fractures immediately. Splint femur fractures with traction. Begin appropriate bacteriocidal broad-spectrum intravenous antibiotics in patients with open fractures.

**Neurologic Examination** Perform an in-depth neurologic examination. Reassess the patient's level of consciousness with the Glasgow Coma Scale and pupillary reflexes. Assess rectal tone and perianal sensation. Examine and palpate the back for swelling and tenderness. Obtain appropriate spine radiographs. Remember that the cervical spine should be assumed to be injured and protected until radiographic evidence reveals otherwise.

**PRINCIPLES OF TREATMENT**

The basic principle of management of the musculoskeletal injury in the polytrauma patient is to obtain a stable skeleton as early as possible, given the overall condition of the patient. Once the patient is properly resuscitated and hemodynamically stable, then stabilization of the skeleton can reduce the physiologic response to trauma and lessen the risk of adult respiratory distress syndrome (ARDS) and multiple system organ failure (2,3,11,17,21). Priorities include external fixation of the anterior pelvis of hemodynamically unstable patients, reduction of dislocations, repair of vascular injuries, debridement of open fractures, stabilization of long bone fractures (especially the femur), and stabilization of the unstable spine (Table 14.3).

### Table 14.3. Priorities in the Operative Treatment of Musculoskeletal Injuries in the Multiply Injured Patient

Intraarticular fractures can be splinted or spanned with external fixators until the soft tissue swelling subsides. Upper extremity fractures, if not treated definitively at the initial surgery, can be fixed at a later time.

The Committee on Trauma of the American College of Surgeons developed an outline of management (Table 14.4) for the optimal care of the injured patient with musculoskeletal trauma (6). The algorithm in Fig. 14.1 is a guide to the management of the multiply injured patient with fractures.
Head-injured patients cannot be monitored for swelling or pressure sores inside a cast and do not tolerate traction well. Operative stabilization with intramedullary rods, plating of periarticular fractures, and external fixation is preferable to casting or traction. Unresponsive or combative the musculoskeletal care that is essential for stabilization and early mobilization of acetabular fractures. With proper monitoring of intracranial pressure, good fluid resuscitation, and oxygen transport, the patient usually can tolerate the anesthetic for open fractures and long bone injuries and timely care of spinal, pelvic, and shoulder girdle injuries.

In a life-threatening situation, such as a ruptured spleen, lacerated liver, or aortic arch rupture, the head-injured patient must undergo general anesthesia. The patient should also undergo early total care with management of the musculoskeletal system for open fractures and long bone injuries and timely care of spinal, pelvic, and acetabular fractures. With proper monitoring of intracranial pressure, good fluid resuscitation, and oxygen transport, the patient usually can tolerate the anesthetic for the musculoskeletal care that is essential for stabilization and early mobilization.

Operative stabilization with intramedullary rods, plating of periarticular fractures, and external fixation is preferable to casting or traction. Unresponsive or combative head-injured patients cannot be monitored for swelling or pressure sores inside a cast and do not tolerate traction well.

**Table 14.4. Care of the Injured Patient with Musculoskeletal Trauma**

**Figure 14.1. Multiple trauma algorithm.**

**PELVIC RING INJURIES**

The patient with unstable pelvic ring injuries who is hemodynamically unstable should have an anterior external fixator applied to temporarily stabilize the pelvis and reduce the bleeding into the pelvis (12). This is an emergency procedure that should be done before angiography. It can be done in the emergency department or in the operating room. If possible, it should be performed on the unstable patient before a laparotomy.

**FRACTURES WITH CONCOMITANT VASCULAR INJURY**

The combination of a fracture and vascular injury requires prompt management. Although there is some debate about which should be addressed first, vascular injuries or fractures, I strongly believe that vascular repair should be performed first. This should be performed after temporary stabilization of the fracture.

Temporary fracture stabilization can be done with an external fixator, a femoral distractor, or with the patient placed in traction on a fracture table. This will place the fractured bone at proper length and provide minimal stabilization to the limb for vascular repairs. Reconstruction of the vascular repair has priority to reduce the time of ischemic hypoxia to the limb.

**FRACTURES AND COMPARTMENT SYNDROME**

The patient with multiple trauma is at special risk to develop a compartment syndrome because of systemic hypotension. A high index of suspicion is needed. Limbs with crush injuries and/or vascular injuries in patients subjected to prolonged shock with fluid resuscitation may experience reperfusion injury and require fasciotomies (15). Although the lower leg and forearm are the most common places to develop a compartment syndrome, any closed compartment is at risk. Open fractures as well as closed injuries may be associated with compartment syndrome.

**FRACTURES WITH OPEN SOFT-TISSUE INJURY**

Treat all open fractures acutely. Proper cleansing, irrigation, and debridement of devitalized tissue are essential. Perform immediate stabilization to reduce fracture motion and further soft tissue damage. Use external fixation or, more commonly now, unreamed or minimally reamed intramedullary nails to stabilize open long bone fractures. Periarticular and intra-articular fractures can be plated or stabilized with tensioned-wire external fixators. Delay soft tissue closure of traumatic wounds. Grade IIIB injuries should have soft tissue reconstruction (local or free flaps) within 72 h if possible.

**UNSTABLE SPINE FRACTURE-DISLOCATIONS**

Unstable spine fracture-dislocations are best stabilized in the primary phase, 24 to 48 h postinjury (15). This allows the patient to be mobilized. Patients who exhibit progressive loss of neurologic function on repeat neurologic examination should be decompressed and stabilized acutely.

**FRACTURE TREATMENT IN THE SECONDARY PHASE**

With the patient's hemodynamic and respiratory status stable, additional fracture management can be addressed: fractures of the acetabulum or posterior pelvis; closed upper extremity fractures; and intrarticular fractures. Perform secondary evaluation of open wounds at this time. Special care needs to be given to those patients with continued respiratory insufficiency, febrile septic state, and liver dysfunction. Patients with decreased platelets (less than 180,000), neutrophil elastase greater than 85 ng/dl, and C-reactive protein greater than 11 ng/dl are at risk of secondary organ failure with secondary surgery 72 h postinjury (22).

**STABILIZATION OF MUSCULOSKELETAL INJURIES UNDER SPECIAL CIRCUMSTANCES**

**Head Injury**

Management of the head-injured patient with multiple injuries presents a special problem. Most of these patients are intubated in the field or in the emergency room because of their severe injuries. It is important to rapidly reverse hypovolemic shock and to maintain high oxygen transport to reduce further neurologic damage. Physical examination followed by computed tomography of the head is needed for diagnosis of the injury. The neurosurgeon treats the patient with an intracranial lesion that needs decompression in the operating room under general anesthesia. If neurosurgical decompression is unnecessary, perform intracranial monitoring through an intracranial bolt or ventricular catheter. Increased intracranial pressure can be managed medically with fluid management and osmotic diuretics and by decreasing the serum carbon dioxide (P\textsubscript{\text{CO}}\textsubscript{2}) with hyperventilation. If necessary, cerebral spinal fluid can be withdrawn to reduce intracranial pressure (15,19).

In a life-threatening situation, such as a ruptured spleen, lacerated liver, or aortic arch rupture, the head-injured patient must undergo general anesthesia. The patient should also undergo early total care with management of the musculoskeletal system for open fractures and long bone injuries and timely care of spinal, pelvic, and acetabular fractures. With proper monitoring of intracranial pressure, good fluid resuscitation, and oxygen transport, the patient usually can tolerate the anesthetic for the musculoskeletal care that is essential for stabilization and early mobilization.

Operative stabilization with intramedullary rods, plating of periarticular fractures, and external fixation is preferable to casting or traction. Unresponsive or combative head-injured patients cannot be monitored for swelling or pressure sores inside a cast and do not tolerate traction well.
Pulmonary Contusion and Femur Fractures

Early stabilization of femur fractures in the polytrauma patient has been shown to reduce the risk of adult respiratory distress syndrome (ARDS) and respiratory dysfunction as well as to reduce time on a ventilator, time in the intensive care unit, and cost of care (6, 11, 17). Recent research has shown that manipulation of the femoral canal—that is, entering the proximal canal, placement of a guide rod, reaming and placement of an intramedullary nail—causes fat and marrow contents to be released into the venous system and embolized to the heart and lungs (9, 23). There was some concern that this embolization caused the development of ARDS in those patients with already compromised oxygenation because of chest injury, that is, pulmonary contusion (13, 14). However, good animal and clinical studies have shown no increased ARDS with acute intramedullary nailing of femur fractures in patients with pulmonary contusion (5, 24, 25).

Intubate and oxygenate these patients appropriately. They need to be well hydrated and hemodynamically stabilized. Acute fracture stabilization can be safely performed with intramedullary nailing. Because there is less embolization with the unreamed femoral nail, this is the recommended treatment of choice in patients with pulmonary contusion or other compromise of pulmonary function (3, 21). If the patient is not well oxygenated or hemodynamically stable, then temporary fracture stabilization with external fixation can be performed.

Those patients who are not hemodynamically stable after surgery for life-threatening injuries of the chest or abdomen, or who have a coagulopathy or hypothermia, should be taken to the intensive care unit, resuscitated, warmed, and well oxygenated. With a stable patient, fracture fixation can proceed as outlined. In critical situations where the patient is systematically unstable, perform temporary stabilization with external fixation.

CONCLUSIONS

Early total care of the multiply injured patient reduces the risk for life-threatening complications such as ARDS and multiple system organ failure. Protocols need to be developed that include management of general surgical and neurosurgical injuries, followed by fracture stabilization. Special considerations have to be made for the patient with pulmonary contusion or head injuries. These considerations do not prevent proper stabilization of the skeleton.

Case Study

The following case report illustrates how effective early total care can be. (Case of Michael Chapman, M.D., University of California, Davis, Department of Orthopaedic Surgery, Sacramento, California.)

History

A 29-year-old woman sustained multiple injuries in a high-speed motor vehicle accident. After a prolonged extrication from her vehicle, she was transported by helicopter to the University of California, Davis, Medical Center. She was found to be unconscious at the scene of the accident but subsequently regained consciousness and had a score on the Glasgow Coma Scale of 15. On arrival in the emergency room, she was complaining of left-sided chest pain and was short of breath.

Physical Examination

Vital signs in the emergency room showed blood pressure 100 over 60, heart rate 158, and respiration 20. She was in shock and hemodynamically unstable despite efforts at resuscitation. Her abdomen was swollen and tender throughout. She was intubated in the emergency room, and a left chest tube was placed for a hemopneumothorax. She had obvious deformity of all four extremities with wounds on the left upper and left lower extremities consistent with multiple open fractures. Her wounds were dressed, and fractures splinted. Further orthopaedic evaluation and x-rays were not possible because of the patient's unstable status. She was rushed immediately to the operating room for a laparotomy.

Surgery

At surgery, laparotomy revealed a ruptured spleen and liver, laceration of the colon, and a perinephric hematoma. The spleen was removed, and a partial lobectomy of the liver was performed. The laceration of the colon was repaired. After the laparotomy she was hemodynamically stable. Because of the potential for a head injury, she then had a CT scan of the head, which was negative. She was then returned to the operating room for orthopaedic evaluation and procedures.

Physical evaluation of the patient under anesthesia and multiple x-rays revealed a normal cervical, thoracic, and lumbar spine and the following 10 fractures:

1. Grade II open, somewhat comminuted midshaft fracture of the left humerus (Fig. 14.2).
2. Closed fracture of the medial condyle of the humerus (Fig. 14.2).
3. Grade II open transverse midshaft fractures of the left radius and ulna (Fig. 14.2).
4. Closed midshaft fracture of the right humerus (Fig. 14.3).
5. Closed transverse fracture of the distal third of the right ulna (Fig. 14.4).

![Figure 14.2. Anteroposterior x-ray of the left arm, elbow, and forearm showing fractures of the midshaft humerus, medial condyle of the humerus, and midshaft radius and ulna.](image)

![Figure 14.3. Fracture of the right humeral shaft.](image)
6. Grade II open, midshaft, slightly comminuted fracture of the left femoral shaft (Fig. 14.5).

7. Grade II open, severely comminuted pylon fracture of the left ankle involving the tibia and fibula (Fig. 14.6).

8. Closed transverse midshaft fracture of the right femur (Fig. 14.7).

9. Careful examination of both hips and AP and lateral x-rays in internal rotation showed no evidence of fracture of the femoral neck. In follow-up, an undisplaced fracture of the left femoral neck was found and fixed with cannulated screws.

10. Pelvic x-rays showed minor pubic rami fractures.

**Orthopaedic Procedures** Two orthopaedic teams were available, an attending surgeon with a second-year resident and a trauma fellow with a third-year resident. The patient was on a radiolucent operating table, and a fluoroscope was available. The patient was rolled into the right lateral decubitus position, and the left lower and left upper extremities were operated simultaneously. All of the open fractures were irrigated and debrided, and the wounds were left open. The midshaft fracture of the left humerus was double-plated with a 3.7 titanium plating system. The left elbow was opened through a medial approach, and the medial condyle fracture was fixed with two interfragmentary screws (Fig. 14.8). The midshaft fractures of the left radius and ulna were compression plated (Fig. 14.9). In the lower extremity, the open midshaft femur fracture was nailed with a nonreamed antegrade femoral nail using open technique (Fig. 14.10). The proximal cross-locking screw was placed, but distal cross-locking was not carried out in order to save time. The pylon fractures of the left distal tibia and fibula were reduced after debridement of the wound, and the leg was placed in a delta-frame-type external fixator (Fig. 14.11).
The patient was then rolled into the left lateral decubitus position, and simultaneous surgery was carried out on the right upper and right lower extremities. The humerus fracture was internally fixed with an antegrade intramedullary nail utilizing closed technique. The right femur was fixed with an intramedullary nail, nonreamed, inserted antegrade, with a small exposure of the fracture site to permit reduction and passage of the nail. Distal cross-locking was not carried out (Fig. 14.12).

The total time from arrival in the operating room for the general surgical procedures until completion of the last orthopaedic procedure and transfer to the surgical intensive care unit was 20 h, including the time required to take her to the CT scanner for examination of her brain.

In the intensive care unit she did extremely well and was extubated on her second postoperative day. Her chest tube was removed on the third postoperative day. On the fifth day after injury, she was returned to the operating room, where all of her open wounds were redebrided, irrigated, and closed. Because of segmental deficiency in the left humerus, a bone graft from the left iliac crest was placed. The distal cross-locking was carried out on both femoral nails, and the pylon fracture was reduced, closed, and fixed with two percutaneously inserted cannulated screws (Fig. 14.13).
Postoperatively it was possible to begin range-of-motion and rehabilitation on all of her extremities. She was discharged from the hospital on her ninth postoperative day, transferring from bed to wheelchair.

We recommended that she avoid weightbearing on all of her extremities until at least 6 weeks postoperatively. Apparently through a misunderstanding, the patient began full weightbearing on both lower extremities and her left upper extremity at about 4 weeks postinjury. Because of that, she bent the plates in the left humerus and bent her right femoral nail.

At 41 days after injury, she was returned to the operating room, where plates on the left humerus were converted to a locked intramedullary nail. The right femoral nail was exchanged for a statically locked reamed nail. At that time she was complaining of pain in the left hip. X-rays revealed an undisplaced fracture of the left femoral neck. This was fixed with percutaneous cannulated screw fixation anterior to the femoral nail (Fig. 14.14). There was excellent early callus around the pylon fracture; therefore, her external fixator was removed, and she was placed in a cast.

By 9 weeks she was fully weightbearing on all extremities and rehabilitating nicely. At 20 weeks she showed delayed union of the right femoral fracture; therefore, her nail was dynamized by removing the distal cross-locking screws.

She went on to heal all of her fractures uneventfully and subsequently married and returned to work. She has excellent function in all of her extremities with no limitations other than some minor loss of motion in her left hip and about 50% loss of motion in her left ankle.

Commentary: The scenario of this patient outlines the excellent results that can be achieved but also illustrates some of the pitfalls and complications that can occur in these challenging patients. This patient was cared for in the early 1990s. Today she would be managed in the supine position on a radiolucent table with the femur fractures fixed with retrograde nails and the upper extremity injuries managed simultaneously by two teams (Table 14.5).

Table 14.5. Management of Combined Injuries

The scenario following this patient’s abdominal surgery could also have found her to be hemodynamically unstable, with a coagulopathy and hypothermia. The patient would then have been best managed either with temporary external fixation of her femur and tibia fractures or, generally more appropriately, with temporary skeletal traction, then taken to the intensive care unit and resuscitated. Once her vital signs were stable and oxygenation was adequate, and she was rewarmed and no longer coagulopathic (generally within 12 to 24 h), she could be returned to surgery where, again, two teams could be used to perform the surgery as described.

SCAPULAR FRACTURES

Scapular fractures account for approximately 1% of all fractures in the body and 3% of all injuries involving the shoulder girdle. Although scapular fractures are relatively uncommon injuries, they are important not only because of the problems they create for shoulder function but also because they may be the harbinger of other injuries. Scapular fractures usually are diagnosed in patients who have sustained violent blunt trauma, and up to 96% of patients with those fractures have associated injuries (2). For that reason, scapular fractures have been referred to as “sentinel injuries” (Table 15.1) (51,138).

Table 15.1. Common Injuries Associated with Scapula Fractures (2,86,103,138)

RELEVANT SURGICAL ANATOMY

The scapula is almost completely covered by muscle on both its anterior and posterior surfaces (Fig. 15.1). The muscles keep the scapula relatively protected from injury and help explain why most fractures occur only after high-energy impact and why fractures of the scapular body frequently can be treated nonoperatively. The lateral aspect of the scapula has three bony processes, each related to important soft tissue structures that can influence surgical decision making:
1. The coracoid process projects anteriorly, superiorly, and laterally from the anterior-superior border of the scapula. The pectoralis minor, coracobrachialis, and short head of biceps originate from it (Fig. 15.2), and all three muscles may contribute to the deforming forces acting on scapular fractures. The conoid and trapezoid ligaments, which make up the coracoclavicular ligament complex, originate from the coracoid process and insert on the inferior surface of the clavicle (Fig. 15.2). The ligaments are key stabilizing structures for the distal clavicle, and their integrity is an important factor in deciding whether or not surgical treatment is indicated. The suprascapular nerve traverses the superior border of the scapula through the scapular notch located just medial to the base of the coracoid process, and the brachial plexus and axillary artery and vein travel below the coracoid process adjacent to its base (Fig. 15.3).

2. The acromion is the lateral extension of the scapular spine. It curves anteriorly to form the acromioclavicular joint with the clavicle (Fig. 15.2 and Fig. 15.3). The supraspinatus and infraspinatus muscles travel below the acromion to insert into the humeral head (Fig. 15.1 and Fig. 15.3). The potential for impingement on these muscles from a fractured and tilted acromion is an important determinant of operative treatment. The coracoacromial ligament is a stout ligament that runs between the coracoid process and the anterior-inferior aspect of the acromial process (Fig. 15.2). Occasionally this ligament may be used to stabilize a distal clavicle rendered unstable by injury, but it should be preserved whenever possible to maintain the integrity of the coracoacromial arch (122).

3. The glenoid process (neck) is the lateral extension of the scapular body and supports the glenoid fossa, which is the articular platform for the humeral head. Relative to the scapular spine, the glenoid fossa is retroverted an average of 6° (129). Posteriorly, the supraspapelar nerve and artery run along the base of the glenoid process as they exit the spinoglenoid notch before supplying the infraspinatus muscle (Fig. 15.3). These structures are at risk for injury during a posterior approach to the glenoid and from displaced fracture fragments.

One other feature of the bony anatomy of the scapula has relevance for surgical decision making. The thin bone that makes up a large portion of the scapular body is not well suited for internal fixation. There are, however, regions that have bone stock adequate to accommodate screw or wire fixation, including the coracoid process, the acromial process, the base of the scapular spine, the glenoid process, and the lateral scapular border (44).

Finally, the concept of the superior shoulder suspensory complex (SSSC), popularized by Goss (45), should be understood because it provides a useful framework for considering shoulder injuries and their treatment. The SSSC is a bony and soft tissue ring composed of the glenoid process, the coracoid process, the acromial process, the coracoclavicular (CC) ligaments, the acromioclavicular (AC) joint, and the distal end of the clavicle. This ring is supported by two bony struts: the clavicle superiorly and the lateral border of the scapula inferiorly (Fig. 15.4).
Isolated injuries to the components of the SSSC such as AC separations or isolated distal clavicle fractures are typically stable injuries and respond well to nonoperative treatment. When the SSSC is injured in two places, however, a so-called double disruption (Fig. 15.5), one or both of the injuries may become significantly displaced because the ring is left unstable. Double disruptions often lead to delayed union, malunion, or nonunion and secondarily to decreased strength and muscle fatigue and, possibly, neurovascular compromise. Osteoarthrosis may result when one of the disruptions involves a joint surface. Examples of double disruptions of the SSSC include a clavicle fracture together with an AC joint disruption, a glenoid neck fracture with either an AC joint disruption or clavicle fracture, and unusual combinations such as ipsilateral fractures of the acromion and coracoid process (45). The most common sequela is anterior, medial, and inferior displacement of the scapula secondary to the weight of the arm and the combined pull of the pectoralis major, pectoralis minor, and latissimus dorsi muscles.

**Figure 15.5.** Types of traumatic ring strut disruptions. Single disruptions of the bone–soft-tissue ring may be a break (A) or a ligament disruption (B). Double disruptions of the bone–soft-tissue ring may be a double-ligament disruption (C), a double break (D), or a combination of a bone break and a ligament disruption (E). Other double disruptions may be a break of both struts (F) or a break of one strut and a ring disruption (G). (© 1995 American Academy of Orthopaedic Surgeons. Reprinted from Goss TP. Scapular Fractures and Dislocations: Diagnosis and Treatment. *J Am Acad Orthop Surg* 1995;3:22, with permission.)

**RADIOGRAPHIC EVALUATION**

A high index of suspicion is necessary to make the diagnosis of a scapular fracture in an acutely injured patient. In one large series, one third of the scapular body fractures were not diagnosed or recorded at the time of the patient’s admission to the hospital (138). Scapular fractures may be evident on the chest x-ray obtained as part of the initial evaluation of a multiply injured patient. More often, special-view radiographs—including scapular anteroposterior, scapular lateral, and axillary views—are necessary to better define the fracture pattern. Computed tomography (CT) scans are useful for detailed assessment and preoperative planning of intraarticular and glenoid neck fractures. Frequently they can be obtained when the patient goes to the CT scanner for evaluation of other injuries.

Scapular fractures are best characterized by anatomic regions because the criteria for operative and nonoperative treatment and the expected outcomes vary accordingly. The regions and the approximate incidence of scapular fractures that occur in each are scapular body (35%), glenoid neck (27%), acromion (12%), scapular spine (11%), glenoid fossa (10%), and coracoid process (5%) (Fig. 15.6) (2). Diagnosis and treatment of these fractures are discussed by anatomic region.

**Figure 15.6.** Incidence of scapular fractures by anatomic location. (From Ada JR, Miller ME. Scapular Fractures: Analysis of 113 Cases. *Clin Orthop* 1991;269:174.)

**SCAPULAR BODY FRACTURES**

The body of the scapula is covered with dense muscular attachments (Fig. 15.1); therefore, extreme force usually is necessary to produce scapular body fractures. Because of the rich blood supply to this region and the stabilizing effect of the surrounding muscular envelope, healing usually occurs uneventfully, and nonunion is rare. Focus treatment on symptomatic relief. Prescribe ice to the local area and sling immobilization of the arm for comfort. Within a week of injury, begin pendulum exercises and advance to the use of overhead pulleys and active-assisted range-of-motion exercises as soon as the patient’s symptoms allow. Malunion with significant displacement may produce a snapping or grating sensation with scapulothoracic motion, but patients rarely complain of restricted motion or pain that limits function (2).

**GLENOID NECK FRACTURES**

Fractures of the glenoid neck occur in three basic patterns (Fig. 15.7): (a) fracture of the anatomic neck; (b) fracture of the surgical neck; and (c) fracture of the inferior neck coursing inferior to the scapular spine to exit along the medial scapula border, leaving the superior portion of the glenoid intact (Fig. 15.8) (46). These fracture patterns can be identified on the standard shoulder trauma x-ray series, but CT scans are helpful in clearly defining the fracture anatomy and assessing associated injuries to the shoulder girdle.

**Figure 15.7.** Three major fracture patterns of the glenoid process. A: Anatomic neck. B: Surgical neck. C: Fracture of the inferior neck, which then courses along the inferior aspect of the scapular spine to exit at the medial border of the scapula. (Redrawn from Goss TP. Fractures of the Glenoid Neck. *J Shoulder Elbow Surg* 1994;3:42.)
In addition to fracture pattern, fracture displacement is important for deciding treatment. Excessive translation and angulation can lead to shoulder dysfunction from altered rotator cuff mechanics and pain. Therefore, we consider glenoid neck fractures as one of two types, as suggested by Goss (46). Type I fractures are undisplaced or insignificantly displaced; type II fractures are displaced at least 1 cm or angulated at least 40° (Table 15.2). Any fracture pattern (A, B, or C) may be either type I or type II. Type I fractures are usually stable and heal satisfactorily because the superior shoulder suspensory complex is disrupted in only one place. Therefore, treatment is nonoperative and aimed at symptom relief. Provide an arm sling for patient comfort and ice the injured region. Instruct the patient to begin gentle pendulum exercises within 1 week and progressively increase use of the arm and shoulder as pain allows. The goal is to promote healing without developing debilitating shoulder stiffness, which often follows prolonged immobilization.

Table 15.2. Glenoid Neck Fractures

Type II fractures require operative treatment for optimum results (2, 141). If the displaced glenoid neck fracture is an isolated injury without a secondary disruption of the SSSC, then treat the fracture via open reduction and internal fixation (ORIF) through a posterior approach. Use interfragmentary fixation and/or a buttress plate as the fracture pattern dictates.

Frequently, in the setting of a type II glenoid neck fracture, there is an associated disruption in the SSSC, rendering the shoulder complex unstable. Most often the clavicle is fractured also; less commonly, the acromioclavicular joint is disrupted. Several authors have described this combination of injuries and the need for ORIF of one or both of them. Herscovici (59), Rikli (117), and Goss (49) suggest that ORIF of the associated injury—a clavicle fracture, for example—would indirectly reduce the glenoid neck fracture and is sufficient to restore stability to the shoulder complex. Leung et al. (81) recommended ORIF of both injuries, suggesting that more rigid fixation would allow more vigorous rehabilitation and better final results.

Authors’ Preferred Operative Technique

- If the displaced glenoid neck fracture is an isolated injury, then approach the fracture directly through a posterior approach. Retract the deltoid with an appropriate retractor rather than detaching it from its origin on the scapular spine whenever possible. Retract the infraspinatus superiority and the teres minor inferiorly to reach the glenoid neck.
- Use either a 3.5-mm reconstruction plate as a buttress plate or interfragmentary screw fixation to stabilize the fracture depending on the fracture configuration and fragment size (Table 15.2).
- If the glenoid neck fracture is associated with a second injury such as a clavicle fracture or acromioclavicular joint disruption, then address the injury that is more accessible first. Usually that means open reduction and plate fixation of the clavicle (Fig. 15.9). If the fixation is solid and reduces the associated glenoid neck fracture within the criteria listed above, then no further internal fixation is required. If the glenoid neck remains displaced beyond acceptable criteria, however, then we openly reduce and fix that fracture also.

Postoperatively, apply a sling and swathe or shoulder immobilizer and prescribe narcotics and local ice for pain control. Instruct the patient to begin progressive passive range-of-motion (ROM) exercises 48 to 72 hours after surgery. Allow functional use of the shoulder within defined limitations depending on the surgical approach and associated injuries. Patients should strive to achieve full shoulder motion by 8 to 12 weeks after surgery. Begin strengthening exercises at 12 weeks. The patient should avoid heavy lifting with the injured arm until that time.

FRACTURES OF THE GLENOID RIM AND GLENOID CAVITY

Fractures of the glenoid cavity make up approximately 10% of all scapular fractures, and only 10% of these are significantly displaced (2, 62, 86). If a glenoid fracture is suspected from physical exam (pain, swelling, ecchymosis, crepitus) or after review of a chest radiograph, obtain a shoulder trauma series to confirm the diagnosis, rule out a dislocation of the glenohumeral joint, and help determine if surgery is indicated. A CT scan is helpful for delineating the articular fracture pattern and is recommended before operative treatment.

Treat minimally displaced glenoid fossa and rim fractures not associated with humeral head subluxation or dislocation nonoperatively with early progressive ROM exercises as the patient’s pain decreases. Progressive shoulder strengthening begins when shoulder ROM has returned to normal. The majority of patients with glenoid...
FRACTURES OF THE ACROMION

For the purposes of this discussion, the acromion is defined as the bony continuation of the scapular spine lateral to the spinoglenoid notch. Acromion fractures account for 8% to 12% of all scapula fractures (44,67). Type I fractures represent a substantial portion of the glenoid rim and occur when a lateral force drives the humeral head into the glenoid rim. These should be differentiated from small capsular avulsions of bone associated with shoulder dislocations. They are considered unstable if they are displaced at least 1 cm or involve at least 25% of the anterior rim or 33% of the posterior rim (4,51,78,133).

Table 15.3. Glenoid Rim and Glenoid Cavity Fractures (44,63)

Type II fractures involve the glenoid fossa and can have several different fracture patterns depending on the position of the humeral head at the time of injury and the direction of the applied force. Type II fractures that are displaced 5 mm or more or associated with inferior subluxation of the humeral head require open reduction and internal fixation (47,61) (Fig. 15.10).

Type III and IV fractures require open reduction and internal fixation if there is an articular stepoff of 5 mm or more, lateral displacement of the superior fragment, or wide separation of the inferior and superior fragments. A posterosuperior approach is recommended for reduction of the fragments (44) and placement of a 3.5-mm or 4.0-mm interfragmentary lag screw from the superior fragment into the inferior fragment. When there is an associated injury to the SSSC, reduction and fixation of the glenoid surface may indirectly reduce the second injury of the double SSSC disruption. However, open reduction and fixation of the associated injury should be performed as well if fixing the glenoid surface does not reduce the second injury adequately. Type V fractures require open reduction and internal fixation if there is an articular stepoff of 5 mm or more, inferior displacement of the inferior glenoid fragment with subluxation of the humeral head, wide separation of the joint surfaces, or an associated SSSC injury leading to a separated superior glenoid fragment (44).

Type VI fractures are severely comminuted and rarely amenable to open reduction and internal fixation. Several nonoperative approaches to these difficult fractures have been advocated, including (a) a sling and swathe followed by early ROM; (b) immobilization in a shoulder abduction (“airplane”) splint and early ROM above the level of the splint as the patient’s symptoms allow; and (c) traction-suspension therapy with ROM within the ranges allowed by the traction setup (44,141).

In summary, the goal in treating fractures of the glenoid rim and fossa is to achieve a smooth articular surface and enough bony stability to allow full shoulder function. Frequently that can be achieved nonoperatively. In cases in which fracture displacement is significant and anatomic alignment cannot be achieved by closed manipulation, open reduction and internal fixation are indicated. Surgical approach, fixation techniques, and postoperative rehabilitation follow the principles outlined above for treatment of glenoid neck fractures.
The majority of acromial process fractures can be treated nonoperatively. Although nonunion or pseudarthrosis may result from fractures treated nonoperatively, most of these are not painful and do not lead to functional impairment. The occasional nonunion that is painful can be treated with bone grafting and internal fixation. There are however several indications for acute surgical treatment (Table 15.4). Avulsion fractures can be repaired with heavy suture through drill holes in the acromion. Table 15.4. Indications for Operative Treatment of Acromion Fractures

**Table 15.4.** Indications for Operative Treatment of Acromion Fractures

**Figure 15.13.** A: Tension band construct of a zone I acromion fracture using cannulated 4.0 screws and 18 gauge wire. K-wires can be used as well. B: Zone II fracture fixed with a contoured, curved 3.5-mm reconstruction plate.

Double disruptions of the SSSC involving the acromial process and the coracoid base usually are treated adequately with fixation of the acromial process fracture alone. If the second injury involves the acromioclavicular joint, however, then temporary fixation with an additional pin across the AC joint may be necessary. If pins are used around the shoulder girdle complex, they must be bent to avoid migration and should be removed once the injured structures have healed.

**Authors’ Preferred Treatment**

The majority of acromial fractures can be treated nonoperatively with a sling to support the arm for comfort. Begin pendulum and active-assisted ROM exercises within the first several days. The patient may increase the use of the involved extremity as her pain allows.

For acromion fractures in the anatomical or Zone I region that require ORIF, we prefer a tension band technique with two cannulated 4.0 screws and heavy number 5 suture or 18 gauge wire. Do not use screws that project beyond the bony surface because they could eventually cut the suture running over their edges. For more medial acromion fractures, we recommend using a curved pelvic 3.5 mm reconstruction plate which has oval holes and allows angled screw insertion if necessary. Use standard surgical approaches (see Chapter 1) to the shoulder girdle to expose, reduce and internally fix the fracture. Postoperatively, begin pendulum exercises as soon as the wound is sealed. If the deltoid required surgical repair due to traumatic injury or take-down during surgery,
avoid active abduction and forward elevation for 4–6 weeks. In all other cases, begin active-assisted exercises within the first 2 weeks to avoid shoulder stiffness. Have the patient use a sling when sitting up or walking, and a pillow under the ipsilateral elbow when in bed to relieve the downward pressure on the acromion from the weight of the arm.

**SCAPULAR SPINE FRACTURES**

Fractures of the scapular spine occur in the plane of the rotator cuff, deltoid, and trapezius. Fractures in this region are commonly associated with scapular body fractures and can lead to some degree of pain and weakness. In one series, 70% of patients with scapular spine fractures had abduction weakness and pain at rest from 3 to 7 years after their injury and many of these patients also had night pain (2). Nevasier referred to this phenomenon as a "pseudorupture" of the rotator cuff caused by hemorrhage and scarring of the supra- and infraspinatus muscles related to the fractures which are frequently comminuted and displaced. Because patients with these injuries may develop problems either acutely or on a delayed basis, some authors advocate that scapular spine fractures should be reduced and surgically stabilized (2, 51). To date, there are no published reports that provide definite indications for surgery.

**FRACTURES OF THE CORACOID PROCESS**

Fractures of the coracoid process account for 5% to 7% of all scapula fractures (2, 66). The typical mechanism of injury is an avulsion fracture caused by traction on the conjointed tendon and/or the coracoclavicular ligaments. Occasionally a direct blow by the humeral head at the time of glenohumeral dislocation produces the fracture (48, 109). In general, coracoid process fractures can be treated nonoperatively (48, 50, 64), although associated injuries may warrant surgery. Prescribe a sling for patient comfort for the first week or two, and then begin progressive range of motion exercises. Avoid heavy lifting and weight training for 8 to 12 weeks since the short head of the biceps brachii and the pectoralis minor (as well as the coracobrachialis) muscles originate from the coracoid and forceful contraction of those muscles might displace the fracture (Fig. 15.9).

Open reduction and internal fixation may be indicated in exceptional cases. For example, a coracoid fracture in a high performance athlete who relies on the precise functioning of his/her upper extremity warrants ORIF. Another indication for surgery is an associated injury such as a type III AC disruption (see below), acromion fracture, glenoid neck fracture, or clavicle fracture that results in wide displacement of the associated injury or both injuries. In most cases, fixation of the associated injury is all that is needed, and doing so indirectly reduces the coracoid process fracture and allows it to heal in satisfactory position. Delayed treatment of an avulsion fracture is occasionally necessary in patients who develop soft tissue irritation from the displaced bony fragments. In those cases, reduce and internally fix large fragments, or, if the bony fragments are small, excise them and suture the conjointed tendon to the remaining coracoid process.

**SUPERIOR SHOULDER SUSPENSORY COMPLEX INJURIES**

A standard shoulder trauma series of radiographs plus a CT scan will delineate the presence of these injuries and assist in choosing a treatment plan and surgical strategy. Anterior and posterior 45° oblique views may be beneficial to show fracture displacement (45). If AC or distal clavicle injuries are suspected, AP shoulder radiographs obtained while 10-lb weights are suspended from the patient’s wrists can be used to accentuate the disruptions and aid in the diagnosis.

Unacceptable displacement of one or both of the SSSC injuries is an indication for surgery. Only recently has attention in the literature been focused on the complex nature of these injuries (45), and, therefore, precise criteria for operative intervention are unknown. The surgeon must rely on his judgment as to the likelihood that the displacement will lead to delayed or nonunion and/or adverse biomechanical and functional outcomes. The more widely displaced the injured structures are, the more likely surgical intervention will be beneficial.

The operative strategy for these combined injuries is straightforward. Identify the injury that is easiest to approach surgically, perform the site-appropriate reduction and stabilization utilizing the techniques described above, and then evaluate the secondary disruption for persistent displacement and instability. Once the initial injury has been reduced and stabilized, it usually produces an indirect reduction of the secondary injury and makes the whole shoulder complex sufficiently stable so that ORIF at the second site is not necessary. For example, ORIF of the clavicle will usually reduce and stabilize an associated glenoid neck fracture, and K-wire fixation or coracoclavicular ligament reconstruction in selected type III AC separations and all type V AC separations (see below) will reestablish the clavicle as the stable superior buttress of the shoulder girdle (Fig. 15.9).

Postoperative management is injury specific. For most of the cases, except those with pins across the AC joint, prescribe sling support for 1 to 3 weeks in conjuction with pendulum exercises. After 2 to 3 weeks, start active assisted ROM exercises and add gentle strengthening exercises after 6 and 8 weeks. By 3 months, most patients should have full shoulder motion and be using their shoulders for all activities of daily living.

**SCAPULOTHORACIC DISSOCIATION**

Scapulothoracic dissociation is essentially a closed for-erquarter amputation caused by severe blunt trauma and traction to the upper extremity. Beneath an intact layer of skin, there is disruption of the scapular rotators, subclavian vessels and the brachial plexus (22, 109). Bone and joint injuries such as AC separations, clavicle fractures, and sternoclavicular (SC) disruptions complete the clinical picture.

Diagnosis may be delayed because of multiple other severe injuries that necessarily divert the resuscitation efforts to life-saving maneuvers. In addition, ipsilateral musculoskeletal injuries may mistakenly be identified as the cause of neurovascular deficits. However, careful attention to the mechanism of injury (thrown motorcyclist or farming accident), critical assessment of the position of the scapula in relation to the spinous processes (the medial borders should normally be equidistant from the midline and the lateral borders should be closer to the lateral border of the scapula), and a thorough physical exam (absent pulses, neurologic compromise, severe swelling over the shoulder region) can lead the resuscitation team to the correct diagnosis. Further workup includes upper extremity angiography to identify the level of the arterial lesion and guide the surgical strategy for vascular repair.

Figure 15.15. Diagnosis of scapulothoracic dissociation can be verified by observing significant lateral displacement of the scapula and shoulder girdle on the affected side. This can be determined by comparing the distance from the medial border of the scapula to the spinous processes between the affected and unaffected sides. (From Butters KP. Fractures and Dislocations of the Clavicle. In: Rockwood CA Jr, Green DP, Bucholz RW, Heckman JD, eds. Fractures in Adults. Philadelphia: JB Lippincott, 1996:1169.)

The first goal of treatment for this condition is to restore perfusion to the affected limb. Frequently, that requires a saphenous vein graft to repair the avulsed subclavian or axillary arteries or a shunt. Next, explore the brachial plexus and reapproximate any transected nerves with appropriate microsurgical techniques. It is much easier to perform the nerves repairs acutely than later, when they are encased in scar. Finally, establish bony stability where needed such as by plating or pinning a clavicle fracture or reconstructing the AC joint to restore the length and stability of the shoulder girdle, protect the neurovascular repairs, and create a stable environment for soft-tissue healing.

In the past, amputation or glenohumeral disarticulation was recommended for patients who presented with complete neurologic deficits in the affected limb (22, 31). Recent improvements in microsurgery, however, have allowed surgeons to salvage limbs that might have been amputated previously. Partial neurologic deficits generally have a good prognosis in terms of return of function and sensation (31). The decision to amputate a revascularized, viable limb because of neurologic or other soft-tissue injuries should be delayed and made only after multidisciplinary consultation and discussion with the patient and family. More specific indications and a
discussion of treatment options regarding brachial plexus injuries are beyond the scope of this chapter but are found elsewhere in this book (see Chapter 60).

COMPLICATIONS

There are several potential pitfalls and complications to avoid when managing scapular fractures. The first is the failure to recognize a double disruption of the SSSC. If one overlooks one or both disruptions in the suspensory complex, further displacement and instability of the shoulder complex may result when movement is initiated. Conversely, a rehabilitation program that is not vigorous enough can be equally problematic and result in excessive shoulder stiffness. A well-designed and supervised exercise program is the key to success.

Another pitfall to avoid is injury of the suprascapular nerve when operating on the scapula. The nerve may be injured at the spinoglenoid notch by careless medial dissection during the posterior approach to the glenoid neck or excessive traction on the infraspinatus muscle. Finally, avoid placing K-wires across the AC joint or into the scapula wherever possible. In rare cases when they are used temporarily to fix small fragments, bend the ends of K-wires to prevent pin migration. Remove them 4 to 6 weeks postoperatively before beginning vigorous shoulder motion to avoid pin breakage and interference with motion.

CLAVICLE FRACTURES

Clavicle fractures account for approximately 4% of all fractures and 35% to 43% of shoulder girdle injuries. Fractures occur most commonly in the middle third of the bone (76%–82%) and less often in the distal (12%–21%) and medial (3%–6%) thirds (103,127) (Fig. 15.16). Proximal clavicle fractures tend to occur in elderly men; middle-third fractures tend to occur in children (typically undisplaced), adolescents (displaced), and young male adults (comminuted); distal-third fractures are frequent in middle-aged patients (103).

Figure 15.16. An analysis of 1,603 shoulder girdle injuries among which were 690 fractures of the clavicle. (From Rowe CR. An Atlas of Anatomy and Treatment of Midclavicular Fractures. Clin Orthop 1968;58:29.)

FUNCTIONAL AND SURGICAL ANATOMY

The structural unit of the sternum and both attached clavicles has been likened to a yoke and serves to keep the shoulder girdle positioned laterally throughout a wide range of motion, enhancing upper extremity function (82). The clavicle also provides a base for muscular attachments of the shoulder girdle, allows maximum upper extremity range of motion for better positioning of the hand, protects vital neurovascular structures, facilitates optimum respiration and circulation via the attached secondary muscles of respiration, and contributes to the cosmetic appearance of the neck region (82,89). The clavicle is an S-shaped bone, concave anteriorly at its lateral end and convex anteriorly at its medial end, and subcutaneous throughout its entire length. The cross-sectional anatomy changes along its lateral-to-medial course from flat to tubular to prismatic (Fig. 15.17). The junction from the flat region to the tubular region is a stress riser; that fact, coupled with the effect of the first rib acting as a fulcrum near the same spot over which the clavicle rides as superior-lateral load is applied to it, explains the high incidence of fractures in that region. The medial end of the clavicle is firmly attached to the sternum and first rib by stout ligaments, the only articulating connection of the upper extremity to the axial skeleton. Laterally, the clavicle is attached to the coracoid process by the coracoclavicular ligaments (Fig. 15.2) and to the acromion by the acromioclavicular ligaments.

Figure 15.17. The clavicle appears straight when viewed from the front (B) but as an S-shaped double curve when viewed from above (A). The lateral end of the clavicle is flat in cross section (C), whereas the medial aspect is more tubular. (From Craig EV. Fractures and Dislocations of the Clavicle. In: Rockwood CA Jr, Green DP, Bucholz RW, Heckman JD, eds. Fractures in Adults. Philadelphia: JB Lippincott, 1996;1111.)

The relationship of the soft-tissue attachments and neurovascular structures with the clavicle help explain some patterns of injuries seen clinically and highlight potential complications to avoid when treating them. For example, because of their insertions, the sternocleidomastoid and trapezius muscles pull the medial aspect of the clavicle superiorly after clavicle fractures (Fig. 15.18). The subclavian artery and vein as well as the brachial plexus pass between the junction of the middle and medial third of the clavicle and the first rib and need to be protected during plating of clavicle fractures. The strong tubular portion of the clavicle, clothed on its underside by the subclavius muscle and fascia, overlies these vital structures, which may account for the low incidence of neurovascular injury associated with clavicle fractures.

Figure 15.18. Muscle forces acting on fractures of the middle third of the clavicle to render them potentially unstable.
RADIOGRAPHIC EVALUATION

Begin radiographic evaluation with two views of the clavicle: an AP view on a large film that includes the upper third of the humerus, shoulder girdle, and upper lung field and a 45° cephalad “oblique” view (126). Together these views are sufficient for evaluating most clavicle fractures except those in the medial third and will show associated musculoskeletal injuries, screen for a pneumothorax, and show both the superior–inferior and anterior–posterior displacement of the clavicle. In fractures that have been treated with internal fixation or in cases of questionable nonunion, an abduction lordotic view is an alternate method of getting a second view at 90° for a more complete representation of the clavicle (116). Distal third fractures are more difficult to assess because of overlapping bony structures. Anterior–posterior oblique stress films with the patient standing and while 10-lb weights are suspended from each wrist should be sufficient to diagnose an unstable distal clavicle fracture or acromioclavicular separation. Computed tomographic scans are useful for evaluating medial clavicle fractures because plain films are usually inadequate for assessing anterior–posterior displacement.

CLASSIFICATION OF CLAVICLE FRACTURES

Clavicle fractures are classified into three groups according to location in the bone because prognosis and treatment vary according to type. Group I (middle-third) fractures are the most common, accounting for approximately 80% of all clavicle fractures. Approximately 97% of fractures in this group are mild to moderately displaced and can be treated nonoperatively, with certain exceptions, outlined below. However, 3% of middle-third clavicle fractures are completely displaced and shortened. This small group of fractures accounts for 90% of nonunions in middle-third fractures and therefore may warrant early open reduction and internal fixation (139).

Group II (distal) fractures occur in the distal third of the bone and account for approximately 10% of clavicle fractures. Critical to the behavior and treatment of these injuries is the condition of the coracoclavicular ligaments. If they are both disrupted, the shoulder girdle loses its superior strut, and the fracture displaces because of four main forces (95) (Fig. 15.19). If the ligaments are not disrupted, the same displacement pattern will still occur if the ligaments are attached to an inferior butterfly fragment (111). The displacement caused by these forces may account for the reported 30% nonunion and 45% delayed union of these fractures when treated nonoperatively (32). Group II fractures can be further subdivided into five subtypes based on fracture location because the anatomic details of the fracture play a role in treatment options (Table 15.5; Fig. 15.20).

Figure 15.19. The four displacing forces that act on the clavicle and shoulder girdle in type II fractures: (1) the weight of the arm, (2) the latissimus dorsi, the pectoralis major and minor muscles, (3) scapular rotation, and (4) the trapezius muscle. The first three forces act only the distal segment, while the trapezius muscle pulls the shaft upward and backward. (From Neer CS II. Fractures of the Distal Third of the Clavicle. Clin Orthop 1968;58:45.)

Table 15.5. Classification of Clavicle Fractures

Figure 15.20. Fractures of the distal clavicle. Type I fractures occur lateral to the coracoclavicular ligaments. Type II fractures functionally detach the coracoclavicular ligaments from the medial fragment of the clavicle. Type III fractures are intraarticular and involve the acromioclavicular joint. Types IV and V are not shown.

Group III (medial) clavicle fractures are usually stable because of the supporting sternoclavicular ligaments (Table 15.5).

PATIENT ASSESSMENT

Proper evaluation of a patient with a clavicle fracture includes a complete history, a careful neurovascular exam of the shoulder and ipsilateral upper extremity, and appropriate imaging. The mechanism and events surrounding the injury as well as the patient’s preexisting medical problems provide useful information about the amount of energy and forces which produced the fracture as well as important clues about associated injuries. Most clavicle fractures are closed, isolated injuries sustained in low energy falls (103); however, they also occur in high energy accidents. Although neurovascular injuries and open fractures are uncommon, subclavian artery and vein injuries, severe chest trauma, and brachial plexus injuries all have been reported. Unfortunately, associated injuries often are missed initially (9,61,118,127); look carefully for them to avoid delays in diagnosis.

TREATMENT

More than 200 methods have been described to treat fractures of the clavicle (26). Group I, middle one-third, clavicle fractures can generally be treated nonoperatively. A figure-of-eight bandage with or without plaster reinforcement has long been recommended and is one very good treatment option (Fig. 15.21) (3,26,118,127). See
Chapter 10 for a description of the use of a plaster bolero. The goal of this method is to reposition the bone ends as much as possible by simultaneously raising the lateral fragment upward and backward while depressing the medial fragment. The advantage of a figure-of-eight brace is that it leaves the ipsilateral hand free for use while splinting the fracture helps keep the patient's shoulders back and the clavicle out to length, minimizing the chance of the bone healing in a shortened position. The disadvantages of this method include the difficulty many patients have keeping the brace adjusted properly and the potential skin problems caused by the brace, as well as impairment of patients' agility, personal hygiene needs, and comfort while sleeping (5).

Figure 15.21. A: A commercial figure-of-eight support. B: Superior view of the patient, showing how the figure-of-eight support pulls the shoulder up and backward. (From Dameron TB Jr, Rockwood CA Jr. Fractures and Dislocations of the Shoulder. In Rockwood CA Jr, Wilkins KE, King RE, eds. Fractures in Children. Philadelphia: JB Lippincott, 1984:618.)

Alternatively, middle-third clavicle fractures may be treated with an arm sling (5,118). Although a sling does nothing to correct shortening or displacement at the fracture site, it is often more comfortable and convenient for patients than a figure-or-eight brace and yet leads to the same rate of union and excellent function as can be achieved with more restrictive treatment methods (5,105).

Treated nonoperatively, the vast majority of middle-third clavicle fractures heal uneventfully and with little or no functional limitations. The nonunion rate for middle-third clavicle fractures ranges from 0.1% in Neer's series of 2,235 patients to 15% in Hill's series of 242 consecutive patients (57,84). Higher rates of nonunion in middle-third clavicle fractures have been associated with humeroulnar fractures, wide displacement (1-2 cm), refracture, soft tissue interposition by the trapezius muscle, and operative treatment (47,65,83,127,139,145).

Operative treatment of middle-third clavicle fractures is indicated in some situations (Table 15.6). The most commonly encountered indication is an open fracture, which should be treated with thorough wound irrigation, debridement, and stable internal fixation (49). The exception may be an isolated clavicle fracture with a small (grade I) inside-out puncture wound, which could be treated by irrigating and debriding the wound and treating the fracture with sling immobilization. If the wound requires surgical treatment anyway, however, then rigid internal fixation of the fracture at the same time is indicated, as the wounds heal much better when the clavicle is stabilized because the fractured ends tend to displace into the wound.

Table 15.6. Indications for Operative Treatment of Middle-Third Clavicle Fractures

Other indications for surgical treatment of group I fractures are less common. Associated neurovascular injuries that do not improve with attempted reduction warrant surgery to decompress and prevent further damage to the underlying structures (9). Fractures that are displaced upward to the point of tenting and threatening the integrity of the skin may need reduction and fixation if closed maneuvers fail to reduce the clavicle. As outlined above, double disruptions of the SSSC that include a clavicle fracture require reduction and stabilization of at least one of the injuries. Surgical treatment of the clavicle fracture is logical in this setting because it is usually the most accessible and simplest disruption to fix.

Widely displaced fractures may benefit from early operative intervention. It has been shown that middle-third clavicle fractures with more than 2 cm of displacement or 15 mm of shortening are at increased risk for nonunion (57,65). Thompson reviewed more than 100 middle-third clavicular nonunions reported in the literature and found that 90% of the original fractures had displacement greater than 100%, overriding more than 1 cm, or had severe comminution (139). Although fractures with this much displacement are uncommon, accounting for 3% of all middle-third clavicle fractures, they warrant open reduction and internal fixation.

Clavicle fractures in the multiply injured patient may need operative management. If a patient has associated ipsilateral upper extremity fractures treated surgically and would benefit from early mobilization of the affected limb, then ORIF of the clavicle fracture is indicated. Patients with bilateral upper extremity injuries including a clavicle fracture benefit from immediate clavicle fixation because it frees up one upper extremity so the patient may perform independent activities of daily living, and patients with lower extremity fractures and a clavicle fracture benefit from fixation of the latter because it facilitates the use of crutches or a walker for early mobilization. Finally, stabilization of clavicle fractures is indicated for patients with multiple ipsilateral rib fractures because it helps stabilize the hemithorax, resulting in less pain and better pulmonary hygiene (102). Other relative indications for the surgical treatment of clavicle fractures are listed in Table 15.6.

OPERATIVE TECHNIQUES

Middle-Third Fractures

Three types of fixation are available for middle-third clavicle fractures: intramedullary devices, plates, and external fixators. Intramedullary fixation can be accomplished with smooth or threaded K-wires, Steinman pins, Knowles pins, Haage pins, or cannulated screws (28,77,101,102,150). The advantages of using intramedullary devices are several: less surgical dissection and soft tissue stripping is needed, and the hardware is less prominent. Disadvantages include possible pin migration and poor rotational control during elevation of the extremity above shoulder level. Most techniques using intramedullary devices utilize the S-shaped curve of the clavicle for hardware placement, a small anterior incision, exposure of the bone ends, and retrograde insertion of the chosen pin or device. Once the fracture is reduced, the pins are advanced back through the fracture into the anterior cortex of the medial fragment. Ngarakos (102) has had good success with two 2-mm smooth K-wires inserted retrograde into the medial fragment and then antegrade into the lateral fragment. The ends of the wires are bent down around the clavicle proximally. If these pins back out, they are very prominent and easy to remove. Two wires are used to prevent rotation. Removal of K-wires is recommended once the fracture has healed (102). In contrast, Knowles pins and screws do not need to be removed unless hardware-related symptoms develop (101).

Plating of acute clavicle fractures, when indicated, is advocated as the preferred fixation method by many authors (61,113,116). Biomechanically, plate fixation is superior to intramedullary fixation because it better resists the bending and torsional forces that occur during elevation of the upper extremity above shoulder level. Patients treated with plate fixation can be allowed full range of motion once their soft tissues have healed. Disadvantages of plate fixation include the necessity for increased exposure and soft-tissue stripping; potential damage to the supraclavicular nerves, which cross through the surgical field; slightly higher infection rates (55); and the risk of refracture after plate removal (19). Despite these shortcomings, plate fixation utilizing careful surgical technique and appropriate use of autogenous bone.
The treatment of type II fractures depends on the size of the lateral fragment and the stability of the fracture. If a type II fracture is diagnosed using stress films, but the...

If surgery is indicated for a middle-third clavicle fracture, we prefer plate fixation.

**Plate Fixation of the Clavicle**

Most medial clavicle fractures are stable because of the surrounding ligamentous attachments (type I, Table 15.5) and can be treated nonoperatively with a sling for comfort and return to normal function as the patient's pain allows (33). Surgical treatment of medial clavicle fractures is rarely indicated and limited to cases in which there is wide displacement of the fracture fragments or impingement of vital neurovascular structures. When treated operatively, the fracture may be fixed using heavy screws or transacromial K-wires (32,95,96). Based on the high rates of delayed union and nonunion, difficult rehabilitation and residual shoulder pain associated with nonoperative treatment in several studies, many surgeons recommend operative treatment of type II fractures (26,32,43,56,95,96,118).

Several surgical treatment options are possible: transacromial K-wires with or without a tension band (32,95,118), coracoclavicular screw (8,32), plate fixation (56), and coracoclavicular suture or taping. If the fracture is widely displaced, a small external fixator may be used to hold the bone ends out to length; this is rarely necessary.

Avoid undermining the skin flaps and damaging the supraclavicular nerves. Limit the subperiosteal dissection to the fracture site. Precontour the chosen plate and place it superiorly on the clavicle. It is important to achieve solid fixation with three screws (six cortices) on each side of the fracture.

Place a small drain in the subcutaneous layer and perform a plastic closure with a subcuticular suture.

We prefer to treat the majority of type I and III distal clavicle fractures with a sling to support the injured extremity for 1 to 2 weeks. Patients are instructed to start pendulum exercises within the first week and to begin using the involved extremity as their pain allows.

**Plate Fixation of the Clavicle**

If surgery is indicated for a middle-third clavicle fracture, we prefer plate fixation.

- Use Langer's lines for the skin incision and expose the superior surface of the clavicle.
- Avoid undermining the skin flaps and damaging the supraclavicular nerves. Limit the subperiosteal dissection to the fracture site.
- Reduce and align the fracture with a pointed tenaculum and place a lag screw across the fracture whenever possible. If regaining the length of the clavicle is difficult, a small AO external fixator can be used to hold the bone ends out to length; this is rarely necessary.
- Place a small drain in the subcutaneous layer and perform a plastic closure with a subcuticular suture.

We prefer to treat the majority of type I and III distal clavicle fractures with a sling to support the injured extremity for 1 to 2 weeks. Patients are instructed to start pendulum exercises within the first week and to begin using the involved extremity as their pain allows.

The treatment of type II fractures depends on the size of the lateral fragment and the stability of the fracture. If a type II fracture is diagnosed using stress films, but the nonweighted x-rays show little displacement, then the fracture is treated nonoperatively with a sling for 6 to 8 weeks. Follow-up x-rays after 1 to 2 weeks are essential to rule out further displacement. If, however, a type II fracture is easily diagnosed without weighted views and is widely separated (100% of the diameter of the shaft), then we recommend open reduction and internal fixation using wire fixation.

- Make an incision in Langer's lines and expose the fracture site with careful soft-tissue handling techniques.
- If the lateral fragment is large enough (2–3 cm), use a wire tension band (18 gauge) combined with two extraarticular K-wires drilled across the fracture from lateral to medial (Fig. 15.22). Bend the wires to avoid pin migration.
and perfused through anastamoses to the anterolateral branch. Close to this point, the humeral head is at risk for osteonecrosis. If the blood supply is disrupted more proximally, then the humeral head will more likely remain viable if the proximal humerus. The posterior circumflex artery supplies only a small portion of the posteroinferior head and the posterior portion of the greater tuberosity. Once the anterolateral branch becomes intraosseous, it becomes the arcuate artery, which supplies the entire epiphysis and all but small portions of the anterior humeral circumflex artery ascends within the intertubercular groove lateral to the biceps tendon and enters the humeral head where the groove meets the attachments to these fragments create the various patterns of displacement seen on the initial x-rays (Codman (23)).

**POSTOPERATIVE MANAGEMENT**

Have patients wear a sling for the first 1 to 2 weeks for comfort but remove it twice a day to perform pendulum exercises and active-assisted ROM exercises below shoulder level. We encourage patients to use the affected extremity for routine activities of daily living below shoulder level as their pain allows. After 3 to 4 weeks, when the wound is completely healed and the patient is comfortable, institute active-assisted ROM exercises above shoulder level and full return to activities of daily living. Most patients resume all normal activities 6 to 12 weeks postoperatively. If the plate is prominent and bothersome to the patient, it can be removed after the fracture heals, but this is not routine.

**COMPLICATIONS**

Most authors agree that poor technique and soft-tissue handling were significant factors in the rates of nonunion and other complications reported in the earlier literature. Therefore, whatever approach is chosen, take great care to avoid excessive soft-tissue stripping, work to achieve solid fixation, and plan on acute bone grafting for fractures that are highly comminuted or where there is bone loss. When exposing middle-third clavicle fractures, be cognizant of the small supraclavicular nerves that cross through the operative field and try to preserve them.

Other reported complications from the operative treatment of distal clavicle fractures include pin migration, coracoid fracture (89), lysis of drill holes in the clavicle when acromion is used (89), wound-healing problems (55), K-wire failure (32), and infection (72). To prevent pin migration, always bend the ends of the pins. Although coracoid fracture and lysis of drill holes have been reported after use of synthetic tapes to stabilize chronic AC separations, this may not be a problem when they are used to help stabilize distal clavicle fractures if bony union occurs and relieves stress on the implants (43). Minimize wound-healing problems and infection by not undermining skin flaps, by handling soft tissues carefully, and by waiting for acutely damaged skin to improve before operating. Use stout K-wires, such as two 2-mm pins as opposed to smaller pins, to decrease the chance for hardware failure. Never use threaded wires. If distal clavicle resection is done acutely, carefully assess the stability of the remaining clavicle after the resection. If it is unstable, repair or reconstruct the coracoclavicular ligaments.

**FRACTURES OF THE PROXIMAL HUMERUS**

Fractures of the proximal humerus occur most often in the elderly and are twice as common in women as in men. Typically they result from falls from a standing height. Although much less common, proximal humeral fractures do occur in younger male patients also, but these usually are the result of high-energy motor vehicle or motorcycle collisions (Table 15.7) (123). Approximately 85% of proximal humeral fractures are nondisplaced by Neer's criteria and can be treated nonoperatively. The remaining 15% of proximal humeral fractures require careful decision making based on an understanding of the anatomy of the proximal humerus, the nature of the injury, the quality of the patient's bone, and the limitations of the fixation devices currently available.

**RELEVANT ANATOMY AND PATHOPHYSIOLOGY**

Codman (23) was one of the first surgeons to recognize that fractures of the proximal humerus occur along the lines of the physeal scar, potentially creating four separate fragments (Fig. 15.23). Neer (87,88) later incorporated this concept into his widely known classification system for proximal humeral fractures. Muscular attachments to these fragments create the various patterns of displacement seen on the initial x-rays (Table 15.8). The vascular supply to the proximal humerus has been well studied and described by Gerber et al. (42) and Laing (78) (Figs. 15.24). Utilizing injection techniques, Gerber et al. (42) found that the anterolateral branch of the anterior humeral circumflex artery ascends within the intertubercular groove lateral to the biceps tendon and enters the humeral head where the groove meets the greater tuberosity. Once the anterolateral branch becomes intraosseous, it becomes the anconeal artery, which supplies the entire epiphysis and all but small portions of the proximal humerus. The posterior circumflex artery supplies only a small portion of the posteroinferior head and the posterior portion of the greater tuberosity. There are abundant anastomoses between arteries, but they occur proximal to the point where the anterolateral branch becomes intraosseous. If there is arterial damage close to this point, the humeral head is at risk for osteonecrosis. If the blood supply is disrupted more proximally, then the humeral head will more likely remain viable and perfused through anastomoses to the anterolateral branch.

PATIENT ASSESSMENT

Patients with injuries to the shoulder girdle often have associated injuries. The mechanism of injury is important. A fracture sustained in a high-energy accident in a young person is more likely to be associated with other injuries than is a low-energy fall in an elderly person. Follow Advanced Cardiac Life Support (ACLS) principles when prioritizing the evaluation of a patient with a shoulder injury (see Chapter 14). During the physical examination, always note the appearance of the injured shoulder compared to the opposite side. An anterior fracture-dislocation will cause a fullness or bulging in the anterior aspect of the shoulder, whereas a posterior fracture-dislocation may leave a hollow impression in the anterior aspect of the shoulder. Assess the radial and ulnar artery pulses and perform a distal sensory and motor neurologic exam. Nerve injuries occur in association with proximal humeral fractures and dislocations in up to 45% of cases (28); they are more common in elderly patients and in the presence of a hematoma. Careful written documentation of the neurologic exam may seem tedious at the time of the initial evaluation but is essential for comparison later in the patient’s treatment course. Sensory loss does not always correlate with motor dysfunction (28), and this should be noted. If pulses are absent, then a vascular consultation may be indicated.

RADIOGRAPHIC EVALUATION

Adequate radiographs are essential for the proper classification and treatment of proximal humeral fractures. A standard trauma series should include a true AP radiograph of the scapula, a lateral scapular view, obtained with the patient in a 60° anterior oblique position, and an axillary view. Computed tomography scans provide the most reliable information and are helpful in several circumstances including the evaluation of intraarticular fractures to assess the degree and nature of damage to the joint surface and the evaluation of fracture displacement, particularly the greater and/or lesser tuberosities (Fig. 15.25).

Figure 15.25. Computed tomographic scans are helpful in evaluating fractures of the humeral head and the degree of articular surface involvement and in ruling out fractures of the glenoid surface. In this case, (A) the extensive comminution of the humeral head is evident (arrow) at the level of the coracoid process (arrowhead). Inferiorly (B), medial displacement of a segment of the humeral head is evident (arrow) at the level of the inferior glenoid, but there is no damage to the glenoid surface.

CLASSIFICATION

Based on Codman’s description of the four parts of the proximal humerus (23)—anatomic head, greater tuberosity, lesser tuberosity, humeral shaft—Neer, in 1970, devised his classic four-part classification of proximal humerus fractures (Fig. 15.26) (97,98). To be considered displaced, one or any combination of the four bone fragments must be separated by 1 cm or more and/or angulated more than 45°. Fractures that do not fulfill these criteria are considered non- or minimally displaced and referred to as a “one part fracture.” Neer emphasized the relationship between displacement and the vascular supply to the head of the humerus. The greater the number of displaced fragments, the higher the risk of osteonecrosis. For example, a two-part fracture of the greater tuberosity is much less likely to develop
osteonecrosis than a four-part fracture.

Figure 15.26. Neer’s four-part fracture classification.

The AO group expanded Neer’s classification to include other fracture patterns that do not fit neatly into Neer’s scheme (AO classification). One such addition is the so-called four-part valgus impacted fracture (64), which seems to have a lower risk of osteonecrosis (26%) than the four-part fractures Neer described (90%) (Fig. 15.27) (87). Head-splitting and impression fractures are special fractures that do not fit the four-part scheme. Head impression fractures are graded by the percent of head involvement: less than 20%; between 20% and 45%; and greater than 45% (12). The AO classification is more detailed but also more cumbersome and is used mostly as a research tool. The Neer classification has been shown to have poor intra- and interobserver correlation (11), but it is still the most widely used and commonly accepted classification scheme for proximal humeral fractures in North America.

TREATMENT INDICATIONS AND METHODS

Nonoperative Management

Most fractures of the proximal humerus can be managed nonoperatively. Factors important in the decision-making process include the fracture pattern and classification as well as the patient’s general health, age, occupation, and avocations. Consider also whether additional benefits might be gained from surgical stabilization of the fracture so a patient with multiple injuries could begin moving the arm and shoulder sooner.

Closed reductions of simple fractures may convert them to “one-part fractures” amenable to nonoperative treatment and should always be tried first. This may occur at the level of the surgical neck of the humerus (106). Also, two-part fracture-dislocations of the shoulder where the displaced part is the greater tuberosity may be amenable to nonoperative treatment if the shoulder can be reduced and the greater tuberosity fragment reduces. These fractures require close follow-up to make sure they do not displace later as a result of the muscle forces acting on them.

Treatment principles for managing proximal humeral fractures nonoperatively are similar to those for managing other shoulder girdle injuries nonoperatively. The goal is to provide comfort and pain relief acutely for the patient and begin rehabilitation as promptly as possible. Immobilize the arm in a sling or collar and cuff initially (see Chapter 10), and begin gentle pendulum exercises within a few days. Once the proximal fragments move together as a unit with the humeral shaft as the shaft is rotated passively, active ROM exercises can be started, usually within 14 days (73).

Operative Management

Two-Part Fractures Two part fractures may fail initial attempts at nonoperative management. If reduction maneuvers in the emergency department are unsuccessful, attempt a closed reduction in the operating room under general anesthesia. If the fracture is irreducible, then an open reduction is indicated to look for possible soft tissue interposition at the fracture site. If the fracture is reducible but unstable, percutaneous pins or an interlocking intramedullary nail can be used to stabilize and secure the reduction. If an open reduction is performed, a small clover-leaf plate, modified clover-leaf plate (35), or a blade plate (66) (Fig. 15.28) can be used to fix the fracture. In osteopenic bone, however, plates and screws should be avoided because of the risk of hardware pullout and failure. Ender’s nails with a figure-of-eight tension band neutralize rotational and translational forces and provide adequate fixation to allow early ROM (Fig. 15.29). Tension band suturing or wiring alone usually do not provide fixation rigid enough to allow early ROM in patients with osteoporosis.

Figure 15.28. A: Preoperative AP radiograph of a two-part surgical neck proximal humerus fracture. Note that although the greater tuberosity is fractured, it is not displaced and therefore not considered a displaced “part.” B: Scapular lateral view of fracture. C: Postoperative AP radiograph showing reduction and fixation with a 4.5 reconstruction plate fashioned into a “blade” plate. The patient also had a #5 nonabsorbable suture placed in a figure-of-eight tension band, which cannot be visualized. D: Postoperative axillary view of fracture fixation.
Two-part fractures at the anatomic neck are difficult to reduce closed and to stabilize with internal fixation, even when open reduction is performed. Theoretically, the blood supply to the head is totally disrupted, making osteonecrosis very likely. Therefore, hemiarthroplasty may be indicated for these fractures, especially for elderly patients (131). In young patients and those with good bone stock, every attempt should be made to preserve the humeral head and perform ORIF. Other salvage procedures or a delayed hemiarthroplasty can always be done later if osteonecrosis develops or the fixation fails.

As mentioned above, two-part fractures involving the greater tuberosity can sometimes be treated nonoperatively (Fig. 15.30), but they must be watched carefully, and management can be difficult. If the greater tuberosity fragment displaces, then open reduction and internal fixation may be indicated (Fig. 15.31). McLaughlin (88) found that shoulder function correlated well with residual greater tuberosity displacement. Fragments displaced more than 1.0 cm lead to permanent disability, but fragments displaced less than 0.5 cm rarely caused problems. Fragments displaced between 0.5 cm and 1.0 cm lead to prolonged recovery time, and 20% of cases require late reconstruction for persistent pain. In patients with good quality tissues, heavy nonabsorbable suture or wire in a figure-of-eight tension band construct placed into the tendinous insertion of the rotator cuff provides satisfactory fixation to allow early motion. If the bone quality is good, a lag screw with a washer is a good technique to provide additional fixation as long as the screw head does not impinge on the acromion (25). These fractures are commonly associated with anterior glenohumeral dislocation and longitudinal rotator cuff tears. Repair the rotator cuff as part of the surgical procedure.

Two-part fractures involving the lesser tuberosity are less common, and when they do occur, they are frequently associated with posterior glenohumeral dislocations. Following reduction of the shoulder dislocation, the lesser tuberosity fragment may reduce to a satisfactory position. If that is the case, then immobilize the arm and shoulder in neutral or slight external rotation (12). If the lesser tuberosity remains significantly displaced (greater than 1 cm), then ORIF is indicated.

Three-Part Fractures Three-part fractures of the proximal humerus are difficult to treat with closed reduction and short-term immobilization because of the rotational forces exerted on the humeral head by the rotator cuff muscles, which are attached to the tuberosities (Table 15.8). However, a recent prospective, randomized study by Zyto et al (153) comparing nonoperative versus tension-band osteosynthesis failed to demonstrate any difference in function between the two groups at 1 and 2 years, although the surgical group had more anatomic position of the tuberosities. Although this study may be reassuring for the patient and surgeon faced with a fracture where surgery is contraindicated, the general view expressed in the literature is that open reduction and internal fixation form the treatment of choice for these injuries, especially in younger, active patients with good bone quality, whereas older patients with poor bone stock should be treated with an arthroplasty.

Several surgical techniques have been advocated. One approach is to use threaded K-wires or cannulated screws percutaneously or through limited incisions (83,115). Some authors recommend open reduction and fragment fixation with wires or heavy nonabsorbable suture (24,97,131), but others advocate open reduction and internal fixation with plates and screws (Fig. 15.32) (35,136). With all the techniques, the treatment objective is to provide stable fixation for early ROM without disrupting any remaining blood supply to the bone fragments and to avoid implants that will cause subacromial impingement or other complications such as pin migration. Many studies have reported poor results and unacceptable rates of osteonecrosis (26) utilizing plate and screw fixation for three-part fractures. In elderly patients with osteopenic bone, screws and K-wires may fail because of poor fixation. Therefore, plates and screws should be reserved for younger patients with good bone quality. On the other hand, patients with severe osteopenia may not be good candidates for suturing or wiring. For those patients, a hemiarthroplasty may be the best option (24).

### Figure 15.28. Anteroposterior radiograph illustrating the use of two Ender's rods and #5 nonabsorbable suture tension band to stabilize an unstable, comminuted, two-part proximal humerus fracture in an elderly patient with osteopenic bone.

### Figure 15.30. Two-part fracture-dislocation of the glenohumeral joint with avulsion of the greater tuberosity (arrow) (A). Reduction produced near-anatomic reapproximation of the tuberosity fragment (B). This injury can be managed nonoperatively but requires careful follow-up and monitoring to make sure there is no subsequent displacement.

### Figure 15.31. A: Anteroposterior radiograph showing a two-part greater tuberosity fracture-dislocation before reduction. B: Anteroposterior radiograph showing the fracture-dislocation reduced with no apparent residual displacement of the greater tuberosity fragment. There is evidence of an old injury to the proximal humerus, however. C: Anteroposterior radiograph 10 days later showing displaced greater tuberosity fragment. D: Scapular lateral view showing the displaced greater tuberosity fragment. E: Postoperative AP radiograph showing reduction of the greater tuberosity (i.e., the fragment can no longer be seen above the humeral head). F: Postoperative scapular lateral view.
Impression fractures typically result from posterior dislocations with anterior head impaction against the posterior rim of the glenoid. The technique of choice is reduction and internal fixation with two or more interfragmentary lag screws. If the articular surface is comminuted, then hemiarthroplasty is the treatment of choice.

Fractures that split the articular surface of the humeral head are treated partially on the degree of comminution. If there are two large pieces amenable to reduction, then open reduction and internal fixation; if less amenable to reduction, then hemiarthroplasty.

Four-Part Fractures

Osteonecrosis of the humeral head is common after displaced four-part fractures of the proximal humerus. For this reason most authors recommend early hemiarthroplasty for the majority of patients. The results include younger, active patients with good bone stock are the exception; for them, open reduction and internal fixation should be attempted first, even though the risk of nonunion and osteonecrosis is high. Stableforth reported the results of a prospective, randomized study comparing nonoperative treatment versus hemiarthroplasty for four-part displaced proximal humeral fractures and compared the results to cases of impacted four-part fractures treated nonoperatively. He found that the prosthesis group and the impacted group had similar results, which were dramatically better in terms of function and range of motion than the group with displaced fractures treated nonoperatively. All patients had some pain; in the patients with displaced fractures treated nonoperatively, however, functional disability and sleep difficulties because of pain were far more common.

Techniques for fixing displaced four-part fractures include using multiple K-wires, cannulated screws, clover-leaf plates, and heavy sutures. If hemiarthroplasty is selected as the treatment method, several technical details should be considered. Hemiarthroplasty

Hemiarthroplasty

- Use an anterior deltopectoral surgical approach.
- Identify all fracture fragments and clean them of hematoma.
- Excise the free floating head fragment.
- Preserve the tuberosity fragments with the attached rotator cuff muscles. The long head of the biceps is the key to the rotator interval between the lesser and greater tuberosities. Insert heavy, nonabsorbable sutures into the edges of these fragments for traction and later repair of both the greater and lesser tuberosities.
- Prepare the intramedullary canal of the humeral shaft according to the instructions provided by the manufacturer.
- Restoration of proper humeral length and retroversion (30° to 40°) is essential for optimum glenohumeral mechanics.
- Select the appropriately sized prosthesis and cement the prosthesis in place. The prosthesis is cemented high enough for the tuberosities to be returned to their normal position. The fin is just posterior to the biceps groove.
- Reapproximate the tuberosities to each other with the two heavy sutures seen in Figure 15.34 and to the prosthesis to restore the rotator cuff. Harvest bone graft from the excised humeral head and pack it around the secured tuberosities to promote healing. Pass cross sutures for each tuberosity through drill holes in the shaft, the holes in the fin of the prosthesis, and around the opposite tuberosities. All sutures are tied with both tuberosities reduced below the articular surface. Close any remaining gaps in the rotator cuff with heavy, nonabsorbable sutures.
- Initiate supervised passive and active-assisted ROM exercises early to prevent stiffness.

The four-part valgus impacted fracture, in which the anatomic head is impacted into the humeral shaft in valgus position, is one subtype of comminuted proximal humeral fractures that warrants special attention. The incidence of osteonecrosis after these fractures is approximately 26% versus up to 90% in the classic Neer displaced four-part fracture, most likely because the fracture fragments remain in close proximity to each other and the blood supply to the humeral head is preserved. Jakob et al. recommended elevation and repositioning of the fractured humeral head where necessary to make a smooth joint surface and improve glenohumeral mechanics. Closed reduction can be attempted and open reduction performed where necessary. Then stabilize the fracture using limited internal fixation; K-wires usually suffice. In cases where the head fragment is laterally or posteriorly displaced, the vascular supply is probably disrupted, and hemiarthroplasty becomes the treatment of choice.

Head-Splitting and Impression Fractures

Fractures that split the articular surface of the humeral head are treated based partially on the degree of comminution. If there are two large pieces amenable to fixation, perform open reduction and internal fixation with two or more interfragmentary lag screws. If the articular surface is comminuted, then hemiarthroplasty is the technique of choice.

Impression fractures typically result from posterior dislocations with anterior head impaction against the posterior rim of the glenoid. Acute impression fractures.
Fractures that involve less than 20% of the joint surface can be treated nonoperatively with the arm held in external rotation for 6 weeks (52). If the impression fracture is between 20% and 45% of the joint surface and less than 6 months old, transfer the lesser tuberosity into the defect and secure it with a screw. Shoulder spica immobilization with the shoulder in external rotation for 6 weeks is recommended postoperatively (130). Impression fractures involving more than 45% of the joint surface or associated with dislocations present for more than 6 months should be treated with hemiarthroplasty. In these cases, the usual retroversion of 30° to 40° is not recommended. Instead, cement the prosthesis in neutral rotation to help restore stability to the glenohumeral joint.

Rehabilitation and Postoperative Principles

Postoperatively, patients will be most comfortable if their shoulders are immobilized for 24 to 72 hours in a shoulder immobilizer or sling and swathe. Once the surgical incision is dry and any drains are removed, however, patients should begin circumduction pendulum exercises. If good fixation was achieved, patients start active-assisted and then early (a pulley system works well). If the deltoid was released from the acromion and repaired, only passive exercises should be performed for the first 4 to 6 weeks to allow for healing of the deltoid. In general, the rehabilitation of a proximal humeral fracture should follow a program very similar to that proposed for other shoulder procedures.

CONCLUSIONS

We treat nondisplaced (“one-part”) fractures nonoperatively, and two-part fractures as well if they can be reduced and held in good position. We recommend an attempt at closed reduction in the emergency room with conscious sedation. To reduce these fractures, apply longitudinal traction while the arm is gently flexed.Adduction of the distal shaft will help improve medial translation as the shoulder is flexed. Counterpressure within the axilla may be helpful to stabilize the humeral head during reduction. Position the proximal shaft under the humeral head and impact it. We do not recommend more than one or two attempts at closed reduction in the emergency department. Further attempts at closed reduction should be done under general anesthesia in the operating room.

We use percutaneous pinning for fractures that are easily reduced but unstable. Insert two pins from the proximal lateral and proximal anterior shaft directed into the humeral head, and add a third pin from the greater tuberosity into the proximal shaft. For fractures that cannot be reduced, we perform an open reduction and fix the fracture internally. We use a blade plate for young patients with good bone quality and Elder’s rods with tension band nonabsorbable sutures in patients with osteopenic bone.

We surgically treat greater tuberosity fractures that are displaced more than 5 mm. We use a deltotoid-splitting approach, being careful not to split the deltoid more than 5 cm from the lateral edge of the acromion to avoid axillary nerve injury. If the fragment is large enough, we use a 4.5-mm or 6.5-mm interfragmentary lag screw with a washer to compress the fragment. We add a figure-of-eight tension band suture through the rotator cuff insertion for additional fixation. Avoid placing the screw high in the tuberosity fragment where it would impinge on the acromion.

We recommend ORIF of three-part proximal humeral fractures in patients with sufficient bone stock to hold the fixation. Patients with poor bone stock are treated with hemiarthroplasty. Similarly, young patients (second to fourth decades) with four-part fractures may be candidates for attempts at ORIF, but all others are treated with hemiarthroplasty or total shoulder arthroplasty if the glenoid has arthritic changes.

COMPLICATIONS

Failing to make the proper diagnosis is the first pitfall to avoid. Posterior fracture-dislocations are often overlooked, especially in patients who have been victims of electroconvulsive therapy and grand mal seizures. Careful radiographic assessment of patients with suspected shoulder injuries is critical. The axillary view is frequently the most useful for diagnosing posterior fracture-dislocations and should be obtained as part of all shoulder trauma workups. A careful neurovascular examination of the involved extremity should not be deferred or neglected because axillary artery injuries and brachial plexus injuries are common in this setting, with incidences of 5% and 6.2%, respectively (134), especially in patients with high-energy mechanisms. A palpable pulse may be present because of the collateral circulation around the shoulder girdle, but look for signs of vascular injury including an expanding hematoma, parasthesias, and pallor. More commonly, the axillary nerve is in danger of injury with fractures of the proximal humerus. In addition, iatrogenic axillary nerve injury is possible if the deltoid is split too far distally (>5 cm from the lateral edge of the acromion) to expose a greater tuberosity fracture.

Malunion of the greater tuberosity in a superior or medial location may cause impingement syndrome with as little as 5 mm displacement. Osteolysis and replacement of the greater tuberosity to its anatomic position for large displacements or exostectomy and arcomioplasty for small displacements may be required. Three-part proximal humerus malunions are much more complex and typically require prosthetic replacement to obtain satisfactory results. Nonunion may occur even in two-part fractures at the surgical neck and is frequently caused by overdistraction using hanging arm casts, soft-tissue interposition, inadequate immobilization, overly aggressive physical therapy, an uncooperative patient, or preexisting glenohumeral stiffness (135).

Nonunion of the tuberosity fragments following humeral head replacement is a difficult problem and can be avoided in most cases by not removing too much bone from the fragments and by securely fixing the fragments to each other, the prosthesis, and the humeral shaft. Avascular necrosis may occur in up to 90% of four-part fractures (87), although other authors have reported lower rates (136). Humeral head replacement usually provides satisfactory pain relief. Postoperative stiffness is a particularly troublesome problem for many patients. Factors important in the development of a stiff shoulder include prolonged immobilization, development of heterotopic ossification, significant malunion, and nonunion. It is far better to prevent stiffness by a well-organized physiotherapy program than to treat stiffness after it has developed. Finally, inferior subluxation of the humeral head after closed or operatively treated proximal humeral fractures may appear worrisome, but in most cases it is transient and resolves within 1 to 3 weeks as the deltoid and rotator cuff muscles regain their normal tone. If the inferior subluxation follows hemiarthroplasty and does not resolve, the prosthesis may be positioned incorrectly too far down the shaft after excessive bone was removed from the proximal humerus, and this may be an indication for revision.

FRACTURES OF THE SHAFT OF THE HUMERUS

Fractures of the humeral shaft are relatively common injuries. There is a wide array of good options for their treatment and controversy over the best methods for many situations. Appropriate decision making for operative and nonoperative treatment depends on a thorough understanding of the regional anatomy, fracture pattern and classification, and factors unique to the injured patient.

RELEVANT ANATOMY

The shaft of the humerus is defined as extending from the upper border of the insertion of the pectoralis major proximally to the supracondylar ridge distally (148). On cross section the shaft is cylindrical proximally, and it narrows in the AP diameter distally as it approaches the supracondylar ridges. The deltoid muscle inserts on the deltopectoral tuberosity, which is on the anterolateral surface of the proximal shaft and extends to a level roughly halfway down the arm. The medial and lateral intermuscular septae divide the arm into anterior and posterior compartments. The posterior surface is covered by the triceps muscle and serves as the origin for the lateral and medial heads of that muscle; those muscle origins delineate the spiral groove. The radial nerve courses through the spiral groove with the profunda brachii artery as it traverses from the posterior arm compartment proximally to the anterior compartment distally. The posterior compartment contains three muscles, the teres major, biceps brachii, and the brachial artery and median nerve. The ulnar nerve passes from the anterior to the posterior compartment as it travels from proximal to distal and enters the cubital tunnel.

Key to understanding the deforming forces at work on a humeral shaft fracture are the muscle insertions and the effect of gravity. Displacement of the proximal fragment will depend in large part on whether the fracture occurs proximal or distal to the insertions of the deltoid and pectoralis major muscles as outlined above in the section on proximal humeral fractures (Fig. 15.35). The distal fragment is always distracted to some degree by the weight of the limb, and this phenomenon is the key to some methods of nonoperative fracture management.
Figure 15.35. The muscular attachments to the proximal humerus shaft will cause predictable deformity depending on the location of the fracture. A: The proximal fragment is abducted and externally rotated by the rotator cuff muscles when the fracture occurs above the level of the pectoralis insertion. B: The deltoid muscle displaces the distal fragment proximally and laterally when the fracture occurs between the deltoid and the pectoralis major. C: Fractures distal to the insertion of the deltoid muscle result in abduction of the proximal humerus.

CLASSIFICATION

There is no classification system for humeral shaft fractures that is accepted universally. In principle, however, humeral shaft fractures can be classified by their location in the bone (relative to the muscle insertions), fracture pattern, and associated soft-tissue injuries (Table 15.9) because these factors influence treatment decisions. Transverse fractures of the midshaft usually occur from low-energy trauma, but they unite slowly and have a higher rate of nonunion. Oblique and spiral fractures have a larger fracture surface area and usually progress to union without surgery. Oblique fractures in the distal third of the shaft may be difficult to immobilize nonoperatively and are more often associated with neurologic injuries (59). Segmental fractures are difficult to reduce and maintain in satisfactory alignment, and nonoperative management may lead to nonunion at one or both fracture levels. Comminuted fractures are especially challenging because they may be difficult to align and hold by closed methods and also are difficult to fix surgically.

Table 15.9. Factors Influencing Treatment of Humeral Shaft Fractures

Soft-tissue injuries frequently dictate the treatment for humeral shaft fractures. Open fractures need urgent surgical management and have a lower rate of complications when treated with adequate debridement and stable fixation (20). Treatment of radial nerve injuries is controversial, as outlined below, but may be an indication for surgery. Fractures associated with vascular injuries require surgical stabilization to help protect the vascular repair.

NONOPERATIVE TREATMENT

Most humeral shaft fractures can be treated nonoperatively with a greater than 90% rate of union (7,130,149). Several methods of treatment have been described and work well. Options include a hanging arm cast, coaptation splints, Velpeau sling, collar-and-cuff sling, abduction humeral splint or shoulder spica cast, and functional brace. The goals of each treatment method are to keep the patient comfortable, establish union with acceptable alignment, and restore full function (see Chapter 10).

Our preferred method is to treat the patient acutely with a U-shaped plaster coaptation splint that extends well above the fracture line laterally. Medially, the plaster should cup the elbow but not extend very high. If the splint is brought up toward the axilla on the medial side, it frequently ends at the level of the fracture and leveres it into varus. A sling is also provided for patient comfort. After 7 to 10 days, when the acute swelling subsides, we switch to a functional brace. The humeral functional brace was first described by Sarmiento in 1977 (130). It works by compressing the soft tissues circumferentially to produce fracture alignment, and it has been shown to be very effective for treating closed humeral shaft fractures (7,130,148,149).

INDICATIONS FOR SURGERY

Several indications for surgical treatment of humeral shaft fractures are summarized in Table 15.10. Some of the specific indications deserve special comment.

Table 15.10. Possible Indications for Operative Treatment of Humeral Shaft Fractures

Polytrauma Patient

Nonoperative treatment of a humeral shaft fracture requires a cooperative patient who is able to use gravity to help maintain fracture alignment. This requires that the patient sleep propped up in bed to avoid angulation at the fracture site, which may occur in the supine position. This does not apply to the multiply injured patient, who is often intubated, at bed rest, and not able to use gravity in the reduction and alignment of the humeral fracture. When there are other fractures of concern, it is advantageous to have free use of the injured upper extremity to facilitate rehabilitation (10,18). This is particularly true in patients with bilateral humeral fractures.

Floating Elbow

When there are ipsilateral fractures of the humerus and the proximal radius and/or ulna, it leaves the elbow unstable or “floating.” Nonoperative treatment of this lesion
leads to high rates of nonunion, malunion, and elbow stiffness (79,121). In this setting, both the humerus and forearm fractures should be internally fixed to achieve optimum results (79).

Failed Closed Reduction

Guidelines for acceptable alignment for humeral shaft fractures were proposed by Klenerman (71), and they have been endorsed by several authors since then: a maximum of 3 cm of shortening, 20° anterior or posterior angulation and 30° of varus. United fractures with up to this much deformity still allow full functional use of the upper extremity. If attempts at closed reduction can not produce or maintain the fracture within these parameters, then surgery is indicated. Closed reduction may be lost in fractures that are managed nonoperatively because of muscle forces, the inability of the patient to comply with the physician's instructions, or the inability to immobilize the fracture adequately in obese patients.

RADIAL NERVE INJURY

A radial nerve injury may occur in association with humeral shaft fractures in up to 18% of cases (110,114). Most commonly this occurs with middle-third shaft fractures (69). The Hohman-Lewis fracture, an oblique fracture in the distal third, is also well known for its association with radial nerve injury (69). Management of the radial nerve injury is controversial. Most injuries are neurapraxias or axonotmesis, and 90% will resolve in 3 to 4 months (41,69). The problem is in diagnosing the remaining 10% that will not recover and deciding when surgical exploration is indicated.

Some authors recommend surgical exploration after 3 or 4 months following a closed injury if there is no evidence of neurologic recovery (4,114). The advantages of waiting include the fact that enough time would have passed for recovery from neurapraxia, the associated fracture will have healed, and the results of secondary nerve repair may equal those of primary repair. If the initial injury is open, the nerve is more likely—64% in one series (39)—to be partially or completely lacerated or incarcerated in the fracture site, which is one reason to explore these injuries early.

Authors' Preferred Management with Radial Nerve Injury

We perform early exploration for radial nerve injuries associated with open fractures, including any penetrating injury, and any time there is a nerve palsy that develops after fracture reduction or surgical treatment. Also, at the time of surgery, particularly when humeral shaft fractures are plated, the radial nerve is carefully dissected out and identified along its entire course through the operative field so that there is no question about its integrity postoperatively. If there is a radial nerve palsy associated with a closed fracture that is present from the time of initial presentation, we treat it expectantly. If there is no recovery clinically by 6 weeks, we obtain a baseline electromyelogram (EMG); an EMG before 3 weeks is not useful. If there is no clinical improvement by 12 weeks, a second EMG is obtained; if it confirms that there is no interval recovery of nerve function, then we explore the nerve surgically with the intention of performing neurolysis, repair, or sural nerve grafting as the intraoperative findings dictate.

DELAYED UNION AND NONUNION

Definitions of time to delayed union and nonunion of humeral shaft fractures have been debated. Foster et al. (37) defined fractures ununited by 4 months as delayed unions and ununited by 8 months as nonunions. In contrast, based on their retrospective reviews, Mast et al. (85) and Foulik and Szabo (59) determined that fractures of the humeral shaft that have not begun to unite by 6 to 10 weeks probably will not unite unless the treatment is changed. This is consistent with the literature, which states that the average time to union of these fractures is 8 to 12 weeks (7,21,71). To optimize outcome and minimize the patient's disability time, surgery should be performed as soon as a delayed union or nonunion is suspected (see Chapter 27).

OPERATIVE TECHNIQUES

Plate Osteosynthesis

- Use Henry's anterolateral exposure or a midline posterior approach for fractures within the distal third of the humeral shaft (see Chapter 1). The plate may be placed on the posterior or anterolateral aspects of the bone. Use generous incisions to avoid excessive retraction on the soft tissues with careful soft tissue dissection and bone-handling techniques.
- Identify and protect the radial nerve and others as necessary.
- Reduce the fracture as accurately as possible and use lag screws for interfragmental compression wherever possible (oblique or spiral fractures). Then apply the chosen plate, in compression mode whenever possible. At least six cortices of screw purchase are needed in the major fragments, both proximal and distal to the fracture (79,1536), and some authors recommend eight to 10 cortices on each side of the fracture (152). In transverse and short oblique fracture patterns, a compression plate works especially well. Predrilling the plate over the fracture site ensures closure of the fracture on the cortex opposite the plate.

The AO group has recommended the broad 4.5-mm dynamic compression plate (DCP) for use on the humerus because the offset hole alignment may allow better fracture fixation and because of biomechanical test results on femur fractures. Testing results on the femur were extrapolated to the humerus, but the need for such a large plate has not been tested directly on humeral fractures. A 4.5-mm broad DCP may be best for large patients, but a narrow 4.5-mm DCP should be used in patients with smaller bones. Dabezies treated 44 consecutive acute fractures of the humeral shaft with plate osteosynthesis (27). Union was achieved in all at an average of 12 weeks. Nine fractures in small patients were plated with the 3.5-mm DCPs, and all healed.

Bone grafts have an important role in treating humeral shaft fractures, particularly if the fracture is plated or openly reduced. Cancellous bone grafts should be used in fresh fractures where there is bone loss, particularly for a cortical defect or comminution. In an open fracture with significant soft-tissue damage, bone grafting is useful but is withheld until there is enough soft-tissue coverage to cover the graft. This may be at the time of delayed primary closure or skin grafting or when the fracture is plated after initial temporary stabilization with an external fixator. Cancellous bone grafting also should be used routinely in treating nonunions.

Results from plate fixation have been excellent. Foster et al. reported 100% union with a good ROM of the shoulder and elbow in 27 patients with multiple injuries treated acutely using plate osteosynthesis for the humerus (37). Similar results have been reported by others (10,142). Plating also works well for humeral nonunions and is still considered the gold standard (92,124,125), although union rates for nonunions treated with intramedullary fixation and plates are nearly equivalent (147).

Intramedullary Devices

Intramedullary nails work well for most long bone diaphyseal fractures including the humerus. They can function as load-sharing devices and are subjected to smaller bending loads than plates because plates sit further from the bone's mechanical axis. There is less stress shielding of the cortex with nails than plates, and the risk of stress fracture after implant removal is less with nails than plates. Less dissection is necessary to insert them, and the fracture site need not be disturbed directly. They are more technically demanding to insert properly, however, and they should not be used when there is a radial nerve palsy that requires exploration anyway or to treat nonunions when there is a true pseudarthrosis that requires open debridement. Two types of intramedullary devices have been used: flexible nails and rigid interlocking nails.
Interlocking Nail Technique

- Place the patient in a semireclining (beach-chair) position close to the edge of the table with a rolled towel between the shoulder blades.
- Prep the entire extremity from the neck to the fingertips and drape the arm free.
- Make a longitudinal incision starting at the lateral acromion and extending distally approximately 4 cm in line with the deltoit. Split the deltoit muscle in line with its fibers for 2 to 5 cm but not further to avoid injuring the axillary nerve.
- Next, incise the supraspinatus tendon laterally in line with its fibers to expose the lateral edge of the humeral head articular surface and the medial edge of the greater tuberosity.
- Make a starting hole with an awl in the sulcus between the articular surface and the greater tuberosity. This entry point is directly in line with the medullary canal of the proximal humerus. Keeping the risk of creating an iatrogenic fracture of the proximal humerus, particularly if the shaft fracture is proximal or has fracture lines that extend proximally.
- Use a T-handled hand reamer to enter the intramedullary canal through the starting hole made by the awl.
- Then, with fluoroscopic assistance, reduce the fracture and pass a 3-mm bulb-tipped guide wire down the shaft, across the fracture site, and into the cancellous bone of the metaphysis of the distal humerus.
- If reaming is indicated, ream the proximal medullary canal using a flexible reamer, beginning with the end-cutting 8-mm reamer. Do not ream distally in the humerus where the medullary canal thins and flattens. In general, open fractures should not be reamed.
- Overream the canal 0.5 mm in young patients with hard bone to avoid incarcerating the nail.
- Carefully determine nail length using a second guide wire of identical length and/or a preoperative template of the opposite humerus. This is important because if the nails were too long, it may impinge in the distal humerus, causing pinch-off distraction of the fracture site.
- The flat ends of the Enders nails will be left lying on the external surface of the humerus and must be placed sufficiently proximally that impingement from the olecranon fossa is avoided. The oval hole outlined with the drill points should be 10 to 15 mm in width and 20 to 25 mm in length along the longitudinal axis of the humerus, depending on the size of the bone and the size of Enders nails used. Usually, two Enders nails are placed. This hole must be large enough to accommodate these two pins side by side and be long enough to avoid accidental fracture of the proximal cortex from the pressure of the pin.
- Use a small thin osteotome to connect the drill holes and remove the window. Use a small-angled rongeur to smooth out the edges of the hole and make it large enough to accommodate the two Interlocking nails of appropriate size.
- Ender nails are available in 3-, 4-, and 5-mm diameters. In the average humerus, 3-mm pins will be used. In some very large individuals, a 3- and a 4-mm pin, or on occasion two 4-mm pins, may be used.
- Determine the appropriate length by pulling on the arm to bring the fracture out to length, laying an Ender nail on the arm as close to the bone as possible, and then visualizing it with the fluoroscope.
- Next insert the first Ender nail with the insertion tool. This T-wrench not only allows you to drive the Ender nail but to control it in rotation which is essential for reducing and maintaining the reduction and for spreading the pins within the humeral head. Sometimes it may be necessary to bend the tip of the pin gently in order to obtain the position desired.
- Drive the pin under fluoroscopic control to the fracture. Reduce the fracture with longitudinal traction and then, under fluoroscopic control, insert the tip of the pin into the medullary canal of the proximal fragment. Twist the pin to reduce the fracture and drive it proximally to within 1 cm of the subchondral bone of the humeral head. In dealing with a fracture of the cervical neck, the same technique can be used.
- With one pin in place, if it is then fairly simple to drive a second pin beside the first, placing the tip of the pin into the opposite portion of the humeral head. This divergence of the pins provides better fixation and superior better fixation and superior control over rotation.
- Impact the fracture to improve stability when the configuration allows.
- Close the wound in a routine fashion, dress sterilely, and support the arm in a shoulder immobilizer.
- Postoperatively, Ender nails do not provide absolute stability; therefore, some motion at the fracture site can occur during the early phases of healing. Gentle pendulum exercises can almost always be initiated as soon as the patient is reasonably comfortable. Active use of the hand, wrist, and elbow are essential. As soon as the first callus is visualized at the fracture site, which is normally between 4 and 8 weeks, there is usually sufficient stability that the patient can begin active motion and overhead rehabilitation exercises.

Ender Nail Technique

Flexible nails such as Ender nails and Hackenthal nails can be inserted antegrade or retrograde, but several must be inserted together to stabilize the fracture, and they do not control rotation (53,54). Rigid interlocked nails provide better stability and rotational control (54). They may be inserted retrograde or antegrade, but if inserted antegrade through the rotator cuff they frequently cause subacromial impingement symptoms and must be removed after the fracture heals.

- Place the patient in the supine or prone position on a fully radiolucent operating table, according to the surgeon's preference.
- The Ender nails can be inserted using either closed or open technique, but radiographic control intraoperatively with C-arm fluoroscopy is essential.
- Prepare and drape the entire upper extremity, excluding the shoulder.
- The Ender nails are inserted through the midportion of the posterior cortex of the distal humerus, approximately 2 cm proximal to the olecranon fossa. For this reason, make a longitudinal midline vertical incision on the posterior aspect of the arm, approximately 3 to 5 cm in length, just proximal to the tip of the olecranon.
- Incise directly down through the subcutaneous fat and deep fascia in the midline and split the muscle fibers of the triceps in the midline, down to the distal humerus, which is exposed by subperiosteal dissection.
- Identify the superior edge of the olecranon fossa and then use a 2- to 3.5-mm drill point to outline an oval-shaped entry site on the posterior surface of the humerus, which should be approximately 15 mm proximal to the olecranon fossa. The flat ends of the Ender nails will be left lying on the external surface of the humerus and must be placed sufficiently proximally that impingement from the olecranon fossa is avoided. The oval hole outlined with the drill points should be 10 to 15 mm in width and 20 to 25 mm in length along the longitudinal axis of the humerus, depending on the size of the bone and the size of Ender nails used. Usually, two Enders nails are placed. This hole must be large enough to accommodate these two pins side by side and be long enough to avoid accidental fracture of the proximal cortical fracture from the pressure of the pin.
- Use a small thin osteotome to connect the drill holes and remove the window. Use a small-angled rongeur to smooth out the edges of the hole and make it large enough to accommodate the two Ender nails of appropriate size.
- Ender nails are available in 3-, 4-, and 5-mm diameters. In the average humerus, 3-mm pins will be used. In some very large individuals, a 3- and a 4-mm pin, or on occasion two 4-mm pins, may be used.
- Detergent nailing by pulling on the arm to bring the fracture out to length, laying an Ender nail on the arm as close to the bone as possible, and then visualizing it with the fluoroscope.
- Next insert the first Ender nail with the insertion tool. This T-wrench not only allows you to drive the Ender nail but to control it in rotation which is essential for reducing and maintaining the reduction and for spreading the pins within the humeral head. Sometimes it may be necessary to bend the tip of the pin gently in order to obtain the position desired.
- Drive the pin under fluoroscopic control to the fracture. Reduce the fracture with longitudinal traction and then, under fluoroscopic control, insert the tip of the pin into the medullary canal of the proximal fragment. Twist the pin to reduce the fracture and drive it proximally to within 1 cm of the subchondral bone of the humeral head. In dealing with a fracture of the cervical neck, the same technique can be used.
- With one pin in place, it is then fairly simple to drive a second pin beside the first, placing the tip of the pin into the opposite portion of the humeral head. This divergence of the pins provides better fixation and superior better fixation and superior control over rotation.
- Impact the fracture to improve stability when the configuration allows.
- Close the wound in a routine fashion, dress sterilely, and support the arm in a shoulder immobilizer.
- Postoperatively, Ender nails do not provide absolute stability; therefore, some motion at the fracture site can occur during the early phases of healing. Gentle pendulum exercises can almost always be initiated as soon as the patient is reasonably comfortable. Active use of the hand, wrist, and elbow are essential. As soon as the first callus is visualized at the fracture site, which is normally between 4 and 8 weeks, there is usually sufficient stability that the patient can begin active motion and overhead rehabilitation exercises.

External Fixation

There are few indications for treating humeral shaft fractures definitively with external fixation. This technique should be reserved for open fractures with significant soft-tissue injuries (15,56,150) and for the rare patient with multiple injuries where stabilization is important and speed essential. It stabilizes the fracture without adding further soft-tissue injury from the surgical trauma. Typically a single frame is placed along the lateral aspect of the arm with two pins above and two below the fracture site. If the Shanz pins are placed laterally, then a limited open approach is recommended to avoid injury to the radial nerve. The frame is usually used as a temporary fixation device until the soft tissues heal and the fracture can be treated with another device or replaced by a functional brace.

Postoperative Management

We recommend use of a shoulder immobilizer and local ice to the arm for initial postoperative comfort. These are used for 2 to 3 days until the incisional and muscle pain decreases and the swelling diminishes. Keep an axillary pad in place to prevent skin maceration. Institute gentle ROM exercises within a few days, depending on the stability of the fixation. It is important to stress the importance of vigorous finger, wrist, and elbow motions to prevent stiffness. Add shoulder pendulum exercises as the patient's pain and fracture stability allow and advance to active-assisted shoulder ROM exercises within a few weeks. A sling is suggested until full muscle function returns without pain. Strengthening exercises are avoided for 12 weeks or until the fracture heals.
CONCLUSIONS

Intramedullary nailing of humeral shaft fractures has not had the same rate of success as intramedullary nailing of femur and tibia fractures. In addition, problems from subcromial impingement have been reported in almost every series utilizing antegrade humeral nailing. Therefore, for humeral shaft fractures treated operatively, particularly because of failed nonoperative treatment, open fractures, or fractures with neurovascular complications, we prefer open reduction and internal fixation with plates and screws using an anterolateral approach. Bone grafting is used following the principles outlined above. We are careful to identify the radial nerve and retract it gently out of the way to avoid injury to it, verifying that it is intact at the conclusion of the case. We treat nonunions with plate fixation (Fig. 15.37) also, but we prefer to make a posterior approach to the humeral shaft and dissect out the radial nerve to be sure it is not injured or incarcerated in the nonunion site (see Chapter 27 for more detail on nonunions).

Figure 15.37. A: Anteroposterior radiograph of a middiaphyseal humeral nonunion. B: Postoperative AP radiograph illustrating proper surgical technique utilizing a compression plate and autogenous bone grafting.

We reserve intramedullary nails for the multiply injured patient who needs a load-sharing device to facilitate rehabilitation, but only if those fractures can be reduced easily so that there is no question about possible soft-tissue interposition at the fracture site. Our list of indications for intramedullary nails also includes pathologic fractures, fractures associated with osteopenic bone, and fractures underlying burns.

COMPLICATIONS

Plate Fixation

Infection following open reduction and internal fixation is a major concern. Fortunately, the humerus is surrounded by a well-vascularized muscular envelope, and when careful soft-tissue techniques are used, infection rates of less than 1% should be anticipated (1). Grade III open fractures have higher rates of infection after plate fixation, which has led some authors to recommend external fixation for these injuries. However, deep infections in pin sites from external fixators can be equally problematic.

Radial nerve palsies can complicate ORIF. The strategy for management is discussed above.

Hardware failure and nonunion may result from inadequate initial fixation of acute fractures (Fig. 15.38) but are seen even more commonly after plate fixation of the delayed unions and nonunions where screw fixation to the bone may be suboptimal because of disuse osteopenia. These problems may be minimized by operating sooner when nonunion is suspected, using a longer plate with at least six and preferably eight cortices above and below the fracture site, adding cancellous bone graft, and using a cast brace postoperatively to augment the fracture fixation and decrease stress on the implants.

Figure 15.38. Nonunion in a patient referred for treatment of a humeral shaft fracture treated with Rush rods and cerclage wiring. This was rotationally unstable, as seen by these attempted AP (A) and lateral (B) views, which demonstrate rotation at the nonunion site. Combining open reduction and wiring with intramedullary devices risks devascularizing the fracture site, a risk factor for nonunion, and is not recommended.

Intramedullary Nails

One of the most common complications seen after antegrade intramedullary nailing of humeral shaft fractures is subacromial bursitis and impingement, causing shoulder pain and decreased ROM. Be sure to use the proper length nail to ensure that the proximal end is flush with the greater tuberosity or buried beneath its cortex. Also, distraction at the fracture site is a pitfall to avoid at all costs, as it can cause a nonunion. If retrograde nailing is done through the condyles, there is a risk of condylar fracture. If this does occur, the condyles should be reattached with lag screws at the time of nailing.

External Fixation

The most troublesome complication we see after external fixation of humeral fractures is elbow stiffness. We prefer not to use external fixation for humeral fractures, but when it is necessary, we do everything possible to start elbow motion early. Avoid using fixators that span the elbow and prevent motion.

Using an external fixator as the definitive fracture management technique after open fractures may increase the potential for delayed or nonunion. This problem may be reduced by bone grafting (14). An alternative is to use the external fixator temporarily until soft-tissue coverage has been obtained and then convert to another method.
of fixation such as plates. Unfortunately, pin tract infections that develop in the interim may preclude internal fixation. In some cases, the temporary fixator may be removed after the soft tissues heal and the fracture is treated to union with a functional brace. (See Chapter 14 for the principles of external fixation.)

TRAUMATIC DISLOCATIONS OF THE SHOULDER GIRDLE

Dislocations of the shoulder girdle joints are common injuries. When they occur in association with fractures, fracture management often dictates the treatment strategy and follows the principles outlined in the previous sections of this chapter. The evaluation and management of glenohumeral, acromioclavicular, and sternoclavicular joint injuries and instability are covered separately in detail in other chapters of this textbook (see Chapter 78 and Chapter 80). However, the principles of diagnosing and treating acute dislocations of the shoulder joints are important to keep in mind when considering fractures of the shoulder girdle and therefore they are reviewed here, also.

GLENOHUMERAL DISLOCATIONS

The glenohumeral joint is dislocated more often than any other major joint (68), usually as a result of a sports injury or a fall, but many other etiologies have been reported. Effective treatment depends on making the correct diagnosis promptly as well as recognizing and treating associated injuries. Injury classification also helps direct treatment appropriately.

Classification

Glenohumeral dislocations can be classified by direction, chronicity, and mechanism. The direction describes the position of the humeral head relative to the glenoid and is most often anterior, but may be posterior, inferior (“luxatio erecta”), or, rarely, intrathoracic. The dislocation may be acute or chronic. Unreduced dislocations presenting or diagnosed after 3 weeks are considered chronic (see Chapter 60).

Injury mechanism can be classified as traumatic or atraumatic. Traumatic instabilities are further characterized as a subluxation or true dislocation of the joint. Atraumatic instabilities can be voluntary or involuntary and may be related to congenital general ligamentous laxity. Some patients with voluntary instability are able to dislocate and relocate their glenohumeral joints almost painlessly. Those patients are poor surgical candidates.

Radiographic Evaluation

Evaluate patients with suspected shoulder dislocations radiographically in the same way as patients with shoulder girdle fractures (see above). Critical to evaluating the joint are two views, one of which is a lateral view that shows the glenoid fossa well, to rule out a posterior dislocation. The axillary or transaxillary (Y) views are best for that purpose.

Internal rotation views of the shoulder are useful for demonstrating the Hill-Sachs lesion, which is a defect in the posterolateral aspect of the humeral head caused by impaction of the humeral head against the anterior glenoid rim at the time of an anterior dislocation. Impaction lesions of the glenoid rim, the counterpart of the Hill-Sachs defect, are difficult to demonstrate with plain radiographs and are seen better with CT scans. Magnetic resonance imaging studies may be helpful for evaluating rotator cuff pathology but are not indicated for acute trauma. As in all cases, postreduction radiographs should always be obtained after the joint is reduced.

Anterior Dislocations

The most common direction of glenohumeral joint dislocation is anterior (84%) (19). Usually the mechanism of injury is forced external rotation of the shoulder while the arm is abducted, levering the humeral head against the anterior capsule. As the restraining effect of the anterior glenoid labrum and capsule are exceeded, the head of the humerus dislocates anteriorly and usually comes to rest below the coracoid process. In approximately 85% of patients, the glenoid labrum is detached from the anterior glenoid rim (a Bankart lesion). The remaining cases occur with interstitial stretching or frank rupture of the capsule without significant detachment of the labrum (Fig. 15.39). This has been proposed as a possible explanation for the decreased incidence of recurrent dislocation in older patients (>40 years). Anterior shoulder dislocation is usually an injury of adolescents and young adults, with most patients being between the ages of 12 and 50 years.

![Figure 15.39](image)

Some of the anatomic lesions around the glenohumeral joint that may result in or from instability.

On physical exam, the humeral head is palpable anteriorly in the subcoracoid position, and there is loss of the normal lateral and posterior contours because of the vacant glenoid. Neurovascular examination is usually normal, but there may be an axillary nerve palsy. This can be difficult to detect before reduction because pain prevents the patient from contracting the deltoid or abducting the shoulder. Decreased sensation to light touch laterally over the deltoid may be the only detectable sign of an axillary nerve injury but is frequently subtle and unreliable. Less commonly, other neurovascular injuries occur (13).

Treatment

After the diagnosis has been made, prompt reduction of the dislocation is the treatment of choice. The key to reduction of any joint dislocation is muscle relaxation, as evidenced by the ease with which most joints can be reduced under general anesthesia with complete muscle paralysis. General anesthesia is rarely necessary to reduce acute shoulder dislocations, however, unless there is interposed soft tissue or an associated fracture with an incarcerated bony fragment.

Many reduction maneuvers have been described, dating back to antiquity. Most rely on the principles of traction, leverage, or rotational forces, and there is considerable overlap between methods. One of the safest and most effective means of reducing an anterior shoulder dislocation relies on traction and countertraction and is best accomplished with an assistant (Fig. 15.40), although it can be done with one person using her foot against the patient’s chest wall for countertraction.

![Figure 15.40](image)

Alternatively, a modification of Kocher’s method works well. It is relatively easy on the patient, can be performed by one individual without force, and is usually successful. The key to this method is avoiding traction, which induces secondary muscle spasm, increasing the patient’s pain and making reduction more difficult. Elevate the patient’s elbow above the midcoronal plane and then gently externally rotate it using a hand placed on the patient’s wrist. If done slowly, it takes little effort to externally rotate the patient’s shoulder. Slowly abduct the extremity during this process to about 90°. It is important to continue external rotation beyond the midcoronal plane. Reduction is usually accomplished by these maneuvers, but if it is not, then the arm is adducted fully across the chest and internally rotated as in the last two maneuvers of Kocher’s method.

Postreduction Management Regardless of the method selected, once the joint is reduced the patient’s pain is decreased dramatically and promptly. For that reason, it is important not to administer an excessive dose of sedation and narcotics to achieve the reduction, particularly in older patients; this is because once the joint is reduced and the pain stimulus has diminished, the residual effects of the medications may cause dangerous respiratory depression. After the reduction, obtain confirmatory radiographs. Immobilize the shoulder in a sling or shoulder immobilizer. The duration of immobilization is controversial, but most authors recommend 4 to 6 weeks total, during which time a rehabilitation program is initiated. The goal is to avoid recurrent dislocations without excessive stiffness. Patients older than 40 should be immobilized for less time (2 weeks) because they are more likely to have problems from stiffness and rotator cuff injuries than from recurrent instability (70).

Posterior Dislocations

Posterior glenohumeral dislocations are uncommon and account for 2% to 4% of all shoulder dislocations (87,126). They warrant particular attention, however, because they are so frequently overlooked; in 60% to 80% of cases (129), the initial diagnosis is missed, and that often leads to major shoulder dysfunction. The mechanism of injury is a posteriorly directed force acting on an adducted and internally rotated humerus. It can also result from violent muscle contractions and therefore may be seen after grand mal seizures, electroshock treatment, or electrocution injuries and should be ruled out in patients complaining of shoulder pain after such events.

On physical examination, the shoulder is usually held internally rotated, and the patient is unable to abduct or externally rotate the joint. It may be possible to feel the fullness of the humeral head posteriorly unless the patient is examined late, when chronic swelling masks this finding. If the diagnosis is made months after the initial injury, there may be atrophy of the shoulder musculature despite the return of limited abduction and external rotation.

Treatment If a posterior dislocation is diagnosed acutely, it may be reduced by rotating the arm to the neutral position and gently lifting the humeral head anteriorly into the glenoid. Reduction of posterior dislocations may be difficult because they are often diagnosed late. Chronic dislocations are much more difficult to treat. They may be irreducible by closed methods and can present with muscle contracture, periarticular fibrosis, associated fractures, or heterotopic bone formation. Commonly, open reduction is necessary together with joint debridement and attempts at soft-tissue repair or muscle advancement into the defect in the humeral head.

Postreduction Management Acute posterior dislocations that have been reduced and are stable may be treated with a sling. If postreduction examination reveals significant instability, however, then the shoulder should be immobilized in neutral or slight external rotation. A variety of orthoses are available to hold the extremity in that position. Rehabilitation of the injured structures is based on principles outlined above for other shoulder injuries, with an emphasis on strengthening the rotator cuff muscles.

Surgical Indications It is not common to see shoulder dislocations that are irreducible in the absence of fractures, but it does happen, usually because of soft-tissue interposition in the joint or because of severe muscle spasm in large, muscular patients. In those cases, general anesthesia may be necessary to obtain reduction. Occasionally an open reduction is necessary when closed reduction fails in spite of general anesthesia. An anterior deltopectoral approach is recommended for most dislocations, although associated injuries or wounds may warrant an alternate approach.

Postoperative treatment depends on the pathology found at the time of surgery and the stability achieved after the reduction and repair of any injured soft tissues. Generally, the shoulder should be immobilized in a shoulder immobilizer or sling and swathe immediately postoperatively. Pendulum exercises can be started in 1 or 2 days, and a graduated rehabilitation program instituted within the first 2 weeks. Less stable injuries require longer periods of immobilization.

Complications The most frequent complication after a glenohumeral dislocation is recurrent dislocation. The rate of recurrence correlates with patient age: 70% to 90% for patients younger than 20 years, 60% for patients between 20 and 40 years of age, and only 10% for patients older than 40 (60). The key to minimizing recurrence is patient education about what joint positions are likely to be unstable based on the original direction of dislocation and careful adherence to a well-designed rehabilitation program that strengthens the weakened shoulder muscles. Those joints that are unstable despite these precautions warrant surgical treatment for chronic instability (see Chapter 80).

Other complications are less common. Neurologic injuries following glenohumeral dislocations are usually transient. Brachial plexus injuries are uncommon, but their presence suggests a more violent shoulder injury. Most often they are neurapraxias and recover, but more significant injuries also occur, such as in scapulothoracic dissociation (see above). Isolated axillary nerve palsies usually resolve within 3 months. In the interim, the shoulder should be supported to prevent persistent inferior subluxation and stretching of the soft tissues. Rotator cuff injuries are more likely in older patients in association with glenohumeral dislocations and should be suspected in patients over 40 with persistent weakness of shoulder abduction (145).

ACROMIOCLAVICULAR DISLOCATIONS

Acromioclavicular (AC) joint dislocations and subluxations (“shoulder separations”) account for approximately 15% of all shoulder girdle dislocations (18,146). The true incidence is probably much higher because patients with low-grade injuries may not seek medical attention. The mechanism of injury is typically a direct blow or fall on the shoulder, in which the acromion is driven downward, tearing the AC joint capsule and restraining ligaments. The most common mechanisms are sports related, but they also occur in motor vehicle accidents. The same mechanism of injury that causes acromioclavicular joint disruptions can also cause sternoclavicular dislocations and fractures of the clavicle or acromion.

Classification

Classification of injuries involving the acromioclavicular joint is shown in Fig. 15.41 (120). The classification hinges on a combination of physical examination and radiographic findings, and as with most classifications in orthopaedics, higher numbers indicate more severe and complex injuries. Types I, II, and III are most common. Types IV through VI are uncommon and usually are caused by higher-velocity injuries; they are characterized by the unusual displacement of the clavicle. It is important to thoroughly evaluate the shoulder girdle clinically and to study the radiographs carefully to avoid overlooking other injuries that may occur in combination with AC joint injuries.

Figure 15.41. Classification of acromioclavicular (AC) joint injuries. Type I, sprain of the AC ligaments; type II, AC joint disruption with sprained coracoclavicular (CC) ligaments; type III, complete disruption of the AC joint and CC ligaments; type IV, complete disruption of the AC joint and CC ligaments and posterior displacement of the distal clavicle into the trapezius muscle; type V, wide displacement of the distal end of the clavicle (one to three times normal distance) associated with detachment of the deltoid and trapezius muscles from the distal clavicle; type VI, inferior displacement of the distal clavicle below the coracoid process associated with detachment of the deltoid and trapezius muscles from the distal clavicle.
Treatment

Treatment varies according to injury classification. Injury types I and II may be considered AC ligament sprains or disruptions, but both may be treated symptomatically with an arm sling for patient comfort. Symptoms usually subside within 1 to 2 weeks, but the patient should be cautioned against heavy use of the shoulder until shoulder motion is painless and equal to the preinjury status. Treatment for type III injuries is controversial. Many authors recommend nonoperative management with a sling for comfort, pointing to the higher complication rate from operative treatment (40,137). A Kenny-Howard sling can be used to maintain joint reduction but requires a motivated, compliant patient and diligent attention to detail to be effective and avoid skin complications (137). Others advocate early surgical treatment, and a wide variety of surgical methods have been described for treating this lesion. The occupational demands and goals of the patient are critical to decision making. Type III injuries can be treated late if symptoms persist after initial nonoperative treatment (see Chapter 78), and that is our preferred approach.

The more severe injuries (types IV, V, and VI) are usually treated surgically because of the extreme displacement of the clavicle and detachment of the deltoid and trapezius muscles. Many different operations have been devised, including transarticular pins, ligamentous repair, synthetic slings (mersilene), and screws securing the clavicle to the coracoid to reduce the AC joint.

Bosworth Screw Fixation of AC Joint Dislocations

- Position the patient in the beach-chair position on the operating room table and pay particular attention to supporting and securing the patient's head and neck appropriately.
- Drape the shoulder so that free access is possible from the middle of the patient's neck to the elbow and from the medial border of the scapula posteriorly to the midline of the chest anteriorly.
- Make a 6- to 10-cm-long strap-like incision in Langer's lines beginning 2 cm posterior to the clavicle and carried anteriorly to a point just medial to the coracoid process, centered over the AC joint.
- Undermine the skin flaps to expose the AC joint, the distal 5 cm of the clavicle, and the anterior deltoid muscle fibers.
- Detach the anterior deltoid from its origin on the clavicle enough to visualize the base of the coracoid process and the coracoclavicular ligaments as well as the remnants of the AC joint capsule and ligaments. In some cases, the deltoid and trapezius muscle fascia may have been stripped away as part of the initial injury.
- Grasp the distal end of the clavicle with a towel clip or tenaculum, retract it, and debride the joint.
- Tag the torn ends of the coracoclavicular (CC) ligaments and any remnants of the AC joint capsule or ligaments with nonabsorbable sutures but do not tie them yet.
- Reduce the clavicle to the acromion and drill a ½-in. hole through the clavicle, aiming for the base of the coracoid process. Use a smaller drill bit (⅜ in.) to make a hole through the base—not the waist—of the coracoid.
- Measure the distance from the top of the clavicle to the bottom of the coracoid process with a depth gauge and then insert the proper size Bosworth screw. Be sure the screw enters the hole in the coracoid process and does not slove off medially or laterally.
- Obtain intraoperative radiographs to verify proper screw placement before beginning the final steps of the procedure. See Figure 15.42.

Alternative Fixation Methods for Treating AC Joint Dislocations

- In some cases it may be possible or desirable to repair the AC joint disruption using local soft-tissue remnants and reinforcing the repair with pins across the joint or other material looped around the clavicle and coracoid.
- Position and prep the patient and expose the AC joint as described above.
- For pin fixation of the AC joint, most authors recommend the use of small, smooth or threaded Steinman pins. The technique of exposure and hardware placement follows the principles outlined for treating distal clavicle fractures (see above).
- If heavy sutures, tape (mersilene), or other synthetic material is used to reinforce the repaired CC ligaments, expose the base of the coracoid as described for the Bosworth screw.
- Pass a curved vascular clamp under the coracoid process, carefully hugging the bone with the clamp as it is passed. It is usually easier to pass the clamp from medial to lateral.
- Grasp the selected material with the clamp and pass it under the coracoid and then over the top of the clavicle. Tie it securely to reapproximate the clavicle to the coracoid, keeping the AC joint reduced, and then tie the sutures previously placed in the CC ligaments.
- Anchor the reinforcing loop to the clavicle with additional nonabsorbable sutures.

Postoperative Management Postoperatively, patients should support their arms in a sling for the first 2 weeks, but be allowed to perform activities of daily living as their comfort allows. The sling can be discontinued after 2 weeks, but heavy lifting should be avoided for 6 weeks. If a Bosworth screw or pins are used, remove them 8 weeks after surgery; normally that is done in the office with local anesthetic. Regardless of the fixation or repair technique selected, patients should avoid contact sports for 12 weeks.

Complications

In the long run, most patients with AC joint injuries recover excellent shoulder function. Heavy laborers and patients who use their shoulders frequently for overhead lifting may develop chronic symptoms, but they are rarely severe or disabling. For patients with significant symptoms or complaints related to chronic AC dislocation, several surgical options are available (see Chapter 78). The simplest treatment is excision of the distal 1 to 1.5 cm of the clavicle. Other options rely on reconstructing the CC ligaments, usually in combination with distal clavicle excision as in the Weaver-Dunn procedure (193). Acromioclavicular arthritis may develop after AC joint injuries, for which resection of the distal end of the clavicle (Mumford procedure) is an effective treatment.

STERNOCLAVICULAR DISLOCATIONS

Injuries to the sternoclavicular joint represent only 3% of shoulder girdle dislocations (19). Because they are unusual and sometimes subtle, their diagnosis is often delayed, especially in the multiply injured patient. Anterior dislocations are significantly more common than posterior dislocations, but because of their potential for associated mediastinal compression, posterior injuries are more frequently reported. The reported ratio of anterior to posterior injuries varies from approximately 3 to 20 to 1 (99).

The sternoclavicular joint is a moderately mobile ball-and-socket joint having approximately 30° of anterior and posterior slide and upward elevation. It is also capable of 25° to 50° of rotation around the long axis of the clavicle. The ligamentous structures binding the medial clavicle to the sternum are very strong (Fig. 15.43), and therefore traumatic dislocations are usually indicative of significant force and often accompany rib and sternal fractures and other chest injuries. Most dislocations result from direct trauma, but indirect forces transferred from lateral compression on the shoulder also may injure the sternoclavicular joint.
On physical examination, the region of the SC joint is tender and swollen. The most striking finding is the asymmetry between the injured and uninjured SC joints. If the joint is dislocated anteriorly, there may be an appreciable prominence, and if the dislocation is posterior, there may be a hollow depression. Posterior dislocations may present with breathing or swallowing difficulties or even cyanosis secondary to compression of the trachea, esophagus, or underlying vascular structures (35,80). Plain radiographs of the sternoclavicular joint are difficult to obtain and interpret, as mentioned above with fractures of this region. Computed tomography scans are best for evaluating suspected joint injuries.

**Treatment**

Anterior dislocations and subluxations are usually easy to reduce but often recur when pressure is removed from the medial end of the clavicle. Whether or not the reduction can be maintained, isolated SC joint injuries should be treated symptomatically. Provide a figure-of-eight clavicle strap or a sling for comfort. The posterior prominence and mild asymmetry persists in most cases but are not functional problems. Operative reduction and internal fixation for acute cases and resection of the medial end of the clavicle for chronic cases have been reported but are rarely indicated (see Chapter 78).

Posterior dislocations should be reduced promptly because of their potential for compression of the underlying structures. Numerous reduction methods have been advocated. Usually, manual traction on the clavicle is sufficient. It is helpful to place a rolled towel posteriorly between the patient's scapulae and apply posteriorly directed force on the lateral clavicle to help lever the medial end of the clavicle anteriorly at the SC joint. Sometimes a sterile towel clip is useful as a handle for grasping the clavicle and guiding the reduction.

Surgery is indicated for posterior dislocations that are irreducible. Make an incision anteriorly directly over the joint and reduce the clavicle under direct visualization. In the absence of fractures, soft-tissue repair alone is recommended rather than internal fixation so as to avoid complications from the latter.

Postoperatively, in the rare cases when surgery is necessary, and after reductions of SC joint dislocations, a figure-of-eight clavicle strap is recommended because it keeps the patient's shoulders up and back, helping maintain the reduction. Unlike anterior dislocations, posterior dislocations are usually stable after reduction.

**Complications**

Complications after injuries and dislocations of the SC joint are uncommon and are related primarily to posterior dislocations. These include compression or laceration of the carotid sheath or subclavian vessels and injury to the trachea or esophagus. Neurologic sequelae are rare, but compression of the recurrent laryngeal nerve and thoracic outlet syndrome have been reported. Complications related to chronic anterior subluxation or dislocation of the sternoclavicular joint are usually cosmetic. The residual prominence over the sternoclavicular joint may be tender but is best treated with benign neglect (see Chapter 78).

CHAPTER 16
FRACTURES AND DISLOCATIONS OF THE ELBOW AND FOREARM

This chapter incorporates chapters from the second edition that were written by Bernhard G. Weber, H. David Moehring, Jerald L. Cooper, Robert D. D'Ambrosia, Bruce A. Mallin, and T. David Sisk.

Michael W. Chapman

FRACTURES OF THE DISTAL HUMERUS

Fractures of the elbow are uncommon compared to other serious joint injuries, constituting only about 4.3% of all fractures. In contrast to shaft fractures, joint fractures are almost always treated by open reduction and internal fixation; conservative treatment is the exception.

TREATMENT CONSIDERATIONS

In spite of the fact that surgical techniques for the treatment of fractures of the distal humerus have advanced substantially over the past 20 years and now are quite sophisticated, the rate of complications remains quite high (21,69,83,86,91,92 and 93,116,124,169). Such complications include nonanatomic reduction of articular surfaces, malunion, nonunion, residual stiffness of the elbow, heterotopic ossification, posttraumatic osteoarthrosis, and generalized functional disability. These injuries are being treated more often now with coexisting multiple injuries or in an extremity with complex ipsilateral open injuries, which previously may have led to amputation. In the very elderly, osteopenia often compromises internal fixation, and total elbow arthroplasty is a reasonable alternative (32).

Elbow and forearm fractures continue to present major problems to orthopaedic traumatologists because of the high occurrence of comminution, the large and complex articular surfaces involved, the close proximity of important nerves and vessels, and the poor soft-tissue coverage. In spite of the best treatment, the result may be poor because of the magnitude of the original injury. In the vast majority of fractures, ideal treatment consists of early open reduction with replacement of any lost bone, and rigid anatomic fixation of the joint surfaces and adjoining metaphyseal bone, with early aggressive active range-of-motion and strengthening exercises (69,84,169). As with all intraarticular fractures, good technique requires careful preoperative planning, adequate exposure of the joint and fracture, biomechanically sound internal fixation, and protection of neurovascular structures. Flexibility on the part of the surgeon and the availability of a wide range of plates and screws are necessary (2,20,87,93,122,130,171,172).

Comminuted elbow fractures in which the bone is osteopenic and the patient is over 70 years old can be nearly impossible to fix. Primary total elbow arthroplasty is a reasonable alternative in these patients, particularly if they have coexisting arthritis or rheumatoid arthritis. Cobb et al. (32) performed arthroplasty in 21 elbows in 20 consecutive patients, whom they followed for a mean duration of 3.3 years with a minimum follow-up of 2 years. Fifteen elbows had an excellent result, five had a good result, and one was not rattle. Of these, one required revision for a fracture of the ulnar component sustained in a fall.
ANATOMIC CONSIDERATIONS

The elbow joint consists of three articulations: the radial-capitellar, the trochlear-olecranon, and the proximal radial-ulnar. The distal humerus consists of two divergent osseous columns, one lateral and one medial, which flare and are separated by the thin or absent bone of the olecranon fossa, and are connected together distally by the trochlea. The end of the lateral column becomes the capitulum. The lateral column is in approximately 20° of valgus relative to the midline of the humeral shaft, whereas the medial column is at a 40° to 45° angle. Viewed from a lateral perspective, the capitellum is tilted 30° to 40° anteriorly, and the trochlea 10° to 20° (Fig. 16.1). The articulation between the trochlear notches of the olecranon and the trochlea is the most important joint of the elbow because it provides the flexion–extension arc of elbow motion as well as approximately half of the intrinsic stability of the elbow (83). Reconstruction of the normal shape of the trochlea is therefore critical to restoration of good motion and stability in the elbow. Because the majority of intraarticular fractures split through the narrow waist of the trochlea with some comminution, there is a tendency during internal fixation to narrow the trochlea. Avoid this, however, because it creates a noncongruous elbow, which will interfere with motion and lead to osteoarthrosis.

BIOMECHANICS OF INTERNAL FIXATION

The anatomic shape of the elbow joint, in particular the ulnar–humeral articulation, is such that the trochlear notch of the olecranon surrounds almost 100° of the trochlea, making the elbow one of the most stable joints in the body (119,138). The olecranon, in its articulation with the trochlea, contributes significantly to anterior–posterior stability, as well as varus, valgus, and rotatory stability. Resection of increasingly larger amounts of the proximal end of the olecranon leads to a linear decrease in the stability of the elbow. Resection of only 25% of the olecranon process decreases the resistance of the elbow to valgus load by 50%. The coronoid process plays an important role, in that it resists posterior displacement of the elbow joint, particularly in flexion, and the anterior band of the medial collateral ligament attaches near the base of the coronoid process; therefore, large fractures involving the coronoid process may result in incompetence of this ligament. In spite of its small size, the radial head contributes to stability and the transmission of longitudinal force across the elbow joint. The load borne by the radial–capitellar joint is maximal when the forearm is pronated and the elbow extended and loaded longitudinally. The continuity of the radial head is most important when there is associated ligament instability in the elbow and in particular when there is incompetence in the intraosseous membrane and distal radial ulnar joint of the forearm (an Essex-Lopresti lesion).

Restoration of a T- or Y-type comminuted intraarticular fracture of the distal humerus requires reconstruction of an equilateral triangle consisting of the lateral column, the medial column, and the trochlea. Fortunately, even in the elderly, the cortical bone of the medial and lateral columns usually provides good purchase for bone screws. In a biomechanical study of internal fixation of the distal humerus, Heffet and Hotchkiss (61) found that double-plate construction with the two plates at right angles, a medial plate on the medial column and a posterior plate on the lateral column, provided the strongest fixation regardless of whether the plate was a one-third tubular or a 3.5 mm reconstruction plate. Schemitsch et al. (154) looked at plates of two designs placed in five different configurations. They found that when cortical contact was present, dual plates placed medially and laterally—whether at 90° to each other or in the same plane—provided equivalent rigidity. When a cortical gap was present, however, they found that the combination of an anatomic designed lateral buttress J-plate and a medial reconstruction plate gave the greatest rigidity. In practice, 3.5 mm reconstruction plates or their equivalent, particularly in titanium, give the best opportunity to obtain a close fit of the plates to the complex surfaces of the distal humerus, and when placed posteriorly on the lateral condyle and medially on the medial condyle, they provide the strongest construct. Interfragmentary screw fixation from the capitellum through the trochlea usually ensures good stability of the articular surface. Reestablishment of good bone contact throughout the construct, using tricortical bone graft from the iliac crest if necessary, substantially improves fixation and chances for union.

Olecranon osteotomy, if used for exposure, is another source of complications if the fixation fails. The biomechanically soundest technique appears to be a chevron type osteotomy through the nonarticular portion of the olecranon, predrilled and fixed with interfragmentary screw fixation augmented by a tension band wire.

CLASSIFICATION

The Association for the Study of Internal Fixation (AO-ASIF) classification (Fig. 16.2) is the most commonly used scheme for determining treatment and clinical research. The Orthopaedic Trauma Association and the International Society for Fracture Repair recently expanded the AO classification (125) to provide a more detailed breakdown to enhance the accuracy of clinical reports. Their system, however, contains 38 separate fractures of the distal humerus. Jupiter and Mehne (86) divide distal humerus fractures into three major groups: extracapsular, transcolumnar, and intraarticular, which includes single- and bicolumnar fractures and articular fractures involving the capitellum and the trochlea (21,88) (Table 16.1).

Figure 16.2. A-O Classification of distal humeral fractures. Type A—Extraarticular fractures: A1 epicondylar avulsions; A2 supracondylar fractures; A3 supracondylar fractures with comminution. Type B—Unicondylar fractures: B1 fracture of the lateral condyle; B2 fracture of the medial condyle; B3 tangential fracture of the condyle. Type C—Bicondylar fractures: C1 T- or Y-shaped fractures; C2 T- or Y-shaped fractures with comminution of one or two pillars; C3 extensive comminution of the condyles and pillars.
The osteotomy of the olecranon for exposure of the posterior humerus and elbow joint proceeds as follows: superiorward by splitting the triceps both medially and laterally. Posterior exposure is best, using either the comprehensive triceps-splitting approach described in plates do not need to extend beyond the upper edge of the olecranon fossa onto the medial and lateral columns. For intraarticular T-type fractures, a comprehensive column and epicondylar or trochlear fractures, a straight medial approach works well. For nonarticular supracondylar fractures, a triceps-splitting approach suffices if medial epicondyle with the intraarticular component next to the capitellum. A particularly difficult fracture is a shear fracture in the frontal plane involving the anterior portion of the capitellum and lateral half of the trochlea. This results in the characteristic double-arc sign seen on the lateral radiograph of Figure 16.3.

The various surgical approaches to the elbow are described in Chapter 1. For fractures of the lateral column and capitellum, a lateral approach is best. For medial column and epicondylar or trochlear fractures, a straight medial approach works well. For nonarticular supracondylar fractures, a triceps-splitting approach suffices if plates do not need to extend beyond the upper edge of the olecranon fossa onto the medial and lateral columns. For intraarticular T-type fractures, a comprehensive posterior exposure is best, using either the comprehensive triceps-splitting approach described in Chapter 1, or an olecranon osteotomy reflecting the olecranon superiorly by splitting the triceps both medially and laterally.

The osteotomy of the olecranon for exposure of the posterior humerus and elbow joint proceeds as follows:

- Prepare a midline screw hole for the fixation screw using the lag technique. Drill a 4.5 mm hole to just opposite the apex of the elbow joint. Place a guide, and drill with a 3.2 mm drill through the anterior cortex (Fig. 16.5A). Tap the hole.
The key components of internal fixation are the following:

- Fragments, particularly those from the groove of the trochlea, are often too thin or too small to hold with internal fixation, even resorbable pins. Often these will reduce during the assembly of one fragment or fracture line will multiply itself as the reconstruction proceeds, making achievement of an anatomic reduction impossible.
- Loose articular surface fragments are less important for smaller metaphyseal fragments.
- Loose articular surface fragments are less important for smaller metaphyseal fragments.

Using a water-cooled oscillating saw, make a chevron osteotomy with the apex distalward (Fig. 16.5A). Cut down to but not through the subchondral bone of the olecranon. Place this at the apex of the joint where there is almost no articular cartilage.

- Complete the osteotomy with an osteotome, levering the proximal piece of the olecranon to crack through into the joint (Fig. 16.5C). Take care to not injure the articular cartilage of the humerus.
- Split the triceps medially and laterally in line with the olecranon and reflect it proximally (Fig. 16.5D).
- Repair the olecranon with a 4.5 mm cortical screw using the lag technique, augmented by a tension band wire placed around the head of the screw (Fig. 16.5E).

In isolated medial approaches or comprehensive posterior approaches, identify and protect the ulnar nerve. In most cases, transfer of the nerve anteriorly is recommended to avoid impingement on the nerve by plates or screws placed medially, and to avoid incorporation of the ulnar nerve into periarticular scar during healing. Techniques for transfer of the ulnar nerve are described in Chapter 51, Chapter 52, and Chapter 57. I prefer to transfer into a subcutaneous pocket, taking care to release the medial intermuscular septum in the arm, and dissecting the ulnar nerve well down into the flexor carpi ulnaris to avoid any tension or kinking of the nerve proximally and distally. Try to maintain soft-tissue attachments to all bone fragments to preserve their blood supply. This is most important for the articular fragments and less important for smaller metaphyseal fragments.

**Fracture Fixation**

- Identify all fracture fragments and clean them of organizing hematoma. Often there are free fragments. It is useful to make a drawing of the distal end of the humerus on a cloth or a piece of paper on the back table and use this to assemble the fragments in their correct orientation.
- Once all the fracture surfaces and fragments are identified, develop a strategy for assembling the fracture. A few minutes of careful thought spent working out a strategy may save an hour or more of operating time because assembling the fracture anatomically, maintaining it in position, and applying fixation can be extremely demanding technically.

If one column is intact, fixation is greatly simplified and the fragments on the other column can be assembled against the intact column. If both columns are fractured, particularly if there is bone loss, the difficulty increases. In looking at the fracture, think about the sequence of assembling the fragments, because not infrequently the fragments key into each other in such a way that if the order of reduction is not appropriate it may be impossible to assemble the fracture after it is partially fixed.

A good approach is to think about turning a multifragmented fracture into a simple two-part fracture, assembling the articular pieces as one unit and the metaphyseal fragments as another unit, and then finally joining them together. Another approach is to assemble one column and fix it in a stable anatomic position and then assemble the other column against it. Nonanatomic reduction of fracture lines cannot be tolerated, particularly in the early phases of reconstruction, because a small error in the assembly of one fragment or fracture line will multiply itself as the reconstruction proceeds, making achievement of an anatomic reduction impossible. Loose articular fragments, particularly those from the groove of the trochlea, are often too thin or too small to hold with internal fixation, even resorbable pins. Often these will reduce into a stable position if held in position as the trochlea and trochlear capitellar fragments are internally fixed, keying these into place and locking them in position.

The key components of internal fixation are the following:

- Anatomic reduction and preliminary fixation with Kirschner wires
- Interfragmentary lag screw fixation of the articular condyles
- Fixation of the lateral column with a well-molded posterior plate
- Fixation of the medial column with a medial plate extending down to, and on occasion wrapping around, the medial epicondyle
- Multiple interfragmentary screws, usually through the plates but sometimes independent of the plates, to secure the fracture construct together

Sometimes screws are preferred by some surgeons because these can be placed over the preliminary Kirschner wires (K-wires), which greatly simplifies fixation. Keep in mind, however, that these screws are much more expensive and weaker than standard screws.

**Figure 16.6** shows initial interfragmentary screw fixation of the articular component of a Y-fracture.

Figure 16.7. Plate fixation of a Y-type fracture of the humerus with dual plate fixation. A: Use of 3.5 mm reconstruction plates: The lateral plate is molded to fit the posterior aspect of the lateral column and a second plate is molded to fit along the medial supracondylar ridge. B–D: Note that contouring the plate to fit the lateral column requires a twist in three dimensions.

For simple single-condyle fractures, an interfragmentary screw across the condyles and a one-third tubular plate conformed to fit the supracondylar ridge act nicely as a buttress plate (Fig. 16.8). Fix the articular portion of the fracture with an interfragmentary lag screw. Then contour a semitubular plate to fit snugly on the supracondylar ridge and secure it with two screws proximally. This plate has a buttress function that prevents proximal migration of the fractured condyle. Insert a third screw distally.

Figure 16.8. Methods for fixation of unicondylar fractures of the humerus. A: Technique for a fracture on the ulnar side. See text for details. B: A similar technique is illustrated for a fracture on the opposite side. C: Contouring of the plate with pliers.

Coronal shear fractures are difficult to fix, and success depends on the size of the fragment. Alternatives for fixation include multiple K-wires, resorbable pins, resorbable screws, Herbert screws, and 4.0 or 2.7 mm cancellous screws. Because the anterior fragment is small, fixation nearly always has to be through the articular surface; therefore, all implants need to be countersunk below the articular surface.

Repair of Fractures with Bone Defects

The most common defects are caused by comminution in the metaphyseal portion of the olecranon fossa (which usually does not require replacement), fragmentation of the supracondylar ridge, or loss of the midsubstance of the trochlea. The superior margin of the iliac crest provides ideal graft for replacing these deficiencies (Fig. 16.9).  

Figure 16.9. Bone grafting for bone defects. A: Examples of bone defects. B: Harvesting corresponding bone grafts from the iliac crest. C: Incorporating the bone grafts into the corresponding defects.

Wound Closure, Dressing, and Splinting

After completion of the fixation, take anteroposterior (AP) and lateral plain radiographs to confirm the reduction and ensure that the internal fixation has been appropriately placed. Sometimes, it is wise to leave the K-wires placed for preliminary fixation, because they add to the strength of the construct. If left, be certain that they are not protruding excessively from the opposite cortex, and cut them flush with the near cortex if you plan to leave them permanently.

Next, carry the elbow through a full range of motion to be certain that there is no micromotion or evidence of weakness in the construct, particularly at the ends of range of motion. If such is detected, add more fixation or plan to use postoperative bracing, which prevents the elbow from reaching the range of motion that causes micromotion in the fracture site.

Place a small suction drain at the level of bone and close the wound in layers. Apply a bulky sterile dressing and splint the elbow in nearly full extension. This position accommodates swelling better, and most patients rehabilitate better from the extended position than from the flexed position.

See Figure 16.10 for an example of a difficult case.

Figure 16.10. Comminuted intraarticular supracondylar fracture of the humerus with double plate fixation. A: AP radiograph showing extreme comminution of the distal humerus in a 17-year-old girl who fell off a horse. The medial and lateral columns are fractured. There is comminution around the olecranon fossa. The junction between the trochlea and the capitellum is comminuted, with the majority of the trocheal notch consisting of two completely free fragments. B: Lateral radiograph
showing the comminution with complete anterior displacement of the capitellum, which is dislocated free from the radial head. C: Postoperative AP radiograph showing reconstruction of the articular components with a lateral to medial lag screw. The two K-wires provide additional fixation for the free fragments. The integrity of the medial and lateral columns has been restored with 3.7 titanium Alfa (Howmedica, Rutherford, NJ) reconstruction plates. The fracture is anatomic. D: Lateral radiograph of the fixation showing anatomic reduction. It was possible to start immediate motion in this elbow. At 6 months follow-up, the fracture had healed and the patient’s range of motion was from 10° to 135° of flexion, with full supination and pronation. Note that this was done with a comprehensive posterior triceps-splitting approach, and olecranon osteotomy was not necessary.

POSTOPERATIVE CARE

Postoperatively, after elbow fixation, elevate the entire extremity above the level of the heart. Observe carefully for excessive swelling and compartment syndrome. Once swelling has abated and the drain has been removed, remove the bulky compression dressing, apply a supportive brace, and begin active range-of-motion exercises. Set fixed limits on the brace if necessary, according to an examination under anesthesia.

Allow the patient to rest with the elbow in extension and work on the range of motion from that position. Discontinue the braces as soon as feasible. If the patient has difficulty gaining range of motion, use dynamic flexion and extension splints on alternating nights. Avoid resistive exercises and any heavy use of the extremity until fracture healing has occurred, which is generally in 10–14 weeks.

RESULTS

McKee et al. (101) reported surprisingly good results in the treatment of shear fractures of the distal articular surfaces of the humerus in six patients. All united without evidence of osteonecrosis. Functional outcomes were good, with an average flexion contracture of 15° with further flexion to 141°. In T-type bicondylar fractures, Helfet and Schmeling (60) reported an average of 75% excellent to good results.

OLECRANON FRACTURES

Fractures of the olecranon process are common in adults (23). Numerous treatment methods have been advocated, but none is clearly superior. The fracture is usually caused by either direct trauma to the olecranon or a fall on the outstretched hand. Restoration of stable elbow function and rapid mobilization are the goals of treatment.

CLASSIFICATION

Nondisplaced olecranon fractures that are stable and have an intact triceps aponeurosis are generally grouped separately. With this injury, the patient can extend the injured elbow against gravity without causing displacement of the fragments. If there is a question about stability, examine under fluorescopy to document it.

Displaced olecranon fractures are classified according to the fracture line and degree of comminution. A modification of Colton’s classification (34) separates these into four types (Fig. 16.11):

- **Type I**: Avulsion of the olecranon process.
- **Type II**: Fracture from the deepest portion of the semilunar notch.
- **Type III**: Fracture at the most distal portion of the olecranon.
- **Type IV**: Fracture through the more distal part of the olecranon and may be associated with anterior subluxation of the radius and ulna.

The AO classification (122) has been modified recently by the Orthopaedic Trauma Association (125) into eight types.

Morrey (117) has not found any of the previous classifications to be useful to him for clinical decision making; therefore, he proposed the Mayo classification:

- **Type I**: Undisplaced fracture
- **Type II**: Displaced stable fracture: Fracture fragments are separated by more than 3 mm, but the collateral ligaments of the elbow are intact and the forearm is stable in its relationship to the humerus. This type can be subclassified as noncomminuted type IIA or comminuted type IIB.
- **Type III**: Displaced unstable fracture: The fracture is displaced and the forearm is unstable in relationship to the humerus. This is a fracture dislocation, and it can be subcategorized into noncomminuted type IIIA or comminuted type IIIB. The latter is the most difficult to treat and has the poorest prognosis.

BIOMECHANICS OF INTERNAL FIXATION

Prayson et al. (132) compared four different methods of tension band wiring. They compared a monofilament wire in a traditional figure-eight loop with K-wires inserted from the tip of the olecranon into the anterior cortex or intramedullary, to similar constructs using cables in both figure-eight and circular loops. They found that insertion of the K-wires from the tip of the olecranon into the anterior cortex and the use of cable provided superior fixation to intramedullary K-wires and monofilament wire. In a prospective randomized study, Hume and Wiss (73) compared tension band wiring to plate fixation. Although plate fixation required longer operative time, it did not have an increased complication rate, and the clinical results were superior to tension band wire. Postoperative loss of reduction occurred in 53% of patients fixed with tension band wires and in only 5% after plating. With plates, good clinical results were 26% more common, and good radiographic results were 39% more common.

TREATMENT

Nondisplaced olecranon fractures may be managed by maintaining the elbow in a semiflexed position (to 90° of flexion, if tolerated) with a cast or splint. Obtain repeat radiographs at 5–7 days to ensure maintenance of reduction. Early, protected range of motion may begin at about 1 week. Rarely, one encounters an undisplaced fracture in a person in whom nonunion or displacement is not tolerable, such as in a professional throwing athlete. A tension band wiring can be applied with minimal exposure, which allows more aggressive early rehabilitation with minimal risk of displacement.

Treatment of displaced olecranon fractures (Colton types II–IV and Mayo types II–III) has been the topic of a significant amount of research and discussion through the
years. Alternative methods include open reduction and internal fixation or fragment excision, and reconstruction of the triceps mechanism (49,70,77,176). I favor anatomic reduction with internal fixation when possible, with early mobilization.

In Colton type I (avulsion) fractures, tension band wiring of the intraarticular fracture restores the continuity of the extensor mechanism and allows early range of motion. For the extraarticular fragment, treatment is dictated by fragment size and patient age. In the young person with a significant bony fragment, open reduction and internal fixation allows bone-to-bone healing. If the patient is older or the fragment size is limited, excision and realignment of the triceps mechanism is preferred.

For Colton type II (transverse or oblique) fractures, internal fixation options include tension band wiring with associated K-wires or a screw (or screws) (79), and intrafragmentary compression screws with or without neutralization plating. I prefer a tension band wire with K-wires or a single screw of appropriate size. This method transforms tension forces into compressing forces across the fracture site (176). Active elbow flexion increases compression and stability because of the tension band construct. Plate fixation plus an interfragmentary compression screw is more stable than a tension band wire but requires more exposure (74).

For Colton type III fractures (fracture–subluxations), those that propagate from the distal third of the olecranon are potentially unstable. The biceps and brachial muscles may cause anterior subluxation of the radial head and displacement of the distal fragment of the ulna. This adds a compressive force to the posterior surface of the olecranon, making tension band wiring less effective (71). Therefore, I recommend rigid internal fixation with interfragmentary compression screws augmented by a neutralization plate. In some cases, a reverse obliquity of the fracture line may result in a proximal fragment too small for plate fixation. In this case, use an intramedullary compression screw to prevent anterior subluxation (Fig. 16.12). Failure to recognize this specific fracture pattern may result in unsatisfactory fixation.

Because of the high energy that causes Colton type IV (comminuted) injury, the fracture is frequently complex and is usually a challenge to reduce and fix (Fig. 16.13). If the fracture extends beyond the coronoid process, length must be restored. Fractures of the coronoid process must be adequately reduced and fixed to preserve stability (117). Reconstruct the joint surface using interfragmentary screw compression wherever possible. Bone graft is frequently needed. Then contour a 3.5 to 3.7 mm reconstruction plate to fit along the posterior–lateral cortex to buttress the fragments and help neutralize the deforming forces (Fig. 16.13C, Fig. 16.13D). A semitubular plate is usually too weak (152). Other possibilities for fixation include tension band wiring and the use of modified plates such as the hook plate (173). Tension band wiring alone is often unstable, allowing telescoping of the fragments with loss of articular congruity. Treatment of these difficult fractures must be individualized, with fixation based on the fracture pattern.

Excision

Previously it was thought that primary excision of the proximal fragment in an olecranon fracture did not significantly impair power or stability (49). However, as discussed in the earlier section on biomechanics, there is a nearly linear relationship between loss of any portion of the olecranon and increasing instability in the elbow with loss of power in extension (4,138,176). Excision in young active patients is not recommended unless it is the only alternative available. In the elderly or inactive patient for whom comminution or poor bone quality limits the ability to internally fix the olecranon, approximately 40% of the proximal olecranon can be excised as long as the triceps is securely reattached so that early motion is possible (104). This will generally result in acceptable range of motion and power in sedentary patients.

Tension Band Wire Fixation

- Position the patient prone with the extremity free over the side of the operating table and with the humerus supported on a movable padded arm board (123). This provides direct visualization of the posterior aspect of the elbow, allows free flexion and extension, and permits the entire extremity to be supported if desired. Prepare and drape the extremity free. A sterile tourniquet is useful.
- Make a dorsal longitudinal incision beginning 2.5 cm proximal to the olecranon, and gently curve laterally around the olecranon process to avoid crossing directly over its tip, as this may lead to a painful scar. Carry dissection down sharply to the fascia overlying the triceps tendon, and develop medial and lateral thick fasciocutaneous flaps. Identify and protect the ulnar nerve; it does not need to be mobilized in the vast majority of cases. Inspect the fracture site and clean the fragments.
- Make a small drill hole in the distal fragment to accept one tine of a reduction forceps. Insert the other tine into the proximal fragment, reduce the fracture anatomically, and compress it. Sometimes, two bone-holding forceps are necessary (Fig. 16.14).

Figure 16.13. Type IV olecranon fracture. A: Lateral view of a comminuted olecranon fracture with an associated radial head fracture and subluxation. B: AP view. C: Contoured plate fixation along the posterolateral cortex with interfragmentary compression where possible. D: AP view after fixation.

Figure 16.14. Tension band wire fixation of an olecranon fracture. See text for a full description. A: Reduction of the fracture with reduction tines. B: Initial fixation with two 1.6 mm K-wires and placement of the transverse drill hole in the distal fragment. C: Initial passage of the 18-gauge malleable wire with a loop bent in one
About 1 cm volar to the dorsal border of the ulna, drill a 2.5 mm transverse hole in the distal fragment (Fig. 16.14B). Next, drill two parallel 1.6-mm-diameter K-wires from the tip of the olecranon at the insertion of the triceps across the fracture and exiting the anterior cortex. These provide best fixation if they are close to the articular surface. Visualization with a C-arm fluoroscope on the lateral view during insertion is helpful. Use of a three-hole pointed guide ensures that the wires are parallel.

Take an 18-gauge malleable wire of appropriate length, twist a loop into its midsection, and pass it volar to the proximal end of the K-wires through the triceps mechanism. Be certain that the wire is against the K-wires and the olecranon. Pass it in a figure-eight fashion through the transverse hole in the distal fragment (Fig. 16.14C).

With the wires crossed, use a wire twister to tighten the free ends of the wire together. Tighten the loop alternately on opposite sides to produce even compression across the fracture site. Bend the free ends of the wire over, making certain that they are not prominent, and cut off the excess wire (Fig. 16.14D, Fig. 16.14F).

Next, cut off excess K-wire, bend it into a sharp loop, and pound it into the tip of the olecranon across the tension band wire (Fig. 16.14F, Fig. 16.14G). Carry the elbow through a full range of motion to test the stability of the construct, and close the wounds in layers. Apply a bulky soft dressing, and immobilize the arm in a splint in about 30° of flexion.

POSTOPERATIVE CARE

In most elbows, immediate active motion through nearly a full range of motion is possible. Patients must avoid any lifting or heavy use of the elbow until it is healed. This is a problem in multiply injured patients who spend the majority of their time in bed, because they tend to use their upper extremities to move themselves about the bed. Warn patients to avoid this. Where the fracture is comminuted or the bone osteoporotic and fixation marginal, determine the safe range of motion intraoperatively and apply a postoperative brace, setting the limits of the brace in the safe zone and allowing the patient early active motion. Once the fracture is healed, which is usually in 6–10 weeks, a full rehabilitation program is possible.

### HINTS AND TRICKS

- If there is segmental comminution in the fracture, tension band wiring is contraindicated because it will narrow the fossa of the olecranon and produce an incongruous joint. These require an intercalary bone graft and plate fixation. (This procedure will be described later.)
- Perfect position of the K-wires can be obtained by inserting them retrograde from the fracture site out the tip of the olecranon, and then inserting them antegrade after reduction of the fracture. This usually eliminates the need for a fluoroscope.
- Because of the cartilage at the insertion of the triceps into the olecranon, and because of the bulk of the triceps insertion, getting the malleable wire against the K-wires and directly against bone can be challenging. Sometimes, drilling a transverse hole through the olecranon just beneath the K-wires is easier.
- An 18-gauge wire may be too bulky in little patients. For small patients, use a 20-gauge wire. Avoid unnecessary kinks or twists in the malleable wire, because this can lead to premature failure.
- To avoid excessive penetration of the K-wires from the anterior cortex, insert them through the cortex and then withdraw them approximately 1 cm; when the wires are pounded home, this will place them in optimal position.
- Bending the K-wires to fit over the malleable wire can be difficult. Leave the K-wire protruding 2–3 cm. Grasp it with thin-nosed pliers and place over the wire a small metal suction tip; use it to bend the wire to a 90° angle. Cut off all but 5 mm of the bent end. Then twist the wire 90° to bring it over the malleable wire. Make a small stab wound in the triceps to accept the K-wire and pound it home with a small punch. Be certain (with a lateral radiograph or fluoroscopic image) that the K-wire is fully buried, trapping the malleable wire.

### MONTEGGIA FRACTURE DISLOCATION

Originally described as a fracture of the proximal third of the ulna with anterior dislocation of the radial head, the Monteggia fracture–dislocation is a term now used to describe almost all ulna fractures associated with radial–humeral joint disruption. Although the ulna fracture is seldom undiagnosed, the associated dislocation of the radial head may elude the examiner in as many as one quarter of the cases (15,52). Regardless of the radiographic view of the elbow, a line drawn down the central axis of the radius and through the center of the radial head should always pass through the middle of the capitellum. Any shift in this alignment indicates subluxation or dislocation of the radial head. Always look for this when fractures of the ulna are present.

### CLASSIFICATION

A well-accepted and commonly used classification of the Monteggia lesion is that of Bado (Fig. 16.15) (9,10,134). The categories have in common a dislocation of the radial head associated with a fracture of the ulna or with lesions at the wrist. Four types of fracture–dislocations are described, based on the direction of the radial head dislocation. A series of equivalent injuries is also described with respect to the mechanism of injury and treatment:

**Figure 16.15**. Bado classification of Monteggia fracture–dislocations. A: Type 1. Ulnar diaphysis fracture with anterior angulation and associated anterior dislocation of the radial head. B: Type 2. Posterior dislocation of the radial head and fracture of the ulnar diaphysis with posterior angulation. C: Type 2–equivalent lesion with posterior dislocation of the elbow, fracture of the ulnar shaft and posterior angulation, and fracture of the head or neck of the radius. D: Type 3. Fracture of the ulnar shaft and associated lateral radial head dislocation. E: Type 4. Fracture through the proximal third of the radius and ulna at the same level, with associated anterior subluxation of the radial head. (From Reckling FW, Cordell LD. Unstable Fracture–Dislocations of the Forearm. The Monteggia and Galeazzi Lesions. Arch Surg 1968;96:999, with permission.)

- **Type 1**: Anterior dislocation of the radial head associated with fracture of the ulnar diaphysis at any level with anterior angulation (Fig. 16.15A); the most common Monteggia lesion, seen in about 60% to 80% of cases (10,134).
- **Type 2**: Posterior dislocation of the elbow, fracture of the ulnar shaft and posterior angulation, and fracture of the head or neck of the radius. D: Type 3. Fracture of the ulnar shaft and associated lateral radial head dislocation.
- **Type 3**: Lateral or anterolateral dislocation of the radial head accompanied by a fracture of the ulnar metaphysis (Fig. 16.15C).
- **Type 4**: Anterior dislocation of the radial head associated with fractures of the proximal third of the radius and ulna at the same level (Fig. 16.15E).

Bado also described equivalent lesions for type 1:
- **Anterior dislocation of the radial head alone**
- **Fracture of the ulnar diaphysis with a fracture of the neck of the radius**
- **Fracture of the neck of the radius**
- **Fracture of the ulnar diaphysis with fracture of the proximal third of the radius, where the radius fracture is proximal to the fractured ulna**
- **Fracture of the ulnar diaphysis with anterior dislocation of the radial head and fracture of the olecranon**
Plate Fixation

The operative approach to stabilize the Monteggia lesion is initially the same as for the isolated ulnar fracture. Position the patient supine with the involved arm on an arm board or across the patient’s chest. Alternatively, place the patient in the lateral decubitus position with the arm supported on a bolster and the elbow flexed 90°. Prepare and drape the arm free. A sterile tourniquet is useful.

Make an incision just lateral to the subcutaneous border of the ulna, centered over the fracture site, carrying the dissection through the subcutaneous tissue. Identify the fascia and periosteum between the extensor carpi ulnaris and the flexor carpi ulnaris muscles, and split this layer directly over the subcutaneous border. Take care not to tear soft-tissue attachments to bone. Limit the placement of retractors and bone clamps to the subperiosteal level; this will avoid damage to the ulnar nerve and artery, which lie under the flexor carpi ulnaris in this dissection.

Identify the bone fragments and clean them of hematoma. Reduce the fracture anatomically, taking care to fully restore length because this is necessary to reduce and stabilize the radial head. Reduction can be difficult, especially in comminuted fractures, and in particular when there is a large free coronoid process. Sometimes, attaching the plate initially to the proximal fragment with a single screw and then using it to reduce the fracture is helpful.

Try to use 3.5 mm regular or reconstruction plates or their equivalent. Semitubular plates tend to be too weak, but they do fit nicely along the subcutaneous border of the ulna and contour around the proximal tip of the olecranon. In very comminuted fractures, I often use a 3.5 mm plate as the primary plate and then use a two- to four-hole one-third tubular plate as a second plate to buttress comminution. Three plate locations are possible: the subcutaneous border, the lateral surface, or the medial surface. In most cases, the medial surface is best because it requires the least contouring and provides better fixation in the proximal fragment. The screws are directed from medial to lateral, so bicortical purchase can be obtained, whereas a plate over the subcutaneous border precludes bicortical fixation in the proximal fragment. Sometimes the plate works best laterally; however, the proximity of the dissection to the radial head increases the risk of a radial-ulnar synostosis. Plates along the subcutaneous border may work best when there is substantial comminution along this border that needs buttressing, but they have the disadvantage noted previously and in addition are quite prominent beneath the skin and therefore usually require removal (Fig. 16.16).

Bone-graft comminuted fractures and those with missing bone substance. Small deficiencies that are nonarticular can be bone grafted with cancellous bone harvested from the iliac crest. Segmental loss or deficiencies in the articular surface often require a structural corticocancellous bone graft from the superior crest of the ilium to maintain length. As long as the congruity of the humeral ulnar joint is preserved, segmental deficiencies in the articular surface are usually well tolerated.

Should intervening soft tissue prevent radial head reduction, open the radioulnar joint; this is likely to occur in fewer than 10% of cases. The joint may be visualized by extending the incision proximally toward the lateral epicondyle of the humerus. Detach the anconeus muscle and the ulnar extensor muscles subperiosteally from the ulna and retract them anteriorly. Take care to protect the radial nerve and its branches, as the posterior interosseous nerve passes over the radial neck. Although uncommon, the nerve itself may even be the soft tissue blocking reduction. Once the joint is opened, reduce the radial head and repair the annular ligament under direct visualization if necessary.

Ensure hemostasis and close the wound in layers. Apply a sterile dressing and then splint the forearm in a position that offers the best stability for the radial head, which is generally 90° of flexion and full supination. Occasionally, the reverse is true.
The most widely used and accepted classification of radial head fractures is Mason’s. Significant ulnar malunion requires corrective osteotomy, and an ulnar nonunion requires reduction, plating, and bone grafting. It is best to preserve the radial head, but persistent dislocation may require resection. The minimally subluxed radial head is probably best left alone, especially if adequate function is present. Minor degrees of ulnar angulation may also be acceptable in these late-presenting cases. A less-than-optimal result is often seen in these patients.

Combinations of different types of internal fixation are often necessary in these difficult fractures. If the fracture has been plated but the proximal fragment is short or osteoporotic, adding a tension band wire to the plate may significantly increase the strength of the construct. It is important to fix large coronoid process fragments. This can be difficult and is discussed in more detail in the next section.

In comminuted, unstable, displaced fractures (Mayo type IIIB), internal fixation alone may be inadequate. In these cases, Morrey uses a distraction-type external hinge fixator (DJG, Howmedica, Rutherford, NJ). He begins with continuous passive motion with the distraction device in place, and then he encourages active assisted motion. He removes the fixator under anesthesia at approximately 4 weeks and then relies heavily on splints to protect the collateral ligaments. To help restore motion, he uses adjustable splints to encourage motion in one direction at night and the opposite motion during the day.

POSTOPERATIVE CARE

Immobilize in a long-arm cast with moderate to full supination for about 2–3 weeks. For type 1, 3, and 4 lesions, maintain flexion at 90°. Position type 2 lesions at 70° of flexion. After removal of the cast, begin active motion. Avoid extremes of motion to prevent recurrent radial head subluxation. A motion restricting brace may be helpful.

CORONOID PROCESS FRACTURES

Coronoid process fractures have been classified by Regan and Morrey as follows:

- Type I is a small chip fracture that has no clinical importance but suggests the possibility of an elbow dislocation.
- Type II involves 50% of the coronoid process and may or may not be associated with an unstable elbow.
- Type III is a fracture of the entire coronoid process.

TREATMENT

Type I fractures require no treatment other than symptomatic, although careful evaluation of the elbow to look for major ligamentous injury is essential.

In type II fractures, if the ulnar humeral joint is unstable, fixation is indicated. If fixation is not possible, the elbow may be stabilized with the distraction external fixator without fixation of the fragment.

Figure 16.17. Fixation of a type 3 fracture of the coronoid process with a 4.0 mm lag screw.

In type III fractures, open reduction and internal fixation are indicated if the fracture is not too comminuted and therefore unfixable. Loss of fixation or redisplacement of these is common; therefore, Regan and Morrey neutralize the deforming forces across the elbow with a distraction hinge external fixator. In comminuted fractures, they do not excise the bone fragments, as this can lead to chronic elbow instability, but stabilize them with nonresorbable sutures to the shaft of the ulna using the distraction device to provide stability. Early motion in all of these fractures is important.

Using these indications, Regan and Morrey were able to obtain satisfactory results in 90% of patients with type I fractures and 67% with type II, but only 25% for type III, showing the difficulty of these fractures.

RADIAL HEAD AND NECK FRACTURES

Fractures of the radial head are a common injury about the elbow, and management remains controversial. The vast majority of these injuries result from an axial load transmitted across the radiocapitellar joint with the forearm in a pronated position. The key factors in clinical decision making are elbow motion and stability. Assessment of the distal radioulnar joint is essential so that associated Essex-Lopresti-type injuries do not result in mismanagement and increased disability.

Take AP and lateral radiographs of the elbow and wrist. Often a posterior fat pad sign, with or without an anterior fat pad sign, is all that is seen, indicating a hemorrhage secondary to a radial head fracture. The radiocapitellar view, a modified lateral of the elbow joint with the tube angled 45° toward the radial head, has been shown to be useful in detecting and evaluating fractures of the head of the radius.

CLASSIFICATION

The most widely used and accepted classification of radial head fractures is Mason’s:

- Type I: Undisplaced
- Type II: Marginal fracture and displacement
- Type III: Comminution of the entire head
- Type IV: Fracture in association with an elbow dislocation.

Excision or Repair of the Radial Head and Neck

- **Type II**: Marginal fracture with displacement (Fig. 16.18A)
- **Type III**: Communion involving the entire head (Fig. 16.18C)

About 10% of all radial head fractures occur in association with an elbow dislocation. This may result in altered treatment and prognosis; thus others have designated this as a type IV injury (Fig. 16.18D).

The Orthopaedic Trauma Association and the International Society for Fracture Repair classification system (125) provides a much more detailed classification, which includes fractures of both the head and neck, both as isolated injuries and in combination with fractures of the ulna. Because all clinical studies published to date use the Mason classification, I use it here.

**TREATMENT**

The goal of treatment is to maintain good elbow function and thus to retain adequate motion and joint stability. To evaluate function acutely, aspirate the elbow and then instill local anesthetic into the elbow joint. This affords two benefits. First, it decompresses the joint and relieves pain (69). Second, once the elbow becomes relatively painless, it is possible to determine whether there is a bony block to motion or not. This procedure is important in all radial head fractures in which closed treatment is being considered.

Much controversy exists concerning the advantages and disadvantages of radial head excision. Advocates feel that it allows early motion and less morbidity for most type II and III fractures (77). Others have disputed this mode of therapy, noting complications of subluxation of the distal radioulnar joint, elbow pain, and cubitus valgus deformity following excision (25,45,110,114,138). Since the radial head has a role as a significant stabilizer of the elbow, recommendations for early excision have probably been overstated. Proponents of saving the head in all fracture types note that late excision is still a viable option that has been shown to give good results (18,117,118,126,178).

To preserve stability of the elbow and prevent proximal radial migration, prosthetic replacement with silicone rubber has been proposed (60,120,121,161). I no longer use silicone implants because they are unstable and lead to silicone synovitis. This view is supported by others (112). Certainly, the routine use of a prosthesis in the treatment of radial head fractures is not favored. Situations in which its use may be indicated are fractures associated with elbow or distal radioulnar instability, for which a rigid stable replacement such as a metallic head or allograft might be useful. We have used both at the University of California Davis Medical Center, but our experience and that of others is limited, and effectiveness is not yet proven (62,160).

Because of the failure of other methods to obtain consistent, reliably satisfactory results in Mason type II, III, and IV fractures, I recommend reconstruction of the radial head and neck with anatomic restoration of the radiohumeral joint, despite its technical difficulty. Current indications for open reduction and internal fixation are as follows:

- **A**: The main fragment includes more than one quarter of the articular surface.
- **B**: The fragment is displaced more than 2 mm.
- **C**: There are additional lesions of the capitellum or fracture of the proximal ulna, as well as a ruptured collateral ligament or distal radioulnar joint injury (61).
- **D**: Clinical exam reveals less than 70° of forearm rotation in both directions, or less than 20° to 140° of flexion.

Small and minifragment screws can be used to reconstruct the radial head, and miniplates can be used on the neck. Try to place fixation where it will not encounter the proximal radioulnar joint (sigmoid notch). Countersinking the screw head is necessary if it is placed within the articular circumference. An alternative method of fixation is the Herbert differential pitch bone screw, which allows for placement beneath the articular surface (69). Absorbable pins may be used as well (127). Long-term studies evaluating operative reconstruction of these injuries are needed before there will be widespread acceptance (117). Treatment is based on the fracture type.

Treat Mason type I undisplaced radial head fractures by aspiration and evaluation for any block to motion. If there is no bony block to motion, then begin early active range of motion after pain has subsided. Initial splinting provides comfort while allowing full pronation and supination. Take frequent follow-up radiographs to check for displacement.

Type II fractures are most controversial. If the fracture pattern is amenable to internal fixation, I favor anatomic restoration (Fig. 16.19). Otherwise, nonoperative treatment is advocated, again with aspiration and evaluation of motion (53). If problems persist, perform late excision.

**Excision or Repair of the Radial Head and Neck**

- Position the patient supine with a pad under the ipsilateral shoulder. Prepare and drape the arm free and rest it on the patient's chest or a small arm table. Use a sterile tourniquet.
- Use a Kocher approach (see Chapter 1). Incise the skin beginning at the lateral humeral epicondyle. Extend obliquely across the radial head, ending at the posterior border of the ulna. Identify and split the fascia between the anconeus muscle and the extensor carpi ulnaris muscle, then spread these two muscles and their associated fascia to bring the underlying capsule of the radiohumeral joint into view. To aid exposure, detach part of the superior anconeus from the lateral epicondyte of the humerus. Pronate the forearm to roll the radial nerve and its posterior interosseous branch to a more anterior position. Then incise the posterolateral aspect of the capsule. Take care not to carry the incision past the annular ligament because this risks injuring the posterior interosseous nerve. Also, avoid applying too much tension with retractors anteriorly or distally because this also risks nerve injury.
- Identify the fracture fragments and clean them of hematoma. In Mason type II fractures, if the fragment has good soft-tissue attachments, try to maintain them. Reduce the fracture and internally fix it with a 2.7 mm screw using lag technique. Try to use two screws if the size of the fragment will permit. Other screw sizes may be indicated for smaller or larger fragments. Countersink the screw heads beneath the articular surface.
- In comminuted fractures, the entire radial head may be free fragments. Assemble the fragments on the back table, internally fixing them in a similar manner. If a
portion of the radial head is intact, fix the preassembled radial head to the intact fragment. If the entire head is comminuted, it can be entirely assembled and internally fixed on the back table. At this point, you are dealing with a neck fracture.

- To internally fix a neck fracture, determine the portion of the radial head and neck that does not encounter the sigmoid notch, and use it for the site of a mini-fracture T-plate. Fashion this plate to fit the contour of the radial head and neck. Securely fix it using compression techniques if possible. Examine the construct before closure to determine its stability and the safe range of motion.
- Thoroughly irrigate the joint and wound and close the wound in layers. Apply a sterile dressing and splint the elbow in the most stable position.
- For resection of comminuted fragments of the radial head, remove all fragments and thoroughly irrigate the elbow joint. Using a high-speed burr, smooth off the stump of the proximal radius level with or slightly distal to the proximal edge of the annular ligament. Purse-string the capsular remnants and annular ligament around the stump of the proximal radius to increase its stability. Be certain not to restrict motion.

Replacement of the Radial Head

- Replacement of the radial head with an allograft is no different from fixation of a radial neck fracture as described above. Secure fixation is required if union is to occur.
- Prosthetic replacement with a metallic prosthesis is rarely performed and is specific to the few prostheses available. Please see the manufacturer’s instructions. The surgical approach and soft-tissue techniques are roughly the same.

POSTOPERATIVE CARE

Early motion is essential for a good result. Having determined the safe and stable range of motion under anesthesia prior to wound closure, apply a motion-limiting brace and begin active motion as soon as the patient’s pain and soft-tissue swelling are controlled. Dynamic splinting after 6 weeks may be helpful in gaining range of motion, as previously described. Avoid resistive exercises or heavy use of the elbow until fracture union has occurred.

### HINTS AND TRICKS

- Holding and reducing these small fragments, which are in many cases covered entirely by articular cartilage, can be very challenging. Insertion of a 1.6 mm K-wire into the fragments to act as a “joystick” helps to grasp the fragments, reduce them, and hold them in position while internal fixation is applied.
- Prior to reduction of a free fragment, drill the screw hole. This guarantees good position of the screw and easier insertion.
- When using the T-plate, if there is insufficient space proximal to the annular ligament, the plate can be slid under the ligament and a screw inserted through a small stab wound. Take care to avoid injury to the branches of the posterior interosseous nerve.
- Sometimes, after fixation, the radial head remains unstable and tends to sublux. This is usually the result of nonanatomic reduction of an associated ulnar fracture. First, be certain that the ulnar fracture is out to length and anatomic. If instability continues and cannot be controlled by positioning of the elbow, insertion of a 2 mm K-wire from the radius into the ulna will provide temporary stability. This increases the risk of synostosis of the radius and ulna. Leave it sufficiently prominent that removal is easy at 3 weeks, when there is usually sufficient stability to begin motion.

### ELBOW DISLOCATIONS

Traumatic dislocation of the elbow is a common injury, second in frequency only to shoulder dislocation (81, 105, 118, 157). It is usually sustained by active older children, adolescents, and young adults. Elbow injuries occurring in younger or older patients are more likely to involve fractures. Pure dislocations or those with small periarticular fractures are the subjects of this section.

### MECHANISM OF INJURY

The usual cause of elbow dislocation is a fall on the outstretched arm. Motor-vehicle accidents are also a common cause of elbow dislocation, frequently with associated systemic injury. These are often high-energy injuries, and the mechanism may involve axial compressive loading on a slightly flexed elbow. In most cases, a posterolateral dislocation occurs with tearing of the radial collateral ligament and lateral capsule (157). Associated fractures are more likely to occur in higher-energy injuries. With hyperextension of the elbow, the capsular constraints are torn and the humerus is driven through the capsule anteriorly, tearing the brachialis muscle. The anterior portion of the medial collateral ligament appears to be the primary stabilizer in resisting valgus stress and is a pivot point that allows the radius and ulna to dislocate posteriorly when the lateral ligamentous constraints are torn (Fig. 16.20) (72, 157). The final position is usually posterolateral, but depending on the resultant force vector, straight posterior or posteromedial dislocation may occur.

**Figure 16.20.** The collateral ligaments of the elbow. A: Lateral. B: Medial. (Redrawn with permission from Rockwood CA, Green DP. Fractures in Adults. Philadelphia: JB Lippincott, 1974.)

Other directions of elbow dislocation are distinctively uncommon. The rare anterior dislocation occurs with extreme hyperextension and may be associated with extensive tearing of the brachialis musculature, or neurovascular injury. Straight lateral dislocations are also rare and are associated with extensive tearing of the medial ligamentous restraints. The reverse is true for the uncommon medial dislocation or subluxation. Divergent dislocations are rare high-energy injuries associated with extensive soft-tissue injury to the interosseous membrane, joint capsule, and collateral and annular ligaments (Fig. 16.21). Usually, this strong musculoligamentous complex binds the radius and ulna securely, so that both bones dislocate together in a linear fashion. Therefore, isolated dislocation of either bone is uncommon, although dislocation of the radial head is frequently associated with fractures of the proximal ulna (139) (i.e., Monteggia type I injury) (Fig. 16.22). In children, the ulnar fracture can be subtle, consisting only of mild ulnar bowing in association with a dislocation of the radial head, which is usually anterior but uncommonly may be posterior or lateral. Occasionally, the radial head remains dislocated after attempted reduction of an elbow dislocation. Congenital or developmental dislocation of the radial head and superimposed acute trauma may present difficulty in diagnosis. These conditions are usually bilateral, and radiographic evaluation of the opposite elbow is helpful in securing the diagnosis.

**Figure 16.21.** Divergent dislocation of the elbow.
Displaced radial head fractures are uncommonly associated with dislocation of the distal radioulnar joint (Essex-Lopresti injury). This injury has been discussed previously with radial head fractures.

CLASSIFICATION

Modification of Hamilton and Stimson’s long-established classification is shown in Figure 16.23. This system includes uncommon varieties of dislocation. However, from a practical standpoint, approximately 90% of elbow dislocations encountered are posterior or posterolateral (Fig. 16.24).

PHYSICAL FINDINGS

The conscious patient has severe pain. The elbow is swollen and usually held in slight flexion, often supported by the uninjured hand. The forearm is foreshortened, and the olecranon and radial head are prominent posteriorly in the typical dislocation. Neurovascular function is usually intact but needs to be accurately assessed. With rare anterior dislocation, neurovascular injury may be present. Crepitus or extensive ecchymosis implies a fracture dislocation. Soft-tissue abrasions about the elbow may exist, although open dislocation is uncommon.

RADIOGRAPHIC FINDINGS

Radiographs in two planes reveal the type of dislocation. They should be scrutinized carefully for associated periarticular fracture, especially of the radial head, coronoid process of the ulna, or medial epicondyle (Fig. 16.25). The latter fracture is seen more commonly in children and is the most likely culprit in irreducible elbow dislocation. When fracture of the medial epicondyle accompanies elbow dislocation, it usually reduces with elbow relocation. Occasionally, it is incarcerated in the joint, preventing reduction and requiring surgical treatment. In the unlikely event that physical examination suggests a vascular injury, obtain an arteriogram promptly.

TREATMENT

Reduce the elbow as soon as possible using closed manipulation. Closed reduction usually is not difficult. Most elbow dislocations can be reduced in the emergency room under conscious sedation. Various methods of reduction have been described. All techniques involve correcting any lateral or medial displacement. Figure 16.26 depicts a method in which the arm hangs off the end of a well-padded table and the patient is prone and relaxed. With the elbow flexed at 90°, apply gentle but firm traction on the forearm while grasping the distal humerus with your opposite hand, and apply thumb pressure on the posteriorly displaced olecranon. Some physicians advise mild hyperextension to diminish impingement of the coronoid process, but this is usually not necessary. After reduction, gently flex and extend the elbow to ensure that reduction is complete and to ascertain stability. Confirm reduction on radiographs.

Figure 16.26. Closed reduction of a posterior dislocation of the elbow. (Redrawn with permission from Rockwood CA, Green DP. Fractures in Adults. Philadelphia: JB Lippincott, 1974.)

Reduce anterior dislocations by slight flexion and posterior displacement of the forearm, accompanied by gentle traction. The rare divergent dislocation usually requires separate reductions of the ulna and then of the radius. Gross instability or residual subluxation may require open reduction and repair of the annular ligament and capsuloligamentous complex.

SURGICAL INDICATIONS

Most elbow dislocations unaccompanied by major periarticular fracture are not difficult to reduce. Inability to reduce an elbow dislocation promptly requires careful reevaluation of radiographs and physical findings to ascertain the impediment. The most frequent indications for operative intervention are irreducible dislocation, associated fractures, incongruous joint after reduction, gross instability or neurovascular injury, and unreduced (chronic) dislocations (44).

Irreducible Dislocations

The usual cause for the inability to reduce an acute dislocation is an entrapped medial epicondyle. This is somewhat more common in children. In most cases, the fracture of the medial epicondyle reduces with reduction of the elbow dislocation. An attempt may be made to reduce the incarcerated fragment by having the patient activate the flexor–pronator muscle mass to which the fragment may be attached. Otherwise, treatment is by open reduction and extraction of the fragment from the elbow joint, followed by internal fixation or excision of the fragment, depending on its size. Before skeletal maturation, significant displacement should be treated by open reduction and pinning of the medial epicondylar fragment.

Associated Fractures

Many fractures occur with dislocations of the elbow; when fractures and severe ligament injuries are associated, treatment can be difficult. For the most part, treatment of these is focused on treatment of the fractures, which usually results in stability of the elbow. This is discussed in detail in the preceding section.

Incongruous Joint

Soft-tissue interposition is a less common cause of the inability to reduce an acute dislocation, and it may involve entrapment of the annular or collateral ligaments, or buttonholing of the radial head through the posterolateral capsule. The joint may be asymmetric or incongruous after reduction for the same reasons. Fragments remaining in the joint or interposed soft tissue require surgical removal. Small fragments that do not compromise joint congruency or interfere with motion can be observed and, if necessary, removed at a later date.

Ligamentous Instability

Most elbow dislocations are reasonably stable after reduction. Occasionally, the lateral capsuloligamentous complex and, rarely, the medial ligamentous structures are extensively torn, necessitating repair because of gross instability (Fig. 16.27) (44,64,81). Use strong absorbable sutures anchored through drill holes in bone to ensure postoperative stability and allow early mobilization. With medial side instability, repair the medial collateral ligament, especially its anterior portion. Gross instability may require both medial and lateral capsuloligamentous repair. Postoperatively, maintain the elbow in the position of greatest stability until sufficient healing has taken place to allow protected graduated exercises, usually in a dynamic splint (72,157).

Figure 16.27. Ligamentous injury accompanying elbow dislocation.

Unreduced Dislocations

Elbow dislocations presenting late may require general anesthesia for reduction. After 2–3 weeks, open reduction is often necessary, usually through a long extensile posterolateral approach. Dislocations existing beyond this time present with progressively increasing musculotendinous retraction, scarring, and articular degeneration. Arthrodesis or arthroplasty may be indicated for the significantly symptomatic patient.

POSTEROLATERAL ROTATORY INSTABILITY OF THE ELBOW

O’Driscoll et al. (124) have described recurrent posterolateral rotary instability of the elbow as a clinical entity that can be distinguished from dislocation of the elbow and is unrelated to dislocation of the radial head. Their patients complained of locking or snapping of the involved elbow. Diagnosis is based on the lateral pivot-shift
test of the elbow, which involves supinating the forearm and applying a valgus moment and an axial force to the elbow while flexing it from full extension. Flexion past about 30° produces a sudden palpable and visible reduction of the radiohumeral joint. The essential lesion is felt to be laxity or detachment of the lateral ulnar collateral ligament. Surgical intervention involves restoring the functional integrity of this ligamentous complex.

Recurrent dislocation of the elbow is distinctly unusual (64,105). Therefore, start motion early in joints that are stable after reduction. A brief period of immobilization (1–5 days) is all that is necessary for stable injuries. Immobilize in a padded posterior splint with the elbow flexed to 90°. Initiate gentle passive and progressive active assistive and active range of motion as soon as practical.

Unstable injuries without associated fracture of the radial head or coronoid process are unusual, but they should be protected for longer periods in the position of maximal stability. Usually, this is 90° or more of flexion at the elbow. Advise the patient of the symptoms and signs of repeat dislocation. As with fractures requiring reductions, a repeat examination at 24–48 hours is recommended, with radiographs taken to confirm that reduction has been maintained. Follow the patient closely during the first 10–14 days; if dislocation recurs, it can be promptly recognized and treated (75). Numerous studies have shown that patients who are mobilized early have the best results and are most likely to regain normal or near-normal elbow extension.

FRACTURES OF THE SHAFT OF THE RADIUS AND ULNA

The five joints of the forearm (ulnohumeral, radiohumeral, proximal radioulnar, distal radioulnar, and radioarticular) constitute a delicately arranged mechanism that may be disrupted in any or all of its parts by a shaft fracture of the radius or ulna. Shortening, angulation, or malrotation of either of these bones will cause functional problems at the wrist or elbow. If functional disability is to be avoided following fracture, precise anatomic reduction is necessary; even a very minor nonanatomic variation of healing may constitute a malunion. Because the muscles of supination and pronation apply rotational and angular forces to the radius and ulna, maintenance of reduction after displaced or unstable fractures requires rigid internal fixation (28). Treatment of fractures of the radius or ulna depends on the amount of displacement and the degree of stability of the fracture pattern.

CLASSIFICATION

The classification of forearm fractures is simple and straightforward. It is based on the level of the fracture(s), from proximal to distal; the bone(s) that are involved; the degree of displacement, angulation, and rotation; the presence or absence of overriding, segmentation, or comminution; and whether the fracture is open or closed. The Orthopaedic Trauma Association and the International Society for Fracture Repair system (125) classifies shaft fractures into 36 types; these are not clinically useful, although they are used in clinical investigation.

Fractures of the ulnar shaft that commence at about the level of the coronoid process, extending to about midshaft, and that occur in conjunction with dislocation of the radial head are known as Monteggia fractures and have been discussed previously in this chapter (1,9,10,15,19,40,133,134,151,158).

Fractures of the proximal third of the radius are characterized by rotational problems; these are discussed later in this chapter.

Midshaft fractures of the radius or ulna, or both, present with varying configurations, depending on the mechanism by which the injury was inflicted and the degree of violence involved (37). The fractures are typically transverse or short oblique if they are simple. Alternatively, in high-energy injuries, they may exhibit extensive comminution or segmentation, with significant soft-tissue involvement.

Fractures of the lower half of the ulna are known as “nightstick fractures,” an obvious reference to the mechanism of injury. Fractures of the radius with disruption of the distal radioulnar joint are termed Galeazzi or Poirier fractures (80,108,109,113).

ASSESSMENT

Perform clinical and radiologic evaluation, together with careful attention to the condition of the soft tissues. Often the deformity of the forearm with fractures of one or both bones will be evident immediately. Refrain from excessive manipulation to avoid further damage to soft tissues. Note any evidence of neurologic or vascular compromise. Check the patient periodically to confirm the continuing integrity of circulatory and neurologic function.

Radiographs must include x-ray views in two orthogonal planes of the entire forearm, including both the elbow and the wrist joints. Fractures of the radius and ulna can be complicated by subtle injuries to these joints. Radial–ulnar dissociation with rupture of the central band of the intracapsular ligament can be difficult to detect and is often diagnosed late (166,170). Especially when fractures of the proximal radius and/or radial head and neck show shortening, look for evidence of proximal subluxation of the radius at the distal radioulnar joint. Comparison films to the opposite normal side may be necessary. On clinical examination, more pain than would be expected and tenderness at the distal radioulnar joint should suggest this injury.

SURGICAL ANATOMY

The ulna, which is relatively straight, has a stable articulation with the distal humerus at the elbow and runs virtually subcutaneously distally to the ulnar styloid at the wrist. The radius is bowed along its length from the widened distal end, which articulates with the carpus, to just distal to the bicipital tuberosity (at the insertion of the biceps tendon). There, it angles at about 13° opposite to the bow to articulate with the capitulum. The radius and ulna form a joint at the distal end, where the striplike radius sweeps and rotates around the relatively fixed distal ulna with motions of pronation and supination.

In treating fractures in the forearm, the radial bow and proper interosseous space must be maintained for normal motion to be achieved. Schemitsch and Richards (153), as discussed previously, showed that restoration of the radial bow is related in a directly linear fashion to the quality of the outcome. Normal rotation of the forearm requires a normal bow in the radius. The normal maximum radial bow, measured by the distance between the radius in the ulna across the interosseous membrane, is 15 mm. To get 80% of normal range of motion, this bow must be within 1.5 mm. The same relationship is related to grip strength. Both the amount of bow and the location are important.

Moore et al. (113) demonstrated the importance of the interosseous ligament to the axial stability of the distal radioulnar joint in cadavers. They showed that osteotomy of the radius allows axial movement of the radius of 3 mm and division of the triangular fibrocartilage increases the movement to 6 mm, whereas division of the central band of the interosseous membrane produced more than 10 mm of proximal migration of the radius. In mechanical tests of cadaver interosseous membranes, Wallace et al. (170) demonstrated elongation of about 10 mm of the central band before failure. In a preliminary study, they demonstrated that ultrasound may be of value in detecting tears of the interosseous membrane.

Markolf et al. (96) showed that when the elbow is in valgus alignment with contact of the radial head against the capitellum, the main pathway for load transmission from the hand to the elbow is through the radius. When the hand was loaded, with the forearm in neutral rotation, the mean force in the proximal ulnar–humeral joint was only 12%, whereas when the elbow was in varus alignment and the forearm in neutral rotation, 93% of the force was transferred via the interosseous membrane through the ulna. It is evident that transfer of a load from the wrist through the radius and ulna to the elbow is complex and dependent on the anatomy of the wrist, the soft-tissue attachments between the radius and the ulna, and the position of the forearm. Radial–ulnar load-sharing changes significantly when the distal end of the radius is shortened by as little as 2 mm, emphasizing the need for anatomic reduction.

The forces of muscle groups originating or inserting at different levels of the radius and ulna are associated with various deformities after fixation. For example, a fracture in the proximal third of the radius, occurring between the supinator insertion and the pronator teres insertion, results in supination of the proximal fragment and pronation and angulation of the distal radius. In addition to supination, the biceps brachii tends to flex the proximal radial segment. If the fracture occurs distal to the insertion of the pronator teres, both fragments are likely to be found in neutral rotation (Fig. 16.28).
Operative Technique

Plates and screws are the most commonly used method of closed forearm stabilization. The transverse 4.5 mm, round-holed, narrow plate in their series and established the efficiency of plate fixation of the forearm bones in North America. These plates are rather large for the forearm and show a 22% incidence of retraction of the bone after plate removal. The 3.5 mm AO-ASIF dynamic compression plate; its more recent version, the low contact dynamic compression (LCDC) plate; and similar plates such as the Alta reconstruction titanium plate are now the most commonly used plates. Sarmiento et al. (150) treated 287 isolated fractures of the ulnar shaft with prefabricated functional braces resulting in a 99% union rate and good to excellent functional results in 96% of the cases.

Distally, the insertion of the pronator quadratus pronates the distal radial fragment. In the presence of an intact radius, fractures of the ulnar shaft are comparatively less affected. Muscles attaching to the proximal ulna are resisted by the stability of the elbow joint. The radial head, of course, is not restricted by that joint. Distally the ulna has little mobility and relatively weak muscle attachments, so it is not often displaced.

Closed Treatment

Fractures of one or both bones of the forearm, if essentially undisplaced and stable, may be successfully treated by closed methods (14,33,35,36,149,150). This requires meticulous attention to molding of the plaster to maintain the necessary relationships among the radius, ulna, and interosseous membrane. The fracture must be evaluated weekly to ensure that no loss of position has occurred. The technique for closed treatment is well outlined in an excellent book by Chanley (31). See Chapter 10 for additional information on application of upper extremity casts. Isolated ulnar shaft fractures with less than 10° of angulation can be treated with casts or braces (149,150).

Chapman et al. (29) have shown that immediate fixation of open fractures of the forearm of all grades can be done with minimal risk of infection if thorough irrigation and debridement are done. Only 1 of 49 open fractures plated primarily became infected, and that resolved with treatment.

Surgical Approaches

Plan the surgical approaches for the treatment of forearm fractures after considering the level of the fracture (especially important in radius injuries), the protection afforded any neurovascular structures that may be encountered, and the best means of providing efficient exposure with minimal soft-tissue damage. Open wounds may require a modification of the “ideal” surgical approach.

Four basic exposures are recommended:

1. Straight ulnar approach to the ulnar shaft
2. Volar antecubital approach to the proximal radius
3. Dorsolateral approach to the radial shaft, from the radial head to the distal quarter of the shaft
4. Palmar approach to the distal third of the radius

Approach ulnar fractures with the patient lying supine or partially turned toward the side contralateral to the fracture. In this way, the arm can be pronated across the chest to facilitate access by the surgeon and the assistant.

Approach very proximal radial fractures through either a volar antecubital incision or a dorsolateral approach (63). The dorsolateral approach provides an excellent extensile approach to the radius from the elbow to the wrist. The key to the exposure is the identification and meticulous reflection of the posterior interosseous nerve along with the supinator muscle off the proximal third of the radius. Exposure of the middle third presents no problems. The distal third of the radius is usually approached volarily, but the dorsal approach is useful as well.

The specific approaches are thoroughly discussed in Chapter 1 and in the classic book by Henry (63).

Plate and Screw Fixation

Bagby (11,12 and 13), Danis (39), and others (5,47,48,65,76,107,128,129,168,177) established the principles used today in plate fixation of forearm fractures. The most appropriate treatment for unstable fractures of the bones of the forearm is open reduction and internal fixation using plates and screws. Anderson et al. (5,6 and 7) used the 4.5 mm, round-holed, narrow plate in their series and established the efficiency of plate fixation of the forearm bones in North America. These plates are rather large for the forearm and have a 22% incidence of retraction of the bone after plate removal. The 3.5 mm AO-ASIF dynamic compression plate; its more recent version, the low contact dynamic compression (LCDC) plate; and similar plates such as the Alta reconstruction titanium plate are now the most commonly used plates in adults and have made it possible to apply these techniques to even small-boned patients such as adolescents and most women.

In a series of 129 fractures of the radius and ulna fixed with the AO 3.5 mm plate, Chapman et al. (29) had a union rate of 98.5%, with 92% excellent or satisfactory functional results, and no refractures after removal of the 3.5 mm plates. Newer, equivalent-size titanium plates are now available that are stronger yet more flexible than stainless-steel plates.
Place the patient supine on the operating table. A hand table is useful. Prepare and drape the entire upper extremity. Use a tourniquet.

- Expose the affected bone(s) using one of the surgical approaches described previously.
- Expose the fracture site with as little soft-tissue stripping as possible. Up to 2 mm of periosteal stripping, limited to each side of the fracture site to ensure anatomic reduction, should be sufficient. It is unnecessary to strip the periosteal sleeve completely around the shaft of either the radius or ulna to apply a plate.
- Expose the bone only directly under the plate (174). Some surgeons advocate applying the plate extraperiosteally, but I see no advantage in that. Be sure that no important structure, such as a nerve, major vessel, or tendon, is trapped beneath the plate.
- If the fracture configuration results in a stable reduction, reduce it and then fit the plate to the bone. If the fracture is not stable due to a butterfly fragment, initial interfragmentary fixation with a lag screw may be worthwhile if it can be done easily without devascularizing the fragment. Otherwise, always apply the plate to one fragment first with a snug (but not tight) screw next to the fracture site. The second major fragment along with the comminuted zone can be reduced to this plate–bone combination. This greatly facilitates reduction and minimizes soft-tissue stripping. Use only pointed tenaculum-type bone-holding forceps. These can be applied without soft-tissue stripping and do not crush soft tissues.
- Contour the plate so that accurate bony contact is made over its entire length. Use of the eccentric holes in the dynamic compression plates has eliminated the need for an external compressing device, but in some cases the external compressor is helpful in reducing the fragments. After applying the plate to one of the major fragments, if necessary use the articulated tension device to distract the fragments by placing the hook end against the end of the plate. This facilitates reduction. Then reverse the hook to apply tension to the plate and to compress the fracture. Fix the plate to the other major fragment using the appropriate screws (Fig. 16.29).

**Figure 16.29.** Use of the articulated tension device to assist in initial reduction and for subsequent stabilization of comminuted fragments. (From Müeller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation, 2nd ed. New York: Springer-Verlag, 1979, with permission.)

**Figure 16.30.** Use of the distractor to assist with reduction and preliminary stabilization of comminuted fractures. (From Müeller ME, Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation, 2nd ed. New York: Springer-Verlag, 1979, with permission.)

- In general, use 3.5 mm dynamic compression plates with 3.5 mm cortical screws with 1.25-pitch threads (122). This pitch allows the screws to grip the cortex of the bone with additional threads, which improves the pullout strength. Also, these screws are much stronger than the earlier designs of 3.5 mm cortical screws. The 3.7 mm titanium reconstruction modular (Alta) plates as well as the AO-LCDC and similar plates work well. The screws must achieve good fixation in at least five cortices on each side of the fracture. Increase this to six to eight cortices in unstable fractures or in poor-quality bone.
- Lag screw fixation across the fracture and any associated fragments increases the strength of the construct by up to 40%. Usually these screws are applied before axial compression of the fracture by the plate. The most accurate placement is achieved by placing drill holes in the bone fragments before reduction, using either a “threaded-hole first” or “gliding-hole first” technique.
- Ideally, place the plate on the tension side of the bone, which is dorsolateral on the radius and dorsal on the ulna. In the distal third of the radius, plates are best placed on the volar aspect to avoid Lister’s tubercle and the extensor tendons. Semitubular or one-third tubular plates are recommended only in unusual circumstances, because they are quite weak. Examples of fixation are shown in Figure 16.31, Figure 16.32, Figure 16.33 and Figure 16.34.

**Figure 16.32.** A closed Monteggia fracture in an 18-year-old man. A: Preoperative AP and lateral radiographs. B: Postoperative radiographs show fixation with a seven-hole, 3.5 mm dynamic compression plate, augmented by an olecranon bone graft. Note the use of the center hole as the site for an interfragmentary
proximal and distal cross-locking capability. These designs (e.g., the Sage nail) often have fluted cross sections, and this offers additional fixation. There is little

More recent locking nail designs such as the ForeSight nail (Smith and Nephew, Memphis, TN), the Lefèvre nail (143) popularized intramedullary nailing of forearm fractures in the late 1950s and the 1960s. Medullary nailing was attractive at the time because closed treatment of displaced forearm fractures in adults was not achieving acceptable levels of function and the principles of plate fixation and the smaller stronger plates had not yet been popularized by the AO group. In addition, the percutaneous techniques of intramedullary nailing that avoided incisions. Drainage prevents the development of a postoperative hematoma. There is no need to close the deep fascia; doing so may produce a compartment syndrome.

Whether bone grafting is necessary for comminuted fractures is controversial. Chapman et al. (26,29) performed autologous cancellous bone grafting at the time of delayed primary closure of all open fractures of the forearm that were plated. They also bone grafted those with comminution and bone deficiency. They had no nonunions in 49 open fractures and an overall rate of union of 98.5% in 129 fractures. Wright et al. (177) studied 198 forearm fractures treated with plate fixation with and without bone grafting. Their union rate in those that were not grafted was 88%. On that basis, they concluded that bone grafting of comminuted forearm fractures was not necessary.

Postoperative Care

Apply a long-arm bulky compressive (Robert Jones–type) dressing with a palmar or dorsal splint for a few days postoperatively while soft-tissue swelling decreases. Remove drains within 24 to 48 hours, depending on the amount of drainage. Keep the forearm elevated 10 cm above the heart. Begin active and passive range-of-motion exercises of the fingers, wrist, and elbow shortly after surgery.

Encourage active and active-assisted range-of-motion exercises of the hand, wrist, and elbow. Obtain radiographs just before wound closure and then again 6 weeks and 3 months postoperatively, and then every 4 to 6 weeks until union occurs. Allow protected use of the limb throughout healing, but prohibit contact sports and the lifting of heavy objects of more than 2 kg during this time. Union usually occurs in 16–24 weeks, at which time a full rehabilitation program without restrictions can begin.

INTRAMEDULLARY FIXATION

Jones et al. (80) in a laboratory study compared the stability of LCDC plates and fluted intramedullary rods for the fixation of fractures of the radius and ulna. They showed that the intact ulna is more important than the radius to forearm stability in bending and torsion. Therefore, if the radius is fractured but the ulna remains intact, medullary nailing will produce constructs with greater stiffness, particularly in torsion, than if the ulna is fractured and the radius is intact. In the case of fractures of both bones, they found that nails resulted in significantly less stiffness in torsion as well as in distraction and compression as compared to plates. Torsional stiffness with intramedullary nails was 2% of intact specimens, whereas with plates it was 83%.

Rush (143). Sage (144,145 and 146), and others (95,156) popularized intramedullary nailing of forearm fractures in the late 1950s and the 1960s. Medullary nailing was attractive at the time because closed treatment of displaced forearm fractures in adults was not achieving acceptable levels of function and the principles of plate fixation and the smaller stronger plates had not yet been popularized by the AO group. In addition, the percutaneous techniques of intramedullary nailing that avoided open incisions was appealing because infection rates in open internal fixation at that time were higher than they are now. As pointed out in the previous discussion on the biomechanics of internal fixation, plates offer superior stability to nail designs currently available. Nailing with smooth nonlocking nails such as rush rods often requires additional immobilization in a long-arm cast, which interferes with restoration of forearm motion. Other problems of intramedullary nailing include the following:

- Small intramedullary canals may preclude nailing or require the use of very small nails.
- Medullary canals less than 3 mm in diameter contraindicate intramedullary nailing with most devices.
- The double curve of the radius makes nailing, especially with closed technique, difficult. Restoration of the normal bow of the radius can be difficult.
- If open reduction is required to place intramedullary nails, then plate fixation is preferable because medullary nails offer less rigid fixation, and the combination of occluding the medullary canal and stripping the periosteum devascularizes the fracture to the point that the risk of nonunion is higher.
- Distraction at the fracture site and loosening with nonlocking nails can lead to nonunion.
- Combining intramedullary nailing, such as for the ulna, with plate fixation of the radius results in a higher incidence of nonunion in the ulna than when plate fixation is used for both, because there is often persistent gapping at the fracture site of the ulna.

More recent locking nail designs such as the ForeSight nail (Smith and Nephew, Memphis, TN), the Lefèvre nail (42), and others offer improved fixation due to their proximal and distal cross-locking capability. These designs (e.g., the Sage nail) often have fluted cross sections, and this offers additional fixation. There is little...
published on these newer nails, nor is a prospective randomized study comparing plates to nails available; therefore, their effectiveness remains unproven at present.

**Indications and Contraindications**

**Indications for intramedullary nailing include the following:**
- Poor skin conditions precluding open surgery at the fracture site
- Diaphyseal fractures in patients with severe osteoporosis, where screws would not be expected to hold
- An occasional segmental fracture not suitable for plate fixation
- An occasional patient with multiple injuries for whom intramedullary nailing can be done more quickly and with less soft-tissue trauma, when access to the extremity is necessary and cast mobilization is contraindicated

**Contraindications to intramedullary nailing are active infection precluding surgery, an open growth plate, and a medullary canal smaller than 3 mm in diameter.**

**Sage Intramedullary Nailing**

Intramedullary nailing of the forearm using specifically designed implants was developed by Sage in 1959. His nail has a triangular cross section, which provides reasonable rotational stability if good cortical contact is obtained. The ulnar nail is relatively straight, but the nail for the radius is specifically contoured to maintain the normal anatomic bow of the radius, and it is designed to enter the radius on the dorsal lateral aspect of the radial styloid. Newer locking nail systems have evolved from the Sage nail. In the radius, the ForeSight nail (Smith and Nephew, Memphis, TN) is similar to the Sage nail but is designed to enter on the dorsum of the radius 5 mm proximal to the joint line, just lateral to Lister's tubercle. The True-Flex nail (Encore Orthopaedics, Austin, TX) and the SST stainless steel nail (Biomet, Warsaw, IN) are both designed to enter on the ulnar side of Lister’s tubercle on the dorsum of the distal radius. The techniques for locking nails are specific to each appliance. The reader is referred to the manufacturer's instructions.

The surgical technique associated with insertion of Sage nails is fairly generic to intramedullary nailing of the forearm. Although nailing can be done using closed technique under fluoroscopic control, Sage performed his nailings open and this is the technique discussed here.

**Be certain that a complete set of Sage nails and insertion equipment is available. This consists of nails for the radius and ulna, a combination driver and extractor, a 3 mm drill, and two reamers that are slightly smaller than their respective nails. Nails for the ulna are available in 4 and 5 mm diameters and three lengths (22.9, 25.4, and 27.9 cm). Nails for the radius are available in similar diameters and are available in 1.3 cm increments from 20.3 to 27.9 cm.**

**Position the patient supine on the operating table. For nailing of the ulna alone, it is convenient to place the patient's arm across his chest. For other nailings, place the arm on a hand table.**

**Expose the fracture of the ulnar shaft through a longitudinal incision on the subcutaneous border. Expose only the ends of the bone. Minimize soft-tissue stripping.**

**Drill a hole with a 3.2 or 4.8 mm drill through the exposed cortex, and then gradually angle the handle distally until the drill is directed toward the lateral epicondyle of the humerus. Advance the drill for 5 or 6 cm, thus producing an oval hole at the point of insertion and a channel that nearly parallels the medullary canal.**

**Insert the point of the nail with the nail rotated so that its dorsal or long bow parallels the long arc of the radius. With the wrist in flexion and ulnar deviation, insert the nail by hand in a proximal direction as far as possible.** If it cannot be pushed in by hand for 6 cm, the angle of insertion is too acute. Withdraw the nail, and drill the channel of insertion more obliquely. Then thread the driver on the nail and, while the nondominant hand exerts pressure to depress the nail toward the ulna, drive the nail in with the dominant hand. If marked resistance is met, angle the nail back and forth a few degrees, and then drive it in with moderate blows until it reaches the fracture. If there is an undisplaced butterfly fragment at the fracture, hold it with a clamp; reduce the fracture, and drive the nail into the proximal fragment, leaving 1.3 cm exposed at the radial styloid.

**Check the position of the fracture and the position and length of the nail with AP and lateral radiographs of the radius and ulna. If the nails are of correct length, finish seating them.** Observe the fractures under direct vision to be sure that no distraction occurs. As recommended by Sage, place autogenous iliac bone grafts about all fractures of the radius and ulna fixed by medullary nails.

![Figure 16.35](Image 102x383 to 302x524) Medullary nailing of the radius. The nail enters the bone at the radial styloid. (Courtesy of Dr. F. P. Sage.)

![Figure 16.36](Image 102x635 to 302x777) Sequence of insertion of the prebent Sage nail for the radius, steps 1 to 7. A hole is drilled in the distal radius, entering the medullary canal from the radial styloid. The nail is bent as it advances in the canal and finally springs back to its prebent shape, maintaining the radial bow. (From Stewart MJ. In: Larmon WA, ed. Instructional Course Lectures of the American Academy of Orthopaedic Surgeons, Vol. 15. Ann Arbor, MI: J. W. Edwards, 1958:50.) Intramedullary Fixation of Forearm Fractures. In: Larmon WA, ed. Instructional Course Lectures of the American Academy of Orthopaedic Surgeons, Vol. 15. Ann Arbor, MI: J. W. Edwards, 1958:50.)

**Position the patient supine on the operating table. For nailing of the ulna alone, it is convenient to place the patient's arm across his chest. For other nailings, place the arm on a hand table.**

**Insert the point of the nail with the nail rotated so that its dorsal or long bow parallels the long arc of the radius. With the wrist in flexion and ulnar deviation, insert the nail by hand in a proximal direction as far as possible.** If it cannot be pushed in by hand for 6 cm, the angle of insertion is too acute. Withdraw the nail, and drill the channel of insertion more obliquely. Then thread the driver on the nail and, while the nondominant hand exerts pressure to depress the nail toward the ulna, drive the nail in with the dominant hand. If marked resistance is met, angle the nail back and forth a few degrees, and then drive it in with moderate blows until it reaches the fracture. If there is an undisplaced butterfly fragment at the fracture, hold it with a clamp; reduce the fracture, and drive the nail into the proximal fragment, leaving 1.3 cm exposed at the radial styloid.

**Check the position of the fracture and the position and length of the nail with AP and lateral radiographs of the radius and ulna. If the nails are of correct length, finish seating them.** Observe the fractures under direct vision to be sure that no distraction occurs. As recommended by Sage, place autogenous iliac bone grafts about all fractures of the radius and ulna fixed by medullary nails.
et al. (usually gives the best results, because this gives the best opportunity to restore the anatomy of the forearm and permits early joint motion and rehabilitation. Yokoyama

HINTS AND TRICKS

- Avoid excessive stripping of bone fragments, because nailing interferes with the revascularization of the fracture through the endosteal canal, so preservation of

the periosteum and muscle attachments is important. To ensure union, bone graft all fractures nailed with open technique.

- Do not drive nails into a tight medullary canal, because comminution of the bone, penetration of the nail into the bone, or incarceration may occur.

- Be certain that the nail at the styloid is not near any of the wrist tendons, which could be abraded by running over the end of the nail, leading to rupture.

Postoperative Care

Apply a long-arm cast with the elbow in 90° of flexion and the forearm in neutral rotation. Continue the cast for 8–12 weeks, at which time enough bridging callus is

usually present. The use of functional cast bracing may permit earlier mobilization of the wrist and elbow if the nailing is stable. Locked nails do not usually require cast

mobilization. Gentle early active range of motion can be encouraged in most cases.

Results

Zinar et al. (180), using a modified titanium Street forearm nail, reported a 97.5% rate of union and 92% good to excellent results in 50 patients with 75 fractures of the

forearm. DePedro et al. (42), using the Lefèvre locking nail, experienced a 100% union rate in 20 patients treated with isolated ulna or both-bone fractures.

ISOLATED FRACTURES OF THE ULNA

Isolated displaced fractures of the radius are common. Remember, if the radial fracture is displaced or shortened, the distal radioulnar joint must be subluxed or

dislocated. Failure to appreciate the distal radioulnar joint injury may result in compromised functional results and significant symptoms in the wrist, even though the

fracture has been internally fixed and has healed. Open reduction and internal fixation of the radial fracture in anatomic position is required. The distal radioulnar joint

disruption can usually be treated by closed means. After recognizing that the ligamentous structures and articular disc have been ruptured, they are almost always

adequately reduced if the radial alignment and length are restored and rigidly internally fixed, and if the forearm is kept in a fully supinated position for 6 weeks. Open

reduction of the distal radioulnar joint is required only if closed reduction in supination fails to achieve reduction. The Galeazzi type of fracture-dislocation usually

requires cast immobilization for 6 weeks, with the forearm supinated for soft-tissue healing and stabilization of the distal radioulnar joint.

An isolated fracture of the radius at the junction of the middle and distal thirds without distal radioulnar disruption has been referred to as the “fracture of necessity,” or

the Piedmont fracture. The former term was coined to indicate that open reduction and internal fixation are necessary to produce acceptable functional results. The

muscle forces acting on this fracture result in angulation of the fracture toward the ulna, compromising the interosseous space and resulting in loss of pronation and

supination even if union is complete.

Fractures of the proximal third of the radius are difficult primarily because of the dangers to the deep branch of the radial nerve when exposing and reducing the

fracture (as discussed previously).

ISOLATED FRACTURES OF THE RADIUS

Isolated fractures of the ulnar shaft without involvement of the elbow or wrist joint are treatable with functional braces. Sarmiento et al. (150) reported on the outcomes

in 287 patients. Union occurred in 95%, and overall good to excellent functional outcomes occurred in 96% of their patients. Fractures in the distal third did best,

averaging a loss of 5° of pronation, compared to an average loss of 12° of pronation in fractures in the proximal third. Fractures of the ulna associated with disruption of

the proximal radial ulnar joint are Monteggia fractures (discussed earlier). In adults, plate fixation of these fractures is nearly always necessary (Fig. 16.34). Indications

for plate fixation of fractures in the middle and distal third include the following:

- Open fractures for which soft-tissue management requires stabilization of the bone in nearly anatomic position

- Displaced both-bone fractures

- Segmental fractures

- Fractures for which satisfactory position cannot be obtained

An occasional patient, such as a dentist or musician, who needs to return early to a highly skilled occupation requiring fine use of the upper extremity; such a

patient may require immediate internal fixation.

FLOATING ELBOW

The “floating elbow” is usually caused by a high-energy injury resulting in fractures of the humerus and both bones of the forearm. These high-energy injuries are often

the result of direct trauma with severe open fractures involving bone loss and accompanying neurologic or vascular injury (84,178). The principles of treatment do not

The principles of treatment do not differ much from those already described for open fractures. In some cases, the magnitude of soft-tissue injury and bone loss precludes effective internal fixation;

therefore, external fixation in two planes bridging the elbow joint from the proximal humerus to the distal forearm is necessary. If the level of wound contamination is not

excessive and comminution is not too severe, then primary plate fixation of the humerus and the forearm, accompanied by local or free-flap coverage if necessary,

usually gives the best results, because this gives the best opportunity to restore the anatomy of the forearm and permits early joint motion and rehabilitation. Yokoyama

et al. (178) reported on 15 floating elbow injuries, one of which led to immediate amputation. In 10 of these, immediate internal fixation was performed, and in three the
fractures were internally fixed on a delayed basis. In spite of this severe injury, 10 of the 15 had a good or excellent result. Complications were common, however, including one deep infection, two nonunions of the humerus, two nonunions of the forearm, one malunion of the humerus, and one forearm bone refracture.

OPEN FRACTURES OF THE FOREARM

Chapter 12 presents a thorough discussion of open fractures. Except for fractures that are unsuitable for plate fixation due to location or comminution, or those that are extraordinarily contaminated, immediate plate fixation is usually indicated (28,27,28,29 and 30,57,58,112). The next best alternative is external fixation (8,137). Fractures in the epiphyseal areas may be suitable for fixation (16,41). In 49 open fractures plated immediately, Chapman et al. (29) had only one infection (2%), and this resolved with treatment. Others (6,6 and 7,112) have shown similar results.

Meticulous debridement and copious irrigation are essential. Stable fixation with minimal soft-tissue dissection is also required. Initially, leave the wounds open or use an antibiotic bead pouch. Cover exposed bone and neurovascular structures by muscle. Administer intravenous antibiotics. Delayed primary wound closure, flap coverage if necessary, and bone grafting are usually indicated 5 days or more after injury if the wound is free of evidence of infection.

PITFALLS AND COMPLICATIONS

SUPRACONDYLAR HUMERUS FRACTURES

Kundel et al. (62) showed 52% excellent to good late results in 77 intraarticular fractures of the distal humerus treated by open reduction and internal fixation. Nerve injuries resulting from the fracture occurred in 26 patients, and 49% had heterotopic bone formation; the results were less favorable in patients with open fractures and those with multiple injuries. Helfet and Schmeling (62) reported an incidence of only 4% of heterotopic ossification, 4% infection, 7% ulnar nerve palsy, 5% failure of fixation, and 2% nonunion. This rate of complications is what would be expected with today’s modern techniques. Neither of these authors mention postoperative stiffness, which in my experience is the primary reason patients have poor outcomes (50,167).

NONUNION, MALUNION, AND FAILURE OF FIXATION

Early failure of internal fixation of all upper extremity fractures is most commonly due to inadequate fixation, poor patient cooperation, or poor-quality bone (72,73,106,138,159). The nature and magnitude of the original injury, because of comminution, may also lead to failure, but the devascularization associated with comminution and severe soft-tissue injuries is more likely to lead to infection or to failure of union. In the absence of infection, the most common causes of failure in the reconstruction of supracondylar fractures of the humerus are poor preoperative planning and failure to follow the principles outlined in this chapter. This can lead to the use of inadequate appliances, or to failure to achieve sufficient stability in the fracture site that early rehabilitation can be tolerated without failure. Fortunately, reconstruction of nonunions and intraarticular malunions of the distal humerus is surprisingly successful, with final functional arcs of motion averaging 100° (83,84,85,103) (see Chapter 27 for more details).

Common errors in the plate fixation of bones in the forearm are failure to choose a plate of adequate length; using plates that are too small, such as one-third tubular plates; and failure to eliminate micromotion in the fracture site. Interfragmentary compression with screws should always be done, if feasible.

As discussed previously, the need for bone grafting forearm fractures after plate fixation is debatable (29,177). In fractures with bone loss or substantial comminution, or where there has been significant soft-tissue stripping, I believe that bone grafting is prudent. Collagragt (Zimmer, Warsaw, IN) (29) has been shown in forearm fractures to be equal in efficacy to autologous cancellous bone graft. This eliminates the morbidity of taking an iliac crest graft. On the other hand, securing a small amount of cancellous bone through a stab incision on top of the iliac crest incurs minimal morbidity. Fortunately, with good technique, union rates of 97% to 98% can be expected. Most nonunions respond well to repeat plate fixation and bone grafting (see Chapter 27).

NEUROVASCULAR INJURIES

Neuropathy in the ulnar nerve at the elbow can be caused by the original injury, operative manipulation of the nerve, inadequate release of the soft tissues around the nerve in a transfer, and postoperative fibrosis around the nerve. The best approach is to avoid any additional ulnar neuropathy by gentle neurolysis of the nerve and well-executed anterior transfer. Ulnar nerve neurolysis and transposition during reconstruction after failure of primary treatment of elbow fractures has a reasonable chance of providing good pain relief, improvement in sensation, and even improvement in hand strength and dexterity (102).

Injury of the median nerve most commonly occurs at the elbow and may coexist with injury of the brachial artery. In fractures, there may be direct contusion or stretching of the nerve over displaced fragments, and in dislocations the nerve can slip around the medial condyle and be stretched across the back of the trochlea. Trapping of the nerve in the trochlear sulcus with compression is possible. In the vast majority of cases, the injury is a neuropaxia, which responds to reduction of the elbow and observation. The posterior interosseous branch of the radial nerve is vulnerable in type I Monteggia fractures because of anterior dislocation of the radial head (173). The vast majority of these recover with nonoperative care. In closed injuries, exploration of any of these nerves around the elbow and the forearm is rarely indicated. If recovery is not seen by the time the fracture heals, then nerve conduction and electromyographic and nerve conduction studies are indicated to determine the nature of the lesion and the need for surgical exploration.

Vascular injuries are uncommon. In fractures of the distal humerus and with injuries around the elbow, any evidence of impaired circulation, unless it returns to normal immediately after a closed reduction, merits an arteriogram. With a disruption of the brachial artery, the collateral supply about the elbow often prevents loss of limb, but poor circulation can lead to long-term pain and dysfunction. Obtain vascular surgery consultation if there is any question of whether a brachial artery exploration and repair are indicated.

COMPARTMENT SYNDROME

Compartment syndrome is uncommon after pure elbow dislocations but is more common after high-energy displaced fractures of the distal humerus, elbow, and forearm. At the time of irrigation and debridement of open fractures about the elbow and in the forearm, it is usually fairly easy to do an open or semipercutaneous fasciotomy of the deep fascia of the compartment in which you are operating. This prophylactic procedure adds little morbidity and may prevent an occasional compartment syndrome. After internal fixation of elbow and forearm injuries, do not close the deep fascia, because closure can precipitate a compartment syndrome. Postoperatively monitor patients carefully for signs of compartment syndrome, measure intracompartmental pressures when there is any question, and proceed with fasciotomy when the diagnosis is made. In the forearm, fasciotomy usually requires release from proximal to the lacertus fibrosis to the midpalmar, including release of the carpal tunnel (see Chapter 13).

HETEROPTIC OSSIFICATION

Heterotopic ossification (HO) about the elbow is actually unusual in the absence of associated predisposing causes such as head injury, high-energy trauma, or thermal injury (88,99,136,165) (Fig. 16,39) (see Chapter 124). Prophylactic treatment with diphosphonate, nonsteroidal anti-inflammatory agents such as indomethacin, and low-dose radiation therapy have been advocated and used with success in total hip replacement and other disorders. I have no experience with using prophylaxis for HO around the elbow. The treatment consists of resection of the heterotopic bone after full maturation, usually in combination with a soft-tissue release of the elbow to gain range of motion (99) (see Chapter 27).
**Figure 16.39.** Heterotopic ossification following prosthetic replacement of the radial head and tension band wire fixation of a fracture of the olecranon.

**RADIUS–ULNAR SYNOSTOSIS**

Radius–ulnar synostosis is most common following fractures of both bones at the same level, particularly when plate fixation of both bones is performed and the hematoma between the bones communicates (83). Minimize the risk of synostosis by limiting dissection so that the hematoma between the two fractures does not communicate, by not placing bone graft in the interosseous space, and by beginning early pronation and supination. Maturation of a synostosis usually requires 12 or more months. Although attempts to surgically remove a synostosis early may result in a recurrence, Jupiter and Ring (88) showed slightly improved results when resection was performed before 12 months in 17 limbs treated by resection and interposition fat graft (see Chapter 27).

**CHRONIC DISLOCATION OF THE ELBOW**

Persistent dislocation of the elbow after injury is usually due to a fracture of the coronoid process with displacement, severe comminution that precludes fixation, or failure of fixation (discussed in more detail in Chapter 27). Use of a functional external fixator in unstable elbows may avoid this complication. Morimoto et al. (114) have described successful reconstruction of the coronoid process for chronic dislocation of the elbow using a graft from the olecranon in two cases.

**POSTOPERATIVE INFECTION**

Infection after internal fixation of upper extremity fractures, even in the presence of open fractures, is unusual, with infection rates generally below 2% (29). When acute infection occurs early after plate fixation and the plate is stable, irrigation and debridement of the wound, combined with administration of intravenous antibiotics, usually results in resolution of infection. An antibiotic bead pouch may be helpful. Low-grade persistent infection can often be managed by appropriate antibiotic coverage until the fractures are healed. Plate removal at that point usually results in resolution of the infection. Major infections, particularly when there is loose fixation, usually require removal of the implants and conversion to external fixation (see Chapter 135).

**FOREARM FRACTURE AFTER PLATE REMOVAL**

Lindsey et al. (94) have demonstrated that retention of diaphyseal plates, with a mean follow-up of more than 8 years, results in no significant change in forearm bone density and grip strength. Milh et al. (107) compared 62 patients who had their forearm plates removed at an average of 19 months after insertion, to 113 patients who retained their forearm plates. The complication rate was much higher in those in whom the plates were removed, including seven refractures through screw holes or through the original fracture site. They recommended against routine removal of forearm plates. Factors that predispose to refracture are the degree of initial displacement and comminution, the use of large screws (implants using screws larger than 3.5–3.7 mm in diameter are rarely necessary), premature removal of the plate, and lack of postremoval protection (29,83,142). To avoid this complication, I use titanium plating systems with screws 3.7 mm in diameter or smaller, and I do not remove these plates unless they are symptomatic or the patient desires removal. In some athletes, such as football linemen, for whom there is substantial risk of trauma to the forearm, removal may be indicated to avoid the stress riser at the end of the plate, but avoidance of refracture may require skipping a playing season.

CHAPTER 17

FRACUTRES AND DISLOCATIONS OF THE PELVIC RING

Dana C. Mears and Sridhar M. Durrahakula

D. C. Mears and S. M. Durrahakula: Division of Orthopaedic Surgery, Albany Medical Center, Albany, New York, 12208.

Significant or displaced fractures of the pelvic ring constitute a diverse group of skeletal injuries that usually result from motor-vehicle accidents, industrial trauma, sporting events, or falls from great heights. Apart from isolated fractures of individual bones of the pelvic ring or avulsion fractures documented in athletes, the typical pelvic ring disruption is notable for the high incidence of late problems, including pelvic pain, abnormalities of gait, limb-length discrepancy, permanent nerve damage, and genitourinary tract problems. During the 1990s, McMurtry et al. (35) and Tile (70) emphasized the need for a thorough diagnostic workup in virtually all patients with pelvic and acetabular fractures so that the associated injuries and the nature of the pelvic osseous disruption are accurately documented.

Historically, the management of a pelvic ring fracture, therefore, requires concomitant diagnosis and treatment of the other systemic and musculoskeletal injuries.

All of these methods were associated with nearly complete immobilization of the patient, with the concomitant complications of prolonged, enforced recumbency including urinary retention, urinary tract infections, pulmonary emboli, infections, decubitus ulcers, and sloughing of soft tissues under a hip spica cast. Such marginally effective methods of stabilization are inadequate for the control of profuse retroperitoneal hemorrhage, which often complicates acute pelvic disruption. Furthermore, bed rest and especially the use of a pelvic sling were notable for extraordinary discomfort and general failure to achieve an accurate reduction of a displaced fracture–dislocation.

There is a widespread—and incorrect—noion among traumatologists that most pelvic fracture victims who survive such an injury is likely to present with other serious or life-threatening injuries involving the musculoskeletal, respiratory, central nervous, gastrointestinal, urologic, and cardiovascular systems (14). The management of a pelvic ring fracture, therefore, requires concomitant diagnosis and treatment of the other systemic and musculoskeletal injuries.

The indications for and techniques of pelvic reconstruction are undergoing rapid change. This chapter is based on our experience and the recommendations of other surgeons with an interest in this field.

PATHOPHYSIOLOGY

GENERAL MECHANISMS OF INJURY
Fractures and dislocations of the pelvis constitute a highly diverse group of injuries that are characterized by the force of the provocative blow; the site(s), magnitude, and nature of adjacent soft-tissue disruption; the quality of the involved tissues; and the potential presence of a total hip replacement (16, 70). A pelvic disruption is the hallmark of violent or major trauma (Table 17.1).

### Table 17.1. Sources of Violent or Major Trauma to the Pelvis

**Major Trauma**

Depending on the vector and magnitude of the provocative blow, specific injury patterns are likely to ensue that involve diverse supportive elements of the pelvic ring (Fig. 17.1). The injury patterns (69) are characterized by the sites of disruption and the magnitude and direction of displacement (Fig. 17.2). The external rotation injuries are further subdivided by the magnitude of the diastasis of the pubic symphysis and the potential presence of a sagittal malrotation or posterior displacement of the involved hemipelvis (Fig. 17.3). A crushing injury is typified by a logger who sustains a blow by an errant tree that strikes his pelvis. The force of the blow is likely to displace the involved portion of the pelvis, especially the iliac wing, into the intraabdominal cavity to provoke a frank or occult injury to the bowel or bladder (Fig. 17.4). Upon elastic recoil of the fracture fragments, a seemingly benign radiographic picture can mask a serious visceral impairment.

In the 2D CT, the highly displaced loop of small bowel superficial to the lateral ilium accompanied the elastic recoil of the iliac fragments, producing a small bowel obstruction.

**Moderate and Minor Trauma**

With the rapidly aging Western population, an explosive increase in pelvic trauma secondary to moderate or minor trauma involving osteopenic bone is being encountered. Osteopenia varies widely in etiology and severity (Table 17.2), and in the most florid cases it accounts for pathologic and insufficiency fractures in which no relevant traumatic insult can be identified. While the healing potential of the bone varies greatly across this spectrum of clinical problems, overall the postirradiation group displays the poorest healing potential. A representative example is shown in Fig. 17.5.

**Periprosthetic Fractures**

Another group of patients have a periprosthetic fracture of the pelvis that acutely or belatedly follows the insertion of a total hip arthroplasty. The injury patterns are markedly heterogeneous, depending on the force of the injury and the presence of osteopenia, typically secondary to steroid ingestion or irradiation. In such a clinical case, the fracture may extend from the sacral ala into the adjacent posterior ilium and across the quadrilateral surface, with loosenning of the cup (Fig. 17.6).

**ASSOCIATED HEMORRHAGE AND IMPLICATIONS FOR THERAPEUTIC INTERVENTION**

At the time of a traumatically induced pelvic fracture, some degree of hemorrhage is inevitable. The principal sites of bleeding are outlined in Table 17.3. The anticipated sites of major hemorrhage correlate with the region of the pelvic fracture, the vector of the provocative blow, and the magnitude of pelvic displacement. For example, a displaced fracture of the posterior ilium that exits through the roof of the greater sciatic notch is likely to be associated with an injury to the superior gluteal vessels.
Table 17.3. Principal Sites of Hemorrhage after a Pelvic Fracture

For a displaced fracture with marked external rotation of one or both hemipelvis, in which the ligamentous floor of the pelvis is disrupted, a large volume of blood may collect in the retroperitoneal space and extravasate into the scrotum, the thighs, and superiorward. With pelvic instability, possibly combined with a consumption coagulopathy in a hypothermic patient, the volume of blood that may be extravasated around the pelvis is truly enormous, and it may require 50 or more units of blood to be transfused. These pathologic responses to major pelvic trauma are minimized by prompt immobilization of the pelvis, correction of major deformity, direct control of hemorrhage from large vessels or tamponade of smaller ones, along with general resuscitation of the patient. In the presence of a large open wound, packing is a critical measure to provide tamponade.

A variety of cutaneous manifestations of pelvic fractures provide a source of potential clinical problems (Table 17.4). The cutaneous disruptions as well as visceral injuries provide a source of contamination for the bone and can lead to an infection of the pelvis and hip joint (Table 17.6).

Table 17.4. Cutaneous Manifestations of Pelvic Trauma

- Extensive edema and subcutaneous swelling (Spicy Turner syndrome)
- Disruption of the subcutaneous fat along with subcutaneous sheaths and periosteum (Hemorrhagic scrotum)
- Open wounds around the pubis
- Perineal laceration or rectal wound
- Extensive perineal laceration around the entire inner thigh with adductor injury
- Perineal laceration
- Perineal or vaginal laceration

Table 17.5. Potential Sources of Infection for the Injured Pelvis and Hip Joint

NEUROLOGIC INJURIES WITH PELVIC TRAUMA

Accompanying neurologic injury is one of the principal sources of late complications after pelvic trauma. The potential sites for neurologic impairment are listed in Table 17.6.

Table 17.6. Potential Sites of Neurologic Impairment with Pelvic Trauma

- Lumbosacral plexus
- Sacral plexus
- Saddle nerve
- Femoral nerve
- Other nerves around the pelvis (e.g., gluteal, obturator, pudendal)
- Lateral femoral cutaneous nerve of the thigh
- Genitofemoral, Obturator
- Lumbosacral nerve roots

The mechanisms of injury include stretching, contusion, laceration, and iatrogenic injury resulting from the surgery. Direct compression of the nerve, caused, for example, by a displaced sacral bone fragment in a foramen, may benefit from surgical decompression. Other types of neurologic injury do not respond favorably to available surgical measures.

VISCERAL INJURIES WITH PELVIC TRAUMA

Visceral injuries are a potential source of life-threatening complications in a pelvic fracture (Table 17.7). Injury to the lower urinary tract is a common consequence of a disruption of the anterior pelvic ring, and it can involve the ureter or, more commonly, the bladder and urethra. Urologic injury occurs in as many as 25% of all cases involving disruption of the pelvic ring, and it is more common with bilateral disruptions of the pubic arch. In the setting of a fractured pelvis, extraperitoneal bladder rupture at the anterolateral aspect near the neck is more common than intraperitoneal rupture along the bladder dome; the converse is true in blunt pelvic trauma without ring disruption. The overall occurrence rate of a pelvic fracture with a concomitant bladder injury is reported to be as high as 15%. Urethral injury is common with a disruption of the anterior pelvic ring, such as a pubic ramus fracture; 65% of these injuries are complete disruptions. The incidence of concomitant bladder neck injury is as high as 2.5%. There is an increased likelihood for shearing of the significantly longer male urethra, with a reported occurrence rate up to 11% for male versus 6% for female patients. In the typical lateral compression type of pelvic fracture, displacement of the pubic ramus relative to the ischial ramus results in a classic urethral disruption just distal to the apex of the prostate gland. If both rami are displaced as a combined unit, the injury is likely to occur at the juncture of the membranous urethra and the bulbous urethra. While no consistent association between a specific urologic injury and a specific mechanism of pelvic fracture has been reported, generally the severity of the pelvic injury pattern determines the extent of the urologic injury.
Table 17.7. Potential Sites of Visceral Injury with a Pelvic Fracture

Clinical features that are suggestive of a urethral tear include the presence of blood at or around the urethral meatus, local swelling, the inability to void, gross hematuria, or a high-riding prostate gland. If any of these signs are present, obtain a dynamic retrograde urethrogram prior to the insertion of a urinary catheter to rule out a significant urethral injury. After catheterization, do a static cystogram to evaluate the bladder. In female patients, a meticulous gynecologic examination is essential, particularly in the presence of vaginal bleeding.

Previously, deferral of internal fixation of a pelvic fracture in the presence of a concomitant urologic injury was a common error, which occurred because of the fear of a postsurgical infection secondary to urinary contamination of the surgical wound. In actuality, these concerns have been exaggerated. Routt et al. (60) reported a low rate of infection and a 30% incidence of late urologic complications when definitive internal fixation of a pelvic fracture was combined with indirect stabilization of a urethral disruption with a temporary stent by the use of two magnetic catheters. Currently, with the diverse methods that are available to stabilize a pelvic disruption in the presence of urethral trauma, an alternative strategy for fixation can be used that minimizes the risk of a wound infection. Admittedly, most urologists favor a delayed urethral reconstruction, which in their view lowers the risk of impotence, incontinence, and urethral stricture. When the urologic injury is a rupture of the bladder, an acute surgical repair may be indicated, while concomitant fixation of the anterior pelvic arch with a plate is strongly recommended. Likewise, concomitant injuries of the urethra and bladder may warrant immediate surgical repair. In the presence of a stable pelvic fracture and an extraperitoneal bladder injury, nonoperative management of both problems may be undertaken. In the case of an unstable pelvic ring disruption with a contaminated suprapubic catheter, external fixation of anterior disruptions of the pelvis can be used to supplement open or percutaneous treatment of the posterior pelvic disruption.

OPEN PELVIC FRACTURES

Traditionally, open pelvic trauma has possessed a considerable mortality, although more recent series have displayed mortalities that are comparable to those for closed injuries (7,11,25,52,77). The principal sites for the open fracture and associated wounds are shown in Table 17.8. Irrespective of the mechanisms of injury (Table 17.9), the presence of an open wound is usually due to tremendous energy dissipation on the pelvic ring resulting in an unstable fracture dislocation.

Table 17.8. Principal Bony Sites and Associated Injuries in Open Pelvic Trauma

| Injury of the skin from within by a sharp bony frag. | Injury or laceration of the skin by a sharp object force without |
| Irregular and painful displacement of the tissue contents to make the skin taut, the widespread abrasion of the skin, |
| Extensive abrasion of skin around the pelvic bone |
| Amputation of the bone or bladder |

Table 17.9. Causes for an Open Pelvic Fracture or Dislocation

Even in the presence of a small and seemingly benign open wound, a highly unstable pelvic fracture may be found for which stabilization is indicated. In the past, internal fixation was felt to be contraindicated in open fractures because of the increased risk of infection. While external fixation remains the most common method of stabilization, improved wound care and newer techniques have made internal fixation an option. Several different strategies for definitive pelvic fixation may be considered, depending on the type and site of the wound, the magnitude of contamination, the fracture pattern, and the resources of the surgical team (Table 17.10).

Table 17.10. Alternative Methods of Pelvic Stabilization Based on Characteristics of the Open Fracture Wound
When the open wound is in proximity to the perineum or anal sphincter, or when it involves a viscus, a diversion colostomy is necessary to divert feces away from the open wound. Other implications of the impact of the open wound on global management are outlined in Table 17.11.

Table 17.11. Impact of an Open Wound on Management Decisions

AGING: ITS IMPACT ON PELVIC FRACTURES

The explosive increase in the aging population in North America and Europe is having a profound impact on pelvic fracture management (29). This statistical trend is anticipated to be even more dramatic over the next half century (Table 17.12).

Table 17.12. Anticipated Changes in the U.S. Over 65 Population

Whereas previously pelvic fractures were primarily due to violent trauma in young adults, currently more than 50% of pelvic fractures occur in the over-60 population (Fig. 17.7), with a female predominance that reflects postmenopausal osteoporosis (46,55). The elderly experience higher mortality and late morbidity than younger patients with comparable injuries (Table 17.13) (29,34). In the elderly person, the potential for intensive-care management and the duration of hospitalization and rehabilitation are likely to be much greater, resulting in increased costs.

Table 17.13. Implications for Injury Patterns in the Elderly

While the pretraumatic comorbidities that may be encountered in the elderly are extraordinarily varied, certain problems (Table 17.14) are frequent cofactors that impact heavily on the management of the pelvic fracture. Antecedent cardiac disease compromises the cardiac reserve during the stressful early posttraumatic period and renders the patient vulnerable to serious arrhythmia and myocardial infarction. Posttraumatic atelectasis, possibly in association with multiple rib fractures or a pneumothorax, is innumerably aggravated by pretraumatic pulmonary disease. Hepatic dysfunction in alcoholics may impair coagulation and compromise the prognosis for retroperitoneal hemorrhage. The trauma may dislodge a preexisting plaque in the common or external iliac artery, resulting in a cold, pulseless limb that requires medical or surgical intervention. With central neurologic impairment, such as pretraumatic senility, intention tremor, or generalized weakness, the rehabilitation after a pelvic fracture may be greatly impeded. Not infrequently in the elderly, the general anesthetic required for initial care will be the only anesthetic that is possible for the first 4–6 weeks of posttraumatic care because of complications.
Table 17.14. Geriatric Comorbidities That Frequently Impact on Pelvic Fracture Management

After an extensive open reduction, the elderly and infirm have a higher incidence of intraoperative hemorrhage, wound infection, and necrosis of flaps (22). External fixation pins tend to loosen quickly. Table 17.15 lists guidelines that can aid in the management of pelvic fractures in the elderly.

Table 17.15. Fixation Strategies in the Elderly and Infirm

MECHANISMS OF INJURY TO THE PELVIC RING

The principal injury patterns correlate with the vector of the provocative blow (Table 17.16). From the observations of Burgess et al. (5) and Dalal et al. (19), the force vectors and pelvic injury patterns also correlate with the anticipated patterns of additional injuries to the abdomen, intrapelvic contents, chest, and head, as well as with the potential for significant hemorrhage. A single anteroposterior (AP) pelvic radiograph, therefore, provides insight into the force vector and the likelihood for co-injuries for which appropriate diagnostic tests can be initiated promptly.

Table 17.16. Principal Pelvic Fracture Patterns Based on the Vector of the Provocative Force

PELVIC STABILITY: CORRELATION WITH ANATOMIC DISRUPTIONS

Pelvic Anatomy

The anatomic basis for pelvic stability is displayed in Figure 17.1. The crucial stabilizing ligaments extend from the sacrum, across the sacroiliac (SI) joints and posterior; they transmit weight-bearing forces either across the hip joints, into the lower extremities for ambulation, or into the ischial tuberosities for sitting. The crucial posterior SI ligaments stabilize the SI joints, along with the iliolumbar, sacrospinous, and sacrotuberous ligaments. With its ring-like configuration, the pelvis is intrinsically highly stable and resistant to deforming forces.

Determinants of Pelvic Instability

The characteristic patterns of pelvic disruption correlate with the vector and magnitude of the provocative blow and the strength of the pelvic ring (Fig. 17.2). Subtle changes in the force vector markedly alter the pattern of the disruption. A direct lateral blow on the posterior ilium usually causes a stable lateral compression injury with impaction of the sacral ala, and accompanying unilateral or bilateral ramus fractures. A blow to the anterior portion of the lateral ilium results in an internal rotational moment that creates an unstable injury in which the ilium sustains a vertical or crescent fracture with the sacral ala acting as a fulcrum (69). With the rotational deformity of the ipsilateral hemipelvis, the sharp edges of the ramus fractures can impale the bladder or occasionally the bowel.

Anteroposterior Compression Injury

The force of the trauma correlates with the width of the diastasis of the pubic symphysis and other manifestations of the injury (Fig. 17.3). With a diastasis of 2 cm or less, the symphyseal and diminutive anterior SI ligaments are disrupted while the rest of the pelvic ligaments are spared. With a diastasis of 5 cm or more, the sacrotuberous and sacrospinous ligaments are torn on one or both sides and sagittal malrotation of the involved hemipelvis is present. With a diastasis beyond 10 cm, the posterior SI ligaments are torn so that the involved ipsilateral hemipelvis also displaces posteriorly.

Vertical Injury

With a vertical shear injury, the iliolumbar ligaments, along with the posterior SI ligaments, are disrupted (Fig. 17.2). With vertical displacement of the pelvis, the ipsilateral lower lumbar transverse processes are fractured. This is pathognomonic of this injury.

Sacral Fractures

Many different sacral fractures (12,68) can be encountered in stable and highly unstable variants (Fig. 17.6; Table 17.17). Lumbosacral dissociation is caused by high
energy falls, such as endured by a suicidal jumper or a paratrooper who sustains a forceful landing on his feet (62). In this insult, usually a comminuted sacral fracture is greatly complicated by a forward displacement of the first sacral body upon the fifth lumbar vertebra.

Table 17.17. Patterns of Sacral Fractures

![Pattern of sacral fractures](image)

**Figure 17.8.** Pattern of sacral fractures. A: Transalar. B: Transforaminal. C: Central.

Avulsion Fractures

Avulsion fractures occur in athletes, especially short-distance runners. The site of the involved fragment is highly variable and includes the anterior superior and inferior spines and the ischial tuberosity, caused by the sartorius, the rectus femoris, and the hamstrings, respectively. While most of these heal uneventfully, a few, especially the larger ones, progress to a symptomatic nonunion.

Occult Fractures

Occult fractures are usually insufficiency fractures; a technetium bone scan or magnetic resonance imaging (MRI) may confirm the diagnosis (18). The most common occult fracture is a sacral injury for which overlying gas shadows may hamper radiographic visualization. A computed tomography (CT) scan is helpful.

PRINCIPLES OF MANAGEMENT

RESUSCITATION AND TRIAGE

Follow the general principles of trauma resuscitation and initial care (5,51) discussed in detail in Chapter 14. If the patient is hemodynamically unstable and has an unstable pelvis, then early stabilization may be very important, as discussed below.

CONTROL OF HEMORRHAGE

Initial Evaluation and Treatment

An algorithm that outlines appropriate measures for the control of hemorrhage is provided in Fig. 17.9. For conspicuous external bleeding, apply a pressure dressing. The pelvis can be quickly and temporarily stabilized by wrapping a sheet tightly around it and securing it with a clamp. On arrival in the emergency department, the patient may be in a pneumatic antishock garment. Deflate it carefully to avoid precipitous hypotension. If hypotension does occur, reinflate the garment and transfer the patient to the operating room so that, upon removal of the suit, immediate alternative surgical measures to restore hemodynamic stability can be undertaken. The diagnosis of intraabdominal hemorrhage can be made by ultrasound (45,54), peritoneal lavage, or minilaparotomy. Abdominal and pelvic CT scans are useful as well (3,83).

![Algorithm that outlines the therapeutic measures for the control of hemorrhage in the patient with a pelvic fracture](image)

**Figure 17.9.** Algorithm that outlines the therapeutic measures for the control of hemorrhage in the patient with a pelvic fracture.

Emergent Pelvic Stabilization

External pelvic fixation is a highly effective method to control intrapelvic bleeding associated with a major pelvic fracture (57). For initial emergent application, pelvic clamps have been devised that permit rapid application and compression of the pelvis directly over the lateral ilium at the level of the SI joints (16,17,51,52,76). The clamp is intended for temporary application with subsequent replacement by a suitable technique of internal fixation once hemodynamic stability has been achieved. These devices have not been popular because of potential complications from misapplication.

Reduction of the pelvic fracture produces an increase in interstitial tissue pressure and provides a tamponade of the retroperitoneal bleeding. It also markedly reduces the volume of the true pelvis in which extravasated blood may accumulate. Reduction and compression of the cancellous fracture surfaces reduces the rate of bleeding. Nevertheless, contraindications to the use of external pelvic fixation for the control of hemorrhage need to be clearly understood (Table 17.18). With a
bilaterally unstable posterior injury, the frame cannot control the pelvic ring. Adding temporary longitudinal skeletal traction to the affected side, combined with external fixation, may be of some help. In the presence of iliac comminution and florid osteoporosis, the pins do not achieve sufficient pelvic anchorage. In a small child, the disproportionately small pelvis is not a realistic target for effective anchorage of the pins.

<tr>
<td>As an alternative to or in combination with fixation, use angiographic embolization of autologous blood clots or Gelfoam clots in combination with the insertion of a stent (1). An example is displayed in Figure 17.10. Angiographic embolization can be done without violating the peritoneal barrier and with minimal risk of infection. It is unsuitable, however, for the management of venous bleeding, and it requires appropriate radiographic resources. In dire circumstances, it can be used to control bleeding of relatively large vessels, such as the internal iliac artery. Such a procedure, however, possesses a considerable morbidity, including necrosis of the gluteal muscles.</td>

| **Direct Surgical Control**                      |
| For the management of bleeding from vessels that are greater than 5 mm in diameter, such as the femoral and common iliac arteries, operative intervention is usually necessary. At least three separate strategies, or various combinations of these, may be appropriate (Table 17.19). A direct repair of a major artery has a high likelihood for a successful result. Aortic cross-clamping is a desperate measure that may provide a brief period of tolerable ischemia while a source of uncontrolled hemorrhage is identified and controlled. Acute retroperitoneal packing can also be effective and may permit a concomitant or sequential open reduction and internal fixation of the pelvis (66). |

</tr>
</thead>
</table>

| **UROLOGIC MANAGEMENT**                          |
| Catheterize the urinary bladder to document urinary output as a crucial determinant of adequate volume resuscitation. In the presence of a major pelvic fracture, urinary catheterization requires special consideration (Table 17.20). The incidence of concomitant injury to the bladder or urethra is about 20% (82,53,60,67,73). A Foley catheter can be placed directly into the bladder of a female patient. In male patients, first obtain a urethrogram if there is any suspicion of a urethral injury. Attempts to pass a catheter blindly through a partially disrupted male urethra can aggravate a partial tear and result in a stricture, incontinence, or impotence. If the urethrogram indicates the passage of contrast medium into the bladder without extravasation, advance the catheter into the bladder. Then perform a cystogram to exclude a rupture of the bladder. |

<table>
<thead>
<tr>
<th><strong>Table 17.20.</strong></th>
</tr>
</thead>
</table>
Finally, undertake an intravenous pyelogram to assess the kidneys and ureters. In the typical pelvic fracture victim, a large pelvic hematoma usually distorts the image of the bladder. The hematoma requires no specific treatment, although it may indicate a large blood loss and the need for supplementary fluid or blood replacement. If a urethral injury is identified, a suprapubic cystoscopy may be indicated. This procedure can be technically difficult in the presence of a large pelvic hematoma.

Recently, as a therapeutic alternative, radiographically visible stents have been inserted primarily into the site of the urethral disruption. Also, magnetic catheters have been devised, which permit simultaneous urethral and suprapubic insertions (53,60). After the magnetic coupling of the catheters at the site of the rupture, advance the urethral catheter into the bladder and remove the suprapubic catheter. The newer methods that eliminate any suprapubic source of sepsis are superior to the more traditional suprapubic catheter.

**NUTRITIONAL CONSIDERATIONS**

Patients with pelvic fractures and concomitant multiple trauma are likely to undergo a lengthy period of nutritional depletion following the acute resuscitation. Nutritional demands are exceptionally great, and oral dietary intake is limited by ventilatory support and multiple visits to the operating room. Certain patients, notably those who are alcoholic and others with peculiar voluntary dietary restrictions, may be nutritionally depleted at the time of injury. Others, especially those with morbid obesity, are vulnerable to a rapid onset of malnutrition following admission, which may not be recognized by the therapeutic team. For these reasons, a sound scheme of nutritional support is necessary for each patient (6).

**PEDIATRIC PELVIC FRACTURES**

Children struck by vehicles can sustain the triad of a pelvic disruption, femoral shaft fracture, and closed head injury (42). Prompt evaluation for a potential intracranial injury is crucial (Table 17.21). Conventional radiographs may not reveal all pelvic injuries, especially when the triradiate cartilage is involved. A three-dimensional (3D) CT is especially useful in this scenario (30,44). External fixation is greatly hampered by the small size of the pediatric pelvis, but a double hip spica cast works well. Flexion of the hips and knees aids indirect reduction of the pelvis by suitable rotation of either hemipelvis. Occasionally, for an unstable and displaced injury, especially one that involves the triradiate cartilage, an open reduction and internal fixation is indicated.

**GERIATRIC PELVIC FRACTURES**

At the other extreme of age, a geriatric fracture also poses special considerations (Table 17.22). Because of the predilection of the elderly for diverse pretraumatic comorbidities, the homeostatic compensatory mechanisms to cope with multiple trauma may be heavily compromised. Similarly, the patient may not possess the reserves to cope with reconstructive surgery. In the presence of osteopenic bone, pelvic imaging may be hampered, particularly in a case of an insufficiency or pathologic fracture. The use of a CT scan, a technetium bone scan, or an MRI merits consideration to confirm the site(s) and nature of the injury (18). A prior history of pelvic irradiation therapy may provide a predisposition for an insufficiency fracture. If prior heavy irradiation of the pelvis is documented, then the role for extensive open surgical reconstruction is markedly diminished, with greatly increased surgical risk and potential for postoperative wound dehiscence. Overall, in the elderly, the role for minimally invasive reduction strategies and percutaneous fixation is increased, while the place for full open reduction and external fixation is diminished.

**ASSESSMENT, INDICATIONS, AND RELATIVE RESULTS**

**CLINICAL ASSESSMENT**

Before treating pelvic disruption, rigorously characterize the injury by its clinical and radiologic features (Table 17.23). Try to determine the direction of the injuring force from the history, and by inspecting for sites of contusion or ecchymosis. The history of a high-energy motor-vehicle or industrial accident increases the likelihood of a major unstable injury and concomitant visceral or neurovascular insults. Importantly, look for evidence of asymmetry or instability, or the presence of an open wound. A laceration in the groin, scrotum, or perineal region or of the vagina and rectum is highly suspicious of an open pelvic fracture. An apparent deformity of the lower extremity in the absence of a fracture in the lower limb may indicate a pelvic fracture.
Table 17.23. Clinical and Radiographic Assessment of the Pelvic Fracture Victim

RADIOGRAPHIC ASSESSMENT

If there is marked hemodynamic instability, limit the initial radiographic assessment of the pelvis to an AP view. Once hemodynamic and other urgent considerations permit, obtain additional radiographic views so that the injury can be precisely characterized (Fig. 17.11). At least three views are required: AP, inlet, and outlet. To obtain an inlet view of the supine patient, direct the x-ray beam from the head to the midpelvis at about 45° with respect to the radiographic table or 45° from the vertical reference axis. Such a projection is perpendicular to the pelvic brim and illustrates the true pelvic inlet as well as anteroposterior displacement of a pelvic disruption. To obtain an outlet projection of a supine patient, direct the beam from the foot to the pubic symphysis at 45° with respect to the radiographic plate. The outlet projection discloses superior displacement of the posterior half of the pelvis and either superior or inferior displacement of the anterior portion of the rami. Apparent limb-length discrepancy originating from elevation of the hip joint secondary to a rotational displacement is highlighted, along with avulsion fractures of the transverse processes of the lower lumbar vertebrae or ramus fractures.

If the AP view indicates a possible acetabular disruption, obtain supplementary Judet or oblique obturator and iliac views. Obtain these views by rolling the injured patient carefully from one side to the other to provide 45° views. Occult pelvic instability may be detected by AP radiographs before and after the application of longitudinal traction on the relevant lower extremity (Fig. 17.11).

Computed tomography is indispensable for documenting sites of pelvic disruption, displacement, and comminution. Its foremost role is to clarify posterior disruption of a pelvic ring fracture. A sacral fracture that is virtually invisible on plain radiographs is readily seen on CT. The degree of separation and instability of a SI joint or sacral fracture is evident. At a minimum, obtain five standard transaxial sections at 2 cm intervals (Fig. 17.12). The most superior section demonstrates the iliac wings and the adjacent SI joints. A second section displays the principal part of the sacrum and the adjacent SI joints. The third section projects the dome of the acetabulum with a circular cross section. The fourth section transects the midacetabular region, where the femoral head opposes the anterior and posterior columns. The most inferior section reveals the inferior pubic rami and the ischial tuberosity at the level of the greater trochanter.

Formulating a detailed plan for the surgical reconstruction of a comminuted, displaced pelvic fracture requires an accurate 3D radiographic perspective to define the optimal method or surgical approach, open reduction, and stabilization. When reviewing the conventional two-dimensional (2D) radiographs and CT scans, even an experienced surgeon has difficulty with the extensive mental integration needed to realize a 3D image. Computer programs now can produce 3D surface reformations, or so-called 3D CT images (44), from sets of contiguous axial computed scans of the pelvis (Fig. 17.13). While the images may be unavailable for truly emergent cases, they can be obtained within 1–12 hours after the arrival of the patient in the radiology suite. Document vascular injuries either by a conventional arteriogram (52) or a 3D CT with a prior insertion of radiopaque catheters into the relevant artery and vein (Fig. 17.14) (20).

CLASSIFICATION

PENNAL AND TILE CLASSIFICATION

Pennon and associates (50) classify the principal pelvic ring disruptions based on the direction of the injuring force and the degree of pelvic disruption (Table 17.24). Injuries may result from anteroposterior compression, lateral compression, vertical shear, or combinations of these forces (Fig. 17.2). This classification provides insight into the nature of the injury, the morbidity, the potential sites of disruption, and the degree of pelvic instability; and it provides some therapeutic guidelines.

Table 17.24. Pennal and Tile Classification of Pelvic Fractures

**Anteroposterior Compression Injury**

An anteroposterior compression injury, also known as an external rotation deformation, results from a blow that strikes the posterior ilium or the anterior pelvis to disrupt the symphysis and the anterior SI ligaments of one or both SI joints. Usually, the crucial posterior SI complex is spared so that the injury is vertically stable, although in a few of these cases the posterior SI ligaments are violated to produce an unstable hemipelvis.

**Lateral Compression Injury**

A lateral compression injury arises from a direct blow to the lateral ilium. A stable impacted fracture of the sacrum or, rarely, the adjacent SI joint may result. In the presence of an anterolateral or posterolateral force, however, the ipsilateral hemipelvis rotates inwardly around the site of the posterior disruption, involving the SI joint or the adjacent sacrum or ilium. While they are characterized as "rotationally unstable," in actuality the injuries may be completely stable, rotationally unstable, or unstable in a rotational and posterior direction. Usually, the contralateral rami are fractured, or sometimes the ipsilateral pubic rami or all four rami are disrupted.

**Vertical Shear Injury**

The vast majority of vertical shear injuries are highly unstable and have complete instability of the posterior ligament of one or both SI joints. Most of the patients are victims of falls from a great height or high-speed crashes. Usually, the associated anterior ring disruption is a diastasis of the symphysis pubis. Supplementary radiologic findings may be consistent with an unstable lateral compression or a vertical shear injury with avulsion fractures of the sacrotuberous and sacrospinous ligaments from the ischial spine of the adjacent sacrum. Another possible associated injury is an avulsion of the transverse processes of L-4 or L-5 at the site of the origin of the iliolumbar ligaments. With the marked posterior displacement, which is well documented in the inlet view or CT scan, the likelihood for profuse hemorrhage secondary to injuries of the superior gluteal vessels is high. An uncommon vertical injury has to be carefully distinguished from the much more commonly encountered pattern with a rotational deformity in a sagittal plane and possibly in a coronal plane. Serious hemorrhage and neurologic complications are uncommon with the latter type.

LETOURNEL CLASSIFICATION

Two other classification schemes for pelvic fractures are available. LeTournel (26) classified them by the site of injury as a combination of two or more of five elementary patterns. This method provides an anatomic description of the sites of involvement and eliminates the mechanism of injury, which usually is poorly defined and generally irrelevant to the treatment. The five sites of injury are listed in Table 17.25. Denis et al. (12) also classified sacral fractures by the region of involvement, using transalar, transforaminal, or central (Fig. 17.8).

Table 17.25. Classification of Pelvic Fractures after LeTournel and Judet
BUCHOLZ CLASSIFICATION

In 1981, Bucholz (4) provided a classification scheme based on an anatomic assessment of multiple-trauma victims in whom pelvic injuries were examined at autopsy (Fig. 17.3; Table 17.26). The clinical significance of the Bucholz scheme was a correlation with therapeutic recommendations. While a group 1 injury responded well to conservative management, a group 2 disruption usually required closed reduction with external or internal fixation. Uniformly, a group 3 pattern required an open reduction with internal fixation of the anterior and posterior injury sites.

Table 17.26. Bucholz Classification of Anteroposterior Compression or External Rotational Injury Patterns

AO/ASIF–OTA–SICOT CLASSIFICATION

More recently, a comprehensive alpha-numeric classification scheme has been devised by the collaborative efforts of Arbeitsgemeinschaft für Osteosynthesefragen (AO), the American Society of Internal Fixation (ASIF), the Orthopaedic Trauma Association (OTA), and Societé Internationale de Chirugie Orthopaedic et Traumatologie (SICOT) (71). The AO/ASIF–OTA–SICOT scheme has gained acceptance as the definitive method of classifying pelvic fractures (Fig. 17.15; Table 17.27), particularly for clinical research.

Table 17.27. Comprehensive Classification Scheme of Pelvic Fractures

PREOPERATIVE MANAGEMENT

GENERAL PRINCIPLES

Once hemodynamic stability is achieved and appropriate diagnostic studies have been completed, outline a definitive management protocol. The management priorities are established through discussions between various surgical teams. If a hemodynamically stable patient has an unstable pelvic fracture, definitive surgical stabilization can be undertaken on the day of the acute injury. In the multiple-trauma victim, however, a considerable delay may be necessary between the time of the injury and the first realistic date for internal fixation. In either event, the goals of management include anatomic and functional objectives (Table 17.28). Also, pelvic stabilization should minimize the likelihood of late problems such as a painful nonunion or malunion of the pelvis.

Table 17.28. Goals of Management
PELVIC STABILIZATION

While the preferred techniques of stabilization remain controversial, the authors’ experience has led to an algorithm that facilitates the selection of the optimal stabilization technique for almost any type of pelvic ring disruption (Fig. 17.16). While the algorithm provides a number of viable therapeutic options, the need for internal fixation has increased in the 1990s as internal fixation provides much more stable fixation than external fixation. With internal fixation, the frequency of postoperative follow-up is decreased, whereas external fixation requires ongoing supervision, including pin-track care. The placement of percutaneous lag screws provides a stable method of internal fixation that requires even less surgical exposure than the application of external fixation (67). In fact, once a surgeon gains familiarity with techniques of percutaneous surgical stabilization, the indications for external fixation as a definitive method of pelvic fixation diminish rapidly.

Stable and Rotationally Unstable Patterns

Stable injuries include those that are undisplaced or minimally displaced as a result of a low-velocity lateral compressive force. Begin with bed rest and mobilize the patient as soon as possible. Progress weight bearing as tolerated. Most patients bear full weight in 3–6 weeks.

In most anteroposterior and lateral compression injuries, there is a simple but displaced pelvic fracture, and the posterior SI ligaments and the sacrum are intact; this scenario is quite common. Treatment options include plate fixation, a simple anterior external frame, or percutaneous fixation of the SI joint. Perform surgical stabilization when the diastasis of the pubic symphysis is greater than 2 cm. If an emergency laparotomy is done, stabilize the pubic symphysis with a plate. Plate fixation also can be used for unilateral or bilateral anterior ramus fractures using a midline vertical incision (24). As an alternative, external fixation can be used to manage an unstable anterior injury with minimally displaced ramus fractures. Where the rami are significantly displaced and impinging on skin or genitourinary organs, perform an open reduction. This minimizes the risk of a persistent nonunion or malunion that can lead to pain and dyspareunia. Where a pubic diastasis is open, or a colostomy or a suprapubic catheter is present, consider a closed reduction with percutaneous fixation of the ipsilateral SI joint.

Complete Posterior Instability

For vertical shear fractures of the posterior pelvis accompanied by superior migration of the hemipelvis, first apply skeletal traction to correct the vertical displacement. Two alternative strategies are available. An open reduction and plate fixation of the symphysis or rami restores the alignment of the pelvic ring, so that percutaneous fixation of the posterior injury is feasible. If realignment of the anterior pelvic ring does not align the SI joint, extend the incision to an ilioinguinal approach and openly reduce and internally fix the SI joint.

If a transfemoral sacral fracture is comminuted, perform a posterior approach and plate the fracture, avoiding compression of the sacral nerve roots. If possible, add supplementary percutaneous screw fixation into the S-1 sacral body to avoid the need for anterior fixation (36). If percutaneous fixation is impossible, anterior column fixation or external fixation are alternative measures, although the former is preferred.

Complex Pelvic Disruptions

The complex ring disruptions are listed in Table 17.29. Most pelvic fractures with bilateral unstable SI dislocations and pubic symphysis diastasis are usually caused by vertical shear injuries. For these highly unstable injuries, use a bilateral ilioinguinal approach to achieve open reduction of the symphysis and SI joints simultaneously. In certain instances, where skeletal traction has provided an accurate reduction of one or both SI joints, it is feasible to undertake percutaneous fixation of the SI joints after fixation of the symphysis. As an alternative, reposition the patient in a prone fashion for a posterior approach to the SI joints and perform either lag-screw fixation or transiliac plate fixation.

The Crescent Fracture

For an unstable SI joint with multiple rami fractures or a pubic diastasis with an iliac “crescent” fracture (i.e., a lateral compression injury), suitable immobilization may be achieved in one of two ways. First, through an iliofemoral approach, perform an open reduction of the lateral ilium with lag screws and plates. Then employ an anterior vertical or Pfannenstiel approach for the anterior injury. If these reductions are accurate, perform a percutaneous fixation of the contralateral SI joint. Alternatively, provided that the imaging technique is mastered, a retropubic screw can be inserted via a medial entry site to stabilize both of the superior ramus fractures (61).

PREOPERATIVE PLANNING

Since most pelvic fractures have at least two principal injury sites, a variety of options are available. In the presence of an open posterior wound, an anterior approach or percutaneous stabilization of an SI dislocation is indicated; in the presence of a left lower quadrant colostomy, however, a posterior approach to an SI dislocation...
When an unstable hemipelvis is malrotated, the sequence of reduction can be initiated at the anterior or the posterior injury. The least invasive approach is to reduce the pelvic ring and plate it anteriorly, followed by percutaneous posterior fixation. By 3 weeks after the injury, reduction of the entire pelvic ring through a limited approach is more difficult and may be impossible. In this situation, a single or bilateral ilioinguinal exposure permits a simultaneous open reduction of the anterior and posterior disruptions. Reduction of an SI joint is easier from the anterior approach than from posteriorly. The stability of anterior SI plating is comparable to that obtained with lag screws across the SI joint. Simultaneous reduction of the anterior and posterior disruptions through an ilioinguinal approach is more efficient and avoids a major liability of sequential anterior and posterior exposures. An imperfect anterior reduction may produce posterior malalignment that cannot be corrected.

In the presence of an unstable hemipelvis, the number of sites that require fixation remains controversial. For the classic pubic symphysis diastasis with an SI dislocation, definitive fixation of the two injuries is well accepted. If the posterior injury is a simple displaced iliac fracture, isolated fixation of the ilium suffices. If the accompanying anterior injury, such as a symphysis diastasis, is not repaired, typically there is a minor residual external rotation of the hemipelvis; usually this is not of functional significance. If the iliac fracture is comminuted, then anterior and posterior fixation is indicated.

A simple vertical sacral fracture, with associated multiple pubic rami fractures, may be sufficiently stabilized solely by percutaneous cannulated screws across the sacrum. Within 3–4 weeks, callus forms on the rami fractures so that walking with crutches can be started. This strategy avoids the application of an anterior external fixator or more aggressive surgery. If the rami fractures are markedly displaced and unstable, then plate them through a lower midline abdominal incision.

THE COLUMNS OF THE PELVIS

If an unstable hemipelvic injury is complicated by comminution or osteoporosis, more stable fixation is indicated. The pelvic ring can be perceived as a system of three columns: the rami, the sacral body, and the posterior sacral elements. For a typical unstable injury, surgical fixation of two columns is recommended. For the most unstable injury patterns or in patients with osteoporosis, fixation of all three columns is advisable. Examples include unstable fractures fixed late, osteoporotic sacral nonunions or malunions, and displaced pathologic pelvic ring disruptions.

Figure 17.17. Schematic view of the pelvic columns to aid in the fixation of unstable injuries.

COMPLEX PELVIC DISRUPTIONS

An unstable SI disruption with multiple rami fractures or symphysis diastasis complicating an acetabular fracture, with or without propagation into the ilium, is another consequence of a lateral compression injury. First, undertake an open reduction and internal fixation of the acetabulum. For an ipsilateral SI fracture, fix it through the same exposure or do percutaneous fixation. Then stabilize the rami with plates or retrograde screws, or external fixation.

Violent trauma produces several patterns of injury, including unilateral or bilateral acetabular fractures, bilateral SI disruptions or other equivalent posterior injuries, and bilateral ramus fractures, with or without a diastasis of the symphysis. In most of these patients, virtually all of the principal ligamentous supports of the pelvic ring are severely compromised. As a rule, each site of pelvic disruption must be stabilized with internal fixation.

OPTIMAL TIMING FOR DELAYED INTERNAL FIXATION

Although the use of external fixation as part of the emergency treatment for hemorrhage and pain control is well established, the optimal timing for delayed fixation of closed fractures remains unclear. Whenever the patient is unstable or at risk for excessive hemorrhage, defer surgery for 24–48 hours after the injury. Further delay is likely to result in pulmonary, thromboembolic, and urologic complications. When the patient’s general condition is satisfactory, early surgical intervention permits the most rapid recovery and minimizes the risk of complications.

Contraindications to internal fixation include the systemic problems just discussed, highly contaminated open fractures, concomitant infection, inadequate bone quality or bone stock, a severely injured soft-tissue envelope, and a surgical team that is not experienced or an operating room that is not equipped for this difficult surgery.

SURGICAL TECHNIQUES

GENERAL CONSIDERATIONS

Operating Table

The radiolucent Jackson or similar table is ideal for pelvic reconstruction. It is completely radiolucent, and the absence of a central post enhances imaging with the C-arm. Newer models provide longitudinal and/or lateral skeletal traction.

Figure 17.18. A Jackson radiolucent operating room table and modern C-arm image intensifier.

Image Intensifier

The most recent designs of image intensifier, with a 9 in. or 12 in. field size and high-resolution capabilities, are a major technological advance for pelvic reconstruction. The integral software package permits magnification of focal areas of interest. While the Siemens, Philips, and OEC-Toshiba models, as well as others, are excellent...
for pelvic applications, the OEC-Toshiba has a unique advantage. Its C-arm gantry possesses an extra articulation that greatly simplifies the iliac and obturator oblique views.

**Special Views**

For pelvic reconstruction, intraoperative image intensification is necessary. The radiographic technician needs to know the AP, inlet, outlet, iliac, and obturator views, along with the direct lateral view of the sacrum (67,81). Once the patient is positioned on the operating table, and prior to draping, rehearse the views to be sure that they can be obtained. Correct any obstruction of the image by an ill-positioned upper extremity, arm board, or other object.

Position and drape to optimize imaging. Use radiolucent bolsters. Drape with adhesive drapes and use skin staples to avoid the use of towel clips.

**Reduction Techniques and Tools**

Reductions can be done closed for percutaneous fixation or external fixation, or open (Table 17.30). Instrumentation and implants specifically designed for pelvic surgery are essential. Currently, the Synthes instrumentation (Synthes, Inc., Wayne, PA) is the most complete. Tenaculum forceps are available in diverse sizes with straight and curved jaws (Figs. 17.19, 17.20 and 17.21). The special pelvic forceps are exceptionally large with respect to the length of the jaws and handles, and they provide a high degree of mechanical advantage. The symmetrical King Tong and the asymmetrical Prince Tong are the most useful models.

</table>
| **Screws** For pelvic fixation, kits of specialized fixation devices are available that provide unique attributes for stabilization of the pelvis (Table 17.31). Of the small-fragment screws, the 4.0 mm fully threaded cancellous design affords excellent purchase in the pelvis. For the crucial load-bearing portions such as the SI joints, we prefer the larger core-diameter of the 4.5 mm cortical or 6.5 mm cancellous screws. The strength of fixation is exponentially related to the length of the thread in bone (42). Wherever possible, we use longer screws. For example, where the available bone stock is limited, such as in the superior pubic rami, long screws of smaller
diameter provide more effective fixation than shorter ones of a larger diameter.

### Table 17.31. Principal Fixation Devices for Internal Pelvic Fixation

**Cannulated Screws** For the large cannulated screws, the various brands utilize corresponding guide wires with a range of diameters between 2.8 and 3.2 mm (37). The 2.8 mm wires are readily inserted but bend easily, whereas 3.2 mm wires are significantly stiffer, but because of greater frictional forces during their insertion they can heat up and cause thermal damage. We prefer 2.8 mm wires, although many pelvic surgeons prefer the larger wires.

Most available cannulated screws can be inserted over a threaded-tip guide wire or a drill bit. Threaded-tip guide wires usually remain in position when the drill is removed, whereas drill bits tend to back out. Threaded-tip guide wires provide relatively poor feedback to the surgeon, which can lead to accidental penetration of the adjacent soft tissues, threatening important structures. Drill bits provide better feedback, although they are more likely to break during insertion.

We prefer cannulated screws that are self-drilling and self-tapping, as this eliminates the need for drilling and tapping. The risk for injury to soft tissues is minimized by using an oscillating power drill. In the dense pelvic bone of young adult men, partial drilling and tapping may be necessary to avoid broken implants.

**Plates** Conventional plates are useful for the reduction of injuries such as an SI joint separation. For anterior SI fixation, use two of the two-hole 3.5 mm or 4.5 mm plates. The narrower span between the 3.5 mm holes is ideal for SI fixation and is consistent with the use of 4.5 mm cortical screws (Fig. 17.19 and Fig. 17.20). Typically, the displaced ilium is posterior and superior to the adjacent sacrum. Anchor the plates to the sacrum with a screw. With the superior displacement corrected, place a screw in the ilium through the plate. Tightening the screw reduces the ilium to the sacrum. In contrast, highly flexible reconstruction plates (Fig. 17.22) are used where the objective is to contour the plate to the underlying curved surface of the pelvis without displacement of the fracture, such as along the iliac crest and true pelvic brim. The 4.5 mm and some steel 3.5 mm reconstruction plates are too stiff for this application. They must be contoured perfectly to the bone prior to insertion of the screws. We prefer the more flexible, straight 3.5 mm reconstruction plates, particularly those of titanium.

**Cables and Wires** Cables or 16-gauge wires provide a minimally invasive way to reduce and immobilize diverse segments of the pelvis (43) (Fig. 17.23). While conventional cable passers can be used, a useful tool for passing along the inner pelvic wall is a Statinski vascular clamp. The insertion of passing tools is hazardous, particularly in the presence of a marked pelvic deformity or delayed surgery, where neurovascular structures may be malpositioned and tethered to the bone, making them more vulnerable to traction injury or a laceration. Cables also may be threaded through the cannulation of screws as a way to augment screw fixation in osteopenic bone (Fig. 17.24).
Figure 17.24. Multiple views of a bilateral sacral insufficiency fracture in a 78-year-old woman after irradiation therapy. A: 3D CT anterior view. B: CT scan of the sacrum. C: Screw heads of cannulated screws with a cable and a two-hole plate at the level of S-1. D: Posterior view after passage of the cable. E: Postoperative AP view. F: Postoperative inlet view.

Threaded Rods Threaded rods are useful for immobilizing a sacral fracture when using an open or percutaneous technique (8,16,65,70). While mechanically effective, the reduction must be anatomic. Rods are usually symptomatic postoperatively and require removal. We prefer transverse plate fixation rather than rods, as plates provide more predictable fixation with a low morbidity, and they rarely need removal.

Intraoperative Neurologic Monitoring

Intraoperative neurologic monitoring helps minimize the risk of iatrogenic neurologic injury, especially with respect to the peroneal division of the sciatic nerve, lumbosacral plexus, and the sacral nerve roots. Formerly, somatosensory evoked potential (SSEP) monitoring was popular, but continuous electromyographic (EMG) motor monitoring has proven to be better (23,72). Disadvantages of SSEPs include the need for highly trained personnel, a significant incidence of spurious results, and a latent period of potentially up to a few minutes between an intraoperative injury to a sensory nerve and a significant alteration of the SSEP signal. Continuous EMGs have the advantage of reflecting instantaneously any compromise to a motor nerve, with a minimum of false negative results. The method also is simpler than SSEPs. We use SSEPs to monitor the S-1 nerve root using penile or labial electrodes, but we prefer continuous EMGs for monitoring the peroneal division of the sciatic nerve. While both techniques can be used to monitor sciatic nerve function, it is not clear that the use of both methods is better than the use of EMGs alone.

Surgical Approaches to the Pelvis

See Chapter 2 for surgical approaches to the pelvis. The following description focuses on specific applications for the pelvic ring, including the authors' preferences. The available approaches are outlined in Table 17.32.

Table 17.32. Pelvic Surgical Approaches

Pfannenstiel and Vertical Midline The Pfannenstiel approach is widely used for exposure of the symphysis, although a midline lower abdominal incision provides a comparable view. For unilateral or bilateral ramus fractures, the midline lower abdominal incision provides a minimally invasive and rapid approach. This approach provides visualization of the pelvic brim to the SI joint and the entire quadrilateral surface. It has a lesser morbidity than the ilioinguinal approach and achieves a comparable visualization. If the rami and lateral ilium need to be exposed, the midline lower abdominal approach can be combined with a limited incision along the iliac crest for what has been termed the ilioanterior approach (Fig. 17.25) (24).

Figure 17.25. Multiple views of bilateral ramus fractures, right SI disruption, and left SI fracture dislocation where an ilioanterior approach was used along with an iliofemoral exposure for the left-sided crescent fracture. A: Preoperative AP view. B: Preoperative anterior 3D CT view. C: Intraoperative outlet view. D: Postoperative AP view.

Posterior Sacroiliac For posterior exposure of the SI joint, we prefer a straight longitudinal incision to a curvilinear incision. The transverse presacral incision (Fig. 17.26 and Fig. 17.27) is useful when exposure of the sacrum and both SI joints is needed (46,39). Cosmetically, it is superior to two parallel vertical incisions, as plastic reconstruction of a wound slough from the latter is complicated. Although a transverse incision is cosmetically superior to a midline vertical approach, a proximal extension to the upper lumbar spine requires a vertical incision (62).

Posterior for Threaded Rods Transiliac rods (Fig. 17.28) can be applied through the transverse presacral incision or through short vertical incisions over the lateral aspects of the posterior superior spines. Restore accurate alignment of the pelvis prior to the insertion of the sacral rods. Advance the threaded bars through parallel rows of drill holes that are prepared under image intensification, secure the nuts to the rods, and compress the fracture. Overreduction is possible in view of the mechanical advantage of the threaded system.

Figure 17.28. Technique for transiliac rod fixation. A: Cutaneous incisions. B: Site for preparation of a drill hole in the posterior superior spine. C: Insertion of a threaded rod. D: Final view.

Iliofemoral Approach We prefer the standard iliopelvic approach for exposure of an iliac crescent fracture and the adjacent SI joint (28). We reserve the extended iliopelvic and triradiate approaches for complex injuries with associated acetabular fractures. Limited versions of both exposures have been described that eliminate the need for an osteotomy of the greater trochanter or a corresponding detachment of the gluteal insertions (21,41).

Ischiopubic Approach Use an ischiopubic incision to expose the inferior pubic ramus (Fig. 17.29) (see Chapter 2). This permits visualization from the base of the acetabulum across the ischial tuberosity to the inferior aspect of the symphysis, which is particularly useful for a nonunion.

Figure 17.29. The use of an ischiopubic approach to stabilize the inferior pubic ramus in a 42-year-old man. A: Inferior 3D CT view. B: Postoperative obturator oblique view.

EXTERNAL PELVIC FIXATION

General Considerations

The following description refers to the application of the Hoffmann-II system. Whichever system is used, a typical frame uses 5 mm threaded half-pins inserted into the anterior ilium. Simple frames use one or two, and rarely three, 5 mm half-pins per hemipelvis, inserted into the anterior iliac crest near the anterior superior iliac spine (ASIS) or the anterior inferior iliac spine (AIIS) (42,53). Where the frame is intended for temporary stabilization for a few days, or when the injury pattern is rotationally
unstable but vertically stable, one pin per hemipelvis suffices. When the pelvis is unstable, insert two pins per hemipelvis, spacing the pins widely to achieve optimal stability. For a markedly obese patient with an unstable pelvis, three pins per hemipelvis may be necessary. We prefer to place the pins into the gluteal tubercle, ASIS, and AIIS.

- Prior to the procedure, determine the required number and length of pins. Organize the appropriate drill sleeves, drill bits, pins, and frame constituents.
- Position the patient supine on a radiolucent table.
- Unless speed is important, take AP, inlet, and outlet views with the image intensifier to assess the deformity and determine the strategy for reduction. If there is superior migration of the hemipelvis, apply longitudinal skeletal traction to restore leg lengths. Correct a diastasis of the symphysis with a rotational deformity after the half-pins have been inserted, using the pins as reduction tools.
- If reduction of the pelvis is not necessary, place the pins through small stab wounds directly over the entry point. If reduction is required, particularly of external rotation, make bilateral oblique incisions in the skin where the reduced pelvis will eventually lie. The incisions must not parallel the iliac crest but be in line with the direction of pin movement. For example, with 5 cm of pubic diastasis, place each incision 2–2.5 cm medial to the crest.

**Percutaneous Technique with Four Pins**

Percutaneous techniques are most frequently used where the pelvis is only minimally displaced and where intraoperative image intensification is available.

- Identify the pin entrance sites on the superior aspect of the iliac crest at the gluteal tubercle and at the ASIS or AIIS.
- Make a stab incision over the site and cut down to the top of the iliac crest. At the AIIS, the ilium is deeper than at the ASIS. Spread the tissues with a small periosteal elevator.
- Slide a 2.0 mm Kirschner (K) wire superiosteally down the inner table of the pelvis parallel to the axis of the pin to be inserted to act as a guide pin. Some surgeons slide a second K-wire down the outer table as well to help define the position of the ilium. Use the C-arm for this and verify that the wires are placed appropriately.
- Drill a 4.0 mm hole at the entry site for the pins, through the cortex but not into the cancellous bone between the tables. A short entry hole minimizes the risk of accidental penetration of the cortex.
- Under fluoroscopic control, insert two Schanz-type long threaded half pins into each ilium so that they advance between the two cortices of the bone. Align the pins so that they are divergent from each other in the AP plane. The deeper the pins, the better the fixation, but avoid penetration of the opposite cortex or the hip joint. Leave enough pin protruding to connect the frame at an appropriate height (Fig. 17.30A, Fig. 17.30C).

**Figure 17.30.** Insertion of half pins for external pelvic fixation. A: Anterior outlet view to highlight appropriate target zone for pins between the iliac tables. The view also displays errant pin tracks from a closed insertion technique without image guidance. B: Optimal pin sites on the anterior iliac crest. C: Ancillary pin site on the anterior inferior spine. D: Outlet view with optimal alignment for a percutaneously inserted pin.

- Attach an 8 mm carbon fiber or other suitable bar of appropriate length to each pin with a pin-bar clamp. Attach the two sets of bars to each other with a bar-to-bar clamp in the midline. Be certain that the frame will not encroach on the abdomen when the patient sits up. Adding cross bars between each set of bars increases stability.
- Reduce the pelvis under fluoroscopic visualization.
- Prior to the final assembly and tightening of the frame, turn the patient into a lateral position and manipulate the hemipelvis until the deformity is corrected.
- When the final position is secured, check the skin about the pins and extend the wounds to relieve any tension where skin has gathered on the pelvis.
- Then close the subcutaneous fat and skin snugly about the pins and dress the wounds.
- Take a full series of plain radiographs before leaving the operating room to check the reduction and pin position.

**Open Technique**

The technique is identical except for the surgical exposure.

- Two different skin incisions can be made. An incision parallel to the iliac crest is simplest, but skin tension frequently requires that the incision be "T"ed. Separate 2.5-cm-long incisions can be made for each pin. Place these in line with the skin tension on the pins, roughly at right angles to the iliac crest.
- Expose the top of the crest and inner table by subperiosteal dissection so that the pins can be placed under direct vision. Some surgeons expose the outer table as well, but usually this is unnecessary.
- Proceed as previously described for the remainder of the procedure.

**THE USE OF A PELVIC CLAMP**

A pelvic clamp is designed for rapid and minimally invasive temporary pelvic stabilization. Currently, two designs of pelvic clamp are available. The original Ganz design (16,17) (Fig. 17.31) immobilizes the region of the SI joints for optimal mechanical fixation. The liability of the design is the proximity of the greater sciatic notches, with the potential for a significant neurovascular injury. The Browner design utilizes anterior iliac pins that afford considerably greater safety, but the frame provides less stability. Whichever method is used, the surgical team needs to be familiar with the techniques for insertion of the pins and erection of the frame. These clamps should be used only by surgeons who have had experience with them, as routine frames are safer. While a clamp can be applied in an emergency room, sterile technique must be maintained.

**Figure 17.31.** Schematic views of the Ganz type of external pelvic clamp (17). A: Site for pin insertion. B: Maneuver for pelvic reduction. C: Postreduction with tightening of the locking nuts. D: Potential displacement of the frame.
Fixation of Bilateral Pubic Rami

Two plates mounted at right angles to one another provide the strongest construct, but one plate is sufficient and decreases the soft-tissue stripping.

3.5 mm and 4.5 mm reconstruction plates are commonly used. We prefer the 3.5 mm plates with longer screws. In our experience, two screws per ramus are symmetrical and the involved hemipelvis shows a change in the shape of the pelvic brim.

Internal Fixation of the Symphysis and Adjacent Rami

Vertical displacement is easily confused with sagittal malrotation of the hemipelvis. On the AP radiograph, vertical displacement is consistent with a hemipelvis that is high riding but otherwise a replica of the contralateral hemipelvis. In sagittal deformity, the ischial tuberosities are at different levels, although the tops of the iliac crests are symmetrical and the involved hemipelvis shows a change in the shape of the pelvic brim.

We feel that a pelvic deformity that exceeds 15° of malrotation or 2 cm of linear displacement in any plane merits consideration for open reduction and internal fixation.

Vector and Magnitude of Pelvic Deformity as an Indication for Internal Fixation

We feel that a pelvic deformity that exceeds 15° of malrotation or 2 cm of linear displacement in any plane merits consideration for open reduction and internal fixation.

Table 17.34. Alternative Approaches for Pelvic and Femoral Fractures

Concomitant femoral and/or lumbosacral spine injuries necessitate alternative strategies, as outlined in Table 17.34.

Internal Fixation of the Symphysis and Adjacent Rami

Different plating systems are used for the symphysis. Specialized plates are available, but they have not been proven to be superior despite increased costs. Both 3.5 mm and 4.5 mm reconstruction plates are commonly used. We prefer the 3.5 mm plates with longer screws. In our experience, two screws per ramus is adequate. Two plates mounted at right angles to one another provide the strongest construct, but one plate is sufficient and decreases the soft-tissue stripping.

HINTS AND TRICKS

- Palpate or visualize the obturator foramen as a guide to the acetabulum.
- Do not insert a screw that is directed toward the center of the acetabulum.
- If a screw in the area of the acetabulum is essential, insert the screw more posteriorly and along the pelvic brim.
- If a retrograde pubic screw is used, for image intensification use inlet, outlet, and iliac and obturator oblique views.

- Insert the first two screws adjacent to the symphysis, parallel to the joint and the posterior surface of the rami. Protect the bladder and determine screw direction by palpating or visualizing the posterior aspect of the symphysis. Be certain that the screws are bicortical. Insert the other two screws.
- Close the wound in a layered fashion over a suction drain.

Fixation of Bilateral Pubic Rami

- Use a vertical midline abdominal incision.
- Look carefully for a corona mortis and ligate it.
- Contour four- to five-hole 3.5 mm plates to fit along the superior posterior aspects of the pelvic brim.
- Insert screws using radiographic control to ensure that the screws miss the hip joint.
- Alternatively, use the retrograde medullary superior ramis screw fixation technique, as described previously.
Close in layers over a suction drain.

**Fixation of the Inferior Pubic Ramus**

Acute fixation of the inferior pubic ramus is not common: In most cases, it is done for a late painful nonunion. Stabilization may require a bone graft for a defect (Fig. 17.29).

- Position the patient in the lateral decubitus position on a radiolucent table with maximum flexion of the ipsilateral hip and knee, which are uppermost.
- Prep and drape carefully to exclude the rectum and genitalia.
- Make an ischiopubic exposure (Chapter 2).
- Reduce the fracture with a small tenaculum or lion-jaw forceps.
- Contour and apply a 3.5 mm reconstruction plate.
- Use the obturator oblique view to ensure that screws do not penetrate the acetabulum and hip joint.
- Close in layers over a suction drain.

**HINTS AND TRICKS**

- For a late presentation with a fixed deformity, a structural bone graft may be needed to reestablish the continuity of the ischium.
- Where the fracture is higher in the ischium and transverse, use lag screws inserted directly in the prominent portion of the ischial tuberosity. (See Fig. 17.39 on p. 578.)

**Anterior Fixation of the Sacroiliac Joint**

Position the patient supine on a radiolucent table.
- Expose the inner ilium, anterior SI joint, and lateral 2.5 cm of sacrum through an ilioinguinal approach (Chapter 2).
- If fixation of the symphysis is required, expose it simultaneously.
- Clear the SI joint of debris and soft tissues.
- Attach a three-hole 3.5 mm plate to the sacral ala in a convenient location, leaving room for a second plate. Use a 4.5 mm cortical screw.
- Place a large tenaculum forceps with one point in the lateralmost hole of the plate and the other on the iliac crest, and reduce the SI joint.
- Contour a second, similar plate and fix it to the sacrum with one screw and to the ilium with two screws.
- Remove the forceps and insert the remaining screws in the first plate.
- Verify the reduction and screw placement with the C-arm using inlet and outlet views.

**Lag-Screw Fixation of the Posterior Sacroiliac Joint**

This technique rests on a clear understanding of the local anatomy (Fig. 17.32). Whether open or closed technique for screw insertion is used, the irregularity of the posterior margins of the SI joint impedes assessment of the reduction. The undersurface or superior surface of the SI joint can be palpated, but intraoperative imaging is essential. Accurate reduction is necessary to provide a safe and predictable site for the fixation screws. For assessment of the target zone in the sacrum, the direct lateral image is the optimal view. When the AP, inlet, and outlet views are used without a lateral image, the most common error is a screw that appears to be satisfactorily positioned but that, on the lateral view, is in fact superior to the S-1 body.

**HINTS AND TRICKS**

- During the exposure, use bone wax on the intraosseous veins at the base of the internal iliac fossa to control bleeding.
- If the articular cartilage of the SI joint is damaged, thoroughly remove it to achieve a fusion.
- Direct the screws parallel to the SI joint.
- Diverge the plate position to increase stability.
- Tightening of the first iliac screw should reduce the posterior displacement of the ilium.

**Figure 17.32.** The use of intraoperative image intensification for iliosacral screw insertion. **A:** General method for the prone patient. **B:** CT of SI malreduction where iliosacral screw insertion is not technically feasible. **C:** Landmarks for screw insertion. **D:** SI cross section with ideal screw placement. **E:** Target zones for iliosacral screws with an open or closed technique.

- Position the patient halfway between prone and lateral so that the involved ilium is parallel to the table.
- Make a vertical incision at the posterior superior spine.
- Palpate the inferior margin of the SI joint through the greater sciatic notch.
- Reduce the SI joint with a tenaculum forceps and check the reduction radiographically (AP, inlet, outlet, and obturator oblique views).
- Identify the insertion site for lag screws on the lateral ilium, halfway between the posterior superior spine and the anterior aspect of the roof of the greater sciatic notch.
- Insert two 6.5-mm-long threaded cancellous screws or corresponding 7.3 mm cannulated screws.
- Assess final imaging using AP, direct lateral, inlet, and outlet views.

**Fixation of the Ilium for a Crescent or Lateral Iliac Fracture**

This technique (Fig. 17.25) is perhaps the least complex technically, with a relatively low risk for injury to neurovascular bundles or viscera, apart from the superior gluteal vessels. The fixation is outstanding, so an accompanying pubic symphysis diastasis or ramus fracture does not have to be immobilized. Since the posterior SI ligaments are intact, the SI joint is stabilized upon fixation of the fracture.

**HINTS AND TRICKS**

- With the posterolateral position, gravity facilitates the reduction.
- Palpation over the superior aspect of the SI joint of the alar region is helpful in the reduction.
- While drilling, feel the drill bit advance across three cortical layers: the superficial iliac table and the iliac and sacral subchondral bone at the SI joint. Do not penetrate a fourth dense layer of bone, which represents the S-1 foramen or the anterior aspect of the sacrum.
- Measure 50–60 mm of penetration of the drill and select a corresponding screw. Usually, the S-1 foramen is 55 to 65 mm deep from the lateral ilium and thereby is avoided.
- Use a direct lateral sacral view to ensure that the screws are anchored in the S-1 body.
Carefully protect the superior gluteal vessels.
Direct the screws through the iliac crest between the tables.
Insert the inferior screws into the posterior inferior spine.
Use the iliac and obturator obtuque views to guide the fixation.
Limit the use of SI screws to comminuted fractures or for the rare occasion when the posterior SI ligaments are completely torn.

- Position the patient halfway between prone and lateral.
- Drape the ipsilateral lower extremity free.
- Make a limited iliopelvic approach and reflect the hip abductors to expose the fracture.
- Reduce the fracture with tenaculum forceps and positioning of the leg.
- Apply a 3.5 mm reconstruction plate along the iliac crest.
- Where the inferior half of the fracture is a simple configuration, insert two 4.5 mm cortical or 6.5 mm cancellous screws using lag technique.
- If the inferior half of the fracture is comminuted, apply a 3.5 mm plate on the lateral ilium.

**Fixation of the Sacrum with a Transverse Plate**

This fixation (Fig. 17.27) has relatively low morbidity and the stability is outstanding. We usually insert supplementary iliosacral screws for two-column pelvic fixation. An alternative is to fix the anterior column where iliosacral screws are not appropriate. If vertical displacement of a sacral fracture is present, use preoperative skeletal traction to reduce it. Maintain traction during the procedure.

- With the patient prone, make a transverse presacral exposure at the level of S-1.
- Expose the fracture and remove any displaced foraminal fragments.
- Reduce the fracture with a large tenaculum and King Tong forceps.
- Make notches in the posterior superior spines.
- Contour and apply a 4.5 mm reconstruction plate with seven to nine holes.
- Insert 4.5 mm cortical or 6.5-mm-long threaded cancellous screws into both ends of the plate. At each end, two screws course between the iliac tables. A third screw is inserted into the adjacent empty hole at either end of the plate which is directed into the sacral ala.

**HINTS AND TRICKS**

- If a large anterior sacral alar fragment is present, reduce it by inserting a tenaculum forceps superior to the SI joint, under image control.
- As an alternative, the transverse plate can be applied superficial to the S-2 segment.
- Direct the sacral alar screws parallel to the SI joint on divergent pathways. Do not fill the central presacral screw holes that are over the spinal canal and foramina.

Verify position with AP, inlet, and outlet images.
If a supplementary iliosacral screw is used, insert it before applying the plate to optimize imaging.

**Sacral Fixation with Alternative Plates**

Bridging plates across a transforaminal fracture have been used by Pohlemann et al. (52). While the method is technically elegant, the sites for safe and effective screw placement are small and anatomically variable and therefore hazardous to the sacral nerves. Prior to performing this procedure, observe the technique in the hands of an experienced surgeon.

**Sacral Fixation with Transverse Rods**

This method (Fig. 17.28) utilizes two rods that span from one posterior superior iliac spine to the other. It is suitable for a single site of posterior injury, such as a vertical sacral fracture. For a bilateral SI dislocation, it affords no intrinsic pelvic stability unless supplementary iliosacral screws are used. Perhaps the most frequent shortcoming of the method is failure to obtain an accurate or acceptable reduction, particularly when using minimally invasive techniques, where malunion can occur. The method also depends on the presence of good quality bone. With osteopenia, premature loss of fixation is likely.

- Use the same approach as described for the insertion of posterior lag-screw fixation of the SI joint, with the addition of a smaller exposure on the contralateral side to expose the lateral aspect of the iliac wing anterior to the posterior spine.
- Reduce the fracture.
- Place drill holes through the posterior tubercles of the ilium just dorsal to the sacral lamina.
- Place two rods posterior to the sacrum and 2-4 cm apart, between the two intact posterior tubercles of the iliac wings.
- Place the first rod just proximal to the S-1 foramen and the second rod just distal to the S-2 foramen.
- Insert the rods proximally to avoid entering the sacrum and endangering the nerve roots within the sacral canal.
- Alternatively, use cannulated rods and imaging to help guide the rod placement.
- Insert nuts and washers to compress the system.

**HINTS AND TRICKS**

- Based on its intrinsic biomechanical limitations, limit the use of this technique to the fixation of a unilateral unstable sacral fracture, or use it in combination with posterior screw fixation to stabilize an SI joint dislocation or a bilateral sacral disruption.
- Avoid overzealous compression of the fracture site, particularly in the presence of foraminal fractures, to minimize the risk of neurologic compromise.

**Fixation of a Lumbosacral Dissociation with a Sacral Fracture**

These complex injuries of the sacrum are most difficult to reduce (56) (Fig. 17.33). The anterior displacement of the sacrum is aggravated by prone positioning of the patient, so the reduction is challenging and potentially hazardous. A pointed reduction forceps or hook must be cautiously inserted around the lateral margins of the sacrum to the edges of the anterior surface to achieve the reduction. With the proximity of the rectum, the maneuver must be done with care. A variety of plates, lag screws, and cables have been used to anchor the sacrum. Supplementary compression rods with pedicular screws may be needed to immobilize the lower lumbar spine to the sacrum (18).
Figure 17.33. A lumbosacral dissociation in a man of 29 years, in whom a combination of cable fixation and lag screws was used. A: Preoperative anterior 3D CT view. B: CT scan. C: Postoperative AP view. D: Postoperative 3D CT posterior view. E: Postoperative CT scan.

- Make a suitable midline longitudinal exposure of the sacrum and relevant portions of the lumbar spine.
- To reduce the anterior displacement of the sacrum, insert a tenaculum forceps from the lateral margin of the displaced segment of sacrum to the neighboring anterior surface and reduce it.
- Apply a transverse plate across the S-1 and S-2 segments, possibly with associated hook plates.
- Immobilize the sacrum to the lumbar spine. Distraction or compression rods can be used to anchor the relevant lumbar spinal segment to the two transverse plates by the use of hooks placed over the superior or inferior margins of the transverse sacral plates. Alternatively, pedicular screws can be employed.
- Three major technical problems must be overcome: sacral realignment, and fixation and immobilization of the sacrum to the lumbar spine.

PERCUTANEOUS INTERNAL PELVIC FIXATION

General Considerations

We prefer to use a 7.3 mm cannulated screw for the principal structural portions of the pelvic ring, notably for iliosacral fixation, and 4.5 mm screws for periacetabular fixation. We use drill sleeves to protect the adjacent soft tissues.

Appropriately position the patient on a radiolucent table with a wholly radiolucent draping technique that eliminates towel clips. A modern image intensifier with a large field size of 9–12 inches is strongly recommended. The appropriate radiographic views for effective guidance of the relevant screws need to be clearly understood and technically feasible. Prior to draping, rehearse the views to ensure their feasibility (Fig. 17.32). Table 17.35 lists the indications and contraindications of the procedure.

Table 17.35. Indications and Contraindications for Percutaneous Internal Pelvic Fixation

This technique is not useful for iliosacral or posterior iliac fixation. Unstable but well-aligned fractures can be fixed in situ. In more complex disruptions, open reduction and fixation of an anterior ring disruption such as a diastasis of the symphysis may realign the posterior ring so that percutaneous stabilization is feasible.

Percutaneous Fixation of the Sacroiliac Joint

Percutaneous iliosacral fixation is feasible in a supine, prone, or lateral position, although imaging is slightly more difficult in the lateral position (33,52,58). When open anterior ring fixation immediately precedes the iliosacral fixation, we prefer the supine position (Fig. 17.34). When the patient is positioned prone for an accompanying procedure, maintain that position. In the presence of external fixation, the lateral position greatly facilitates reduction of an SI dislocation. Irrespective of the position, the method for screw insertion is similar.

Figure 17.34. An example of iliosacral screw fixation in a man of 33 years. A: Anterior 3D CT scan. B: Postoperative outlet view. C: Postoperative CT scan.

- After positioning and draping, place a 2.8 mm threaded tipped guide pin transversely on the exposed abdominal wall or on the skin of the back at the S-1 level. With AP imaging, draw a line along the pin on the trunk, including the relevant side to provide a guide to pin placement.
- Make a 2 cm transverse incision on the lateral flank, along the line that is halfway between the greater trochanter and the posterior surface of the back.
- Spread the underlying soft tissues to bone.
- Insert the guide wire and drill sleeve to the bone and confirm the position in the AP view.
- Using power, advance the guide wire just across the SI joint (use AP, inlet, outlet, and direct lateral views).
- If the first wire is not where you want it, leave it in place and insert a second wire, using the first as a supplementary guide.
- Advance the guide wire to the level of the S-1 foramen.
- Insert a second guide wire into the S-1 body.
- Measure for screw length with a depth gauge and insert the appropriate long-threaded screws of 45–60 mm in length.

HINTS AND TRICKS

- For the ideal inlet view, adjust the gantry until the anterior margins of S-1 and S-2 coincide.
- Use the AP view for transverse orientation, the inlet for AP positioning, the outlet for the S-1 foramen and superior S-1 endplate, and the direct lateral of S-1 for location of the screw tips.
- If the screw is 45 mm, use the obturator oblique view to confirm that the screw threads are not across the joint so it can be lagged together.
- Do not use screws longer than 60 mm.
- For bilateral screw insertion, insert all of the guide wires before any screws to optimize imaging.

Iliosacral Screws for Sacral Fixation

While the method for sacral immobilization with iliosacral screws is similar to that described for an SI joint, there are some additional considerations (59). Once the
screw passes beyond the S-1 foramen, the potential for neurologic injury increases. The target zone for the iliosacral screw markedly diminishes, while the corresponding demands imposed on the intraoperative imaging increase. Anatomic variations of the L5–S1 articulation can further compromise the target zone available in the sacrum (Fig. 17.35).

Using the supine or prone position, draw a reference line as described previously. As described under iliosacral screw insertion for the SI joint, make a lateral incision and insert a guide wire into the S-1 body. Place it mid axially from anterior to posterior, and centralized between the superior endplate and the S-1 foramen (use AP, lateral, inlet, and outlet views). Advance the guide wire to the level of the contralateral S-1 foramen. For an unstable fracture, insert a second guide wire for another iliosacral screw that is anterior and inferior to the first but still in the S-1 body. Measure for depth and insert two long threaded screws of appropriate length. Obtain final imaging.

HINTS AND TRICKS
As an alternative site, the S-2 body can be used, although the target zone is much smaller than S-1. To account for the variable degree of lumbar lordosis, select the inlet view where the anterior margins of S-1 and S-2 are superimposed. The direct lateral view is crucial to determine appropriate insertion of the guide wire.

Bilateral Transforaminal Sacral Fractures
Bilateral transforaminal sacral fractures are usually comminuted and highly unstable. If unstable, plate fixation is recommended to augment iliosacral screws. For bilateral transforaminal sacral fractures without additional comminution, either of two strategies for iliosacral screw fixation can be used. Insert either ipsilateral screws for each injury site (Fig. 17.36) or insert long screws that transfix both sides of the sacrum. The latter method necessitates an anatomic reduction, the absence of congenital sacral anomalies, and highly accurate placement of the guide wires. Where bilateral transfixing screws are inserted, advance the guide wires with a perfectly transverse orientation and mid axial from anterior to posterior in S-1 (Fig. 17.24). The screws are usually 120–150 mm long.

Percutaneous Iliac Fixation
Certain vertical iliac fractures with minimal displacement and extending from the iliac crest to the greater sciatic notch are appropriate for percutaneous screw fixation (S2). For the more posterior injuries that are at or posterior to the anterior border of the SI joint, use the prone position. If the iliac fracture is further anterior, either a prone or a supine position is feasible. In the prone position, the insertional site is the posterior superior spine (Fig. 17.37). In the supine position, use the anterior inferior spine. Insert two parallel screws into either site with a spacing of about 15 mm. Keep in mind the divergent pathway of the ilia, from posterior to anterior throughout the target zone (S2).

Figure 17.37. The method for percutaneous insertion of a transiliac screw to immobilize the posterior ilium. A: Iliac oblique 3D CT view. B: CT view. C: Intraoperative iliac oblique view. D: Intraoperative obturator oblique view.

Place the patient prone. Make a 10 mm stab wound that is about 20 mm superior to the posterior superior spine.

HINTS AND TRICKS
When using the supine position, use a similar technique, with the anterior inferior spine as the initial target for the guide wire. Direct the guide wire toward the posterior superior spine.

- Insert a guide wire into the wound and down to bone. Direct the guide wire on the iliac oblique view toward the anterior inferior spine and on the obturator oblique view between the inner and the outer iliac tables.
- Advance the guide wire until at least 35 mm is into bone beyond the fracture.
- Insert a second parallel guide wire.
- Measure for and drive the two screws.

**Percutaneous Fixation of the Superior Pubic Ramus**

It is possible to fix the superior pubic ramus with a screw inserted antegrade from laterally, or alternatively retrograde from medially. The former is difficult and hazardous. The antegrade screw is not recommended for routine use, as the obliquity of the screw, the limited target zone of bone, and the juxtaposition of the external iliac vessels makes the technique hazardous. When inserted retrograde, the shorter length of the screw limits the technical complexities, although a virtually anatomically reduced fracture is necessary (52,61) (Fig. 17.38).

![Figure 17.38](image1.png)

**Figure 17.38.** Schematic views of the insertion of a percutaneous retrograde ramus screw. A: Obturator oblique view. B: Iliac oblique view.

**HINTS AND TRICKS**

Drape the ipsilateral lower extremity free to permit passive movement of the hip after screw insertion.

**Percutaneous Fixation of the Ischium**

The posterior portion of the ischium and the lower posterior column of the acetabulum can be fixed using percutaneous screws. The entry site for the screw is the ischial tuberosity with vertical orientation of the screw along the posterior column (Fig. 17.39).

![Figure 17.39](image2.png)

**Figure 17.39.** Schematic views of the insertion of a percutaneous posterior column screw via the ischial tuberosity. A: Obturator oblique view. B: Iliac oblique view.

- With the patient in the supine position, make a 10 mm incision anterior, medial, and slightly inferior to the pubic tubercle.
- Perform a closed reduction of the injured hemipelvis.
- Advance a guide wire to bone. On an oblique outlet fluoroscope view, direct the guide wire into and up the superior pubic ramus. On the inlet view, direct the guide wire parallel to the inner border of the true pelvic brim.
- Advance the guide wire beyond the fracture.
- Measure for screw length and insert an appropriate 3.5 mm or 4.5 mm cortical screw and tighten.

**Cable and Heavy Wire Fixation**

**General Considerations**

Cables of 2.0 mm diameter and 14- to 18-gauge wires can be used for supplementary reduction and fixation. The ringlike configuration of the pelvis makes cables and wires particularly useful (43).

None of the available cable systems were designed with the pelvis as the principal site for intended use. When a cable is tightened, it shortens its pathway. To control the pathway and the vector of displacement of the bone, we usually pass the cable through a small drill hole in the pelvis. In this way, the displacement of the tightening cable and its effect on bony alignment can be controlled. Many cable systems possess a tightening mechanism at one end of the cable that blocks its insertion into a drill hole. In some applications, both ends of the cable have to be passed through drill holes. In this situation, the use of a “double-ended” cable or wire is essential.

Most tools used to pass cables or wires are based on a semicircle designed for the femoral shaft. Such a design does not work well on the pelvis. For example, at the greater sciatic notch, the semicircular design can injure the sciatic nerve. As an alternative, use a Statinski vascular clamp, which has angled jaws and a blunt tip and is available in various sizes that work well on the pelvis.

Various tools for tightening cables are available in many sizes. They vary from excessively bulky to low-profile configurations. Some tightening devices can be removed while a cable is provisionally held tight. We prefer to use double-ended cables with a low-profile tighter. Cable fixation is useful for a wide variety of unusual problems, such
as sacral dissociation (Fig. 17.33).

Lateral Ilium

- Whether a medial or lateral exposure is used, pass the cable through the greater sciatic notch.
- Anteriorly pass it around the base of or through a drill hole in the anterior inferior spine. Align the lateral ilium and tighten and secure the cable (Fig. 17.23).

Posterior Column

- At the base of the posterior column, pass the cable through the lesser sciatic notch. Then pass it through a drill hole at the base of the anterior inferior spine.
- After reduction of the fracture, tighten and secure the cable.

Quadrilateral Surface Certain pelvic and acetabular fractures include a large quadrilateral surface fragment that is difficult to fix. The opposing articular surface of the hip joint eliminates most of the bone from consideration for screw fixation. Buttress plates are highly vulnerable to late displacement. A cable or heavy wire can be used to supplement a plate on the pelvic brim (Fig. 17.23).

- Reduce the iliac and superior pubic ramus portions of the fracture and apply a plate along the pelvic brim.
- Drill 2.5 mm holes through two the central holes in the plate that exit on the quadrilateral surface.
- Prepare a 4.5 cm structural bone graft from the inner iliac table and make two corresponding drill holes in it.
- Pass the cable or wire down through the pelvic brim, out through the quadrilateral table, and through the holes in the structural graft. Then retrograde the cable through the quadrilateral surface and pelvic brim.
- Tighten and secure the cable.

Sacrum Where osteopenia of the sacrum hampers lag-screw fixation, a cable can be used to supplement the fixation (Fig. 17.33).

- Under image intensification, inset two iliosacral screws that just traverse the entire posterior width of the pelvis (120–150 mm length).
- Through a transverse posterior exposure, identify the sites of the screw heads and screw tips.
- Pass a cable through the cannula of one screw.
- Apply a two-hole 3.5 mm plate on either end of the cable and feed each end of the cable through the second hole in the appropriate plate.
- Retrograde one end of the wire through the second cannulated screw.
- Tighten and secure the cable.

POSTOPERATIVE CARE AND REHABILITATION

The postoperative regimen for the pelvic fracture patient varies considerably, depending on the specific nature of the injury and the presence of a wide variety of associated injuries to the appendicular skeleton or spine. Nevertheless, certain general principles provide helpful guidelines. The fundamental goal is to mobilize the patient as rapidly as possible without an excessive likelihood for a loss of the pelvic reduction.

Early after stable fixation of a pelvic fracture, begin chair transfers and resume protected ambulation (16,40,42,64). The morale of patients with these severe injuries is low because of the physical impact of the injury, the vocational and financial implications, and sometimes the injuries to other family members or friends in the same accident. Rapid mobilization is a great boost to morale. Outpatient and home-based rehabilitation is preferred to institutionalization. If inpatient therapy is needed, arrange for it to be near the patient's home so that friends and family members can visit easily.

EARLY POSTOPERATIVE PHYSICAL THERAPY

For isolated pelvic fractures with stable fixation, and whenever the general condition of the patient permits, begin bed-to-chair transfers, possibly with a sliding board the day of surgery. This facilitates pulmonary toilet and heightens morale. Encourage the patient, as soon as practical, to begin touchdown walking. About 6 weeks later, advance the patient to a partial weight-bearing gait, and progress to full weight bearing over the next 6–8 weeks. Prescribe progressive resistance exercises to the muscle groups around the pelvis and in lower extremities, with emphasis on the hip abductors and the quadriceps muscles.

Where external pelvic fixation without supplementary internal fixation is used, the activity level depends on the degree of pelvic instability. For a vertically stable injury, early touchdown gait training may be feasible. For an equivocally stable situation, encourage bed-to-chair transfers. Defer gait training for 6 weeks until the external frame is removed. At home, use a wheelchair and a bedside commode.

LATE OBJECTIVES OF REHABILITATION

Three issues to be addressed are overall motor function, specialized needs for persistent physical disability, and vocational planning. A generalized weakened state follows most pelvic fractures, especially in multiple trauma, because of malnutrition and prolonged disuse. Nutritional advice is needed after discharge.

Begin early focal progressive resistance exercise of the pelvic muscles, followed in a month with a generalized strengthening program. Include water therapy with a pool, ambulation, and swimming. At 6 weeks after the injury, initiate an aerobic exercise program with, for example, a stationary bicycle or a rowing machine. Full rehabilitation often requires 1–2 years of enthusiastic participation in a program. Return to a laboring job is likely to require at least 6–12 months.

A frequent problem is foot drop. Acutely, provide a resting ankle–foot orthosis along with a custom-molded shoe insert. Initiate passive stretching exercises of the heel cord, and muscle stimulation. As recovery progresses, institute active and active assistive exercises.

PAIN MANAGEMENT

For the initial postoperative period, the use of patient-controlled anesthesia (PCA) with narcotics is effective in alert patients (15). While patient satisfaction is usually good, nausea, urinary retention, drowsiness, confusion, and overdosage can occur. Within a day or so, oral narcotics usually replace the PCA. A muscle relaxant may be necessary to manage muscle cramps.

Epidural analgesia with an indwelling catheter provides effective pain control, but an indwelling Foley catheter is usually required. Resultant motor weakness may interfere with mobilization.

When significant pain persists for more than a few days, look for persistent pelvic instability; wound hematoma; infection; dysesthetic pain from a nerve root, plexus, or a peripheral nerve injury; and other causes.

A significant problem is late dysesthetic pain resulting from lumbosacral plexus injury, scarring, or reflex sympathetic dystrophy. Referral to a pain management specialist clinic may be necessary to identify the cause. Reassure the patient that substantial or complete recovery is likely over a period of many months (42,51,52,70).

THROMBOEMBOLOGIC PROPHYLAXIS

Because of the high risk for deep venous thrombosis (DVT) and pulmonary embolus (PE) in pelvic trauma and reconstruction, routine prophylaxis is indicated (47,48 and 60). The role for differing regimens is controversial. We use early mobilization from bed, as well as either low-molecular-weight heparin or coumadin for a postoperative period of 2–3 weeks. When long-term prophylaxis is indicated we use coumadin.

We use inferior vena cava (IVC) filtration in high-risk patients (2,74). In patients transferred late to us, and in other high-risk patients, we do a duplex ultrasound evaluation. If clots are found in the thigh veins, we insert an IVC filter prior to surgery. Another option is transient heparinization, with a temporary reversal for the pelvic surgery followed by reanticoagulation with heparin, coumadin, or low-molecular-weight heparin (see Chapter 5 for more details).

FOLLOW-UP
Remove sutures or skin staples 2–3 weeks after insertion. Examine the patient and obtain radiographs at 6 and 12 weeks after surgical management or acute trauma. Most pelvic injuries heal by 12 weeks.

With the recent socioeconomic pressure for prompt return to work, at least in some capacity, a few salient observations may be helpful. For sedentary workers with a stable pelvis, part-time return to work may be feasible within 2–3 weeks after injury. Typically, a patient can tolerate 2–4 hours per day provided that suitable transportation is feasible. Within 12 weeks, the sedentary worker may resume full-time work in an incremental fashion.

At the opposite extreme, a heavy laborer is likely to require a disability period of 6–12 months. About half of the individuals complain of long-term posterior pelvic or low back pain that impairs their recovery and may necessitate industrial retraining or work modifications.

**MANAGEMENT OF EXTERNAL FIXATION**

For details on pin-site care, see Chapter 11.

All the available external frames are subject to spontaneous loosening of the clamps. Provide patients with wrenches so that they can tighten all the nuts weekly until the frame is removed. Typically, the frame is removed under a short-acting general anesthetic as an outpatient procedure.

In some cases, isolated external fixation is used to immobilize the pelvis. When the horizontal bars that connect the opposing hemipelves are removed, the residual portions of the frame can be grasped and manipulated to document the degree of pelvic stability. When persistent instability is evident, which is unusual, reassemble the frame. After pin removal, irrigate with weak betadine solution and apply dry dressings. Allow a partial weight-bearing gait with crutches, and in the next month progress to full weight bearing. In more severe pelvic disruption, progress weight bearing over an 8-week period. When a stable union is evident radiographically and clinically, resume full activity.

### Supplementary Fixation

External fixation provides only limited fixation of an unstable pelvic injury. Therefore, it is important to be able to recognize the various clinical presentations of inadequate fixation, and to mount an appropriate response.

Isolated external fixation alone may result in hemodynamic instability and instability of the pelvis.

- Once the pelvic instability is recognized, use supplementary skeletal traction for vertical instability.
- If the general condition improves, add or replace with internal fixation.

Another example is isolated external fixation for a presumed stable injury. The patient may complain of persistent posterior pelvic pain that hampers sitting, transfers, or gait; or radiographic loss of reduction is noted when the patient is mobilized.

- Obtain additional radiographs or use CT to confirm an occult unstable posterior injury.
- Perform secondary posterior internal fixation with possible replacement of the frame by anterior internal fixation.

A third example is an unstable fracture managed with isolated external fixation in an ill, elderly individual. In view of the comorbidities, there is usually no possibility of later internal fixation.

- After 6 weeks of conservative treatment, remove the frame and associated skeletal traction.
- Mobilize the patient to tolerance.
- Once the general condition and nutrition of the patient have stabilized, evaluate the residual pelvic problem clinically and radiographically.

### PITFALLS AND COMPLICATIONS

#### GENERAL PITFALLS

While a seemingly endless list of pitfalls could be cited, the most salient examples are highlighted here.

- Lack of an integrated acute resuscitative protocol. Prior to the emergency management of these patients, the trauma team must have a cohesive resuscitative and diagnostic protocol.
- Needless deferral of definitive pelvic reconstruction. Deferral of definitive surgical treatment of the disrupted pelvis beyond the optimal period of a few days after injury leads to enforced recumbency with its complications: increased technical difficulties with open reduction, increased pain, and other systemic problems.
- Inadequate preoperative imaging. A thorough understanding of the injury through a complete radiographic assessment, including CT and potentially 3D CT, is necessary to formulate an appropriate operative strategy.
- Inadequate preoperative planning and lack of appropriate resources for effective pelvic reconstruction. Pelvic fractures and disruptions are complex. Meticulous preoperative planning and often consultation with a more experienced surgeon, even in another location, is necessary to devise appropriate fixation and avoid complications. Early transfer of the patient to a regional center that possesses specialized resources and experience may be prudent.
- Excessive use of external fixation. External fixation is useful for open pelvic fractures, unstable pelvic injuries with acute hemodynamic instability, and external rotation injuries with a symphysis diastasis, but it is not a particularly effective method for many unstable disruptions. External fixation compromises the cutaneous envelope and increases the risk of infection. External fixation tends to be overused on stable but perhaps slightly deformed internal rotation injuries, where immediate weight bearing to tolerance would be a better choice.

### COMPLICATIONS

#### Uncontrolled Hemorrhage

After a pelvic fracture, a constellation of problems and associated major injuries can result in fatal hemorrhage. Prolonged exsanguination at the accident site, delays in transfer of the patient to an appropriate treatment facility, hypothermia, and antecedent comorbidities are contributing factors. The risk of hemorrhage can be minimized with standing protocols for resuscitation and an integrated team approach to management.

Hemodynamically unstable patients usually require immediate laparotomy in the operating room and early reduction and stabilization of pelvic disruptions. See Chapter 5 and Chapter 14 for more details.

#### Complications of External Fixation

Most complications of external fixation are the result of pin loosening or infection, and inadequacies of the reduction and fixation. Improper insertion and location of fixation pins in the ilium usually results in early loss of fixation. This leads to pain, loss of reduction, and pin-track infection. Open insertion of the pins with exposure of both tables of the ilium minimizes the risk in the hands of less experienced surgeons. A snug fit of the skin around the pins to avoid excessive motion at the skin–pin interface or skin tension at the pin site minimizes the risk of wound problems.

The limited stability of external fixation means that unstable pelvic injuries merit serious consideration for supplementary internal fixation or replacement with internal fixation.

#### Complications of Internal Fixation

Other than infection, most complications of internal fixation of the pelvis are caused by a lack of appreciation for the complexity of the deformity, particularly rotary displacement, which results in inadequate fixation leading to persistent instability, nonunion, and malunion. Referral of the patient to a center that specializes in treating
pelvic injuries is advisable in many cases. A thorough understanding of the mechanism of injury, the 3D pathologic anatomy, complete imaging, and careful preoperative planning will minimize these risks. The risk of postoperative infection of pelvic surgery is significant, as the coexistence of other injuries compromises the patient's immunologic status and provides additional sites for bacterial contamination and infection, such as intravenous lines and suprapubic catheters. For that reason, minimally invasive, percutaneous techniques are advantageous. The soft-tissue envelope around the pelvis may also be compromised, requiring alternative approaches or delay in the surgery. See Chapter 18 for more details.

Neurologic Complications. Neurologic injury is a major cause of long-term morbidity after a pelvic ring disruption, particularly a posterior ring disruption. The incidence of neurologic injury varies between 2% and 50% (53, 51, 56, 72), depending on the mechanism and severity of the injury. Typically, the injury involves the lumbosacral trunk and/or the superior gluteal nerve. The lumbosacral trunk is injured as a result of traction from significant external rotation and posterosuperior displacement of the hemipelvis. The superior gluteal nerve usually is injured directly by fracture fragments near the SI joint. Neurologic assessment may be hampered by the presence of a concomitant hemorrhage, edema, and entrapped, necrotic, and ischemic soft tissues. Careful neurologic and bladder function to rule out sacral plexus injury. Urologic consultation may be helpful. Myelography and EMG studies can help in the diagnosis after 3 weeks.

Recovery from neurologic injury is unpredictable (13, 51). Most nerve injuries are traction induced and require early conservative treatment. Some advocate prompt exploration and decompression of sacral nerve roots, although results have not demonstrated a clear benefit (52). The results of surgical repair of the sciatic nerve are poor, so surgical exploration is limited to situations where impalement of the nerve on a bone spike or in a fracture merits removal of the offending bone fragment.

Symptomatic Hardware. Most retained hardware is not symptomatic unless it is immediately subcutaneous. The unusual problems are a painful plate on the anterior iliac crest that is aggravated by a belt, or a plate on the superior public rami and symphysis in a lean individual that causes dyspareunia. Be aware that pain near hardware may represent an occult nonunion, for which a CT scan, tomograms, or a technetium bone scan merit consideration. Rather than removal, revision of the fixation and bone graft may be necessary. Transverse posterior rods are nearly always symptomatic and merit removal.

Thromboembolism. Deep venous thrombosis (DVT) with the potential for a subsequent fatal PE is a common complication of a pelvic fracture for which the risk can be minimized by the use of appropriate prophylactic measures. The availability of enhanced DVT screening techniques such as magnetic resonance venography has led to earlier and more frequent detection of proximal and distal clots in the venous system (2, 47, 48, 49). While a distal thrombus is not as likely to embolize, a proximal thrombus is at high risk for dislodgement and fatal PE. In a pelvic fracture victim, the incidence of DVT is 25% to 35%, and the incidence of a proximal clot is 25% to 35%. The incidence of a subsequent PE is 2% to 12%, with a 0.5% to 10% risk of a fatal PE. These rates may become much higher if the patient has sustained polytrauma with involvement of multiple organ systems. A high injury severity score, increased age, a direct venous injury, multiple blood transfusions, a concomitant lower extremity or spinal cord injury, and a past history of venous stasis disease increase the risk. Prophylaxis and treatment for thromboembolic disease are discussed in Chapter 5.

Persistent Pelvic Pain. About 60% of pelvic fracture victims have prolonged posterior pelvic pain (13, 42, 51, 70). Other sites of late discomfort are less common. Frequently, the specific site of the pain is difficult to identify. More than half of patients with pelvic fractures have also sustained injuries to the lumbosacral spine. Examples include fractures of the transverse and spinous processes, a crack in a vertebral body, a herniated nucleus pulposus, and a traumatic spondylolysis or spondylolisthesis. Associated neurologic injury is common as well. The SI joint may be a source of pain because of instability or posttraumatic arthritis. All of these possibilities must be considered.

Electromyographic studies and nerve conduction velocities and an MRI or myelography may be useful for evaluating neurologic pain. Evaluate the SI joint with plain radiographs and CT as well as a CT-guided injection of local anesthetic and a technetium bone scan. Before considering fusion of a posttraumatic arthritis seen on a CT scan, it is important to check for increased activity on a bone scan and temporary relief of pain after a CT-guided injection of xylocaine. If these tests are negative, an SI fusion is unlikely to result in relief of pain.

Nonunion and Malunion. Late deformities and a nonunion can involve one or more sites around the pelvic ring (13, 27, 32, 36, 51). These are discussed in Chapter 28.

Urологic and Gynecologic Problems. Information about the influence of a pelvic fracture on female genitourinary, sexual, and reproductive function (5, 51) is limited. Late sequelae may include incontinence, urinary dysfunction, dyspareunia, dysmenorrhea, and difficulty with vaginal delivery and overall sexual function. Overall, serious problems appear to be relatively uncommon. Even after surgical fixation of the symptoms and both SI joints, a vaginal delivery is uneventful in many women. Evaluation for potential cephhalopelvic disproportion, however, is necessary. In male patients, impotence is the most common long-term genitourinary problem after pelvic fracture. In 145 male and female patients, Tscherne et al. (51) reported only a 6% incidence of long-term urologic disturbance and less than a 1% incidence of impotence and dyspareunia. In contrast, other studies have reported rates of complete impotence as high as 50% (60, 87, 73). Further study is clearly needed.

AUTHORS' PERSPECTIVES. While there is a well-defined role for the use of external fixation in selective pelvic fractures, in many regions excessive reliance on external fixation remains a problem. As more orthopaedic surgeons become familiar with the alternative techniques of internal fixation, this problem should resolve.

A thorough diagnostic evaluation using plain radiographs and CT is crucial for preoperative planning to avoid inadequate fixation. Because of the highly diverse fracture patterns, the presence of concomitant injuries, and other variables of age and pretraumatic health of the patients, the surgeon must be familiar with a wide range of surgical methods and choose those best suited to the circumstances. With the rapidly aging population and increasing incidence of insufficiency fractures, improved fixation strategies for osteopenic bone are needed. Because of the obvious advantages of minimally invasive techniques, such as cannulated screw fixation under image guidance, these techniques are being expanded and refined. Closed reduction of these injuries remains a challenge.

New techniques such as surgical navigation with computer-aided technologies are progressing rapidly. With the limited size of bony targets and irregular columns of bone suitable for screw fixation, computer-aided navigation should be an enormous technical advance for pelvic surgery.

To minimize blood replacement, erythropoietin is available new as a therapeutic aid. Between the period of acute resuscitation and the definitive pelvic reconstruction, the use of erythropoietin may help to lessen transfusion needs (49). Late pelvic pain remains a perplexing problem that needs further investigation to identify etiologies and design therapeutic interventions.

FRACTURES OF THE ACETABULUM

Judet and Letournel introduced the concept of anterior and posterior columns of the innominate bone (25). The acetabulum is contained between these two columns, as they meet in the shape of an inverted Y in the innominate bone. The anterior column, which consists of the iliac wing and pelvic brim, extends to the pubic symphysis and contains the anterior one half of the acetabular articular surface. The posterior column consists of the greater and lesser sciatic notches, the retroacetabular surface, and the majority of the quadrilateral surface (25). Similarly, the posterior column contains the posterior one half of the acetabular articular surface. The goal of surgical treatment of fractures of the acetabulum is an accurate reconstruction of the articular surface (28).

The terminology used to describe the anatomic aspects of the innominate bone is important in the discussion of acetabular fractures. We emphasize several descriptive terms in the discussion of acetabular fractures. The internal iliac fossa, the quadrilateral surface, and the retroacetabular surface describe large cortical surfaces of the innominate bone. The pelvic brim marks the junction of the internal iliac fossa and quadrilateral surface. The sciatic notch marks the junction of the quadrilateral surface and the retroacetabular surface (Fig. 18.1).

ASSESSMENT

To understand the radiographic anatomy of acetabular fractures, the surgeon must appreciate how the radiographic landmarks of the pelvis correlate with the actual bony anatomy of the innominate bone. Six basic landmarks of the acetabulum are described on the anteroposterior (AP) view (Fig. 18.2A) (25). The iliac oblique and obturator oblique radiographic views are 45° oblique views of the pelvis. Both of these views are often referred to as Judet views (Fig. 18.2B and Fig. 18.2C) (25).

Figure 18.1. A: Anatomic regions of the internal aspect of the innominate bone are illustrated. The pelvic brim is contiguous anteriorly with the internal iliac fossa and is its medial border inferior to the sacroiliac joint. The pelvic brim also serves as the anterior border of the quadrilateral surface, which is bounded by the pelvic brim anteriorly, the greater and lesser sciatic notches posteriorly, the obturator foramen inferiorly, and the sciatic buttress superiorly. The iliopectineal eminence lies directly over the anterior wall of the acetabulum. The nutrient foramen of the iliac wing is a consistent landmark found adjacent to the sacroiliac joint. B: The external aspect of the innominate bone is shown. The retroacetabular surface is outlined. The greater and lesser sciatic notches make up the posterior border of the retroacetabular surface. (Reproduced with permission from Fractures of the Acetabulum—Classification and Radiographic Assessment. In: Oxford Textbook of Orthopaedics and Trauma. Oxford Press, in press.)

Figure 18.2. A: The normal radiographic lines of the acetabulum are shown as they appear in the anteroposterior radiographic view. 1, The iliopectineal line; 2, the ilioschial line; 3, the roentgenographic U, or teardrop; 4, the roof; 5, the anterior rim; and 6, the posterior rim. The iliopectineal line corresponds to the inferior three fourths of the pelvic rim and is a landmark of the anterior column. The ilioschial line represents a posterior portion of the quadrilateral surface seen in tangent by the x-ray beam, and it is generally considered a landmark of the posterior column. Similarly, the roof of the acetabulum represents a portion of the superior acetabular...
subchondral bone seen in tangent by the x-ray beam. The medial limb of the teardrop is likewise formed from the obturator canal and inferior portion of the quadrilateral surface, seen in tangent by the x-ray beam. The anterior and posterior rims represent the lateral margin of the acetabular articular surface anteriorly and posteriorly, respectively. In the AP view, the anterior rim is typically medialized to the posterior rim. B: The normal radiographic landmarks of the obturator oblique view. 1, The iliopectineal line; 2, posterior rim; 3, obturator ring; 4, anterosuperior iliac spine. The obturator oblique view is taken with a 45° rotation of the affected hip, away from the x-ray cassette. The iliopectineal line, as visualized on this normal view, has a similar relationship with the pelvic brim as seen on the AP view. The posterior rim of the acetabulum is best seen on this view. Fractures of the posterior wall and subtle amounts of anterior subluxation of the femoral head are best detected on the obturator oblique view. C: The normal radiographic landmarks of the iliac oblique view. 1, posterior border of innominate bone; 2, anterior rim; 3, anterior border of iliac wing; 4, posterior rim. Oblique views with appropriate rotation have the tip of the coccyx superimposed on the femoral head on the obturator oblique view. (All images reproduced with permission from Jutrd, R, Judet, J, Letournel E. Fractures of the Acetabulum: Classification and Surgical Approaches for Open Reduction. J Bone Joint Surg 1964;64A:1615.)

Computerized tomography (CT) can also be used to visualize acetabular fractures (19). In the majority of cases, the fracture pattern can be identified and thus classified from plain films alone. Plain films are usually best for assessing the congruence between the femoral head and the roof of the acetabulum. Plain-film radiography has been the standard by which articular displacement has been measured, both before and after surgery. In the emerging age of digital radiography, however, in which the size of the AP pelvis and Judet views is altered, the CT image may become a more reliable method of articular assessment. CT is better suited for evaluating certain fracture characteristics including marginal impaction, rotation of major fragments, coronal fracture lines, and incarcerated osteochondral fragments (Figs. 18.3) (18-28,51).

**Figure 18.3.** A: Computerized tomography can demonstrate marginal impaction. (Reproduced with permission from Olson SA, Matta JM. Surgical Treatment of Acetabulum Fractures. In: Browner BD, Jupiter JB, Levine AM, Trafton PG, et al., eds. Skeletal Trauma, 2nd ed. Philadelphia: WB Saunders, 1997:1181.) B: The impacted articular surface and posterior wall fragments and posterior wall fractures are shown. C: The impacted articular fragments are elevated to match the contour of the femoral head, and bone graft is placed behind them to fill the defect created by their reduction. D: The posterior wall fracture is then reduced. (Modified from Letournel E, Judet R. Fractures of the Acetabulum. Berlin: Springer-Verlag, 1993.)

### CLASSIFICATION

Anatomic classification systems enable the surgeon to gain a thorough understanding of the fracture and its displacement pattern before intervening surgically. Such knowledge helps determine what maneuvers may be necessary to reduce the displacement of a particular pattern and which surgical approach will be used to treat the fracture (28,38,62). Letournel's classification is the most widely used system (25,28). It comprises five simple fracture types and five associated types (28).

#### Simple Patterns

1. Posterior wall fractures typically disrupt the posterior rim of the acetabulum, a portion of the retroacetabular surface, and a segment of the articular cartilage (28). Instability of the hip (subluxation or dislocation of the femoral head) can be associated with this fracture pattern. Marginal impaction of the articular cartilage commonly occurs and should be diagnosed preoperatively on plain films or CT scan (Fig. 18.3) (1). Marginal impaction of the articular surface and underlying cancellous bone occurs when the femoral head subluxes into a displaced major fracture line. The articular surface of the edge of the major fracture line is displaced secondary to impaction of the underlying cancellous bone, with malrotation of the overlying articular surface. In Figure 18.4, marginal impaction is noted as a change in the radius of curvature of the articular surface. It is important for surgeons to recognize this radiographic feature of articular displacement so that they can correct the displacement. Complex posterior wall fractures can involve the entire retroacetabular surface and include a portion of the greater or lesser sciatic notch and the ischiatic tuberosity. The ilioischial line remains intact on the AP view (Fig. 18.4A).

2. Posterior column fractures affect only the ischial segment of the bone (28). The retroacetabular surface is displaced with the posterior column. The fracture line separating the anterior from the posterior column commonly enters the obturator foramen, and an associated fracture of the inferior pubic ramus is typical. Fractures that run just posterior to the obturator foramen, splitting the ischiatic tuberosity, constitute a transitional pattern between the posterior wall and posterior column. The ilioischial line is typically displaced and disassociated from the teardrop. Uncommonly, when a large portion of the quadrilateral surface remains intact and in continuity with the posterior column, the teardrop and a portion of the pelvic brim are displaced with the posterior column (Fig. 18.4B). Fractures of the anterior wall disrupt the central portion of the anterior column (3). Communion of the quadrilateral surface occurs in most cases; fracture of the inferior pubic ramus is less often seen. The AP and obturator oblique radiographs show displacement of the ilioischial line. The AP and iliac oblique radiographs show interruption or displacement of the anterior rim contour (Fig. 18.4C).

3. Anterior column fractures can occur anywhere on the column (28). Very low fractures involve only the superior ramus and pubic portion of the acetabulum. High fractures can involve the entire anterior border of the iliac wing. The fracture line typically runs in the coronal plane through the superior acetabulum. The iliopectineal line is displaced. Medial translation of a portion of the roof or the entire roof can be seen with displacement of a high or intermediate type of anterior column fracture. This type of displacement also can be seen with anterior column and posterior hemitransverse fractures, and both-column fracture patterns as well (Fig. 18.4D).

4. Transverse fractures divide the innominate bone into two portions (28). An oblique sagittal plane fracture line crosses the acetabulum at a variable level and is often displaced. The innominate bone is then divided into a superior part composed of the iliac wing and a portion of the roof of the acetabulum; the lower part of the bone, the ischiopubic segment, is composed of an intact obturator foramen with the anterior and posterior walls of the acetabulum. Letournel subdivided transverse fractures as: transrectal, a transverse fracture line that crosses the superior acetabular articular surface; juxtapectal, a transverse fracture line that crosses the junction of the superior acetabular articular surface and superior cotyloid fossa; and infratectal, a transverse fracture line that crosses through the
Associated Patterns

1. The association of a posterior column and posterior wall fracture splits the posterior column into a larger posterior column component and an associated posterior column component (Fig. 18.4F).

2. The association of a transverse fracture with a posterior wall fracture shows features of both—a typical transverse configuration with one or more separate posterior wall fragments (Fig. 18.4G). A fracture of the inferior pubic ramus is not typically associated with this very common pattern (Fig. 18.4H). In the case of a displaced posterior wall fracture, pay careful attention to the plain films to avoid missing a nondisplaced transverse fracture line.

3. The T-shaped fracture is similar to the transverse fracture except that a vertical fracture line runs along the quadrilateral surface and acetabular fossa (the stem of the T), which separates the anterior from the posterior column (Fig. 18.4I). An associated fracture of the inferior pubic ramus is typically present. This vertical fracture line can enter the obturator foramen or leave it intact, exiting through the ischiium (Fig. 18.4J).

4. The anterior plus posterior hemitransverse fracture combines an anterior wall or anterior column fracture with a horizontal transverse component, which typically traverses the posterior column at a low level (Figure 18.4K). The distinction between the associated anterior column and posterior hemitransverse and T-shaped patterns is often subtle. In the anterior column plus posterior hemitransverse fracture, the anterior component is typically at a higher level and is more displaced than the posterior component, whereas the T-shaped fracture is a transverse fracture with an additional fracture line splitting the anterior and posterior columns of the ischiopubic portion. The femoral head typically follows the displacement of the anterior column in the associated anterior column plus posterior hemitransverse pattern, whereas the femoral head typically follows the posterior column in a T-shaped pattern.

5. Fractures of both columns constitute a distinct category in which the anterior and posterior columns are separated from each other. All articular segments are detached from the intact portion of the posterior ilium, which remains attached to the sacrum (Fig. 18.4L). The surgeon should differentiate transverse, associated transverse plus posterior wall, T-shaped, and anterior plus posterior hemitransverse fractures—all of which show involvement of the anterior and posterior columns of the acetabulum—from both-column fractures. In those four fracture types, a portion of the articular surface remains in its normal position, attached to the intact portion of the ilium. The both-column fracture is therefore unique, with its division of all segments of articular cartilage from the ilium. The both-column fracture is associated with the spur sign, in which the obturator oblique radiographic view prominently reveals the fractured edge of the intact posterior iliac wing relative to the medially displaced articular segments. This sign is pathognomonic of a both-column injury (Fig. 18.5) (28).

Figure 18.5. An obturator oblique view demonstrates the spur sign of a both-column fracture. This spur represents the intact portion of the iliac wing as seen prominent and laterally (arrow) on this view because the remainder of the articular segments of the acetabulum have been displaced medially. (Reproduced with permission from Olson SA, Matta JM. Surgical Treatment of Acetabulum Fractures. In: Browner BD, Jupiter JB, Levine AM, Taffet PG, eds. Skeletal Trauma, 2nd ed. Philadelphia: WB Saunders, 1997;1181.)

As with all anatomic classification systems, there is some overlap between fracture types in Letournel’s system. If this system of classification were perfectly symmetric, there would be more than 10 categories. The extra groups are included within the 10 fracture types; for example, associated anterior column and anterior wall are included with anterior column fractures. Similarly, a fracture of the anterior wall plus posterior hemitransverse fracture is included with anterior column plus posterior hemitransverse fracture. Associated posterior column and anterior hemitransverse fractures, as well as associated transverse and anterior wall fractures, are considered T-shaped fractures. Table 18.1 outlines some tips for classification.

Table 18.1. Simple Tips for Classification of Fractures of the Acetabulum

INDICATIONS FOR SURGERY

Operative treatment is indicated for most displaced acetabulum fractures to decrease the incidence of posttraumatic arthritis. It also permits the patient to return to normal function earlier than nonoperative treatment. Nonoperative treatment, however, is successful in a minority of displaced acetabulum fractures. Indications for nonoperative treatment are based on the condition of the patient, analysis of the fracture configuration, and congruence of the hip joint.

The decision to operate is based on the initial series of plain films and CT scans (52-54). In patients who are candidates for surgery, attempts at closed reduction by manipulation under anesthesia or skeletal traction are not applicable for the treatment of displaced fractures of the acetabulum. Typically, significant displacements tend to recur over time. If the surgeon concludes from the initial radiographs that an accurate reduction of the articular surface is necessary for a good prognosis, surgery is usually indicated. Nonoperative treatment is reserved for patients with nondisplaced fractures, those with tolerable incongruity or displacement, and those in whom surgery is contraindicated. (See Table 18.2 and Table 18.3 for specific criteria.)
Advanced age is not an absolute contraindication to surgery (ideally, so that the fracture fragments remain mobile. Three weeks after injury, bony callus is usually present, which makes reduction of the fracture more difficult.

Skeletal traction has been commonly advocated for improving patient comfort preoperatively, but we have not found it necessary. Schedule surgery before 10 days, traction preoperatively for posterior fracture patterns with hip instability out of traction. In displaced transtectal fracture patterns, traction can help prevent erosion of the

Surgery is usually undertaken 2 to 3 days following the injury, when the initial bleeding from the fracture and intrapelvic vessels has subsided. Generally, use skeletal traction through a proximal tibia pin is often used. The goal of nonoperative treatment is to reduce the fracture and to prevent displacement from worsening. Skeletal traction through a proximal tibia pin is often used. Neufeld roller traction is a useful form of treatment that allows motion of the hip and knee while the patient is in traction (40). Traction should not be so great that it distracts the femoral head from the acetabulum. Skeletal traction, particularly if initiated early while the fracture hematoma is liquid, can occasionally produce a

Displaced fractures that should be considered for nonoperative treatment are usually in one of two categories (54). In one group, a large portion of the acetabulum remains intact and the femoral head remains congruous with this portion of the acetabulum. In the other group, a secondary congruence is present following only moderate displacement of a both-column fracture.

A large portion of the acetabulum may remain intact with any of several different fracture types. Many low anterior column fractures that involve only the pubic portion of the acetabulum can be treated nonoperatively. Rarely, low T-shaped or transverse fractures can be treated nonoperatively. In the case of posterior wall fractures, indications for surgical stabilization include instability or subluxation of the hip, associated marginal impaction of the articular surface, and retained osteochondral fragments with joint incongruence (54).

Various studies have attempted to correlate the size of the posterior wall fracture with the degree of instability of the hip (6,27,64). Each study reports three ranges of fracture size; in the first, the hip is stable; in the second, the hip is unstable; and in the third, instability is inconsistent, varying from 20% to 65% width of the posterior wall, depending on the method of measuring the posterior wall defect. Small posterior wall fractures associated with a stable hip joint that have a congruent reduction can be managed nonoperatively. Careful follow-up is needed to monitor for signs and symptoms of late instability in the initial months following injury.

Carefully examine the congruity of the hip joint on radiographs and CT images. Loss of the normal congruent relationship of the femoral head with the acetabulum is frequently associated with osteochondral fragments incarcerated within the acetabulum (54). Review the three standard radiographic views of the pelvis (AP, obturator oblique, and iliac oblique) to detect loss of parallelism between the curvature of the femoral head and acetabular articular surface on all three views (28). Similarly, evaluate CT images to detect widening of the distance between the anterior and posterior walls or acetabular fossa, and the femoral head (54). Loss of congruity between the femoral head and acetabular articular surface is often associated with the development of degenerative arthritis of the hip.

When considering operative treatment, it is useful to assess the size of the intact portion of the acetabulum, which can be determined using roof arc measurements (34,35 and 36). We prefer to make them on CT scans. A CT scan of the superior acetabular articular surface from the vertex to 10 mm inferior to the vertex is equivalent to an area described by all three roof arc measurements of 45° (Fig. 18.6) (62). At 10 mm below the acetabular vertex, the subchondral bone appears as a ring or arc (Table 18.2 and Table 18.3).

Figure 18.6. The acetabulum with a line at the level of CT image at 10 mm inferior to the vertex of the acetabulum. The area of the acetabular articular surface, superior to this line, represents the minimum amount of intact bearing surface necessary for consideration of nonoperative treatment. This area is equivalent to the interval where all roof arc measurements are 45°. The inset diagram illustrates evaluation of the superior acetabulum by CT to 10 mm inferior to the vertex, in 2 mm intervals. (Reproduced with permission Olson SA, Matta JM. The Computedized Tomography Subchonital Arc: A New Method of Assessing Acetabular Articular Continuity After Fracture (A Preliminary Report). J Orthop Trauma 1993;7:402.)

Both-column fractures with secondary congruence present a unique situation. In both-column fractures, all articular segments are detached from the intact ilium (28). Even though displacement of the fracture has occurred, the fracture fragments can remain congruously grouped around the femoral head despite medial and proximal displacement of the femoral head and some rotational displacement of the fragments (28,54). Assess the three standard radiographic views of the pelvis to detect loss of parallelism between the curvature of the femoral head and acetabular articular surface. Consider loss of parallelism on any of the three views to be an indication for surgery.

The goal of nonoperative treatment is to reduce the fracture and to prevent displacement from worsening. Skeletal traction through a proximal tibia pin is often used. Neufeld roller traction is a useful form of treatment that allows motion of the hip and knee while the patient is in traction (62). Traction should not be so great that it distracts the femoral head from the acetabulum. Skeletal traction, particularly if initiated early while the fracture hematoma is liquid, can occasionally produce a surprisingly good reduction (62). Release of traction before complete healing, however, typically results in redisplacement of the fracture. We believe that lateral skeletal traction through the greater trochanter is not beneficial and can even cause severe problems such as infection of the greater trochanter or soft tissues lateral to the hip joint. Do not use traction through the greater trochanter if any surgical treatment is being considered.

Percutaneous techniques of fixation for minimally displaced and nondisplaced acetabular fractures have been described (58). Percutaneous fixation of moderately displaced (2–5 mm) acetabular fractures may not improve the reduction and often provides less-than-optimal fixation. Percutaneous fixation has also been used in nondisplaced fractures to allow early patient mobilization (58). In our experience, patients with nondisplaced acetabular fractures can be moved from bed to chair without risk of significant displacement. Percutaneous fixation techniques may have potential benefits, but at this time definitive indications for percutaneous fixation have not been developed.

Surgery is usually undertaken 2 to 3 days following the injury, when the initial bleeding from the fracture and intrapelvic vessels has subsided. Generally, use skeletal traction preoperatively for posterior fracture patterns with hip instability out of traction. In displaced transtectal fracture patterns, traction can help prevent erosion of the femoral head cartilage on the residual intact acetabular roof. It is also indicated for associated femoral fractures.

Skeletal traction has been commonly advocated for improving patient comfort preoperatively, but we have not found it necessary. Schedule surgery before 10 days, ideally, so that the fracture fragments remain mobile. Three weeks after injury, bony callus is usually present, which makes reduction of the fracture more difficult. Advanced age is not an absolute contraindication to surgery (19). Factors such as general medical status, pre-existing arthritis, and bone quality may affect decision
CHOICE OF SURGICAL APPROACH

No one surgical incision is ideal for all fractures of the acetabulum. Following radiographic analysis and classification of the fracture, the surgeon should be able to draw the fracture configuration on a model or drawing of the innominate bone (32). Preoperative considerations should include an understanding of the fracture configuration on the outside and inside of the innominate bone, and of the orientation of the fracture planes. This information combined with appreciation of the benefits and limitations of each surgical approach will allow the surgeon to select the appropriate surgical procedure.

All surgical approaches provide some access to both anterior and posterior columns, but each has its advantages and disadvantages. We prefer to use the Kocher-Langenbeck, the ilioinguinal, or the extended iliofemoral approach. Alternatively, the triadiate approach gives an exposure roughly comparable to that of the extended iliofemoral but provides limited access to the posterior portion of the iliac wing.

The Kocher-Langenbeck approach provides the best access to the posterior column. The ilioinguinal approach gives the best access to the anterior column and the inner aspect of the innominate bone. The extended iliofemoral approach gives the best simultaneous access to the two columns, but it does not expose the anterior column as well as the ilioinguinal approach does (28,37,61). We prefer to choose a surgical approach with the expectation that the entire reduction and fixation can be performed through that single approach.

Position the patient appropriately for the single approach—that is, prone for the Kocher-Langenbeck approach, supine for the ilioinguinal approach, and lateral for the extended iliofemoral approach. Although the extended iliofemoral provides the best access, it has the longest recovery period and the highest incidence of ectopic bone formation (18,53). It is therefore preferable to choose the ilioinguinal or Kocher-Langenbeck approach, if feasible. See Table 18.4 for indications for the extended iliofemoral approach.

TECHNIQUES OF REDUCTION AND INTERNAL FixATION

Once the surgeon has completed preoperative radiographic evaluation and has chosen the approach, re-duction of the fracture remains the primary problem. Reduction of an acetabular fracture can be extremely challenging. The technique of reduction is always tailored to fracture type. Even for a specific fracture type, the choice of technique frequently depends on the exact configuration of the individual fracture (28,33,54).

Use of a fracture table helps in the reduction and maximizes the possibilities of each surgical approach. The fracture table lessens the need for extensile as well as dual approaches (28). It does not directly reduce the fracture but facilitates reduction by returning the femoral head to normal position and aiding visualization of the interior of the joint. An alternative to the fracture table is the A-O femoral distractor (Synthes USA, Paoli, PA), which can be placed between the ilium and proximal femur to apply distraction across the hip joint. Although the femoral distractor can be effective, the direction of pull it provides is sometimes not ideal and it can block access to the wound.

Various kinds of reduction forceps are useful for reducing acetabular fractures. Several different types can grasp the heads of screws, including Farabeuf clamps, adapted to grasp 3.5 mm or 4.5 mm diameter screws, and Jungbleuth forceps (A-O pelvic reduction forceps, Synthes USA, Paoli, PA). Pointed reduction forceps are helpful, as is a ball spike-tipped instrument that can be used for pushing fracture fragments. A femoral head corkscrew or Schanz screw can be inserted into the bone to control rotational displacement (Fig. 18.7).

The reduction and fixation usually proceed in a stepwise fashion, with reduction followed by fixation of individual fragments, with progressive assembly of the fracture fragments. Initial lag screw fixation (28,54) usually allows removal of the reduction forceps, followed by more definitive plate fixation (Fig. 18.8) (50). Assess the reduction by visualization and palpation of the accessible fracture lines. It is usually preferable to visualize the final reduction on the articular surface, although sometimes the surgical approach might preclude visualization. The final articular reduction can be inferred to be correct by reduction of the fracture lines on the extrarticular cortex of the innominate bone.
It is usually helpful to include extraarticular fragments in the reduction and fixation; these fragments are commonly found along the pelvic brim, sciatic notch, and iliac crest. These small fragments often provide an essential guide to the reduction of the larger articular fragments and aid in providing final stability (28). In reducing the initial fragments, it is important to obtain absolutely accurate reduction. Any errors in reduction will be magnified as other fracture fragments are reduced. Preliminary fixation with Kirschner wires may be useful, but we prefer to use interfragmentary screws. Screws work best that are 3.5 mm (or similar sizes) and must be available in lengths exceeding 100 mm. Unless you need to penetrate thick cortical bone, insert these screws without tapping; their purchase in the bone is enhanced by the compression of cancellous bone adjacent to the screw. The AO (Synthes U.S.A., Paoli, PA) oscillating drill attachment is useful to minimize the risk of injury to soft tissues. You need special long, flexible-handled drill guides and depth gauges, and a full set of straight and precontoured 3.5 mm or similar reconstruction plates. Make certain that a set of large fragment screws is available.

OPERATIVE TECHNIQUES

Posterior Wall Fractures

- Use the Kocher-Langenbeck approach.
- Consider positioning the patient prone for isolated posterior wall fractures with marginal impaction, as well as complex patterns involving the greater sciatic notch. The prone position prevents subluxation of the femoral head, which may complicate reduction.
- Maintain capsular attachments to posterior wall fragments to enhance vascularity of the posterior wall fragment and improve postreduction stability.
- Expose the entire fracture and clean it of hematoma.
- In the case of marginal impaction, elevate the impacted articular surface with underlying cancellous bone. Use the femoral head as a template for reduction of the impacted articular segment. Be certain that the femoral head is in a reduced position (Fig. 18.3) (3, 28).
- Stabilize the marginal impaction. Use bone grafting behind the elevated articular surface to fill the void left by impacted bone. (The role of bone graft substitutes in supporting marginal impaction is unclear at this time.) Bone graft is commonly obtained from the ipsilateral greater trochanter (Fig. 18.3B, Fig. 18.3C and Fig. 18.3D).
- Reduce the posterior wall fragments using the acetabular rim and the retroacetabular surface as guides. Consider using screws for provisional interfragmentary fixation.
- Contour a 3.5 mm or similar reconstruction plate to buttress the posterior wall fragment. The plate should curve to parallel the rim of the acetabulum (Fig. 18.9).

Figure 18.9. Fixation of a posterior wall fracture through the Kocher-Langenbeck approach is shown.

- Undercontour the plate to buttress the posterior wall.
- Apply the first screw into the ischial tuberosity (in an inferior and anterior direction), initially leaving it three to five turns loose.
- Apply a screw superior to the posterior wall fragment, through the plate. Hold the plate and fracture in a reduced position with a ball spike to ensure that the plate is congruent superiorly with the iliac wing.
- Tighten the ischial screw to tension the plate, and buttress the posterior wall fracture.
- Ideally, insert one or two interfragmentary screws through the posterior wall fragment, either through or outside of the plate.
- Use springplates to hold small rim pieces with capsular attachments in place (28). We recommend not excising bony fragments from the capsular attachments, because it is difficult to reattach the hip capsule securely (Fig. 18.10).

Figure 18.10. Springplates are illustrated. This type of fixation can be used to secure small periarticular fragments. Top Figures: A one-third tubular or reconstruction plate is flattened. The end hole is divided, and the remaining two tines bent. Bottom Figures: The spring effect of applying the plate allows the prongs to stabilize as small fragments. Often these plates can be buttressed with an overlying posterior wall plate, using a common hole to allow a screw to secure both plates at once. (Modified from Mast J, Jakob R, Ganz R. Planning and Reduction Technique in Fracture Surgery. Berlin: Springer-Verlag, 1989.)

Posterior Column Fractures

- Position the patient prone and use the Kocher-Langenbeck approach.
- Reduce the fracture with Farabeuf or Jungbluth forceps. Insert a Shantz pin, if necessary, in the ischial tuberosity to control rotation (Fig. 18.11) (28).
Transverse Fractures with an Associated Posterior Wall Fracture

Anterior Column Fractures

- Assess reduction, using the fit to the posterior rim and greater sciatic notch as guides. Assess the retroacetabular surface and quadrilateral surface for rotation of the posterior column fragment.
- Obtain fixation with an interfragmentary screw and, if possible, double plates.

Stabilize the posterior wall with a buttress plate, as described above. Reduce the posterior wall, as described in the posterior wall fracture section. Use anterior and posterior column lag screws or an anterior column lag screw and posterior column plate for provisional fixation. The reduction techniques are similar to those used for a transverse fracture. Use the posterior wall fracture as a window to view the articular reduction of the transverse fracture. Reduce and provisionally stabilize the transverse component first.

Fig. 18.12. Control of the anterior column rotation can be performed with a Farabeuf forceps about the inner spinoous notch, as shown. A ball spike or other instrument applied to the inferior iliac fossa in combination with a Farabeuf forceps can provide a force to counteract the deformation and displacements of the anterior column.

- Impact of the articular surface should be recognized preoperatively. Occasionally, by externally rotating or distracting the anterior column fragment, the surgeon is able to work through the fracture to reduce the impacted fragment. In other cases, you may need to reduce the anterior column first. Then use a tamp or other instrument to reduce the articular surface through a drill hole in the innominate bone, the way you would to reduce the articular surface in a centrally depressed tibial plateau fracture.
- Assess the fracture reduction along the internal iliac fossa and at the pelvic brim. It is often necessary and important to palpate a fracture line that extends posterior to the pelvic brim on the quadrilateral surface. You must be certain that there is no excessive residual medial translation of the anterior column segment.
- For initial fixation, insert interfragmentary screws perpendicular to the fracture plane; insert additional interfragmentary screws or plates at the iliac crest.
- Use lateral and distal traction to assist in the reduction.
- Quadrilateral surface comminution can often be secured with a lag screw from the lateral surface of the iliac wing inserted just above the acetabulum into the quadrilateral surface. Leave the screw slightly long (approximately 5 mm) to act as a buttress inside the quadrilateral surface.

Anterior Wall Fractures

- Position the patient supine and use an ilioinguinal approach.
- Fractures that are incomplete near the iliac crest usually must be completed to gain access to and reduce the joint.
- Initially, reconstruct comminuted fragments at the level of the pelvic brim. These small fragments often provide important keys to reduction of the larger anterior column segment.
- The displacement of the anterior column fragment is typically in external rotation, medial translation, and flexion. Reduction requires that these elements of displacement be addressed. Internal rotation, lateral translation, and a posteriorly directed force usually are required to reduce the anterior column segment. Lateral or distal traction can aid in obtaining the reduction (Fig. 18.12).

For most fracture patterns, position the patient prone and use the Kocher-Langenbeck approach.

- Use a Jungbleuth forceps to distract the fracture. Clean the fracture of hematoma, and reduce the ischiiopubic segment.
- Reduce the fracture by levering the ischiopubic segment posteriorly and laterally. Insert a Schantz pin, if needed, in the ischium for rotational control. Avoid excessive compression of the transverse fracture. The transverse fracture is most often an oblique fracture line in the sagittal plane. Excessive compression leads to malreduction with the shearing of the fracture fragments along the fracture line. Place a small angled forceps through the greater sciatic notch, if necessary, to control rotation.
- An alternative reduction technique is to use an antiglide plate on the retroacetabular surface. This technique requires accurate contouring of the plate before application.
- Use lateral and distal traction to assist in the reduction.
- Impaction of the articular surface should be recognized preoperatively. Occasionally, by externally rotating or distracting the anterior column fragment, the surgeon is able to work through the fracture to reduce the impacted fragment. In other cases, you may need to reduce the anterior column first. Then use a tamp or other instrument to reduce the articular surface through a drill hole in the innominate bone, the way you would to reduce the articular surface in a centrally depressed tibial plateau fracture.

- Note that applying the posterior plate in an undercontoured manner, as described for a posterior wall fracture, causes a gap in the anterior portion of the transverse fracture line.
- Initially, reconstruct comminuted fragments at the level of the pelvic brim. These small fragments often provide important keys to reduction of the larger anterior column segment. Use lateral and distal traction to assist in the reduction.
- Quadrilateral surface comminution can often be secured with a lag screw from the lateral surface of the iliac wing inserted just above the acetabulum into the quadrilateral surface. Leave the screw slightly long (approximately 5 mm) to act as a buttress inside the quadrilateral surface.

Transverse Fractures with an Associated Posterior Wall Fracture

- Position the patient prone and use the Kocher-Langenbeck approach.
- Reduce and provisionally stabilize the transverse component first.
- Use the posterior wall fracture as a window to view the articular reduction of the transverse fracture.
- The reduction techniques are similar to those used for a transverse fracture.
- Use anterior and posterior column lag screws or an anterior column lag screw and posterior column plate for provisional fixation.
- Reduce the posterior wall, as described above in the posterior wall fracture section.
- Stabilize the posterior wall with a buttress plate, as described above (Fig. 18.13).

Fig. 18.13. A pelvic reduction (Jungbleuth) forceps is used to reduce the posterior column fracture line. A Schantz pin in the ischial tuberosity is used to help control rotation of the posterior column fragment.
Combined Posterior Column and Posterior Wall Fractures

- Position the patient prone and use the Kocher-Langenbeck approach.
- Reduce the posterior column fragment first, as described above in the posterior column section.
- Provisionally fix the posterior column fragment with an interfragmentary screw or with a plate that will not interfere with the reduction or fixation of the posterior wall fracture.
- Reduce the posterior wall fracture and plate it (see posterior wall section, above).

Anterior Column Fracture Plus a Posterior Hemitransverse Fracture

- Position the patient supine and use an ilioinguinal approach. Fractures with a markedly displaced anterior column component and a displaced low posterior column component may benefit from sequential ilioinguinal and Kocher-Langenbeck approaches.
- First address the anterior column or anterior wall component.
- Reduce the anterior column, as detailed above, in the anterior column section.
- Insert interfragmentary screws in the anterior column to gain initial fixation.
- Often, you can assess the reduction of the posterior column fracture on the quadrilateral surface. The typical displacement is medial translation of the posterior column. Use a large or so-called King Tong clamp or an offset clamp from the AO pelvic reduction instruments (Synthes USA, Paoli, PA) to reduce the quadrilateral surface segment. Place one tine on the external surface of the iliac wing, and one tine on the quadrilateral surface to provide a lateral displacement force through the posterior hemitransverse component.
- Use posterior column screws to fix the posterior hemitransverse fracture. Insert the screws through the most lateral window of the ilioinguinal approach, parallel to the greater sciatic notch and contained within the posterior column. Use the C-arm fluoroscope to confirm position; obtain an iliac oblique view.
- Neutralize the entire construct with a plate on the anterior pelvic brim (Fig. 18.14).

Anterior Column Fracture Through a Posterior Hemitransverse Fracture

- Significant displacement of both anterior and posterior column segments of the T-type fracture are especially difficult to manage. Displaced transtectal T-shaped fractures can be managed through an extended iliofemoral approach. Significant displacement of juxtatectal and infratectal T shapes may require sequential Kocher-Langenbeck and ilioinguinal approaches. In the situation in which there is significant displacement of both anterior and posterior portions of the T-shaped fracture, address the less comminuted portions first (Fig. 18.15).

Both-column Fractures

- In the majority of instances of both-column fractures, position the patient supine and use the ilioinguinal approach. Approximately one quarter to one third of cases require an extended iliofemoral approach. The ilioinguinal is preferable, when possible, because it involves minimal stripping of the outer aspect of the innominate bone, which decreases the postoperative recovery time and decreases the amount of heterotopic ossification postoperatively.
- When choosing the ilioinguinal approach, first reduce the anterior column and fix it provisionally.
- Lateral traction is frequently necessary to lateralize the femoral head before the anterior column can be adequately reduced.
- The anterior column fracture is reduced and internally fixed, as described in the section on the anterior column.
- Reduce the posterior column segment through the second window of the ilioinguinal approach. The posterior column is typically medially displaced, with occasional posterior translation. Reduce the fracture-scribed reduction forceps, placing one tine on the quadrilateral surface, and the other tine on the outer aspect of the iliac wing. Assess the reduction both visually and by palpating the quadrilateral surface and the contour of the greater sciatic notch (Fig. 18.16).
To fix the posterior column, insert lag screws from the internal iliac fossa, near the pelvic brim, into the posterior column. Use an image intensifier to confirm reduction and screw placement.

When choosing the extended iliofemoral approach, position the patient in the lateral position on the fracture table. The extended iliofemoral approach allows the surgeon to perform a nearly circumferential capsulotomy (avoiding transsection of the capsular attachments to the posterior wall fragments) and provides the most commanding view of the articular surface.

In most cases, reduce the anterior column and fix it initially to the intact portion of the ilium.

Occasionally, if the posterior column segment is large and involves a portion of the sacroiliac joint, it is often easiest to proceed with reduction of the posterior column first.

In most cases, use a two-screw technique to reduce the fragment. Use the Farabeuf forceps to grasp the screw left prominent in each fracture fragment. Following reduction, fix the posterior wall and column as described in previous sections.

POSTOPERATIVE CARE

At the completion of the operation, obtain at least an AP pelvis radiograph in the operating room. The iliac oblique and obturator oblique views can be obtained in the operating room or later. Following gait training, and prior to discharge, obtain another AP pelvic radiograph to confirm that loss of reduction has not occurred during ambulation. Obtain a single AP pelvic radiograph at each follow-up examination.

Place the patient on bed rest for the first postoperative day, or longer if you have used the extended iliofemoral approach. Have a physical therapist institute passive motion of the hip and extremity. Alternatively, use the continuous passive motion machine. At 3 to 7 days after surgery, pain has usually subsided enough so that the patient can start gait training. Allow up to 15 kg of weight bearing. Encourage the patient to ambulate with a step-through gait and a heel-toe walking motion, using crutches or a walker.

Instruct the patient in active flexion, abduction, and extension exercises to be performed at the hip while standing (active abduction and passive adduction are prohibited for the first 4 weeks with the extended iliofemoral approach). Continue limited weight bearing for 8 weeks postoperatively. At that point, the patient can bear weight to tolerance using external support only, as needed. If the fracture has been reduced accurately and ectopic bone does not develop, the range of motion can be expected to return to about 90% of normal. Physical therapy is therefore directed primarily toward regaining muscle strength at the hip, particularly abductor muscle strength.

Results of Surgery

The goal of surgical treatment of acetabular fractures is to restore the normal shape and contour of the acetabular or articular surface accurately and thereby to restore the hip joint’s normal capacity. The results of surgical treatment of acetabular fractures are generally reported on those who underwent surgery within the first 3 weeks after injury and those who waited longer than 3 weeks. Letournel observed that in delayed surgeries, fractures were more difficult to reduce and had less favorable outcomes.

Letournel reported 569 acetabular fractures that were surgically repaired within 21 days of injury. In 418 (73.5%) cases, articular reductions were reported as perfect, implying that the articular surface and radiologic landmarks of the acetabulum were returned to normal alignment on the AP pelvis and 45° oblique views of the pelvis. Osteoarthrosis was reported in 97 cases (23%), 43 (10.2%) had a perfect reduction, and 54 (12.9%) had an imperfect reduction. Of 492 cases available for a minimum of 2 years of follow-up, 366 had a perfect reduction. An excellent or very good clinical grade applied in 283 (77%) cases, and 316 (86%) had a good, very good, or excellent result. Of 126 imperfect reductions, 24 (19%) had an excellent clinical grade and 81 (64%) had a good, very good, or excellent result.

**Table 18.5. Accuracy of Reduction by Fracture Type for 567 Acetabular Fractures Surgically Repaired within 21 Days of Injury**
Table 18.6. Number of Cases Developing Osteoarthritis (OA) Versus Accuracy of Reduction by Fracture Type for 492 Acetabular Fractures Surgically Treated within 21 Days of Injury

At 20 years (or longer) of follow-up, Letournel reported that 28 of 35 cases initially graded excellent remained excellent (40 of 75 cases were lost to follow-up) \(^28\). The outcome of fractures followed for more than 20 years showed that none of three very good results and four of eight good results maintained the initial clinical grade. Letournel also noted that patients with initially excellent clinical results who had developed an asymptomatic collarette of osteophytes about the femoral head had an increased incidence of osteoarthritis, 22% and 53% at 20- and 25-year follow-up, respectively \(^28\).

Matta has reported on 262 displaced acetabular fractures treated surgically within 21 days of injury and followed for 2 to 13 years \(^38\). Reductions were graded on the maximum articular displacement seen on the AP pelvis and 45° oblique radiographic views of the pelvis. Reductions were categorized as anatomic: 0 to 1 mm maximal displacement; imperfect: 2 to 3 mm maximal displacement; and bad: more than 3 mm maximal displacement. Clinical outcome was determined by a modified d'Aubigne and Postel hip score (Table 18.7). The quality of reduction per fracture type is listed in Table 18.8.

Table 18.8. Accuracy of Reduction by Fracture Type for Acetabular Fractures Treated Surgically within 21 Days of Injury

Of these patients, 199 (75%) had good or excellent clinical results (Table 18.9) and 92% of excellent and good clinical results were also graded excellent or good radiologically with no or minimal changes of osteoarthritis \(^38\). Anatomic reductions \((p = .002)\) paired with a congruent relationship of the femoral head to the superior acetabulum \((p = .04)\) were associated with a good or excellent outcome \(^38\). Age greater than 40 years and increasing complexity of the fracture decreased the likelihood of a perfect reduction. Anatomic reductions in patients over the age of 40 years, however, are not associated with a decreased incidence of good or excellent clinical results. Kaplan-Meyer survivorship analysis of these data indicates that an excellent radiographic appearance of the hip joints at 2 years after surgery indicates an 85% likelihood of excellent hip function at 10 years after fracture \(^56\).

Table 18.10. Other Authors have reported less favorable results following surgical treatment of acetabular fractures, with up to 43% incidence of poor results \(^21, 26, 68\). These reports typically represent the outcomes of patients at a single institution whose operations were performed by a number of different surgeons. As a result, the statistics cannot be compared with any one surgeon's experience with these complex injuries. The results of Letournel and Matta emphasize the correlation of accuracy of articular restoration with improved clinical outcome \(^28, 38\). Mayo has reported similar results \(^39\).

These results reflect the work of surgeons with a dedicated interest in the treatment of acetabular fractures. The importance of the knowledge, interest, and experience of the operating surgeon in the treatment of these complex injuries cannot be overemphasized. We disagree with the philosophy of approaching acetabular fracture reconstruction as restoration of bone stock for a future total hip replacement. Inherent in this way of thinking is the assumption that the development of osteoarthritis is inevitable. This misconception may lead some surgeons to accept significant malreductions of the articular surface, leading to the development of unnecessary
disability caused by osteoarthrits of the hip. We believe the goal of obtaining a perfect reduction must be in the mindset of the operating surgeon as she undertakes reduction and fixation of acetabular fractures (54).

Although not all acetabular fractures have a good outcome, it is difficult to predict which fractures will have a poor outcome following open reduction and internal fixation. The long-term follow-up data of Letournel and Malata suggest that a minority of patients will require further hip surgery following acetabular fracture reconstruction (28-38). We do not recommend total hip arthroplasty as a primary treatment for fractures of the acetabulum.

Displaced acetabular fractures treated surgically later than 21 days after injury are challenging to even the most experienced surgeons. There is increased difficulty in mobilizing fracture fragments and reducing the articular surface. Johnson et al. reported on 188 fractures treated surgically between 21 and 120 days after injury (24). There was an increased incidence of sciatic nerve palsies (12%) and osteonecrosis of the femoral head (13%), with 50% of the osteonecrosis occurring with persistent dislocation for more than 3 weeks. Overall, there was a 65% incidence of good or excellent results. The poorest results occurred in simple anterior wall fractures, simple posterior wall fractures, associated transverse and posterior wall fractures, and T-shaped fractures.

COMPPLICATIONS

The most common serious complications following surgical treatment of an acetabulum fracture include infection of the surgical wound, iatrogenic sciatic nerve palsy, periartrial ectopic bone formation, and thromboembolic complications. Posttraumatic arthritis is the most common late complication (28).

If the patient is in generally good condition and has no associated injuries, the risk of infection should be no higher than for other types of major hip surgery. Most patients with acetabular fractures, however, have associated injuries, including injuries to the abdominal and pelvic viscera, chest, or the extremities. A bladder rupture or a bowel, rectal, or vaginal injury can increase the chance of infection in the surgical wound and can influence the indications for surgery.

A relatively common problem associated with acetabular fracture is local soft-tissue injury, including local wounds, abrasions, and a closed degloving injury (17). With the closed degloving injury, the subcutaneous tissue is torn away from the underlying fascia. There is a significant cavity that contains hematoma and liquefied fat between the subcutaneous tissue and deep fascia. The degloving injury occurs as a result of the blunt trauma that has caused the acetabular fracture. When this lesion is present over the greater trochanter, it is known as a Morel-Lavalle lesion (17). Drain and debride these areas before or at the start of surgery to decrease the risk of infection. After drainage and debridement, it is advisable to leave this area open through the surgical incision or a separate incision. Dressing changes and wound packing are sometimes necessary over a prolonged period, until the wound has closed secondarily or with delayed primary closure. In our experience, primary excision of the necrotic fat and immediate closure over drainage tubes has been unsuccessful.

Infection of the surgical wound does remain a concern, even without associated injuries. There is an increased risk of postoperative heterotopic bone formation in the large wounds that are necessary for acetabular surgery. Make liberal use of suction drains. Good hemostasis at the time of wound closure is essential. During the procedure, keep the large areas of exposed soft tissue moist and irrigated frequently with antibiotic solution. It is often helpful to place moist sponges over exposed soft tissue to prevent desiccation.

Always strive to preserve soft-tissue plicides to all bone fragments to maintain the blood supply to the bone. If a fragment is devascularized, it generally revascularizes rapidly, as long as no infection develops. In the presence of infection, however, bacteria rapidly colonize an avascular fragment, and it will usually need to be debrided and excised. Some bloody drainage can seep from the wound for the first 1 or 2 days after surgery, but it should subside rapidly. It is not uncommon for a clear, yellow, serous drainage to be present for as long as 10 days after surgery without infection being present. If the wound has been benign for a number of days, and bloody or cloudy yellowish drainage then occurs, the patient should be returned to the operating room immediately for irrigation and debridement of the wound. If a wound hematoma is present, the amount of hematoma is usually much greater than initially suspected, and surgical drainage is indicated.

If you suspect infection, do not wait for the results of culture of a wound aspiration but proceed with reopening the wound. If it is later found that no infection was present, the wound has already been opened. If an infection was present at the time of the earliest clinical suspicion, then you have acted properly by treating the infection expeditiously. Hip aspiration may be particularly helpful in evaluating fractures in which the surgical approach has been ilioinguinal.

If the infection is extrarticular, it can probably be controlled successfully and the functional result will not be impaired. In the case of an intrarticular infection, however, the cartilage of the joint is almost invariably destroyed and hip function is significantly impaired.

Iatrogenic sciatic nerve palsy may be caused by too vigorous or prolonged retraction of the nerve (20,28). This event occurs primarily with the Kocher-Langenbeck approach and mainly involves the peroneal branch of the sciatic nerve (28). There is also a small chance of a stretch injury to the sciatic nerve with the extended iliofemoral approach and a slight possibility of injuring the femoral nerve by stretch injury during the ilioinguinal approach, but these outcomes are unusual. The surgeon must constantly monitor the force and duration of pull that surgical assistants place on retractors in the vicinity of the sciatic nerve. It is helpful to keep the patient's knee flexed at least 60° and preferably at 90°, and the hip extended whenever the Kocher-Langenbeck or extended iliofemoral approach is used (28). Several authors have reported using neurologic monitoring with somatosensory evoked potentials or electromyography (20,44,65). This technique is not available in every center. If a nerve palsy develops, it is best treated with an ankle-foot orthosis. Iatrogenic nerve palsies are often a form of axonotmesis (13). Electromyography can be helpful in determining reinnervation of affected muscle groups.

Ectopic bone formation is influenced by the surgical approach and probably also by the initial muscle trauma suffered by the patient (16,45,65). The combination of the two injuries creates an inflammatory response that is correlated with heterotopic ossification: the extended iliofemoral approach, multiple (two or more) findings at time of surgery, T-shaped fractures, associated head or chest trauma, and male sex (16,26,45,65).

Ectopic bone formation, or heterotopic ossification (HO), most commonly occurs with the lateral exposure of the innominate bone. The incidence of significant ectopic bone formation is highest with the extended iliofemoral approach, followed by the Kocher-Langenbeck approach; it is almost nonexistent with the ilioinguinal approach (28). Prevention of ectopic bone formation should, in part, be directed toward choosing the ilioinguinal approach whenever possible and limiting muscle trauma during surgery.

Indomethacin given in a dose of 25 mg tid perioperatively, and for several months following surgery, has been reported to be helpful in decreasing the incidence and extent of ectopic bone formation (48). A prospective randomized series comparing indomethacin to no prophylaxis, however, showed no difference in the incidence of HO (21). Postoperative radiation has been shown to be effective in decreasing the incidence of ectopic bone formation, but the long-term carcinogenic effects are unknown (42). The combination of indomethacin and postoperative radiation has been reported to be very effective in preventing nearly all HO (47). The risk of HO may be reduced by avoiding elevation of the peristeum, minimizing muscle trauma, preventing hematomas, and by debridement of devitalized tissue following completion of internal fixation of the acetabular fracture.

Patients develop a significant amount of ectopic bone, as seen on radiographs, but muscle function and range of motion may remain satisfactory. Radiographic evaluation should include AP and 45° oblique views of the pelvis (48). In other patients, rotation and abduction are limited; if patients can extend the hip to the neutral position and have flexion of at least 90°, however, they might be happy with the result and have no need for further surgery. CT is important to locate HO about the hip when excision is being considered (54).

Whenever possible, surgery for excision of ectopic bone should be delayed for 6 to 12 months following injury. If it is performed at this time, there is usually no problem with recurrence and motion can be expected to return to more than 80% of normal, assuming no arthritis is present. Some patients show a spontaneous regression of ectopic bone within the first year years. If the indication for excision of the bone is unequivocal, it might be best to wait, with the hope of some spontaneous regression of the ectopic bone with improvement of motion. See Chapter 124 for more details.

There is significant potential for deep venous thrombosis (DVT) and pulmonary embolism with fractures of the acetabulum (49,67). A 33% incidence of preoperative pulmonary embolism. The DVT detected with magnetic resonance imaging (MRI) angiography has been reported (49). We normally use pneumatic compression boots on both lower extremities from the time of admission until the patient is fully ambulatory. In older and high-risk patients, partial anticoagulation is begun with heparin following surgery. Patients are discharged to home with warfarin anticoagulation until they are ambulating actively, typically for 3 to 4 weeks following surgery (14). The level of anticoagulation with warfarin is maintained at about 1.5 times normal, an international ratio (INR) of 2 to 3. Although the potential for thromboembolic complications is always present, the surgeon must be cautious about too much anticoagulation, because a large-wound hematoma can have a devastating effect on the patient if a deep infection in the hip results.

HIP DISLOCATIONS AND FRATURES OF THE FEMORAL HEAD

MECHANISM OF INJURY AND CLASSIFICATION
Dislocation of the femoral head produces a significant trauma to the hip joint. Motor vehicle accidents or other high-energy traumas account for the majority of hip dislocations. Athletic injuries, falls, and other causes are less common. Hip dislocations are generally categorized by the direction of dislocation of the femoral head, either posterior or anterior. Posterior dislocation accounts for approximately 90% of all traumatic hip dislocations (12). Posterior dislocation is typically caused by axial load on the femoral shaft with the hip in the position of flexion and adduction. The most commonly cited classification is that of Thompson and Epstein (Table 18.10) (12). Acetabular fractures associated with posterior hip dislocations have been postulated to result from impact of the femoral head on the hip with the thigh in a flexed and adducted position. Epstein reported that fractures of the femoral head occurred in 9% of posterior hip dislocations (12).

Anterior dislocations account for 10% of all hip dislocations (12). Anterior dislocations can be divided into pubic or obturator dislocations. Well over 90% of all anterior dislocations are obturator in nature. We have not personally managed a patient with a pubic anterior dislocation.

Anterior dislocations are associated with a higher incidence of femoral head fracture (4,9). DeLee reported 12 of 22 patients with anterior hip dislocations who sustained femoral head fractures (9). The majority of these cases were impact fractures of the femoral head. The articular impaction presumably resulted from impingement of the femoral head against the anterior rim of the acetabulum as it rebounded against the anterior rim of the acetabulum. Anterior dislocation typically occurs when the hip is overabducted and overextended.

Pipkin proposed a classification describing fractures of the femoral head associated with hip dislocation (Fig. 18.18) (55). Pipkin's classification is commonly used with or without a hip dislocation when there is a displaced osteochondral fragment of the femoral head. Brumback et al. proposed a classification system that separates anterior dislocations of the hip with either a femoral head impaction fracture or transchondral loss into a distinct group (4). No uniform system exists to quantify femoral head impaction following hip dislocation.

EVALUATION

Posterior Dislocations

Hip dislocations frequently accompany a wide spectrum of injury, ranging from isolated trauma to significant polytrauma. The classic position of the lower extremity with a posterior hip dislocation is one of shortening of the involved extremity, with flexion, adduction, and internal rotation of the extremity at the hip (Fig. 18.19) (1,2,12). Injury to the sciatic nerve has been reported to occur in approximately 10% of all hip dislocations (12). The involvement of the sciatic nerve may be partial or complete. More severe involvement of the peroneal division of the sciatic nerve is typical. A detailed neurologic exam, which may be difficult to obtain in the emergency setting, is important. Carefully examine the patient's neurologic status both before and after reduction of the hip.

Figure 18.19. Posterior dislocation of the hip is shown. The adducted and internally rotated position of the femur is classic for this type of dislocation. The overlapped appearance of the femoral head and the roof of the acetabulum on the radiograph is pathognomonic for dislocation of the femoral head.

Anterior Dislocations of the Hip

In anterior dislocations of the hip, the femoral head is displaced anteriorly and inferior to the acetabulum in the region of the obturator foramen, with the extremity held in extension, wide abduction, and external rotation at the hip (Fig. 18.20) (12). Carefully examine for possible injury to the femoral artery and femoral nerve.

Figure 18.20. Anterior dislocation of the hip is shown in these drawings. The obturator (inferior) presentation shown is by far the most common pattern. It is characterized by abduction and external rotation of the femur. Impaction fractures of the femoral head are common with this type of dislocation.

Radiographic Evaluation

Initial evaluation of patients with suspected hip dislocation requires an AP view of the pelvis. The majority of hip dislocations can be diagnosed on this view. The
addition of a cross-table lateral view should confirm an anterior or posterior dislocation. Following reduction of the hip dislocation, repeat the AP radiograph of the pelvis and lateral view of the hip, looking for evidence of incongruent reduction of the femoral head. If there is a question of an acetabular fracture, 45° oblique views of the pelvis (Judet views) are indicated (54). CT is helpful for evaluation of residual incongruence between the femoral head and the acetabulum, evaluation of acetabular fractures identifying femoral head fractures, and identification of retained osteochondral fragments within the hip joint (15).

REDUCTION OF THE DISLOCATION

Once the diagnosis of dislocation of the femoral head is established, perform reduction of the hip as soon as possible, ideally with complete muscular relaxation under a regional or general anesthesia to minimize the risk of chondral injury to cartilage of the femoral head. In addition, it is possible to examine the hip while the patient is still under anesthesia to assess the stability following reduction. Such assessment may aid in deciding postoperative care.

Reduction of the hip can also be accomplished in the emergency room setting with appropriate intravenous sedation. Use short-acting paralyzing agents with caution and only when appropriate airway management is available. Delay in reduction of hip dislocations has been shown to increase the incidence of avascular necrosis. Yue et al. reported that posterior dislocation of the hip causes kinking of the external iliac artery over the pelvic brim, impeding flow through the medial femoral circumflex artery in cadaver specimens (69). Perform reduction of the femoral head early, ideally within 6 hours of injury, to minimize the risk of avascular necrosis (12,22).

Carefully evaluate the initial radiographs to look for associated fractures of the femoral head and femoral neck. When these associated fractures are present, the reduction should be accomplished under general anesthesia, preferably with image intensifier control to ensure that significant displacement of the femoral neck fracture does not occur. In selected cases, fixation of the femoral neck fracture before reduction may be necessary.

Several methods of reduction of a dislocated hip have been described that involve traction in line with the existing deformity. For posterior dislocations, the Allis and Bigelow maneuvers are performed with the patient supine; an assistant provides countertraction to the pelvic ring (Fig. 18.21) (1,2). The Stimpson maneuver, performed with the patient prone, eliminates the need for countertraction on the pelvis. Other injuries and the need for sedation may contraindicate the prone position (69).

![Figure 18.21. The Bigelow reduction maneuver for a posterior dislocation of the hip.](image)

Reduction of a posterior dislocation requires traction on the involved hip in a flexed and adducted position. Gentle rotational oscillation of the hip may assist in easing it over the acetabular rim into the socket.

The same maneuver can be used with the patient in the lateral decubitus position. Use of a sheet around the pelvis for countertraction provides the surgeon added mechanical advantage. Once the femoral head has been located, the hip is easily abducted and extended accompanied by restoration of leg lengths and external rotation of the hip. If in rare instances, the dislocation may be irreducible and requires open reduction through a posterior approach (5).

Anterior hip dislocations may also be reduced by applying traction in line with the deformity in abduction, with progressive flexion of the hip and neutral rotation (12). This technique allows the femoral head to move superiority and posteriorly into the acetabulum. Rarely it may be converted, temporarily, to a posterior dislocated position before location of the hip.

Following relocation of the hip, obtain an AP radiograph of the pelvis and look for incongruence between the femoral head and acetabulum, as well as for fractures of the femoral head and femoral neck, and retained osteochondral fragments. Obtain a cross-table lateral view of the hip if there is a question about the adequacy of the reduction or of a femoral neck fracture. Persistent incongruence of the hip joint with retained osteochondral fragments requires open reduction and removal of the intraarticular debris. CT can also be used to assess the hip joint for incongruence and retained osteochondral fragments following reduction of a hip dislocation (7,51).

Routine use of CT following hip dislocation is controversial (15). CT is indicated, however, whenever the surgeon suspects the presence of a significant retained osteochondral fragment or other foreign body within the hip joint. Occasionally, small osteochondral fragments are seen in the acetabular fossa which are attached to the ligamentum teres. When these osteochondral fragments are present, AP and Judet views of the hip, CT, or both are indicated to assess the femoral head for a congruent reduction. There is no need for surgical intervention as long as a congruent reduction between the femoral head and acetabulum is present (54). Perform neurovascular examination immediately after reduction.

POSTREDUCTION CARE

Epstein reported a series of hip dislocations in which skeletal traction was used following reduction of the femoral head (11). More recent series have demonstrated similar results without postreduction skeletal traction (57). Several authors have speculated that postreduction traction would provide the benefit of decompressing the injured hyaline cartilage while the torn capsule heals (12,57). This observation, however, has not been borne out in clinical results.

After reducing the femoral head, examine the hip for stability by gently flexing the hip from 0° to 90° with the hip in neutral rotation. Those patients who have a stable hip to 90° of hip flexion must avoid excessive flexion, adduction, and internal rotation of the hip and can be permitted to walk with crutches with limited weight bearing for 4 to 7 days after reduction. Weight bearing can be gradually increased after that point. Continue these precautions for at least 6 weeks after dislocation as healing of the soft tissues takes place.

If examination of the tissues demonstrates instability between 45° and 90° of flexion, protect against dislocation with an orthosis. Use either a knee mobilizer or hip abduction brace for 6 weeks and allow the patient to walk using crutches as described above. If the hip is unstable at 45° or less of flexion, we recommend skeletal traction for approximately 3 weeks postoperatively, followed by bracing or crutches as described above.

Hip dislocations associated with fractures of the acetabulum require treatment of the acetabular fracture, as outlined in the first part of this chapter. Hip dislocations associated with femoral neck fractures are, fortunately, a rare occurrence. Treatment of these injuries requires careful reduction of the hip under image intensification control. Make every attempt to ensure that the femoral neck is not displaced during reduction. If there is any question regarding displacement of the femoral neck during the attempt at reduction, fixate the femoral neck before performing open or closed reduction of the femoral head dislocation. Place a Schanz pin from the lateral cortex up into the femoral head, attached to a T-handle to reduce the shear forces across the femoral neck and aid the reduction. Hip dislocations with a displaced femoral neck fracture are an absolute indication for open reduction of the femoral neck fracture and femoral head dislocation.

FRACTURES OF THE FEMORAL HEAD

Pipkin type I fractures of the femoral head are the most common type of femoral head fracture (Fig. 18.18) (55). It is important to characterize the inferior femoral head fragment and fracture line on plain films. Moed et al. described the use of CT to determine the plane of inclination of the femoral head fracture relative to the sagittal plane (43). Plain radiographs taken with the x-ray beam oriented at this inclination were shown to provide good evaluation of the fracture and subsequent healing.
Pipkin Type I fractures that are reduced anatomically may be successfully managed in postoperative traction or, on occasion, in pelvic-hip orthoses for 6 weeks (22,29). Displaced Pipkin type I fragments treated nonsurgically have poor clinical outcomes (11,22,29). Excise comminuted fragments. Large fragments without comminution can be successfully treated with open reduction and internal fixation. Epstein (10) recommended a posterior approach for open reduction and internal fixation of these fractures, but recently Lewinnek et al. and other authors (5,29,60) have advocated an anterior approach. Typically a Smith-Peterson approach or direct anterior approach to the hip can be used with an arthrotomy along the acetabular rim, with a T extension in the anterior hip capsule. These fragments can be stabilized with various small fragment screws countersunk below the articular cartilage or with absorbable screws (Fig. 18.22).

Pipkin Type II Injuries involve the superior portion of the femoral head (Fig. 18.18), which is important in load transmission across the hip joint (55). Pipkin type II fractures that are reduced anatomically may be treated in traction for 6 weeks (6,11,22,29). Reserve internal fixation of anatomically reduced Pipkin type II injuries for those patients in whom prolonged traction is contraindicated. Displaced Pipkin type II fractures require open reduction of the fragment through an anterior approach (66).

Although it is technically feasible to perform an open reduction of a Pipkin type II fracture through a posterior approach (12), this procedure requires redislocation of the hip. Additionally, soft-tissue attachments of the head fragment to the ligamentum teres must be cut in order to reduce and fix the fracture. Visualization of the fragment is limited, compromising the procedure.

Pipkin Type III Injuries present a serious challenge (Fig. 18.18) (55). A fracture of the femoral neck can accompany either a type I or type II femoral head fracture. In this situation, reduction and fixation of the femoral neck fracture are of paramount importance to help restore normal blood supply to the femoral head. An anterior approach to the hip joint provides direct access to both the femoral neck and femoral head, allowing the surgeon to perform an open reduction of both fractures.

Iatrogenic fracture of the femoral neck during forceful attempt at closed reduction of a dislocated hip has been reported (12). Carefully inspect preduction radiographs for evidence of a femoral neck fracture. If you find a nondisplaced femoral neck fracture, it is advisable to perform percutaneous fixation of the femoral neck before attempting reduction of the hip. In this case, use either a posterior or anterior approach to the hip. The outcome of type III Pipkin injuries is frequently poor; satisfactory outcomes have been reported in a minority of cases (11,22,29). For this reason we recommend open reduction and internal fixation, particularly in the young patient with this complex injury.

Pipkin Type IV Injuries have combined type I or type II femoral head fractures with an associated acetabular fracture (Fig. 18.18). In this situation, treat the acetabular fracture as described in the previous section (53). If the femoral head fracture is nondisplaced, it can be treated with 3 to 4 weeks of traction postoperatively. If mobilization is contemplated, however, it may be necessary to perform internal fixation or excision of the femoral head fragment. Consider sequential surgical approaches for an unstable inferior posterior wall fracture that requires open reduction. Use internal fixation, followed by an anterior approach, to repair or excise a femoral head fragment. Occasionally, a superior posterior wall segment can be treated through a Smith-Peterson approach at the time of incision or repair of the femoral head fragment.

Femoral Head Impaction Fractures

Impaction or indentation of the femoral head is commonly associated with anterior dislocation of the hip. This kind of injury has been shown to predispose patients to posttraumatic arthritis (8). At this time, there is no effective treatment for reduction and fixation of femoral head impaction injuries. Intertrochanteric osteotomy to move the fracture away from the hip joint has been proposed as a treatment method to prevent the development of arthritis in small femoral head impaction injuries. There are no data, however, to demonstrate that this method prevents the development of posttraumatic arthritis in the long term.

COMPLICATIONS

Entrapment of the femoral head by soft tissues can prevent relocation of a dislocation and require open reduction (5).

Osteonecrosis of the femoral head following isolated hip dislocations has been reported in 2% to 17% of injuries (10,22). Epstein reported a 25% incidence of avascular necrosis with dislocation of the hip for 24 hours before reduction (12). Recent work by Yue et al. has demonstrated that posterior dislocation is associated with kinking of the external iliac artery over the pelvic brim and causes obstruction of flow in the medial femoral circumflex artery (59). Prompt reduction of the femoral head is recommended following the diagnosis of dislocation to decrease the incidence of osteonecrosis. Osteonecrosis often does not manifest clinically for 12 to 36 months.
following injury. Letournel reported an incidence of osteonecrosis of 7% with posterior fracture dislocation of the hip associated with acetabular fractures (G8).

**Traumatic Arthritis**

Traumatic arthritis is a significant long-term complication of hip dislocation (21,23,41). Upadhyay et al. reported a long-term follow-up of 74 cases of isolated hip dislocations (63). They noted a 16% incidence of traumatic arthritis, with an additional 8% incidence of arthritis secondary to avascular necrosis. In their series, manual laborers were more likely than sedentary workers to develop traumatic arthritis of the hip following hip dislocation.

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

A. Epidemiology and Mechanisms of Injury

Hip fractures have a bimodal age distribution: Approximately 97% occur in patients over 50 years of age (the incidence increases with age), and only 3% in patients under 50. In the latter group, they occur most commonly between 20 and 40 years of age, usually in men, and are due to high-energy trauma associated with sports and industrial and motor-vehicle accidents (106,136). In this young group, most hip fractures are subtrochanteric or basicervical. In contrast, fractures of the hip in patients between 40 and 50 years of age usually occur in alcoholics or patients with multiple medical diseases, whose fractures are related to osteoporosis.

Fractures in the elderly are serious injuries, often occurring in the terminal years of life, and they have a major impact on society, our health care system, and the cost of care (45). Annually, 250,000 fractures of the hip occur in the United States. The number of fractures is projected to double by the year 2050 as the population ages (78). Health care costs for fractures exceed $6 billion per year. Martin et al. quoted in Koval and Zuckerman (78) showed that in Canada from 1972 to 1984 the incidence of initial fractures of the proximal femur in persons older than 50 years increased 60% in women and 42% in men. The incidence increased exponentially with age, doubling for every 6 years of age and reaching a maximum incidence of 4% of women over 90. Martin et al. attributed this increase to a gradual decline in physical activity, which contributes to the bone loss (78). At 1 year after a hip fracture, mortality rates in elderly people range from 14% to 36% (78). The highest risk of mortality occurs in the first 6 months after fracture; after 1 year the mortality rate approaches that of persons who have not sustained a hip fracture.

Koval and Zuckerman (78), in an extensive study of functional recovery after fracture of the hip, state that the factors influencing morbidity and mortality are best understood if broken into three phases: the patient status before the fracture, preoperative management, and postoperative care. Age at the time of fracture does not necessarily correlate with a higher mortality rate. Systemic illnesses, however, such as congestive heart failure, coronary artery disease, diabetes mellitus, chronic obstructive pulmonary disease, and rheumatoid arthritis have been shown to increase the mortality rate. Koval and Zuckerman (78) pointed out other preoperative factors that worsened the prognosis, including cerebral dysfunction in the form of chronic organic brain syndrome, cerebral vascular disease, or psychiatric illness; and permanent habitation in an institution as opposed to a home.

An increased mortality rate after fracture of the hip is associated with male sex, advanced age, untreated or poorly controlled systemic disease, cerebral dysfunction, institutionalization, internal fixation before control of medical comorbidities, and postoperative complications.

White et al. (149) used the preoperative grading system of the American Society of Anesthesiologists to predict mortality. They found that grade 1 or grade 2 patients...
had a 1-year mortality rate of 8%, whereas grade 3 and 4 patients had a 1-year mortality rate of 49% (Table 19.1).

Zuckerman et al. (160) examined the effect of timing of internal fixation on mortality. They concluded that patients with two or fewer comorbidities benefited by internal fixation of the hip within 2 days after admission, whereas delay to better treat comorbidities and better prepare the patient for surgery was beneficial for patients with three or more comorbidities.

The goals of treatment of a hip fracture, other than reducing mortality, are to return the patient to walking, and to give her sufficient independence that she can live at home with or without assistance. The factors that have been reported to be predictors of return to ambulation are male sex, younger age, absence of mental impairment, and use of a cane or walker before injury. The factors that predict discharge to home are younger age, independent ambulation before fracture, capability in activities of daily living, and the presence of another person in the home. Similar factors apply to return to activities of daily living. In addition, Zuckerman et al. (159) showed that an interdisciplinary hospital program specifically designed to manage elderly patients with hip fractures resulted in fewer postoperative complications, fewer incidences of treatment in an intensive care unit, significantly improved ability to walk at the time of hospital discharge, and fewer transfers to a nursing home.

For a discussion of hip fractures in children (61,75,99,102), see Chapter 164.

B. FRACTURES OF THE FEMORAL NECK

OSSEOUS AND VASCULAR ANATOMY OF THE PROXIMAL FEMUR

The femoral side of the hip is made up of the femoral head with its articular cartilage, and the femoral neck, which connects the head to the shaft in the region of the lesser and greater trochanters. The synovial membrane incorporates the entire femoral head and the anterior neck, but only the proximal half of the neck posteriorly. The shape and size of femoral necks vary widely. In our practice, for example, there is a large discrepancy between those seen in small Asians and those in large blacks. The neck–shaft angle does not vary much, however, and is approximately 130° ± 7° (154). Anteverision of the femoral neck is 10° ± 7° in normal individuals, with no variation between the sexes (153). The diameter of the femoral head ranges from 40 to 60 mm, depending on the size of the individual (63). The thickness of the articular cartilage varies from 4 mm at the apex of the head to 3 mm at the periphery (63). In contrast to the medial femoral neck as seen on an anteroposterior (AP) radiograph of the hip, the calcar femorale is a dense plate of bone that originates from the posterior medial portion of the femoral shaft, where it blends into the neck of the femur and extends superiorly toward the greater trochanter, fusing with the posterior cortex of the femoral neck. It is more of a posterior than a medial structure (134).

The vascular supply to the femoral head arises from three sources (Fig. 19.1). In the majority of persons, the major blood supply to the head comes via the lateral epiphyseal vessels, which penetrate into the bone of the femoral head at its junction with the neck. As seen in Figure 19.1, these vessels are supplied by the subsynovial intracapsular arterial ring, which derives from the ascending cervical arteries running beneath the synovium of the femoral neck. These vessels originate from the extracapsular arterial ring, which is primarily the termination of the medial femoral circumflex artery on the posterior aspect of the hip along the intertrochanteric basi-ossseous line. The lateral femoral circumflex artery on the anterior aspect of the neck also contributes to this blood supply; however, the medial femoral circumflex artery usually dominates. The artery of the ligamentum teres usually originates from the anterior obturator artery but it contributes to the blood supply of only a small area of the femoral head near the attachment of the ligamentum teres. Intraosseous cervical vessels derived from the femoral neck also penetrate into the femoral head but are not the major blood supply (24,45,142).

Figure 19.1. Posterior (A) and anterior (B) views of the hip, showing the extraosseous blood supply to the femoral head.

A fracture of the femoral neck disrupts the intraosseous cervical vessels, making femoral head viability totally dependent on the retinacular vessels and the artery of the ligamentum teres. Displacement of the femoral neck fracture nearly always results in severe compromise of the blood supply to the head (27,28,98,119).

Another possible source of devascularization of the head is the accumulation of an intracapsular hematoma, which can interfere with venous outflow from the head and perhaps vascular inflow. As a result, some authors recommend routine aspiration of the hip or incision of the hip joint capsule after fracture (30,134). Opinions on this are not uniform, however (88).

If the fracture is not totally displaced, resulting in complete disruption of the epiphyseal vessels, mild to moderate distortion of alignment at the fracture site may compromise intact vessels. After 12 hours of disruption of the blood supply to the femoral head, all cells within the head are most likely necrotic. Therefore, in any patient in whom an effort will be made to preserve the femoral head, the fracture should be gently reduced as soon as possible. This can be achieved in the emergency room by aspiration of the hip and injection of a small amount of local anesthetic to provide pain relief. Simple longitudinal traction and mild gentle internal rotation, placing the limb in 5–7 pounds (2.3–3.1 kg) of Buck’s traction with the leg lying on a pillow, will nearly always result in marked improvement in position, thus optimizing the opportunity for early return of blood flow to the femoral head (131,133). Anatomic reduction and excellent stability optimize the conditions for rapid revascularization across the fracture into the femoral head. This can occur by lumen-to-lumen reconnection of existing blood vessels. The foveal blood supply may be important in this revascularization. Rotary and valgus malposition have an adverse effect, not only on the retinacular blood supply, but on that of the foveal blood vessel as well (126).

The method of fixation also influences vascularity to the femoral head. Fixation devices placed in the superior lateral aspects of the femoral head can inadvertently injure the lateral epiphyseal vessels. Devices that are driven into the head rather than being screwed into the head or inserted in an atraumatic manner can lead to an increased incidence of avascular necrosis (132). Twisting of the femoral head while inserting hip screws and using large implants that occupy a substantial cross-sectional area in the femoral neck have also been identified as increasing the incidence of avascular necrosis (84).

Unfortunately, no attempt to determine the viability and vascular supply to the femoral head at the time of internal fixation has produced uniformly reliable results;
Therefore, the decision as to whether to preserve the femoral head or to go on to hemiarthroplasty remains a clinical surgical decision.

**BIOMECHANICS OF THE FRACTURE**

The vast majority of femoral neck fractures occur when an elderly person falls from a standing position, resulting in a direct blow over the greater trochanter. It has been hypothesized that fatigue fractures of the femoral neck in the elderly with very osteoporotic bone may be the precipitating cause of the fall rather than the fall being the causal factor. It appears that this is highly unusual and that the vast majority of fractures are indeed caused by a fall (100). Femoral fractures in young and middle-aged adults are usually caused by high-velocity vehicular trauma or a fall from a substantial height, resulting in axial loading of the femur while the hip is abducted (79). This same method of loading with the hip in abduction is more likely to result in a dislocation with or without associated fractures of the posterior acetabulum or femoral head (69). Extreme external rotation tightening the anterior capsule and perhaps leading to impingement of the posterior cortex of the femoral neck on the acetabular rim can cause fracture as well and is compatible with the marked posterior comminution of the neck frequently seen in displaced fractures (5, 110).

Postmenopausal and senile osteoporosis predispose to fracture; by 65 years of age, 50% of women show bone mineral content below the threshold for fracture, and by 85 years of age this climbs to 100% (102). Osteomalacia plays a much smaller role—Wilton et al. (151) found that only 2% of a large population of patients who had sustained fractures of the femoral neck showed evidence of osteomalacia.

**CLASSIFICATIONS**

Three classifications are commonly applied to femoral neck fractures: These describe the anatomic location of the fracture (148), the degree of displacement of the fracture fragments (48, 52, 53), and the direction of the fracture angle in the frontal plane (87).

**ANATOMIC CLASSIFICATION**

Fractures of the femoral neck located just distal to that portion of the femoral head covered by cartilage are termed subcapital. Fractures in the midportion of the femoral neck are termed transcervical. The base of the neck are termed basilar neck fractures (Fig. 19.2). The first two are intracapsular and the third can be partially intracapsular and extracapsular posteriorly. Subcapital fractures are at greatest risk for disruption of the blood supply to the femoral head, transcervical fractures have a somewhat lower risk, and the risk is extremely low in basilar neck fractures. This is dependent mostly on the degree of displacement, which is addressed better by the Garden classification, discussed next. Fractures with a high shear angle, such as high-velocity fractures in young persons, can begin in the basilar neck area, traverse the femoral neck proximally, and exit in a subcapital location. Usually these are not displaced because they are commonly associated with fractures of the shaft of the femur, which dissipates most of the energy. If displaced, these fractures have an incidence of avascular necrosis of the femoral head similar to that seen in displaced subcapital fractures.

*Figure 19.2. Types of intracapsular fractures of the femoral neck: subcapital (A), transcervical (B), basilar neck (C), and high-angle shear fracture typical of those seen in ipsilateral concomitant fractures of the hip and femoral shaft (D).*

Other than the effects of the location of the fracture on the blood supply to the femoral head, the major importance of the anatomic location of the fractures is its influence on the choice of internal fixation device. Subcapital fractures and proximal transcervical fractures are usually best internally fixed with multiple screws, which threaten the blood supply to the femoral head least, and leave the largest cross-sectional area in the femoral neck for bone healing and revascularization. More distal fractures, in particular those that are basilar neck and have a high shear angle, do not provide enough bone stock for adequate purchase of the multiple screws in the distal fragment; therefore, sliding compression hip screws with side plates are indicated for basilar neck fractures, particularly in young active individuals.

**THE GARDEN CLASSIFICATION**

The Garden classification (7, 48, 49, 50, 51, 52 and 53) applies to subcapital fractures and focuses on the degree of displacement (Fig. 19.3). Barnes, Garden, et al. (7), in a large multi-institutional study, found a reasonably good correlation between the Garden classification and the incidence of nonunion and avascular necrosis, as indicated in Table 19.2. The interrater reliability of orthopaedic surgeons using the Garden classification is not particularly good; therefore, from a practical viewpoint, most surgeons lump Garden stage I and II fractures together as “undisplaced” and Garden stage III and IV fractures together as “displaced.” Undisplaced fractures, if internally fixed in good position and stable, have a favorable prognosis, with union rates of 95% or better and an incidence of avascular necrosis of under 10%. Whereas displaced fractures have rates of avascular necrosis as high as 40% (in Garden stage IV fractures) and nonunion rates of 10% or more. This difference in prognosis is the key factor in deciding whether to perform prosthetic replacement of the femoral head or internal fixation in elderly patients with these fractures. This is discussed in more detail later.

*Figure 19.3. Garden classification of femoral neck fractures. A: Stage I: Incomplete fracture that is abducted and impacted. B: Stage II: Complete fracture without displacement. C: Stage III: Complete fracture with partial displacement. The neck is still in apposition posteriorinferiorly, therefore, the fragments have rotated in opposite directions like two cogwheels. Note that the compression trabeculae are angulated. D: Stage IV: Complete fracture with full displacement. Contact between the fracture surfaces is lost. The distal fragment is in full external rotation and lies anterior to the proximal fragment. The proximal fragment is free to resume its natural position in the acetabulum; therefore, the compression trabeculae lie in their normal alignment.*

Postmenopausal and senile osteoporosis predispose to fracture; by 65 years of age, 50% of women show bone mineral content below the threshold for fracture, and by 85 years of age this climbs to 100% (102). Osteomalacia plays a much smaller role—Wilton et al. (151) found that only 2% of a large population of patients who had sustained fractures of the femoral neck showed evidence of osteomalacia.
with nondisplaced fractures, perform internal fixation ideally within 24 hours but no later than 48 hours to avoid the complications of prolonged immobilization. In healthy patients, if the patient has two or fewer comorbidities, surgery is indicated within 48 hours of admission. However, if the patient has three or more comorbidities, surgery is generally postponed to treat the comorbidities, which can reduce the incidence of postoperative medical complications. In healthy patients with nondisplaced fractures, perform internal fixation ideally within 24 hours but no later than 48 hours to avoid the complications of prolonged immobilization.

The decision of when to carry out surgical treatment is based on whether the fracture is displaced, and on the health of the patient. The decision of when to carry out surgical treatment is based on whether the fracture is displaced, and on the health of the patient.

5 ml of 0.5% Bupivacain without epinephrin. This usually provides dramatic pain relief and permits gentle further reduction of the fracture in the Buck’s traction, if necessary. To detect and aspirate any hematoma, but more important, to inject a hemostatic agent.

In the emergency room, immediately apply Buck’s traction (Chapter 10) with approximately 5 pounds (2.3 kg), with the foot in neutral rotation, the knee and hip slightly flexed, and the calf supported on one to two pillows. This immediately increases patient comfort and places the fracture in a more anatomic position, which minimizes distortion of the vessels providing the blood supply to the femoral head. The flexed position helps accommodate the increased intracapsular pressure that might be present from a hematoma. Immediate AP and cross-table lateral radiographs will confirm the diagnosis. It is important to plan the preoperative workup and radiography to minimize moving the patient, because transfers are painful and risk further comminution of the fracture.

Although the importance of an intracapsular hematoma as a threat to the blood supply to the femoral head remains somewhat controversial, I routinely place an 18-gauge or larger-diameter needle into the hip joint through either a lateral or an anterior approach to detect and aspirate any hematoma, but more important, to inject 5 ml of 0.5% Bupivacain without epinephrin. This usually provides dramatic pain relief and permits gentle further reduction of the fracture in the Buck’s traction, if indicated. For the majority of these patients, early internal fixation is indicated, so immediate consultation with the primary-care physician or a medical consultation is indicated to clear them for surgical treatment.

TIMING OF SURGERY

The decision of when to carry out surgical treatment is based on whether the fracture is displaced, and on the health of the patient. Zuckerman et al. (196) showed that healthy patients with two or fewer comorbidities did better if the hip was treated within 48 hours of admission, whereas unhealthy patients with three or more comorbidities benefited from delay in surgery to treat comorbidities, which reduced the incidence of postoperative medical complications. In healthy patients with nondisplaced fractures, perform internal fixation ideally within 24 hours but no later than 48 hours to avoid the complications of prolonged immobilization.

PAUWELS’S CLASSIFICATION

Pauwels’s classification (67) is based on the angle the fracture line makes with the horizontal (Fig. 19.4). Pauwels’s type I fracture is the most horizontal, is often impacted, and therefore with internal fixation tends to stabilize with weight bearing, whereas the Pauwels’s type III fracture is nearly vertical, experiences a large degree of shear with weight bearing, and is therefore unstable.

All of these classifications are based on the interpretation of routine AP and lateral radiographs. For reproducible interpretation, the AP view must show the femoral neck in full profile, which requires internal rotation; in addition, the cross-table lateral must also not have a rotational component. It is quite difficult to obtain these radiographs in the emergency room setting. Once the patient is taken to surgery, repeat the AP and lateral plain films, or obtain good fluoroscopic views with the patient on the fracture table and the hip positioned for ideal radiographic views.

There are limitations to these classifications, in that none of them take into account the maximum displacement that occurred at the time of injury, the degree of vascular or capsular damage, or the amount of comminution of the posterior femoral neck, which makes the fracture more difficult to reduce and much more unstable.

EVALUATION AND PREOPERATIVE MANAGEMENT

HISTORY

The vast majority of fractures of the femoral neck occur in the elderly; therefore, the history usually one of a slip and fall and landing on the side, resulting in a direct blow to the lateral aspect of the greater trochanter. Pathologic fractures are suggested when the patient's hip suddenly “gives way” during normal activities of daily living, associated with sudden severe pain, which then leads to a fall. Fractures of the femoral neck in young active adults are rare and nearly always due to high-energy trauma. In all fractures of the femoral shaft, a concomitant ipsilateral fracture of the femoral neck must be suspected (as discussed in Chapter 29). The past medical history, the social and family history, and a review of systems are very important, as indicated in the previous discussion on epidemiology. Associated diseases and social circumstance have a major influence on the outcome in fractures of the femoral neck and must be considered early for discharge planning.

PHYSICAL EXAMINATION

Typically, the affected extremity shows shortening and excessive external rotation. The hip is tender, and any motion usually produces severe pain. A gentle blow to the bottom of the heel usually results in hip pain. Because the fracture is intracapsular and the capsule is usually intact, the amount of external rotation and shortening seen is much less than that seen in intertrochanteric fractures or fractures of the shaft. In the latter, shortening of an inch or more may be present, and the lateral border of the foot lies completely flat on the examining table. In neck fractures, shortening is usually less than 1 inch and the degree of external rotation does not usually allow the foot to lie completely flat on the tabletop unless the hip is abducted. Usually there is not much swelling, and large ecchymosis or hematomas such as seen in intertrochanteric or subtrochanteric fractures is not usually found. The surrounding hip joint capsule limits bleeding from the fracture; therefore, anemia is rarely a problem.

PREOPERATIVE MANAGEMENT

In the emergency room, immediately apply Buck’s traction (Chapter 10) with approximately 5 pounds (2.3 kg), with the foot in neutral rotation, the knee and hip slightly flexed, and the calf supported on one to two pillows. This immediately increases patient comfort and places the fracture in a more anatomic position, which minimizes distortion of the vessels providing the blood supply to the femoral head. The flexed position helps accommodate the increased intracapsular pressure that might be present from a hematoma. Immediate AP and cross-table lateral radiographs will confirm the diagnosis. It is important to plan the preoperative workup and radiography to minimize moving the patient, because transfers are painful and risk further comminution of the fracture.

Although the importance of an intracapsular hematoma as a threat to the blood supply to the femoral head remains somewhat controversial, I routinely place an 18-gauge or larger-diameter needle into the hip joint through either a lateral or an anterior approach to detect and aspirate any hematoma, but more important, to inject 5 ml of 0.5% Bupivacain without epinephrin. This usually provides dramatic pain relief and permits gentle further reduction of the fracture in the Buck’s traction, if indicated.

For the majority of these patients, early internal fixation is indicated, so immediate consultation with the primary-care physician or a medical consultation is indicated to clear them for surgical treatment.
patients with displaced fractures, particularly where salvage of the femoral head with internal fixation is to be performed, take the patients to surgery urgently because early anatomic reduction and internal fixation optimizes the conditions for preservation of the blood supply to the femoral head. In unhealthy patients with three or more comorbidities, whether the fracture is displaced or undisplaced, treatment in Buck’s traction as outlined previously and thorough medical workup and treatment of comorbidities are indicated prior to surgical treatment.

Table 19.3. Timing of Fixation

If surgery is contraindicated, femoral neck fractures can be treated in skeletal traction utilizing a proximal tibial or distal femoral traction pin with an internal rotation component to the traction to reduce the fracture. Because these fractures often require 6 months to heal, this is rarely practical. I have not used nonoperative treatment in traction for a femoral neck fracture in the past 30 years. In the elderly, when operative treatment is not possible, it is usually better to abandon treatment of the fracture and mobilize the patient as symptoms permit. Many of these patients are very sedentary or confined to nursing homes, so they will often go on to a relatively pain-free nonunion, which is compatible with their level of function. The other alternative is a head and neck resection, but the decision to perform this procedure is usually best delayed to see how the patient does with simple neglect of the fracture.

INDICATIONS FOR SURGERY

NONDISPLACED FEMORAL NECK FRACTURES

Crawford et al. (29) showed that stable fractures that were impacted into moderate valgus could be successfully managed nonoperatively with initial traction for symptomatic relief followed by limited protected weight bearing. Bentley (9), however, showed in his series that 16% of stable fractures treated nonoperatively subsequently displace, resulting in a much worse prognosis. For that reason, the nonoperative treatment of stable impacted femoral neck fractures is of historical interest only. The low morbidity of percutaneous cannulated screw fixation of these fractures is such that the benefits of surgical stabilization far outweigh the risks (Fig. 19.5).

Figure 19.5. Percutaneous cannulated screw fixation of an impacted, Garden stage I, subcapital hip fracture. A: AP radiograph of the hip fracture prior to fixation. B: Lateral radiograph. C: AP radiograph after cannulated screw fixation. D: Lateral radiograph; ideally, the screws could be spread out somewhat more and be more parallel.

DISPLACED FRACTURES

In active adults, try to treat all femoral neck fractures, whether displaced or undisplaced, with internal fixation rather than prosthetic replacement (Fig. 19.5, Fig. 19.6). Even in displaced fractures such as a Garden stage IV where treatment is delayed, good internal fixation in anatomic position usually results in union of the fracture even though the incidence of avascular necrosis may be 40% or more. This means that up to half of these patients may have a satisfactory outcome, which is always superior to an arthroplasty, in both the short and the long term. In addition, if these patients are followed closely, subsequent conversion to an arthroplasty, if required, is not compromised.

There is no question that patients do better in the long run if their fracture heals; they experience no avascular necrosis, and they retain their own femoral head. Because modern techniques of percutaneous, multiple-cannulated-screw fixation has a low morbidity, I feel that fixation is indicated in all nonpathologic, displaced fractures regardless of the patient’s age, assuming that their bone quality is sufficiently good that the screws can be expected to hold. The controversy as to whether to perform internal fixation or prosthetic replacement arises for patients 65 years of age or more (127). People are living much longer today and, as a result of better living conditions and health care, are physiologically quite young in their middle 60s and are remaining athletically active into their middle 70s and occasionally even into their early 80s. For that reason, the decision of whether to internally fix or replace a displaced femoral neck fracture should be based on life expectancy, the presence of chronic disease, bone quality, and level of function at the time of fracture, as well as on expected function. In our practice, this means that we commonly internally fix displaced fractures in active 70-year-olds who have no comorbidity, and we reserve prosthetic replacement for patients who are physiologically in their 80s (64). In a meticulous review of the literature on fractures of the femoral neck, Swiontkowski (134) stated that major deficiencies in the design of most studies did not permit a meta-analysis of the literature to prove whether primary internal fixation or a prosthetic replacement in older patients provided the best results.
On the basis of my personal experience, visits to many other institutions, and a review of the literature, I have drawn the following conclusions regarding this controversy:

- In community-based practices in North America, the vast majority of displaced femoral neck fractures in patients over 65 years of age are currently treated with hemiarthroplasty (Fig. 19.7).

- Although more displaced fractures are treated with internal fixation at academic trauma centers, the art of successful closed reduction, in my opinion, is being lost because of the default to arthroplasty.
- In most published series, the early complication rate, including infection, other wound complications, dislocation of the prosthesis, and medical complications, are higher after hemiarthroplasty than after multiple-percutaneous-screw fixation (16,67,69,70,74,86,101,123,127).
- Because of average reported incidences of 16% for avascular necrosis and 32% for nonunion in the series of Söreide et al. (127), the need for reoperation after internal fixation was 35% at 2 years, compared to an average incidence of revision of arthroplasty of between 12% and 15%. This means that approximately 65% of patients after internal fixation either have a successful outcome, or failure of their fixation does not result in sufficient symptoms to require revision surgery. In more active patients between 65 and 75 years of age, this may well be acceptable because of the advantages of retaining the patient's own hip in this group.
- Rehabilitation after internal fixation, in spite of perceptions to the contrary, is usually faster because of the advantages of retaining the patient's own hip. In young vigorous patients for whom the stronger device is needed to resist deforming forces across the fracture site. I will often augment the latter with a 6–7 mm cannulated screw to improve rotational control. In patients with severe osteoporosis, augmentation with apatite cements has been used to increase the strength of the fixation construct, but at this time this is an experimental technique (59).

**TYPES OF FIXATION**

Many different methods of internal fixation (2,80,92,126) have been used in the past; however, today most surgeons prefer three to four 5–7 mm in diameter lag screws utilizing cannulated screw techniques because of the advantages of placing guide pins prior to the screws (135). Various types of compression hip screws have also been used. I use three cannulated screws routinely and reserve the standard compression hip screw for high shear angle fractures in young vigorous patients for whom the stronger device is needed to resist deforming forces across the fracture site. I will often augment the latter with a 6–7 mm cannulated screw to improve rotational control. In patients with severe osteoporosis, augmentation with apatite cements has been used to increase the strength of the fixation construct, but at this time this is an experimental technique (59).

**TYPES OF ARTHROPLASTY**

The types of arthroplasty available include unipolar, such as the older Austin Moore (57) or similar prostheses (62,67,68,69) and 85,101,153), or the newer bipolar prosthesis, including those that can be converted to a total hip. These are available in both cemented and noncemented versions (Fig. 19.7).

In addition to the factors already mentioned, indications for arthroplasty include the following:

- Inability to achieve a satisfactory reduction when open reduction with preservation of the femoral head is not indicated
- Severe neck comminution that precludes a satisfactory outcome
- Some pathologic fractures
- Coexisting arthritis

Some neurologic conditions characterized by spasticity, contractures, or poor motor control have been mentioned as indications for arthroplasty; however, the increased incidence of dislocation in this group may in some cases make internal fixation a better choice. Kozkina et al. (74), in a prospective outcomes study, compared noncemented unipolar prostheses to cemented or press-fit bipolar prostheses. Patients with the bipolar prostheses had better pain relief and function compared to the unipolar prostheses at 2 years follow-up. The total cost of the bipolar was approximately 30% more than the unipolar. Cornell et al. (38), in a smaller study comparing cemented unipolar and bipolar prostheses, at 6 months follow-up found no differences in hip rating outcomes; therefore, they suggested that the less expensive unipolar prostheses might be justified. Neither study addressed the issue of whether conversion to total hip arthroplasty was easier, or less expensive, with the bipolar prostheses designed for conversion to a total hip. Based on personal experience and a review of the literature, I have drawn the following conclusions regarding this controversial issue:

- Because most patients undergoing arthroplasty for fracture of the hip are over 65 years of age, in appropriate quality bone, a cemented prosthesis is more likely to offer early function and minimize the risk of long-term thigh pain.
- In patients with a limited lifespan or who have low functional demands, a unipolar prosthesis is less expensive and less likely to dislocate, and it provides satisfactory function.
- A cemented bipolar prosthesis offers optimal function and are more important in the younger group of patients, for whom eventual conversion to total hip arthroplasty might be necessary. A bipolar that offers conversion to total hip arthroplasty without removal of the femoral stem should be used.
- Total hip arthroplasty is indicated only in patients with coexisting arthritis or pathology of the acetabulum that makes a hemiarthroplasty impractical (124).

Some authors advocate routine total hip replacement in view of the revision rate of hemiarthroplasty previously mentioned, but I do not subscribe to that approach at the present time (23,26,33,55,66,72,108,123,137). An algorithm for the decision-making cascade is presented in Figure 19.8.

**Figure 19.7.** Hemiarthroplasty for a week-old Garden stage IV subcapital fracture of the femoral neck. A: AP radiograph showing a fully displaced fracture with some erosion of the head and femoral neck due to delay in fixation. B: Lateral radiograph. C: AP radiograph after cemented bipolar hemiarthroplasty. D: Lateral radiograph.

**Figure 19.8.** Treatment of adult subcapital hip fractures.
CLOSED REDUCTION AND PERCUTANEOUS MULTIPLE-SCREW FIXATION

- Administer a general or regional anesthetic. When this is contraindicated, the procedure can be done under local anesthesia in a cooperative patient; use conscious sedation supervised by an anesthesiologist.
- Gently transfer the patient to an orthopaedic fracture table that is compatible with the use of a fluoroscope.
- In undisplaced fractures, and in those in satisfactory position for fixation when a reduction is not required, place the affected hip in neutral abduction, in neutral flexion–extension, and in sufficient internal rotation to place the femoral neck parallel to the floor, assuming that this will not displace the fracture. Apply only enough traction to stabilize the limb on the table while avoiding disimpaction of the fracture site. Fractures that have good apposition but are simply angulated beyond the desirable range can often be reduced in this manner without a formal reduction maneuver, as described next.
- In fully displaced fractures, use the following protocol:
  - It is critical in the reduction of displaced fractures to have the pelvis completely stable on the fracture table. This is best achieved by putting both lower extremities in longitudinal traction.
  - Using a perineal post in the groin, secure both feet firmly into traction stirrups, padding the feet well to avoid bruising or injury to neurovascular structures. Abduct the uninvolved hip to 45° or as needed to allow access for the C-arm fluoroscope, and place the limb in sufficient traction to tip the pelvis slightly toward the unaffected hip. If an adduction contracture of the hip precludes placing this limb in abduction-traction, then place it in a 90°–90° leg holder, but stabilize the pelvis by padding and binding the thigh to the vertical post of the leg holder. A separate post mounted on the fracture table above the iliac crest of the uninvolved hip will work as well, if available (Fig. 19.9).

**Figure 19.9.** Patient on a fracture table for percutaneous screw fixation of a subcapital hip fracture. Note that the uninvolved hip is in traction and abducted 45°, permitting access for the C-arm. The fractured limb is in the reduced position with the lower extremity in line with the body and internally rotated to bring the femoral neck level with the floor. The C-arm fluoroscope is best located between the legs.

- Bring the fluoroscope in between the legs. Make certain that good-quality AP and lateral images of the fractured hip are obtainable. Lock the base of the fluoroscope and adjust it so that both views can be obtained without having to shift the position of the base.
- Gently place sufficient traction on the fractured hip to pull it out to length and disengage the fracture fragments.
- Place the hip in approximately 45° of abduction and 45° of external rotation.
- Then gently and slowly adduct the hip to neutral while simultaneously internally rotating the hip to bring the femoral neck parallel to the floor. Having an assistant provide a lifting and internal rotation pressure on the greater trochanter may assist in the reduction.
- Now visualize the hip on an AP view (Fig. 19.10). One of three situations will usually be present. The fracture may be anatomic (Fig. 19.10A), or there may be a valgus reduction (Fig. 19.10B), where the femoral neck is supporting the femoral head. Note that point X on the neck lies somewhat medial and distal to the matching point Y on the head. As long as the valgus angle does not exceed 15°, either of these positions is acceptable. Excessive valgus interferes with the ability to place the screws. This can be eliminated by easing off on the traction. If the fracture is in varus (Fig. 19.10C), where point X lies lateral and superior to point Y, then further reduction is necessary using the maneuver described next.

**Figure 19.10.** Reduction of a subcapital fracture on the AP view. **A:** Anatomic reduction. **B:** Valgus reduction. Notice that the femoral neck supports the head. This is acceptable. **C:** Varus reduction. There is no support of the femoral head by the neck. Do not accept this reduction. Convert this to anatomic reduction (A) or valgus reduction (B) by applying traction and pushing the femoral shaft medially, as indicated by the arrows.

- Under fluoroscopic control, pull additional traction to bring point X even with or slightly distal to point Y, then displace the neck medially to bring point X slightly medial to point Y to provide support for the femoral head. Achieve this by stabilizing the femoral shaft with a hand on the medial side of the knee, while pushing on the greater trochanter with the other hand to drive the femoral neck beneath the head (Fig. 19.11). Do this using frequent spot images on the fluoroscope to control the reduction and to avoid comminution of the neck.

**Figure 19.11.** Reduction maneuver for varus position on the AP view. Apply traction and then shift the femoral neck medially beneath the femoral head by supporting the medial aspect of the knee with one hand and pushing on the trochanter with the other as illustrated.

- With this maneuver, sometimes the neck will not remain in the reduced position because of excessive traction. To stabilize the reduction in that situation, hold the fracture reduced and release the traction enough to engage the fracture fragments.
- Now look at the fracture on the lateral view. Normally you will see one of the three situations illustrated in Figure 19.12. The fracture may be anatomic (Fig. 19.12A), or the fracture may be reduced in a stable configuration, with point W representing the posterior proximal corner of the femoral neck, displaced posterior to and supporting the posterior corner of the femoral head as represented by Z (Fig. 19.12B). As long as the neck is not posteriorly displaced more than 15% of the width of the neck at the fracture, this position is acceptable.
The details of insertion of guide pins and screws depends on the manufacturer, but the general principals are as follows:

- Additional strength, but more important, it allows the use of a larger guide pin that is stiff enough to prevent deflection during insertion.

Insert three or more guide pins or cannulated screws. I prefer titanium lag screws, 6–7 mm in diameter and self-tapping. The somewhat larger diameter provides elevation can be done to expose the bone just below the greater trochanter on the lateral cortex where the guide pins and screws will enter.

Use a Cobb elevator to further establish the hole in the fascia and to longitudinally split the muscles down to the femur, where a small amount of periosteal fascia in line with the angle of the K-wire.

Make a longitudinal skin incision on the mid-lateral aspect of the thigh approximately 2–3 cm in length, and incise the underlying subcutaneous fat and deep fascia in line with the angle of the K-wire.

- Sterilely prep the hip and, under fluoroscopy, lay a 0.062 mm K-wire on the anterior aspect of the skin of the hip so that it subtends an angle of 130° with the femoral shaft and is located directly over the middle of the femoral head and neck. Once this location is established, mark it. Then pierce the K-wire into and out of the skin on the anterolateral aspect of the hip, securing the pin with a section of skin approximately 5 mm in length. Do the same maneuver at the tip of the pin over the femoral head. This will secure the K-wire and prevent it from shifting. The distal end of the K-wire then marks the region for the skin incision, which can be marked. Then cut off the excessive projection of the pin laterally, leaving the K-wire on the anterior aspect of the hip (Fig. 19.14).

Now sterilely drape. I prefer the fully transparent, lateral wall drape because the ability to fully visualize the patient and the C-arm greatly facilitates orientation for placement of the guide pins. It also facilitates communication with the x-ray technician who will be standing behind this drape.

- Make a longitudinal skin incision on the mid-lateral aspect of the thigh approximately 2–3 cm in length, and incise the underlying subcutaneous fat and deep fascia in line with the angle of the K-wire.

- Use a Cobb elevator to further establish the hole in the fascia and to longitudinally split the muscles down to the femur, where a small amount of periosteal elevation can be done to expose the bone just below the greater trochanter on the lateral cortex where the guide pins and screws will enter.

- Insert three or more guide pins or cannulated screws. I prefer titanium lag screws, 6–7 mm in diameter and self-tapping. The somewhat larger diameter provides additional strength, but more important, it allows the use of a larger guide pin that is stiff enough to prevent deflection during insertion.

- The details of insertion of guide pins and screws depends on the manufacturer, but the general principals are as follows:
  - The configuration of screw placement I strive for is illustrated in Figure 19.15. Świntokowski [134] has shown that three screws provide sufficient stability, and that four or more screws are usually not necessary. This minimizes the number of screws and maximizes the surface area available for healing and revascularization. The keystone position is screw 1, which is placed in the midline on the lateral view and 5–10 mm proximal to the inner cortex of the medial femoral neck on the AP view. Insert this guide pin first, staying parallel to the guide K-wire and maintaining an angle of approximately 130°. This position is less likely to disrupt the reduction, and it is a good position for securing the reduction.

- If, however, point Z on the femoral head lies posterior to point W on the femoral neck, particularly if there is any comminution of the posterior neck, then this position is unstable and further reduction is necessary (Fig. 19.12C). To solve this problem, place your hand directly over the intertrochanteric region on the anterior surface of the hip and gently push the proximal femoral shaft posteriorly (Fig. 19.13) to obtain an anatomic or slightly overcorrected position (Fig. 19.12A, Fig. 19.12B).

If the fracture will not remain in the reduced position because of excessive traction, use the technique just described to engage the fracture fragments in the reduced position.

- Once a final position is obtained on the lateral view, return the C-arm to the AP view to verify that the reduction has not been lost on this view.

- Acceptable ranges of angulation after reduction are 130° to 150° of valgus on the AP view, and less than 15° of either anterior or posterior angulation on the lateral view.

- Insertion of the initial guide pin for the cannulated screws is greatly facilitated by having the femoral neck parallel to the floor. This provides a reference for pin insertion on the lateral view. Place a Kirschner (K) wire as a radiopaque guide on the anterior aspect of the hip for guidance in the AP view. When using a percutaneous technique, this also helps to localize the site of the incision used for inserting the guide pins and screws.

- Once a final position is obtained on the lateral view, return the C-arm to the AP view to verify that the reduction has not been lost on this view.

- Acceptable ranges of angulation after reduction are 130° to 150° of valgus on the AP view, and less than 15° of either anterior or posterior angulation on the lateral view.

- Insertion of the initial guide pin for the cannulated screws is greatly facilitated by having the femoral neck parallel to the floor. This provides a reference for pin insertion on the lateral view. Place a Kirschner (K) wire as a radiopaque guide on the anterior aspect of the hip for guidance in the AP view. When using a percutaneous technique, this also helps to localize the site of the incision used for inserting the guide pins and screws.

- Sterilely prep the hip and, under fluoroscopy, lay a 0.062 mm K-wire on the anterior aspect of the skin of the hip so that it subtends an angle of 130° with the femoral shaft and is located directly over the middle of the femoral head and neck. Once this location is established, mark it. Then pierce the K-wire into and out of the skin on the anterolateral aspect of the hip, securing the pin with a section of skin approximately 5 mm in length. Do the same maneuver at the tip of the pin over the femoral head. This will secure the K-wire and prevent it from shifting. The distal end of the K-wire then marks the region for the skin incision, which can be marked. Then cut off the excessive projection of the pin laterally, leaving the K-wire on the anterior aspect of the hip (Fig. 19.14).

Figure 19.12. Reduction of a subcapital fracture on the lateral view. A: Anatomic reduction. B: Neck posterior reduction. This is acceptable because the neck supports the femoral head and prevents it from collapsing posteriorly. C: Neck anterior reduction. This is unacceptable. Convert it to anatomic reduction (A) or neck posterior reduction (B) by pushing the shaft posteriorly.

Figure 19.13. Reduction maneuver for displacement on the lateral view. To provide support for the femoral head posteriorly, push the shaft posteriorly with the palm of your hand located over the proximal femur as illustrated.

Figure 19.14. A K-wire pierced through the skin in two places on the anterior surface of the thigh in line with the femoral neck, as seen on the fluoroscope image, provides a guide to the incision and fixation.

Figure 19.15. Screw positions for fixation of femoral neck fracture as seen on a cross section of the femoral neck. Keep all screws in the inner two-thirds of the head to avoid accidental penetration of the articular surface of the femoral head. Try to use positions 1, 2, and 3, inserting the guide pins and screws in that order. If more than three screws are desired, use positions 4 and 5. Caution: Site 4 is the most risky for injuring the extraosseous blood supply to the
Next, place guide pin 2, which is important to support the posterior neck.

Place guide pin 3. In Figure 19.15, screw positions 2 and 3 are shown in the midssection of the femoral head, but they can be placed more superiorly if more spread between the screws is desired.

Guide pin positions 4 and 5 are usually not necessary, but if additional fixation is required, place 4 next and then 5. Position 4 is good for neutralizing tension across the superior aspect of the fracture, but usually it is not placed because of the risk of injury to the blood supply to the femoral head if the superior cortex were accidentally penetrated.

To avoid accidental penetration of the articular surface, keep the guide pins within the central two thirds of the head (93), as shown in Figure 19.15.

I prefer to use guide pins that have a threaded tip that can be secured into the subchondral bone of the femoral head; then I drill for the screw 5–10 mm short of the tip of the guide pin. This helps prevent dislodgement of the guide pin on removal of the drill.

Measure for the depth of the drill and screw length.

Now overdrill the guide pin with the drillpoint specified by the manufacturer for the screw being used. Do this under direct fluoroscopic control to avoid accidental penetration of the hip and/or loss of the guide pin. Do not use the screws to apply the initial compression. With the three guide pins in place and before inserting the screws, loosen the traction somewhat and impact the fracture by pounding directly on the greater trochanter. Visualize this on the fluoroscope. At this point, measure for screw length and then in-sert the screws and washers, compressing the fracture site (Fig. 19.6).

Select a screw length that will permit compression of the femoral neck while placing the tip of the screw no closer than 7 mm to subchondral bone. Now insert the appropriate-length lag screw with a washer, being certain that the screw threads do not lie across the fracture site.

Remove the guide pins, irrigate the wound, and close in layers.

Prior to breaking sterile technique, obtain AP and lateral radiographs.

OPEN REDUCTION

If satisfactory position cannot be obtained after the closed reduction maneuvers as described, and if the patient is sufficiently young and healthy that internal fixation rather than hemiarthroplasty is indicated, perform an open reduction. The usual cause of failure of reduction is severe comminution of the femoral neck, which usually occurs posteriorly. The key to success of open reduction is the avoidance of further damage to the blood supply to the head, achievement of a stable anatomic reduction, and good stable fixation in good-quality bone. Because of the threat to the blood supply of the head caused by any type of bone grafting of the comminution of the posterior neck, do not bone graft the femoral neck.

For this procedure, leave the patient on the fracture table with the fracture in the best-reduced position obtainable. Prep the hip and then use traditional draping rather than the translucent drape sheet. Sterilely drape the head of the fluoroscope so that it is available throughout the procedure.

Expose the lateral aspect of the greater trochanter and the hip through a Watson-Jones approach (Chapter 3). Expose the femoral neck through a longitudinal skin incision in the hip joint capsule parallel to the femoral neck. “T” this at the base of the femoral neck only enough to visualize the fracture for reduction.

Irrigate the hip to remove any blood clots and to provide good visualization of the femoral neck fracture.

Now reduce the fracture by direct manipulation of the femoral neck under direct visualization, using the C-arm and the traction arm of the fracture table, which is manipulated by an assistant surgeon. This direct manipulation must be gentle and it must avoid disruption of the lateral epiphyseal vessels or any other soft-tissue connections to the femoral head. The pointed pusher from the pelvic fracture tray and small elevators are helpful. I almost never use reduction forceps. If forceps are necessary to grasp the femoral neck, use only a large pointed tenaculum forceps on a portion of the neck where injury to the blood supply will not occur.

HINTS AND TRICKS

- Place the femoral neck parallel to the floor to facilitate insertion of the screws. In some fractures, more internal rotation may be necessary to reduce posterior angulation at the fracture on the lateral view because of posterior neck comminution.

- If the initial alignment of the fracture is satisfactory, with the exception of posterior tilt of the head caused by posterior neck comminution, this tilt can often be reduced by placing the first guide pin along the posterior neck using the guide pin to push the head into acceptable position.

- If, after the reduction sequence just described, the fracture remains unsatisfactory position on either view, then repeat the entire sequence once more. If satisfactory reduction is not present after that, proceed with either open reduction or hemiarthroplasty.

- Insertion of guide pins can be difficult because they tend to “walk” along the femoral shaft when power is activated. Palpate the lateral cortex of the femur with the guide pin anteriorly and posteriorly to be certain that the initial guide pin is directly in the center of the shaft. Verify the location of the entry point of the guide pin and begin initially with the guide pin at right angles to the longitudinal axis of the femur. Once the guide pin has entered the cortex just barely enough to obtain purchase, but before penetrating so deep that its angle cannot be changed, align the guide pin on the AP and lateral views.

- The surgeon can easily judge alignment on the AP view, but the nurse or an assistant must visualize the guide pin on the lateral projection to keep it parallel to the floor.

- Once all three guide pins are fully inserted, it often saves time to next impact the fracture, because then the initial measurement of screw length will be more accurate.

- In hard cortical bone, tapping of the lateral cortex and/or the femoral head may be necessary prior to insertion of the screw. Avoid inserting screws where excessive torque is required, because this may displace the fracture.

- Always washers on the screws to permit compression of the fracture and to avoid penetration of the lateral cortex by the screw head.

- Do not place screws at more than 135° of valgus because this narrows the cross-sectional area of the femoral neck available for screw insertion and may necessitate entry of the screws at or below the lesser trochanter, which increases the risk of subtrochanteric fracture (117).

- Take time to ensure that the entry of each guide pin and screw is perfect, because mistakes requiring additional unused drill holes in the lateral aspect of the femur may displace the patient to subtrochanteric fracture.

- If a screw must be changed, insert the guide pin back into the screw before the change because this greatly facilitates location of the hole in the lateral cortex and ensures that the screw passes down the same track.

- When there is any question about the quality of reduction or location of the screws, examining the hip on the AP view under direct live fluoroscopy by rotating the hip through a full range of motion provides a three-dimensional visualization of the hip that is very helpful.

Because these fractures are very unstable, it is often necessary to manually reduce the fracture and then hold it while an initial guide pin is placed by an assistant surgeon, as previously described. Once one guide pin has been placed, the fracture usually is stable and the insertion of fixation screws can proceed as described for closed percutaneous fixation.

In young patients with a high-shear-angle (Pauwels’s type III) transcervical or basilar neck fracture, a compression hip screw with side plates may be indicated.

The screw and plates are inserted with the technique described in Section C of this chapter on intertrochanteric fractures.

Keep the hip joint capsule open until internal fixation is completed, because this will ensure maintenance of reduction and will assist in the visualization of placement of the fixation.

Open final radiographs prior to wound closure, and then irrigate the wound, place a suction drain, and close in layers.

COMPRESSION HIP SCREW FIXATION

See the discussion on compression hip screw fixation of intertrochanteric fractures in section C of this chapter.

HEMARTHROPLASTY

The technique for hemiarthroplasty is described in Chapter 105.

POSTOPERATIVE CARE

After internal fixation, nearly all patients can be mobilized to a bedside chair the day after surgery and can begin immediately to walk using a walker or crutches. Assuming that the reduction is stable, fixation good, and bone stock acceptable, most elderly patients can be allowed to bear weight as tolerated. Most patients will voluntee to use the weight of the leg without weight-bearing with assistive devices, although most elderly patients will continue to use assistive devices for a number of additional months until they regain muscle strength and endurance, and the fracture is healed. There is no point in keeping these patients non-weight-bearing because the simple maneuvers of getting on a bedpan, getting out of bed, and rising from a sitting position in a chair subject the internal
fixation to the same forces as nonassisted full weight bearing (3).

The least stress on the implants and femoral neck occurs when the patient slides the affected lower extremity along the floor without activating hip musculature. This is best achieved by weight bearing to the weight of the limb, combined with the use of a walker or crutches. The latter regimen should be used in younger persons with unstable fracture patterns until fracture healing occurs at about 6 months. We monitor patients with physical examination and radiographs at 6 and 12 weeks, 6 months, and 12 months after injury and then follow them yearly as needed. Avascular necrosis can occur even 2 years or more after injury.

**PITFALLS AND COMPLICATIONS**

The most common complications following internal fixation of fractures of the femoral neck include avascular necrosis, which, in large series including all grades, occurs in approximately 25% of fractures; nonunion, which in large series occurs in up to 25%, and early failure of fixation. Because percutaneous techniques are used, infection is uncommon, but it can occur. Most other complications are related to perioperative medical problems.

In the elderly, nonunion and avascular necrosis generally require prosthetic replacement. For a discussion of the treatment of nonunions of the femoral neck in younger patients, see Chapter 29. Infection after internal fixation generally does not result in osteomyelitis or pyarthrosis and can be treated with irrigation and debridement of the wound, delayed primary closure after debridement, and an appropriate course of intravenous bacteriologic antibiotics based on the results of culture. In most cases, the fixation implants can be left in place. If pyarthrosis or osteomyelitis occurs, then failure of fixation normally results, and head and neck resection as a definitive procedure or followed by late total joint arthroplasty is usually required. For complications following hemiarthroplasty, see Chapter 105.

**C. INTERTROCHANTERIC FRACTURES**

Half of all hip fractures are intertrochanteric. The mortality rates associated with these fractures varies from 10% to 30% within the first year of injury (9). One year after hip fracture, the life expectancy of the patient returns to the normal value for the age group. In general, there is a slightly greater mortality rate for intertrochanteric fractures than for intracapsular fractures; this is because of the advanced age of patients who suffer intertrochanteric fractures. Patients who are in nursing homes before the fracture have the highest mortality and mortality rate (30%) and are least likely to resume ambulation (71). In the socially independent population, most patients recover to their previous levels of functioning if complications do not occur.

Compared to patients with femoral neck fractures, patients with intertrochanteric fractures are significantly older, more likely to be limited to home ambulation, and more dependent in their activities of daily living; therefore, they tend to have an overall poorer prognosis (27-28).

**ANATOMY AND BIOMECHANICS**

Intertrochanteric fractures occur in the peritrochanteric area about the insertion site of the abductor musculature, a region with a very generous blood supply. Marked bleeding may result after fracture, so watch carefully for excessive blood loss. The nonunion and avascular necrosis rate in intertrochanteric fractures is less than 1% because of the ample blood supply in this region.

When a high-energy intertrochanteric fracture produces comminution, a large fragment of the posterosmedial wall of the femur, often including the lesser trochanter, splits free. This bony buttress is important to the stability in the intertrochanteric region; therefore, its comminution results in an unstable fracture.

To correctly apply sliding fixation devices for these fractures, it is essential to understand the mechanics of the devices and the forces that they must withstand. The magnitude and direction of the force exerted across the hip joint are dictated by body weight and the muscles acting on the hip. Pauwels (97) and others (46,69,96,110) showed that the forces acting on the hip in single-limb stance amount to about three times the body weight applied at an angle of 159° to the vertical plane. This same force acts on any hip fixation device placed across the fracture site.

A sliding device that has a screw-plate angle closest to this force vector allows optimal sliding of the hip screw and impaction of the fracture. The closer the nail-plate angle is to the resultant force across the hip, the more force is available to assist impaction (65) (Fig. 19.16). Devices of lower angles are subject to lower forces parallel to the sliding axis of the device and greater forces perpendicular to the axis; these perpendicular forces act to jam or bend the device, thereby preventing impaction. Technically, however, the surgeon cannot place the sliding device at an angle greater than 150°. It is desirable mechanically to place the sliding fixation device at as high an angle as clinically possible and still maintain placement of the fixation device in the center of the femoral head to prevent cutout. Fixation of the medial fragment, particularly if large, allows bony impaction and creates a stable osteosynthesis with less shortening. For this reason, in addition to bony impaction with a higher-angle device, interfragmentary fixation of a large medial fragment is desirable when possible.

![Figure 19.16](image1.png)

**Figure 19.16.** The ratio of available to resistive forces for the initiation of sliding, plotted against nail-plate angle (β), assuming a constant applied load (P) and constant offset (p), for the fracture shown in the inset.

![Figure 19.17](image2.png)

**Figure 19.17.** Failure rate versus nail position in Kyle type III fractures.
Den Hartog et al. (35), in addition to emphasizing the importance of central placement of the screw combined with a 150° angle plate, showed the importance of reestablishing bony contact between the femoral shaft and the main head and neck fragment medially. In their cadaveric study, they accomplished this with a limited osteotomy of the greater trochanter.

Although osteotomies were once very popular (37,114), more recent clinical experience with newer sliding hip screws has not demonstrated an advantage of osteotomy over anatomic reduction or use of a valgus reduction and high-angle nail to restore the medial buttress (39,54). Equally important, addition of an osteotomy has been found to increase operating time, blood loss, and contribute to excessive shortening and occasionally external rotation of the extremity. Introduction of the Medoff sliding plate, which achieves compression not only along the femoral neck but also along the longitudinal axis of the femoral shaft, has not shown improved results over traditional compression hip screws, and the added complexity of the device may add to longer operating times and increased blood loss (147).

At our institution, the most common mechanism of failure today is the head and neck fragment cutting off the hip screw, due to severely osteoporotic bone in the very elderly or in those with metabolic bone disease. Fatigue failure of sliding screws occurs but is rare (128). This observation has been echoed by others (155). Modi-fication of the traditional hip screw by replacement of the screw with a dome plunger (Alta, Stryker-Osteonics-Howmedica, Rutherford, NJ) uses the principle of an expandable molly bolt, which resists cutout by compressing the cancellous bone of the femoral head around the expandable dome, by providing a larger smooth surface area rather than sharp threads, and by providing a mechanism for delivery of bone cement that integrates the dome plunger with the cancellous bone of the femoral head. The dome plunger alone fails at a load 50% higher than that of stainless steel lag screws. Adding cement augmentation supports higher loads, and it eliminates failure by cutout through the femoral head (21) (Fig. 19.18). Intramedullary fixation devices, which combine a hip screw with either a short or long intramedullary nail such as the Gamma nail (Stryker-Osteonics-Howmedica, Rutherford, NJ), have the theoretical advantages of percutaneous insertion, a lower bending moment on the fixation device, and an intramedullary buttress that precludes excessive medial migration of the shaft. Biomechanical comparison of intramedullary devices to sliding hip screw devices have not demonstrated any distinct advantage of one system over the other; however, the intramedullary devices transmit progressively decreasing loads to the proximal femur with increased instability of the fracture, and failure of the intramedullary devices occurred through the distal cross-locking holes when short-stemmed devices were used (87,339).

![Figure 19.18. A: The Alta dome plunger (Howmedica, Rutherford, NJ) when implanted in the femoral head provides superior resistance to cutout in osteoporotic bone, compared to compression hip screws. B: Insertion of the plunger into the dome expands it like a molly bolt. C: Polymethylmethacrylate cement can be placed in the dome and when the plunger is driven home to expand the dome, the cement is extruded into the surrounding cancellous bone, as illustrated here, resulting in superior fixation in osteoporotic bone. D: AP radiograph of a dome-plunger in a femoral head.](image)

The primary principle in the treatment of intertrochanteric hip fractures is to reestablish the continuity of bone between the head and neck fragment and the shaft and to place the fixation device central in the femoral head. This will allow the bone to carry the majority of the load transmitted across the hip (46), minimizing the risk for failure, and allowing frail patients to be mobilized early with sufficient weight bearing so that they can gain a reasonable degree of independence.

**HISTORY OF TREATMENT**

The treatment of intertrochanteric fractures has advanced greatly in the last three decades. In the early 1900s, patients suffering intertrochanteric fractures were simply placed in traction in bed for prolonged periods of time until healing, or more commonly until death. In the 1930s, Smith-Peterson (126) introduced his nail, which allowed immediate fixation and earlier mobilization. Unstable fractures remained a problem, so in the mid 1960s, various osteotomies were advocated by Dimon and Hughston (37) and Sarmiento (113,114) that used rigid fixation devices to create a stable fracture from an unstable configuration. Unfortunately, both of these procedures have been associated with increased morbidity and mortality due to the increased surgery, and postoperative shortening was not well accepted by patients. During this same period, Clawson (22) and Massie (89) introduced sliding devices that allowed impaction of fracture fragments. These devices have led to superior results in the treatment of intertrochanteric fractures.

Intramedullary devices were introduced in the 1970s in the form of the Ender nail (113,39) and the condylocephalic nail (60) for fixation of intertrochanteric fractures. These devices are placed retrograde from entry sites near the knee using percutaneous technique under fluoroscopic control. Theoretical advantages include the decreased bending moment on the device as previously described for the Gamma nail; elastic fixation, which was proposed to aid fracture healing; and percutaneous technique, which hastened fracture union by preserving the blood supply to the fracture and decreased operating time and blood loss. In spite of early reports of high rates of success, later series showed a high incidence of varus deformity and knee pain caused by the distal migration of pins (121,130). This led to a high incidence of reoperation for pin tract irritation and correction of deformity, which was a problem in elderly patients. Shortening and external rotation were problems in many of those who otherwise healed uneventfully. This has led most authorities to recommend abandoning these devices for fixation of intertrochanteric fractures. However, some surgeons believe that there is still a place for Ender nails in the elderly debilitated patient who has a stable fracture and who can tolerate only minimal operative intervention. The details of the surgical technique described later in this chapter are critical. The most recent development has been the antegrade intramedullary devices such as the Gamma nail, which are very popular in central Europe but seem to have outcomes similar to sliding hip screws (8,128,83,144). These are discussed in more detail later in section D on second-generation interlocking nails.

**CLASSIFICATION**

A fracture classification system is of value only if it leads to better care of the fracture or permits a more accurate prognosis. In intertrochanteric fractures, the classification should allow the surgeon to predict the stability of the fracture because stability is the key to selection of treatment as well as prognosis. Intertrochanteric fractures can first be classified as stable or unstable. In the stable intertrochanteric fracture, the postero-medial buttress remains intact or is minimally comminuted, and therefore substantial collapse of the fracture fragments is unlikely. In the unstable intertrochanteric fracture, however, a large segment of the postero-medial wall is fractured free and comminuted, and therefore the fracture tends to collapse into varus.

The classification proposed by Evans (41,42) and Boyd and Griffin (15) is useful because it further divides stable fractures into those without comminution, those with minimal comminution, and those that are subtrochanteric. A modification of Boyd's classification is that of Kyle, Gustillo, and Premer (81), which recognizes four basic intertrochanteric fracture types. Type I fractures consist of nondisplaced stable intertrochanteric fractures without comminution (21%) (Fig. 19.19A). Type II fractures represent stable, minimally comminuted but displaced fractures (36%); these are fractures that, once reduced, allow a stable construct (Fig. 19.19B). Stable fractures are not a problem and hold up well with any type of fixation device. The unstable type III intertrochanteric fracture (26%) is a problem fracture and has a large postero-medial comminuted area (Fig. 19.19C). The unstable type IV fracture is uncommon (15%) and consists of an intertrochanteric fracture with a subtrochanteric component (Fig. 19.19D). This is the most difficult type of fracture to fix because of the great forces imposed by muscle forces and weight bearing on the subtrochanteric region of the femur (81,160).
SURGICAL TECHNIQUES

SLIDING HIP SCREW TECHNIQUE

- Place the patient supine on an orthopaedic fracture table after administration of a general or regional anesthetic. Place the unaffected leg into gentle traction to stabilize the pelvis on the peroneal post, and abduct the hip 45° to provide access for the C-arm fluoroscope.

- Apply gentle traction to the affected leg and use image intensification to discern the fracture elements.
- Reduce the fracture with traction in line with the body and enough internal rotation to place the femoral neck parallel to the floor on the lateral view. Confirm reduction on the AP and lateral views with image intensification.
- Type I fractures are undisplaced, so they do not require a reduction maneuver and simply need to be placed in the appropriate position for pinning, as previously described.
- Type II fractures require somewhat more vigorous traction and internal rotation to close the fracture. Internally rotating the hip to bring the femoral neck parallel to the floor usually suffices. This helps to orient the surgeon to the placement of the guide pin on the lateral view. Sometimes slight valgus in these fractures produces a more stable position, particularly if there is some medial comminution.
- Type III and type IV unstable fractures require more vigorous traction and should be reduced in valgus of 140° to 150° because this is more likely to result in good bone contact medially. The valgus will compensate for the shortening that may be necessary to gain good bone contact medially, and it will reduce the bending moment on the fracture site.
- If traction alone does not reduce the fracture, then abduction to obtain the appropriate position on the AP view may be necessary. On the lateral view, gravity often causes the fracture to sag posteriorly, producing excessive anterior angulation of the head and neck fragment. This may be difficult to manage but can often be corrected by supporting the trochanteric region with a crutch placed under the proximal femur or greater trochanter, as illustrated.

- Prepare and drape the hip in the usual manner. Make an incision over the lateral aspect of the thigh, beginning at the flare of the greater trochanter and extending 12–15 cm distally. Carry dissection down through the skin and subcutaneous tissue to the fascia lata. Split the fascia lata along its posterior extent, trying to avoid the muscle belly of the tensor fascia lata. This exposes the vastus lateralis. Retract the vastus lateralis superiorly with a rake and split it longitudinally if it is thin, or reflect it anteriorly from the lateral intermuscular septum and subperiosteally off the lateral aspect of the femoral shaft. Detach the origin as necessary. Retract the vastus lateralis and fascia lata anteriorly with a Bennett retractor.
- Under fluoroscopic control, place a guide pin along the anterior aspect of the femoral head on the AP radiograph, and parallel to the inferior femoral neck. This helps to locate the site for the hole drilled in the lateral aspect of the shaft.

- Using a drill slightly larger than the size of the selected guide pin, perforate the lateral aspect of the femoral shaft at the appropriate level as dictated by the guide pin. If the femoral head and neck lie posterior on the lateral view, start the drill hole slightly anterior; if they are anterior, start the drill hole slightly posterior.
Prior to insertion of the guide pin, be certain that the fracture is well reduced on both the AP and lateral views. If the fracture is sagging posteriorly, adjust the crutch (if it is being used), or place a bone hook on the posterior aspect of the fracture and lift the fracture to reduce the posterior sag and to place the femoral neck in line with the shaft or in slight anteversion.

Now insert the guide pin specified by the manufacturer for the type of sliding hip screw being used. In most systems, side plates with angles from 130° to 150° at 5° increments are available. If this is the case, some surgeons prefer to insert the guide pin freehand, without using an angle guide, placing the guide pin as close to the medial cortex of the neck of the femur as will accommodate the hip screw, and ending up with the tip of the guide pin in the dead center of the femoral head on both AP and lateral views. Once satisfactory position of the guide pin has been obtained, they use the angle-measuring device provided by the manufacturer to select the side plate angle that is closest to the pin they have inserted. This technique can lead to a maximum error on the AP view of 2.5°, which is usually tolerable. I prefer to insert the guide pin through a guide set at the desired angle, so that more precision can be gained in the placement of the hip screw, which reduces the risk of displacing the fracture (Fig. 19.23). In young, dense bone, the guide pin may need to be drilled, but in the average elderly patient it can be driven with a mallet. The tip of the hip screws should not lie closer than 7 mm to the subchondral bone of the femoral head. This needs to be taken into account, depending on the particular instrumentation being used.

**Figure 19.23.** Use a guide to establish the angle of the guide pin in the femoral neck. Insert the guide pin through the guide using a drill or mallet, placing it dead center in the femoral head. On the AP views, some surgeons prefer to have the guide pin somewhat inferior to the midline of the head.

Determine the length of screw to be used by measuring the amount of the guide pin that is inside the proximal femur and the head and neck fragments (Fig. 19.24). Once the length has been measured, it is advisable in most systems to drive the guide pin up to subchondral bone so that the guide pin is not accidentally removed when the channel for the hip screw is reamed.

**Figure 19.24.** Use a depth gauge to determine the length of the hip screw. Plan to place the screw no closer than 7 mm from the subchondral bone of the head.

Then place a step drill over the guide pin and ream a hole in the lateral aspect of the femoral shaft to the appropriate depth. Depending on the device used, place a tap over the guide pin and advance it across the fracture site into the neck and head fragment to the level of the desired position of the screw (Fig. 19.25).

**Figure 19.25.** Place a tap over the guide pin and tap the dense cancellous bone of the femoral head. In osteoporotic bone, tapping is usually not necessary or advisable.

Place the screw or nail over the guide pin and insert it to the proper level under image intensification (Fig. 19.26).

**Figure 19.26.** In most systems, the sliding hip screw and side plate can be preassembled and the hip screw then screwed into place over the guide pin.

After seating the screw, insert the plate, ensuring that it is parallel to the femoral shaft and lies snugly against it. A fixed nail-plate angle device that does not lie parallel to the shaft after the screw has been inserted may cause a subtrochanteric fracture if forced down on the shaft. If an inappropriate angle has been selected, so that the plate diverges by more than 5° from the shaft, select a plate with the proper nail-plate angle.

Fix the plate to the lateral aspect of the shaft with three or four bicortical bone screws (Fig. 19.27). Secure medial fragments with screw technique or a circlage cable, if possible. This is possible in most current designs by the oval-shaped hole in the side plate. Use image intensification during the final seating of the screw to ensure that it is well located in the femoral head and within 7 mm of subchondral bone.
Fit the plate snugly against the femoral shaft and secure it with at least three bicortical screws. The sliding between the hip screw and the side plate now allows impaction of the fragments to a stable position. Release traction from the affected hip and grasp the patient at the knee through the sterile drapes to ensure that traction is released and that impaction can occur. Accomplish impaction by a direct blow on the plate with an impactor. Then insert a compression screw, if available, to secure the position. Obtaining impaction with the compression screw alone is usually not advisable because in weak bone the screw can be pulled out of the femoral head (Fig. 19.28).

Release the traction on the foot and impact the fracture using the impaction device.

Last, rotate the hip through its full range of motion under fluoroscopic visualization to ensure that the nail is within the confines of the femoral head and the fracture is stable. Thoroughly irrigate the wound, ensure hemostasis, place a suction drain, close the wound in layers, and apply a sterile compressive dressing.

See the AP and lateral radiographs of Figure 19.29 for a typical case.

The patient may sit within a few hours of surgery or the day after surgery, as dictated by comfort. As soon as practical, begin ambulation with aids, allowing weight bearing on the injured extremity as tolerated if solid fixation of a stable reduction has been obtained. Progress weight bearing as tolerated. Take radiographs at weekly intervals for the first 2 weeks to ensure proper impaction of the fragments and function of the sliding device. If there is a subtrochanteric component to the fracture, or the bone quality or reduction is marginal, delay weight bearing until callus is seen on radiographs.

OPEN TECHNIQUE ON A REGULAR TABLE

Comminuted four-part intersubtrochanteric fractures can be very difficult to internally fix on a fracture table. I prefer to place these patients in a lateral decubitus position on a regular operating table and expose the base of the neck as well as the shaft with a limited Watson-Jones exposure.

- Visualize the femoral head and fracture with a C-arm fluoroscope placed in the AP position over the top of the patient. The C-arm of the fluoroscope must be sterilely draped. It can be rotated up over the torso out of the way when it is not needed and then swiveled into the AP position on the hip when used.
- Expose the fracture with a limited Watson-Jones exposure. In this type of fracture, the greater trochanter is fractured and free of the shaft fragment; therefore, the trochanteric fragment and the shaft can be pushed posteriorly out of the way to expose the base of the head and neck fragment. This needs to be exposed only enough to have good visualization of the base of the neck, and a good feeling for the axis of the neck anteriorly.
- Insert a guide pin into the inferior half of the base of the neck parallel to the medial neck under fluoroscopic control to place the guide pin dead center in the middle of the femoral head on both the AP and lateral views. Obtain fluoroscopic visualization of the head and neck fragment by manipulating this fragment alone, rather than by moving the extremity or the C-arm. With a T-handle on the guide pin and a sharp pointed tenaculum grasping the base of the femoral neck, rotate it to obtain perfect AP and lateral views. Then ream the channel for the hip screw and insert the hip screw under direct fluoroscopic control. Judge the proper length screw by measuring the guide pin in the head and neck fragment and adding to it the width of the femoral shaft at the level of the hip screw.

HINTS AND TRICKS
If patients are thin and lightly muscled, a direct split of the vastus lateralis is easiest and quickest. In younger, heavily muscled patients, or in comminuted fractures where extension of the approach into a Watson-Jones exposure may be necessary, release the vastus lateralis from the anterior and lateral aspects of its origin, elevate it off the lateral intermuscular septum, and reflect it anteriorly as a single unit. This provides a clean exposure for management of comminuted fragments in the subtrochanteric area, facilitates a Watson-Jones exposure, and allows identification of the proximal arterial perforators for control of bleeding.

Many different types of hip screws and instrumentation systems are available. Most of these offer various guiderails and mechanisms for setting the depth of the reamers, for example. Do not rely solely on these mechanical devices, but visualize the insertion of tools and implants on fluoroscopy at all times. Use of the step image minimizes radiation exposure of the patient and surgeon.

If the patient is being treated supine on a fracture table, and reduction of the fracture is difficult or maintenance of the reduction is challenging, do not hesitate to extend the exposure somewhat proximally in the manner of Watson-Jones to gain exposure of the base of the femoral head and neck fragment, because this greatly facilitates reduction.

Most stable fracture patterns can be done through a relatively small incision. Three bicortical screws in the plate are nearly always sufficient. The plate can be slid subperiosteally beneath the vastus lateralis and the screws inserted through a stab wound in the muscle, which minimizes soft-tissue dissection. Where longer plates are needed, the modular Alfa system (Howmedica, Rutherford, NJ) facilitates this minimally invasive technique.

Controlled implantation of the fracture on the table under fluoroscopic control produces immediate stability of the fracture in most hips. Careful examination under fluoroscopy will, in most cases, demonstrate sufficient stability in the fracture site to confidently allow early weight bearing.

During rehabilitation, even though you are allowing early weight bearing, always have the patient use an assistive device. In the elderly, walkers are usually the best—not so much for protection of the fracture, but to prevent the patient from having another fall and sustaining additional injuries.

Postoperatively, keep these very unstable fractures on limited weight bearing to the weight of the leg until bridging callus is seen on radiographs.

The advantages of this technique are that the set-up time is much quicker because a fracture table is not involved; the effect of gravity, which causes the fracture to sag, is diminished much more than that produced by the effect of the spinal segmental lordosis. Surgeons plus the muscle fibers of the gluteus maximus and medius.

Insert a guide pin into the tip of the trochanter and open it with a reamer.

Then insert a ball-tip guide pin across the fracture into the shaft of the femur, and use flexible reamers to ream the intramedullary canal 2–3 mm larger in diameter than the Gamma nail to be inserted. The proximal femur down to the lesser trochanter must bereamed to at least 17 mm in diameter to accommodate the nail. Remove the guide pin.

Assemble the appropriate-size Gamma nail on the driver, selecting the valgus angle most suitable for the fracture. More comminuted fractures can be nailed in a more valgus. Available angles are 125°, 130°, and 135°. The nail is 17 mm in diameter proximally and 11 mm in the shaft portion. Ten degrees of anteverision is built into the nail. When the reduction is done, if the femoral neck is placed parallel to the floor, then the nail can be inserted in a neutral position, which facilitates proper placement.

Under fluoroscopic control, locate the entry site for the hip screw and make a 2.5 cm longitudinal incision in the skin, over the lateral aspect of the hip, at the appropriate point. Carry dissection sharply down through the deep fascia and vastus lateralis, and expose sufficient lateral femur just below the greater trochanter in a subperiosteal manner. Assemble the targeting jig on the nail. Insert the appropriate guide sleeve (tissue protector) down to bone, make a starting point with the awl, and insert a guide pin under fluoroscopic control. Make certain that the guide pin on the AP view is at or inferior to the midline of the neck, and that it is dead center on the lateral view, with the guide pin ending up dead center in the femoral head. Be certain that the angle of the targeting jig matches that of the nail.

Measure the length of the hip screw off the guide pin.

Now ream over the guide pin to the appropriate depth for the hip screw, and tap the hole if hard cancellous bone is present.

Then insert the appropriate-length hip screw to the appropriate depth, under fluoroscopic control; confirm that it is in appropriate position, and then release the traction and impact the fracture to ensure good bone contact and a stable position. Particularly in osteoporotic bone, it is essential that good medial bone contact occur.

Finally, place the set screw through the top of the nail to secure the position of the hip screw. Tighten it, and then loosen it one-quarter turn to permit sliding between the hip screw and the nail.

If the fracture is unstable and comminuted, and further resistance to shortening and additional rotational control is desired, distally cross-lock the nail, using the cross-locking guide for the short Gamma nail and the free-hand technique for the long Gamma nail.

After closure of the wounds and application of a sterile dressing, take AP and lateral radiographs on the fracture table to be certain that the fracture is well reduced and in stable position, and that the Gamma nail is in appropriate position (Fig. 19.30).

Ender Nail Technique

Ender's technique of fixing intertrochanteric hip fractures, which was extended to include shaft fractures using multiple solid elastic stainless steel nails, using a retrograde percutaneous approach, became popular in the 1970s (11,39). Although some surgeons still use Ender nailing as their primary means for fixing hip fractures, the technique is not used much in North America today. The nails offer little resistance to shortening in unstable fracture patterns, and fractures tend to externally rotate. Prominence of the nails at the knee may require a second operation to remove them. In addition, because the fixation is much less rigid than with a comparable hip screw, patients experience more pain postoperatively and do not rehabilitate as quickly. Ender nailing of the femur, tibia, and humerus, however, is a very useful technique that should be in the armamentarium of every surgeon treating these fractures, because in the femur there are certain situations for which the nail is ideal:

HINTS AND TRICKS

- Use it for internal fixation of fractures in the proximal femur when the condition of the skin about the hip precludes a surgical approach at the hip.
- Use it for severely ill patients with stable fracture patterns, in whom percutaneous technique with minimal soft-tissue dissection offers the advantages of rapidity and minimal blood loss.
- Use it for patients with hip fractures in severely osteoporotic bone, in whom a medullary device is preferred because of the risk of a pathologic fracture at the site of the plate and a hip screw. Exercise caution with Ender nails, because supracaudal fractures can occur through the distal entry holes.
- Use it for fractures in children and adolescents with open physes, where internal fixation is required but larger intramedullary devices would threaten the growth plates or blood supply to the femoral neck. Ender nails are currently the device of choice for older children with femoral shaft fractures accompanied by multiple injuries, who require intramedullary fixation of the femur (see Chapter 164).

The Ender nail technique for fixing intertrochanteric hip fractures is as follows:

- Place the patient supine on a fracture table in the same position as described for the sliding hip screw. In type I and II fractures, reduce the fracture anatomically. In type III and IV fractures, use a valgus reduction of up to 15° because this greatly facilitates insertion of the Ender nails. Because of the tendency of the nails to run straight rather than curve into the femoral head fragment as much as you might like, comminuted fractures are often easier to fix than more simple fracture patterns reduced anatomically. Ender advises placing the hip in more internal rotation than you would for a traditional hip screw to compensate for the tendency of the fractures to externally rotate as they compress into stable position. In unstable fracture patterns, the crutch beneath the greater trochanter is very useful in Ender nailing, because having a straight shot proximally into the femoral head and neck fragment from the medullary canal on both views greatly facilitates the nailing.
- Prepare and drape the knee circumferentially from the mid thigh to below the tibial tubercle.
- Because the primary entry site for the Ender pins is in the distal medial femur, stand between the legs with your assistant on the lateral side of the knee, and the operating nurse behind you. Locate the C-arm just above the affected hip on the lateral side, making certain that good-quality AP and lateral views can be obtained without moving the base of the C-arm.
- Make a longitudinal skin incision 7 cm long, beginning just distal to the medial epicondyle and extending proximalward. Split the deep fascia just anterior to the medial intermuscular septum, and use the vastus medialis anteriorly to expose the femur subperiosteally just above the superior medial geniculate artery. Identify and protect the superior medial geniculate artery because this is the landmark to the entry site for the pins. Laceration of this artery can lead to profuse bleeding. Ligate it if it is in the way or if significant bleeding occurs.
- Next, mark the entry hole for the nails (Fig. 19.31). The distal end of this hole should be 1 cm proximal to the medial geniculate artery. The hole needs to be at least 15 mm wide to accommodate two 4.5 mm Ender nails side by side, and it must have a length of 20–25 mm to accommodate at least three nails without causing enough pressure on the proximal end of the hole to lead to unexpected fracture of the entry hole or distal femur. Make an initial entry hole with a Steinmann pin or drill point, and follow this with a Küntscher awl. Use this to enter the cancellous bone of the metaphysis of the femur. Take care to not use it to open the harder cortical bone near the diaphysis, because this can lead to fracture of the cortex. Follow the awl with a small-angled rongeur and use this to develop an oval hole with a smooth contour. Use a nail as a reference to be certain that the hole is of adequate size. The longitudinal axis of this hole must be directly in line with the shaft of the femur, and it is better placed slightly more posterior than anterior, because the nails in a more anterior position are more likely to result in knee pain.

Figure 19.31. Entry site for retrograde Ender nailing of a hip fracture just proximal to the medial epicondyle. See text for full description.

- Use a Küntscher skin protector distally. Standard femoral nails are 4.5 mm in diameter, with lengths of 34 to 49 cm. Shorter nails of 4 mm diameter from 28 to 44 cm long are available for smaller people. Be certain that reduction of the hip fracture has been maintained. Determine the nail length by inserting a forceps into the distal end of the entrance hole as a landmark, and then placing the nail on the anterior aspect of the thigh with the tip directly over the femoral head. The nail length will be correct when the tip touches or is just slightly distal to the subchondral bone of the femoral head (use visualization on a fluorescent image) and the flange of the nail rests on the cortex immediately distal to the entry hole. The nail will bend as it is being inserted, shortening its effective working length and resulting in the tip of the nail lying approximately 5–7 mm below the subchondral bone of the femoral head. If the nail length is not quite correct after insertion, leave the nail in place and insert a second nail of appropriate length prior to withdrawing the first nail. Sometimes the first nail can be left in as a stacking nail (see later) if multiple nails are to be used to gain stability in a wide medullary canal.
- Nails are available with a C or an S curvature. For intertrochanteric fracture, use the C nails. In anatomic reductions, particularly when placing the first nail along the lateral aspect of the femoral neck, bending the tip of the nail to increase its curvature is helpful as long as the bend in the nail is not so much that it impedes the passage of the nail through the medullary canal. The tip of the nail has a smooth bevel that facilitates passage of the nail when it encounters a cortex. When passing the nails, think about driving the tip of the nail along the curvature of the femur, as you would drive a car down a winding highway. Insert the first nail by hand with the T-handled driver into the hole, matching the curvature of the nail to the curvature of the femur. Begin at an angle of approximately 45° to the longitudinal axis of the femur, and then reduce the angle to come in line with the femur as the nail progresses proximally. The nail passes smoothly across the fracture and into the medullary canal. The tip of the nail has a smooth bevel that facilitates passage of the nail when it encounters a cortex. When passing the nails, think about driving the tip of the nail along the curvature of the femur, as you would drive a car down a winding highway. Insert the first nail by hand with the T-handled driver into the hole, matching the curvature of the nail to the curvature of the femur. Begin at an angle of approximately 45° to the longitudinal axis of the femur, and then reduce the angle to come in line with the femur as the nail progresses proximally. The nail passes smoothly across the fracture and into the head and neck fragment if it is twisted to stay in the middle of the medullary canal until it reaches the level of the lesser trochanter. At the lesser trochanter twist the nail internally to place the maximum curvature along the medial aspect of the femoral neck. Insert this first nail just past the fracture site, being certain that it is firmly located in the proximal fragment, but do not insert it to its full depth until all of the nails are in place. Next, insert a second and third nail, making an effort to fan the nails in the femoral head on both the AP and lateral views (Fig. 19.33). Once all three nails are in the head and neck fragment, they can be sequentially driven as a group to within 5–7 mm of the subchondral bone of the head. Distally, the nails should lie flush with the medial cortex of the femur, above the epicondyle (Fig. 19.33).
The vast majority of inter- and subtrochanteric fractures can be treated with primary internal fixation. Indications for primary prosthetic replacement using a proximal femoral component are delayed until 12 or more weeks after surgery. In fracture patterns that are unstable or with a subtrochanteric component, full weight bearing is avoided until early callus is seen on radiographs, which is usually at about 6 weeks. At this time, progress weight bearing as tolerated until full weight bearing is achieved. In stable fracture patterns, this usually occurs within 1–2 or more weeks, but in unstable patterns, particularly those with a subtrochanteric component, full weight bearing is often delayed until 12 or more weeks after surgery.

**PRIMARY PROSTHETIC REPLACEMENT**

The vast majority of inter- and subtrochanteric fractures can be treated with primary internal fixation. Indications for primary prosthetic replacement using a proximal femoral component are delayed until 12 or more weeks after surgery. In unstable fracture patterns, particularly those with a subtrochanteric component, full weight bearing is avoided until early callus is seen on radiographs, which is usually at about 6 weeks. At this time, progress weight bearing as tolerated until full weight bearing is achieved. In stable fracture patterns, this usually occurs within 1–2 or more weeks, but in unstable patterns, particularly those with a subtrochanteric component, full weight bearing is often delayed until 12 or more weeks after surgery.
femoral replacement prosthesis would include the following:

- Peritrochanteric fractures in the presence of severe arthritis of the hip, especially if the hip is stiff
- Pathologic fractures in which the bone stock precludes internal fixation
- Unstable, severely comminuted fractures in the very elderly, whose bone is so osteoporotic that internal fixation, even with cement augmentation, is expected to fail

The last indication is controversial, but a prospective randomized study by the Stappaerts group (18,129) that compared compression hip screws to a Vandeputte endoprostheses in these fractures suggested that primary prosthetic replacement might have fewer early complications and satisfactory functional results.

**PITFALLS AND COMPLICATIONS**

Complications of fixation of intertrochanteric fractures are minimal compared with other hip fractures if the surgeon uses the appropriate device and pays close attention to the mechanical principles involved. The overall failure rate using a sliding hip screw or nail of newer alloys should not exceed 10%. Nail breakage is extremely rare with use of current high-technology metals. The infection rate in intertrochanteric fractures should not exceed 1% to 2% with the use of prophylactic antibiotics. Acute infection usually responds well to irrigation and debridement, possibly implantation of antibiotic-impregnated beads, and intravenous antibiotics if the fracture construct is stable. Avascular necrosis is extremely rare in intertrochanteric fractures and has not been reported to occur in more than 1% of patients in any series (122). If nonunion does occur, the success rate after removal of the device and reaming in a more valgus position is 90%; for this reason, repeated fixation is recommended.

Failure with Gamma nails is usually caused by a varus reduction with a too-superior placement of the nail, which results in the head and neck fragment cutting off the hip screw. This can usually be salvaged by rereduction and nailing in a valgus position, either with a new Gamma nail or with conversion to a compression hip screw. The other complication in Gamma nails is fracture of the femur at the tip of a short Gamma nail. This is best treated by conversion to a long Gamma nail. Failure in Ender nails is usually caused by a varus reduction, persistent instability, and failure to fill the canal with nails, which results in back-out of the nails and collapse at the fracture site. This can often be corrected by rereducing the fracture, reinserting the same nails using proper technique, and adding nails to produce stability. Supracondylar fracture at the entry hole can be managed by circlage wiring in many cases. Instability and displacement, however, may require conversion to a condylofemoral interlocking nail or plate fixation distally.

**D. SUBTROCHANTERIC FEMUR FRACTURES**

The subtrochanteric area of the femur has been defined as the region between the lesser trochanter and the junction of the proximal and middle third of the femur. Although fractures in this area affect all age groups, there are two peak ages of incidence. The first occurs during late adolescence and early adulthood, when high-energy trauma from motor-vehicle and motorcycle accidents causes displaced or comminuted fractures (1). With these mechanisms of injury, severe injuries to other organ systems are frequent. The other age group of increased incidence is the geriatric population, for whom minor slips and falls are common, often resulting in subtrochanteric fractures. Metastasis from tumors (e.g., lung and breast cancer) often cause pathologic subtrochanteric fractures through compromised bone stock.

These troublesome injuries combine many of the least desirable features of intertrochanteric and femoral shaft fractures. If they are comminuted, stable internal fixation may be difficult to achieve with plates and screws. Moreover, the predominantly cortical nature of the subtrochanteric region prolongs healing times (120). For even the experienced traumatologist, subtrochanteric fractures may present formidable problems in management (120).

**BIOMECHANICS**

The subtrochanteric region is an area of high stress concentration (4,20,43,44,73,115,138,146). The proximal end of the femur has been likened to a cantilevered arch that transfers the force of weight bearing from the lower extremity to the hip and pelvis. Vertical loading forces on the femoral head generate a large moment arm in the proximal femur, concentrating compressive forces medially and tension forces laterally. When comminution, bone loss, or tumors create deficiencies in the medial cortex, the delicate balance of forces is altered, leading to deformity.

If the medial cortex can be reconstituted at the time of surgery, a plate placed laterally acts as a tension band, allowing impaction with protected weight bearing. If the medial cortical contact is not restored, bending stresses are concentrated in one small area of the plate, which often results in mechanical failure of the internal fixation device with delayed union, nonunion, or malunion of the fracture (143). Until recently, restoration of the continuity of the medial cortical of the proximal femur has been the key to success. However, the superior strength and mechanics of locked intramedullary nails combined with closed nailing techniques have eliminated the mandate to reconstitute the medial cortex at the time of surgery (13,17,152). The major advantage of intramedullary fixation is that it allows the bone to carry a substantial portion of the load, which significantly reduces the risk of implant failure while preserving the blood supply to bone when a percutaneous technique is used, which hastens healing.

Ever since the introduction of locked intramedullary nails in the 1980s, the indications for closed nailing of subtrochanteric fractures have dramatically expanded. Locking the nail into good-quality bone above and below the fracture site produces immediate fracture stability. Patients can be mobilized shortly after surgery without fear of loss of length or malrotation. The load-sharing intramedullary nail lies within the weight-bearing axis of the leg and is better suited to resist torsional and bending forces than a plate and screws.

**CLASSIFICATION**

There is no universally accepted method of classification for subtrochanteric femur fractures. In 1949, Boyd and Griffin (15) classified trochanteric fractures of the hip into four types. In their classification, type III injuries were pure subtrochanteric fractures, and the type IV fractures were combined intertrochanteric–subtrochanteric fractures. Fielding and Magliato (15) classified trochanteric fractures of the hip into three basic types and ten subtypes, based on their radiographic appearance (Fig. 19.36).

In 1978, Seinsheimer (116) developed a classification for subtrochanteric fractures that allowed the surgeon to analyze results based on a specific fracture group or subtype (Fig. 19.36). The II A subtrochanteric fracture was associated with a poor outcome in eight of nine patients treated with internal fixation in his series. In what is probably the most widely used classification of subtrochanteric fractures, the Association for the Study of Internal Fixation (AO-ASIF) group (81) divides these injuries into three basic types and ten subtypes, based on their radiographic appearance (Fig. 19.36).
Classifications that influence treatment or prognosis are the most useful. Unfortunately, anatomic fracture classifications fail to address associated conditions commonly seen with subtrochanteric femur fractures, although they often influence treatment or outcome. The factors that play a dynamic role in fracture management have been termed the personality of the fracture. Among these are the amount of fracture displacement, the extent of soft-tissue injury, the presence or absence of open wounds, associated neurovascular injuries, the degree of osteoporosis, multiple trauma, and complex ipsilateral injuries (e.g., ipsilateral femoral neck or segmental fractures). A large number of fracture patterns are seen in clinical practice, and some do not fit neatly into any classification scheme. This emphasizes the fact that every case must be individually evaluated and that the “personality” of the fracture must be considered in selecting the method of treatment.

NONOPERATIVE TREATMENT

During the past 30 years, there has been nearly a complete elimination of nonoperative treatment in adults and a corresponding increase in operative treatment of subtrochanteric fractures. A thorough understanding of the anatomy and biomechanics of the subtrochanteric region is essential if nonoperative treatment is to be used. Powerful hip and thigh muscles lead to significant deformities after fracture. The iliopectas and hip abductors cause flexion, abduction, and external rotation of the proximal fragment, and the strong pull of the adductors produces shortening and varus of the distal fragment. Skeletal traction followed by a spica cast or a cast brace 4–6 weeks later is still the method of choice for most fractures in childhood and early adolescence.

Skeletal traction is occasionally indicated in adults with subtrochanteric fractures with extreme fracture comminution. Lack of appropriate implants and surgical inexperience make operative intervention hazardous (34). Although this method of treatment eliminates many operative complications, such as anesthetic methods complications, blood loss, and infection, it is not without its own complications. In adults, prolonged costly hospitalization is necessary, and acceptable alignment may be difficult to achieve despite frequent adjustments of the traction. Knee stiffness and varus malunion remain common problems after skeletal traction. Furthermore, traction treatment is usually contraindicated in the multiply injured or elderly patient.

In adults, skeletal traction for 8–12 weeks followed by a hip spica cast is invariably required. Traction modalities depend on the patient’s body habitus and the radiographic fracture pattern. For some patients, a Thomas splint and Pearson knee attachment can be effective. In other patients, alignment is better maintained with a modified form of Russell’s traction using a proximal tibial pin. If the hip must be flexed more than 45° or if significant external rotation is required to achieve alignment, a distal femoral pin with 90°–90° traction may be more practical (Fig. 19.37). Approximately 30–40 lbs (14–18 kg) of traction is required to reduce the fracture in adults. After length and alignment are restored, the weight can usually be decreased (see Chapter 10).

INDICATIONS FOR SURGERY

Internal fixation of displaced subtrochanteric femur fractures has gained widespread acceptance as surgical techniques and implants have improved over the past 40 years. The combination of properly engineered implants, a better understanding of soft-tissue handling, perioperative antibiotics, and improved anesthetic methods have made internal fixation safe and effective (111). The goals of surgical treatment of subtrochanteric femur fractures are anatomic alignment, stable internal fixation, rapid mobilization of the patient, and early functional rehabilitation of the limb. However, it is important to remember that internal fixation of subtrochanteric fractures is difficult.

The surgical techniques remain complex, and it is essential to have complete sets of instruments and implants, and experienced surgical, nursing, and physiotherapy staff. If these criteria are met, the following may be considered indications for surgery:

- Displaced subtrochanteric fractures in adults
- Fractures in multiply injured patients
- Most open fractures
- Associated vascular injuries requiring repair
- Severe ipsilateral limb injuries
- Unacceptable alignment after attempted closed treatment
- Pathologic fractures
- Certain fractures around a hip prosthesis
There are no absolute contraindications to surgical stabilization, but there are several relative contraindications to internal fixation:

- Active infection
- Severely contaminated high-energy open fractures (grade IIIB)
- Massive comminution or bone loss
- Severe osteopenia
- Fractures in hemodynamically unstable, multiply injured patients
- Unavailability of adequate implants
- Unavailability of experienced surgeons

In isolated closed subtrochanteric femur fractures that require surgery, perform internal fixation as soon as practical, and within the first 48 hours if possible. If surgery is delayed at all, place the patient in skeletal traction. Stabilize closed fractures in patients with multiple injuries during or at the conclusion of the thoracic, abdominal, vascular, or neurosurgical procedures, if possible.

DEVICES AND TECHNIQUES

There are two major types of internal fixation devices widely used in the management of subtrochanteric femur fractures: locking intramedullary nails and plates. Because the spectrum of injuries to the subtrochanteric region is so great, no single implant can be suitable for every case. Careful assessment of the patient and a critical review of the radiographs and the personality of the fracture are essential.

REAMED INTRAMEDULLARY NAILS

Conventional reamed intramedullary nailing of subtrochanteric fractures with Küntscher-type nails does not provide reliable fixation of the proximal part of the femur because of its wide medullary canal. Their use is restricted to transverse or short oblique fractures without comminution. Even with these simple fracture patterns, shortening, malrotation, or nail back-out often leads to unacceptable results. In comminuted fractures, supplemental fixation with cerclage wires or unicortical plates has frequently been necessary. The major advantage of intramedullary fixation is that it allows the bone to carry a substantial portion of the load. This significantly reduces the risk of implant failure. Additionally, fixation can be done using closed nailing techniques, minimizing soft-tissue disruption at the fracture site with better preservation of periosteal blood supply.

First-Generation Interlocking Nails

Since the introduction of locked medullary nails in the early 1980s, the indications for closed nailing of proximal femoral fractures has expanded (17,152). All closed adult subtrochanteric fractures below the level of the lesser trochanter can be safely nailed with a first-generation nail, regardless of the fracture pattern or degree of comminution (Fig. 19.38). Nails with transverse proximal locking, such as the Alta nail (Howmedica, Rutherford, NJ), can be used for fractures at or above the lesser trochanter (Fig. 19.39). Closed locked intramedullary nailing is the current treatment of choice in adults for all acute nonpathologic subtrochanteric femur fractures that require operative stabilization.

![Figure 19.38. A: A comminuted subtrochanteric femur fracture in a 23-year-old man was the result of a motorcycle accident. B: Length and alignment were restored after static locked intramedullary nailing. C: At 6 months, the fracture is healed.](image1)

![Figure 19.39. A: AP radiograph of a subtrochanteric fracture. B: Radiograph after fixation with a standard Alta intramedullary nail with static proximal and distal cross-locking. Note the location of the proximal transverse cross-locking screws in the femoral neck.](image2)

Two types of interlocking nailing—static or dynamic—can be performed, depending on the fracture location and configuration. In static locking, screws are inserted in the proximal and distal fragments. Rotational stresses are minimized, and shortening at the fracture site is prevented. With dynamic nailing of subtrochanteric fractures, a proximal screw is inserted. Rotational movement is neutralized, but shortening of the fracture site is not always prevented. Because of the small proximal fragment in subtrochanteric fractures, always lock subtrochanteric fractures proximally.

Distal locking is strongly advised in Winquist-Hansen (see Chapter 20) comminution types II, III, and IV and in long spiral fractures. If any doubt exists about the stability of fixation after nailing, the nail should be statically locked. Locking the nail into the bone above and below the fracture site produces immediate fracture stability. Distal locking adds little to the procedure, so I now statically lock all nails. Patients can then be mobilized shortly after surgery without fear of malrotation or loss of length. Closed locked femoral nailing can now be performed routinely in the vast majority of patients who previously would have required open reduction and internal fixation or prolonged traction. Early mobilization should reduce postoperative medical complications, maintain joint motion, and decrease hospital stay (Fig. 19.40).
The technique ofreamed locked intramedullary nailing of femur fractures is described in Chapter 11 and Chapter 20; therefore, only those features pertinent to subtrochanteric fractures are emphasized here.

Patients can be operated on using closed technique on a fracture table in the lateral decubitus or supine position, or open exposure of the fracture site can be done with the patient in the lateral decubitus position on a regular table. I prefer the lateral decubitus position on a regular table for most comminuted subtrochanteric fractures. Positioning on a fracture table in the lateral position is somewhat more difficult than in the supine position, but the fixation of the fracture is greatly facilitated because there is far superior access for the instrumentation, and reduction of the fracture is much simpler. The supine position is much more familiar to most surgeons and therefore is preferred by many. The flexed adducted position of the proximal fragment, however, makes reduction of the fracture difficult, and the patient's buttocks and thigh are frequently in the way of the instrumentation, particularly in heavily muscled or obese patients. I use the lateral position with open technique when speed is essential, or when the patient is already on a regular operating table because of general surgical procedures that have just been completed for multiple injuries. In addition, in intertrochanteric–subtrochanteric combinations, open technique makes obtaining a satisfactory reduction and solid fixation easier at the expense of a larger wound, more blood loss, and more threat to the blood supply of bone.

Particular issues in using closed technique, whether lateral or supine, are as follows:

- The proximal fragment is frequently quite flexed and externally rotated. This alignment is often difficult for the surgeon to ascertain. It is critical that the very best images on the C-arm be obtained, and this can be difficult in large patients. Because of the position of the proximal fragment, it is quite easy to place the starting point much too anterior and too medial on the femoral neck. When using first-generation nails, be certain that the starting point is directly over the intramedullary canal.
- Again, because of the flexed–adducted position of the proximal fragment, reaming of the proximal fragment may be eccentric and produce malposition when the nail is inserted. Avoid this by paying attention to the alignment of the proximal fragment. If satisfactory position cannot be maintained, make a small incision and insert a bone hook or bone-holding forceps to hold the proximal fragment in proper position. Sometimes the fracture must be opened.
- My custom is to distally cross-lock first, and then to use the driver on the nail to back-slap the nail to ensure optimal contact between the proximal fragment and the shaft, so that the femur can load-share when there is greater than 50% contact between the fragments.
- Nails such as the Grosse-Kempf (Howmedica, Rutherford, NJ), with an oblique proximal cross-locking screw, require an intact lesser trochanter to obtain adequate fixation in the proximal fragment. Nails that offer transverse cross-locking screws proximally, such as the Alta nail, can be positioned more proximally (the Alta nail is specifically designed to do this), and the cross-locking screws can be inserted into the medial femoral neck, which gives excellent fixation and does not threaten the mechanical integrity of the femoral neck or the blood supply to the femoral head (158) (Fig. 19.39).

Second-Generation Intramedullary Nails

The dramatic success of first-generation interlocked nails for complex subtrochanteric fractures expanded the indications for closed nailing of these difficult injuries. However, as the indications for nailing were extended to more proximal fractures, an increased incidence of implant and proximal screw failures were noticed in comminuted fracture patterns. Furthermore, most first-generation nails provided inadequate fixation if the fracture extended above the level of the lesser trochanter. These problems led to the development of a new generation of interlocked nails that provided better fixation by directing screws into the head of the femur, and that allowed distal interlocking (Fig. 19.41). These implants are called reconstruction or second-generation nails. They have an increased wall thickness proximally, stronger and larger proximal screws, and reliable proximal targeting devices.

The best indication for the use of a reconstruction or second-generation nail is a "high" subtrochanteric fracture, in which the lesser trochanter is fractured but the greater trochanteric mass remains intact (Fig. 19.42). With this fracture pattern, most conventional first-generation interlocked nails may not provide stable fixation. The use of a second-generation nail for a combined intertrochanteric–subtrochanteric fracture requires considerable surgical experience because these fractures are very difficult to fix (Fig. 19.43). If fracture comminution involves the greater trochanter or the region of piriformis fossa, reconstruction nailing is associated with an increased incidence of complications, particularly varus deformities and implant cutout. A Gamma nail might be a better alternative because it enters through the top of the trochanter (see previous section). In these complex fractures, treatment with a compression hip screw or an angled blade plate may be a better alternative. Although reconstruction or second-generation nailing remains an exciting new surgical technique, there are few published reports of treatment results.

Figure 19.40. A: Displaced subtrochanteric femur fracture of a 31-year-old woman who sustained multiple injuries in a motor-vehicle accident. B: Closed intramedullary interlocking nailing restored the length and alignment. No attempt was made to reduce the medial butterfly fragment. C: Follow-up at 14 months showed union of the fracture with incorporation of the butterfly fragment.

During the past decade into a method termed biological fixation. The aim of current fracture treatment is to achieve stable rather than rigid fixation with a minimum of

With a better understanding and appreciation of the role of the soft tissues and fracture repair, the methods and techniques of internal fixation have gradually evolved

French and Tornetta (47) analyzed the results in 45 Russell-Taylor type IB subtrochanteric fractures stabilized with a reconstruction nail. Their intraoperative complication rate was 13.5%, with the most frequent problem being varus malposition. The final outcomes, however, were excellent: 100% of the fractures healed at an average of 13.5 weeks. There were no implant failures and 96% of patients gained greater than 120° of knee motion.

Bose et al. (12) reported on their experience with the use of the Russell-Taylor reconstruction nail (Smith Nephew Richards, Memphis, TN) for five ipsilateral femoral neck and shaft fractures and six comminuted subtrochanteric fractures. All of the fractures united. Technical errors occurred in three patients, and three patients ended up with malalignment or shortening, demonstrating that this method of fixation is challenging.

Rodriguez-Alvarez et al. (107) reported their experience with 42 patients treated with the Gamma nail, of which 31 were subtrochanteric fractures. All 31 subtrochanteric fractures healed, but 16 patients had shortening that averaged 1.7 cm with a range of 1 to 4 cm. Six healed with varus deformity, and three of those also had external rotation deformity. Apparently, these authors did not cross-lock the nails distally. An acceptable reduction of the hip must be achieved and maintained during the insertion of the hip screw. In the vast majority of fractures, distally cross-locking is advisable to avoid the shortening and external rotation deformity encountered by Rodriguez-Alvarez et al. See Chapter 11 and in particular Chapter 20 for details on the surgical technique for these devices.

Zickel Nails

Zickel (156,157) provided the first major advance in the treatment of subtrochanteric fractures when he introduced his reinforced nail, which provided proximal cross-locking into the femoral head and neck in the early 1970s. His nail enjoyed its greatest success in the treatment of impending and acute pathologic fractures in the subtrochanteric area (15,35,112). The Zickel nail is no longer used, for the most part, because it does not provide distal cross-locking. Complete stabilization of the fracture requires additional fixation at the fracture site, and re fracture of the femur upon removal of the nail has been reported (10,94,139,164).

Ender Nails

Ender nails have been advised for the management of subtrochanteric fractures (73,96). As discussed in the previous section on intertrochanteric fractures, the Ender nail has particular advantages in unusual situations where the soft tissues around the hip preclude the use of any device that enters from around the hip and where a retrograde device inserted through the knee, such as the Endler nail, is particularly advantageous. As pointed out in the discussion on Ender nails in the intertrochanteric fractures section, the Ender nail does not offer enough stability in unstable subtrochanteric fractures to permit immediate mobilization of the patient. Either the fracture must be opened and supplementary fixation applied, or the patient must be protected in traction postoperatively. For that reason, Ender nails are rarely used now for the treatment of subtrochanteric fractures.

Postoperative Care after Nailing

After stable locked reamed intramedullary nailing, patients can be mobilized from bed to chair as soon as they can tolerate it, and can begin crutch ambulation. If the patient’s bone quality is good, the fracture is a stable pattern, and if there is at least 50% cortical contact between the proximal and distal fragments, then 50% weight bearing with crutches is usually possible immediately. Weight bearing can be progressed to full weight bearing once bridging callus is seen on both AP and lateral views. In unstable fractures, patients can bear weight to the weight of the leg, but they must not progress weight bearing until bridging callus is seen on two views. In nearly all patients, there is sufficient stability that knee and hip range-of-motion exercises can begin immediately. An aquatic therapy program and use of a stationary bicycle are useful for building range of motion and enhancing muscle strengthening while the fixation must be protected. Healing usually requires 12–24 weeks.

PLATES AND SCREWS

Modern concepts in the surgical management of subtrochanteric femur fractures using plates was developed by the AO-ASIF group (61). When internal fixation of subtrochanteric fractures was first promoted by this group, the technique aimed at anatomic reduction and stable fixation of all fragments. Primary bone healing was found to be possible if fracture gaps were closed and if rigid stabilization was achieved. However, in comminuted fractures for which extensive soft-tissue dissection was necessary to achieve anatomic reduction, the incidence of delayed union, nonunion, infection, and implant failure was significant (4) (Fig. 19.44). The favorable experience with interlocked nailing for comminuted subtrochanteric fractures gave the surgeon the opportunity to treat difficult fractures with much less soft-tissue dissection. It showed conclusively that anatomic alignment rather than anatomic reduction combined with stable fixation results in a high percentage of favorable fracture outcomes. However, interlocked nailing did not solve the dilemma of difficult intraarticular or epiphyseal-metaphyseal fractures. For these injuries, plate and screw osteosynthesis remains the treatment of choice (58,75,80).

soft-tissue dissection and implants. The goal is to preserve the blood supply to bone to enhance early callus formation.

A key component to this is detailed preoperative planning. Perform the surgery on paper or on the computer before going to the operating room. Executed properly, this surgical tactic shortens operative time, minimizes intraoperative decision making, and improves surgical results. In preoperative planning for a subtrochanteric femur fracture, take high-quality radiographs of the intact femur and the injured side. Using plastic templates, trace the fracture and its subsequent reduction, the type and size of implants, and the exact position of screws on tracing paper. Multiple drawings are frequently necessary to arrive at the optimal fixation construct with the least soft-tissue dissection. Careful preoperative planning ensures that the proper implants are available at the time of surgery (56,75,90). When subtrochanteric fractures are reduced open and fixed with plates, always consider autologous bone grafting.

The 95° Blade Plate

- Perform surgery on a standard operating table or a fracture table with planar image intensification (75). Make a standard lateral approach to the proximal femur (see Chapter 3). Take down the vastus lateralis from its origin at the base of the greater trochanter, and carefully detach it to expose only the lateral aspect of the proximal femur. Do not dissect the anterior and medial soft-tissue envelope. To protect the anterior and medial tissues, avoid using Bennet-, Cobra-, and Hohmann-type retractors.
- To achieve the desired position for the blade on the AO 95° blade plate on the AP view, enter in the region of the prominence of the greater trochanter. Be sure that the contour of the lateral plate matches that of the femur, with the blade traversing transversely into the center of the femoral neck, inferior to the midline of the neck. On the lateral view, the chisel should be absolutely dead midline. Because the corners of the chisel can accidentally penetrate the articular surface if the tip of the blade plate is placed too close to subchondral bone, always leave it a minimum of 1 cm from subchondral bone on any view. Prior to inserting the seating chisel, drive a 2 mm K-wire into the bone, visualizing it on the AP and lateral views, just superior to where the seating chisel will be placed and exactly parallel to the anticipated path.
- Either using the drill guide or free hand, use a 4.5 mm drill point to open up three drill holes in the lateral cortex, transverse to the long axis of the femur in the plane that the blade will sit. In hard young bone, removing about 5 mm of the inferior edge of this hole with a small osteotome at a 45° angle allows room for the bend of the blade plate to seat into the greater trochanter.
- Take the seating chisel (a tuning fork mallet can be slipped over it to provide additional rotational control) and drive it with the U-shape of the blade facing superiorly to match that of the blade on the plate blade. Confirm proper position on AP and lateral views with the fluoroscope.
- The length for the blade is measured directly from the seating chisel at the lateral cortex. Now insert the seating chisel into the proximal femur, matching the level determined in the preoperative drawings.
- In patients positioned on a regular operating table, a modified Watson-Jones approach (Chapter 3) and an anterior arthrotomy of the hip with visualization of the femoral head and neck help to guide the placement of the seating chisel. In patients positioned on a fracture table, exposure of the femoral head and neck is not necessary because the position of the seating chisel and blade can be determined solely with the aid of the image intensifier.
- Next, secure the side plate to the lateral side of the femur with bone-holding forceps. Reduce the subtrochanteric fracture to the plate by one of three techniques. One method uses the fracture table to restore length by longitudinal skeletal traction. A second technique to overcome significant shortening uses the femoral distractor (Fig. 19.45). Initial overdistraction often permits gentle teasing of comminuted fracture fragments into near-anatomic positions. A third method of reduction uses the articulating tension device as a distractor (Fig. 19.46). With the fracture temporarily overdistracted, the medial fragments often reduce spontaneously because of their soft-tissue attachments, or they may be reduced by gentle manipulation. Try not to manipulate fragments from the cortical surfaces to avoid soft-tissue stripping. Anatomic reduction is carried out whenever possible, but neither anatomic reduction nor restoration of the medial buttress is absolutely necessary when a biologic approach is employed.

Figure 19.45. Indirect reduction technique using a 95° angled blade plate and the femoral distractor.

Regardless of the reduction maneuver, after the comminuted fracture fragments are realigned axially, compress the fracture using the articulating tension device. The plate then acts as a lateral tension band, with compressive forces transmitted through the fractures and the restored medial cortex. If the medial comminuted fracture fragments are not keyed into place because of extensive comminution, they are considered a vascularized bone graft and left in situ. Supplemental bone graft is not required if the medial soft-tissue envelope has been respected. However, the plate should still be loaded to partially offset varus tendencies. Occasionally, supplemental interfragmentary screws outside the plate increase the stability of the fixation.

Always apply an autologous cancellous bone graft when the soft tissue has been stripped medially. Or, a bone graft can be inserted medially through the fracture before reduction and fixation of the fracture.

Compression Hip Screw

The sliding compression hip screw with a long side plate has been advocated by several orthopaedists for the treatment of subtrochanteric fractures (4,73,115,140,145). In the past, orthopaedic implant manufacturers warned against its use in subtrochanteric fractures, but newer devices with improved design and materials with higher fatigue strengths have overcome many of the obstacles to its use in the treatment of subtrochanteric fractures. The compression hip screw is more forgiving of imperfect insertion than the blade plate, allowing for sliding impaction of the fracture surfaces with slight medialization of the shaft. Secure fixation in the proximal and distal fragments allows controlled collapse with a decrease in the bending moment and resultant forces. This method of treatment is attractive in high subtrochanteric fractures and in those with proximal extension into the intertrochanteric region. These devices usually must be used in a keyed or locked mode to prevent rotation between the compression hip screw and the barrel of the side plate. A keyless system may lead to instability between the proximal and distal fragment with institution of hip flexion. In cases with medial comminution, place bone graft medially to hasten fracture union (14). This is usually necessary because, unlike the 95° blade plate technique, indirect reduction techniques are not as easily accomplished with a compression hip screw.

The 95° Dynamic Condylar Screw

The compression screw with a 95° sided blade was developed for the treatment of supracondylar and intercondylar fractures of the femur, and it has been adapted for use in the proximal femur. The dynamic condylar screw appears to be a reasonable alternative to the fixed angled plate for the surgeon who only occasionally uses this device (111). However, as with all laterally based plates, reconstruction of the medial calcar is important. Many orthopaedic surgeons suggest cancellous bone grafting if the medial cortex cannot be restored at the time of surgery (73,88).
In all plate devices, if the medial side of the fracture cannot be rendered stable, then consider double plate fixation to reduce the risk of fatigue fracture of the side plate. Use a smaller plate such as a 4.5 mm, four- to six-hole narrow plate placed anteriorly through a modified Watson-Jones exposure.

**Postoperative Care after Plate Osteosynthesis**

After internal fixation with a 95° blade plate, a 95° dynamic condructal screw, or a compression hip screw, mobilize patients as soon as their overall condition permits. If stable fixation has been achieved at the time of surgery, protected crutch ambulation can begin on the second or third postoperative day. Depending on the fracture pattern, the completeness of restoration of the medial cortex, protected weight bearing can usually begin at 4 to 6 weeks. This is gradually increased as clinical symptoms subside and radiographs show progressive fracture union. Do not allow full unrestricted weight bearing until at least 12 weeks, at which time callus should be seen bridging the fracture on two views. Failure to show progressive signs of radiographic union 4–6 months after internal fixation is cause for concern. Bone grafting, with or without revision of the internal fixation, should be considered to prevent delayed union, nonunion, or mechanical failure of the implant.

**EXTERNAL FIXATION**

External fixation is used infrequently in the management of subtrochanteric femur fractures. The most common indication for its use is severe open fractures, particularly grade IIIB injuries in multiply injured patients. Depending on the location of the wounds and the degree of fracture comminution, fixation into the iliac crest may be necessary. For most patients, the external fixator is a temporary device used for initial management of the fracture and soft tissues. After control of the soft tissues is achieved, delayed internal fixation can be done. Place fixator pins to avoid areas of planned surgical incisions and implant placement, if possible. The major advantages of external fixation are rapid application, minimal soft-tissue dissection, and the ability to maintain length, provide wound access, and mobilize the patient. Problems associated with its use include pin loosening and infection, loss of knee motion secondary to binding of the quadriceps mechanism, increased risk of delayed union and nonunion, and loss of reduction after its removal.

**OPEN FRACTURES**

Open fractures constitute approximately 3% to 5% of all subtrochanteric femur fractures, excluding gunshot wounds. The traumatic wound is usually anterior or lateral but may be located anywhere. As with all open fractures, thorough irrigation and debridement of the fracture and traumatic wounds remain the single most important step in the prevention of infection. Serial debridement may be necessary in many grade III open fractures. With few exceptions, the traumatic wound should be left open. If immediate internal fixation of the open fracture is performed, the surgical extensions can be closed, but the open fracture wounds should not be closed primarily. Although immediate internal fixation is done in most cases, it is not indicated for all fracture patterns. The risk-to-benefit ratio for the patient must be carefully assessed when contemplating primary internal fixation. Advantages of immediate internal fixation in open subtrochanteric fractures include ease of wound care, pain relief, and protection of the soft tissues of the patient and the uninjured extremity. The major disadvantage of immediate internal fixation is the increased risk of infection as a consequence of further soft-tissue dissection and interference with local blood supply.

In patients with grade I, II, or IIIA open subtrochanteric femur fractures, I favor definitive internal fixation after debridement of the wound. For all grade IIIB and IIC open subtrochanteric fractures depends on the circumstances. Some of these fractures may be more safely managed with external fixation or skeletal traction and delayed internal fixation. For less-experienced fracture surgeons, delayed internal fixation of all grades of open subtrochanteric fractures may be advisable. After irrigation and debridement of the wounds, the injured limb can be splinted or placed in skeletal traction. Subsequent surgery can be carefully planned with optimal operating room personnel.

Unfortunately, many open subtrochanteric fractures occur in patients with multiple injuries, and failure to stabilize the fracture early often leads to missed opportunities. Associated injuries and pulmonary problems may delay definitive fixation for days or weeks. This increases the technical difficulty of the procedure, contributes to patient morbidity, and compromises the full benefits of internal fixation.

**RESULTS**

The superiority of interlocking nails in the treatment of subtrochanteric fractures, compared to blade plates and the Zickel nail, was shown by Brien et al. (17) in a nonrandomized, nonconsecutive series. They had 21 patients in the Zickel nail group, 25 treated with blade plates, and 33 treated with the interlocking nail. Operating times were shorter and blood loss lowest with the interlocking nail. Combining the incidence of malunion, nonunion, and infection, the overall complication rate in the Zickel group was 57%; in blade plate patients, 36%; and in the nail patients, only 9%, with two malunions, one nonunion, and no infections.

**AUTHOR'S PERSPECTIVE**

For subtrochanteric fractures where the lesser trochanter is intact—and even for some where it is fractured but the head and neck and trochanters are one solid unit—I prefer to use a standard Alta titanium intermedullary nail that has two transverse cross-locking screws both proximally and distally. When this nail is seated with its top flush with the top of the femoral neck, the transverse locking screws are located just superior to and inferior to the lesser trochanter. Seating the nail more proximally to place it level with the tip of the trochanter places these two screws in the femoral neck, and seating it 1 cm proximal to the tip of the greater trochanter allows the most proximal position to be placed into the femoral head. Placement of the screws in the femoral neck eliminates the need to worry about the position of the screws relative to the axis of the femoral neck fragment, which is one of the more difficult technical aspects of placing reconstruction nails, whose screws must traverse up the femoral neck and into the femoral head. Whether these screws are in the posterior, medial, or anterior cortex is irrelevant because a solid hold is obtained in all of these positions, and none of these creates a significant stress riser in the femoral neck, or has ever been shown to interfere with the blood supply to the head (158).

When there is comminution extending into the trochanteric region, I prefer to do these fractures in the lateral-decubitus position on a regular operating table, under fluoroscopic control, utilizing an Alta CFX nail (Howmedica, Rutherford, NJ). When the trochanters are so comminuted that the head and neck fragment is totally free and the entry site for an intramedullary device is essentially destroyed, my implant of choice is usually a compression hip screw and occasionally a blade plate. When using this open technique, it is very difficult to preserve the anterior and medial soft-tissue attachments to the femur; therefore, I routinely do autologous bone grafting.

**PITFALLS AND COMPLICATIONS**

Most of the pitfalls and complications have been discussed in the text under the individual techniques. The most common complication of subtrochanteric fractures of the hip is early failure of fixation, with failure of the side plate when hip screws or 95° blade plates are utilized, and cutting of the femoral head and neck fragment off the hip screws when the bone is osteoporotic and there is inadequate medial stability. Because of the large muscle forces around the hip, which are encountered even with the simplest of day-to-day activities such as getting in and out of a chair, fatigue failure of appliances inadequately supported by a good reduction can occur fairly early. Although fracture reduction is under the control of the surgeon, comminution and poor bone quality can preclude adequate stability, so subtrochanteric fractures continue to be a problem. Whenever early failure occurs in a subtrochanteric fracture, infection should be looked for as well. Most early device failures can be treated by early reoperation, replacement with a smaller or stronger device, addition of additional fixation such as an anterior plate, and copious autologous bone grafting. Postoperatively, these patients must be very carefully protected until bone union occurs. They must be taught how to get on and off toilets and in and out of chairs, and how to walk to minimize the stress on their implants.

**DELAYED UNION AND NONUNION**

Delayed union and nonunion can also manifest itself as implant failure, but with intramedullary devices this is less common. Lack of any visible callus at the fracture site at 3 months after fracture is characteristic of delayed unions. The chances of these progressing to a nonunion are high; therefore, some surgeons feel that bone grafting at 12 weeks, if bridging callus is not seen, is indicated to prevent a nonunion. Nonunions in compression hip screws and blade plate devices at 6 months are usually best treated by conversion to an intramedullary implant combined with bone graft. Nonunion in intramedullary devices is uncommon and can often be treated with exchanged reamed intramedullary nails to a larger device, usually done by closed technique, but sometimes combined with bone graft with the addition of a unicortical plate. See Chapter 29 for more details.

**MALUNION**

Malunion is usually characterized by varus, shortening, and external rotation. Treatment of these complications is complex, usually requiring an osteotomy and repeat
INFECTION

Acute infection is usually evident within the first 4 postoperative weeks. Management depends on the severity of the infection and the organism involved. Acute staphylococcal and streptococcal infections without intramedullary involvement, regardless of the device used, usually respond to thorough irrigation and debridement of the wound, closure over antibiotic-impregnated beads, and treatment with appropriate bacteriocidal intravenous antibiotics. Most patients respond quickly, showing resolution of systemic and local signs of infection within a few days. The wound can be re开放ed again in 5–7 days for removal of the beads; closure over suction drainage or reinstallation of beads can be repeated as many times as is necessary to control the acute infection. Some type of antibiotic treatment for up to 6 weeks is usually required. In more benign infections, intravenous antibiotics followed by oral antibiotics suffice. See Chapter 132 and Chapter 135 for more details.

Chronic infection can be complex to treat if it is accompanied by nonunion with unstable implants. Chronic infection in the presence of bone union usually responds nicely to removal of the implant, debridement, and antibiotic therapy as already described. This complex topic is addressed in detail in Chapter 133 and Chapter 135.

A. FEMORAL-SHAFT FRACTURES

There are major physiologic reasons to avoid prolonged bed rest in fracture treatment. Immobilization is implicated in complications ranging from constipation and atelectasis to osteoporosis and pulmonary embolism, the last of which can cause death. For patients with multiple injuries, the complications of immobilization can lead to significantly increased morbidity and mortality (see Chapter 14). Fractures of the femoral shaft are of special significance because of the femur's size and proximal position in the lower extremity, necessitating long periods of bed rest with nonoperative treatment. This problem has stimulated two different approaches to treatment: the nonoperative approach of cast bracing, and operative treatment using intramedullary nails or plates.

Early techniques of open, retrograde (meaning insertion initially into the proximal fragment in a retrograde direction, as opposed to retrograde insertion through the knee, which is addressed later in this chapter) placement of medullary nails for stable, mid-shaft fractures had an unacceptable rate of infection. With the introduction of closed medullary nailing, infection became a rare problem, and early mobilization was possible with stable fracture patterns (18). With open reduction, adjunctive cerclage wiring was used in unstable and comminuted cases. Because the nail extended the full length of the femur, there was no stress riser effect. Devascularization of a significant portion of the inner wall of the femur occurs as a result of reaming, but this is rarely clinically significant (see Chapter 11). Because in most fractures the nail functions as a load-sharing device, rather than bearing all of the load, axial loading across fractures with stable patterns is encouraged, thus promoting callus formation.

Medullary nailing is the fixation of choice for virtually all diaphyseal femur fractures. Reaming and nailing can be performed immediately after injury for most open femur fractures. It was once feared that this practice would lead to complications such as infection, fat embolism, nonunion, or, in the case of the patient with multiple injuries, adult respiratory distress syndrome (ARDS) and multiple organ failure. It is now recognized that infection is not a major problem and union rates are actually improved; fat embolism, ARDS, and other problems are all substantially decreased or prevented by femur stabilization soon after injury.

The current designs of interlocking nails permit stabilization of proximal diaphyseal as well as subtrochanteric and associated femoral neck fractures and very distal supracondylar fractures. As experience with interlocking femoral nails has grown, it has become apparent that interlocking of femoral fractures using proper technique does not delay union and that the early removal of locking screws (dynamization) to facilitate fracture union is not typically required (7,8,11,12,39). Further impetus for the use of interlocking nails has come with the finding that a number of femur fractures are more comminuted than initially recognized, necessitating the added fixation of locking screws.

CLASSIFICATION

Two types of classification are necessary for fractures of the femur: a grading system for soft-tissue injuries and a system for classifying the fracture pattern (33,57,73).
GRADING OF SOFT-TISSUE INJURIES

The grading of soft-tissue injuries is more an art than a science. The system developed by Gustilo and Anderson (33) for open fractures and that of Tscherne for closed injuries, which has been modified by the AO group (65,67,73), are the most widely used. See Chapter 12 for details.

GRADING OF FRACTURE PATTERNS

The purpose of grading the fracture pattern is to assess the intrinsic stability of the fracture and guide the selection of treatment. In most diaphyseal femur fractures, this translates into a decision whether to lock the nail proximally, distally, or at both locations. Pattern, location, and degree of comminution contribute to overall fracture stability. For example, short oblique fracture patterns are usually stable with standard (i.e., unlocked) nailing when they occur near the isthmus and are committed not more than Winquist-Hansen type II (Fig. 20.1) (18). At more proximal or more distal locations, or if more comminuted, these fractures are not stable under axial loading. On the other hand, even in apparently stable patterns such as the short oblique fracture, there can be a split extending proximally or distally from the fracture site that cannot be seen on preoperative or even postoperative radiographs. With weight bearing, this can shift, resulting in malposition. As a result, I now statically lock all fractures of the femoral shaft proximally and distally, impacting the fracture site to maximize bone apposition and thereby eliminating any gap, when nailing Winquist-Hansen type I and type II fractures. For the purposes of this chapter, the Winquist-Hansen classification is simple, practical, and useful for clinical decision making, particularly if it is applied to the proximal, middle, and distal thirds of the diaphysis. The Orthopaedic Trauma Association has adopted and expanded the classification of the AO Group. Their system is much too detailed and complex for presentation here but is very useful for exploring the nuances of fracture management and for research. Interested readers are referred to the Special Edition of the Journal of Orthopaedic Trauma devoted to this classification system (57).

Figure 20.1. The Winquist-Hansen classification of comminution in fractures of the femoral shaft.

BIOMECHANICS

The biomechanics and physiology of intramedullary nailing in the subtrochanteric area and the hip are addressed in detail in Chapter 11 and Chapter 19. A few comments are required here, however. Measures of torsional rigidity, bending stiffness, and resistance to compression (shortening) have shown conclusively that first-generation interlocked nails using either an oblique proximal cross-locking screw and transverse distal cross-locking screws, or transverse cross-locking screws both proximally and distally, are mechanically superior to unlocked nails and to early designs such as the Brooker-Wills with internally deployed distal fins (5,15,31,35,42). Some interlocking nails are provided with cross-locking holes in both the anteroposterior (AP) and mediolateral planes and/or have a slotted hole available so that the fracture will compress with weight bearing. In recent systems developed for insertion without reaming, the maximum diameter is smaller, and therefore the cross-locking screws have had to be of smaller diameter as well. In spite of modifications in both design (solid nails) and materials (titanium alloys), these smaller nails have increased breakage rate. In resisting torsional forces, one screw proximally and distally appears to be just as effective as two screws (39). For fractures in the distal third of the femur, where there is no effective contact between the inner wall of the cortex and the nail in the distal fragment, two transverse cross-locking screws are necessary to provide adequate stability (15). Stability in supracondylar fractures is enhanced with larger-diameter nails, insertion to subcondral bone at the knee, and use of two cross-locking screws (15,31,34). In mid-diaphyseal fractures with stable patterns, Winquist-Hansen I and II, one cross-locking screw proximally and distally is adequate. In Winquist-Hansen III and IV patterns, use the maximum number of cross screws available in the nail design being used (34).

TREATMENT OPTIONS

NONOPERATIVE TREATMENT

Nonoperative treatment is standard in children and young adolescents. In mid to late adolescents and in some younger children who have associated multiple injuries, particularly head injuries, internal fixation with devices such as the Ender nail is necessary to avoid injury to the growth plates (see Chapter 19 and Chapter 164). In adults, the indications for treatment of femur fractures in balanced suspension and skeletal traction and/or functional cast braces have nearly disappeared due to the tremendous advantages of intramedullary nailing, particularly since the sophistication of current techniques has reduced the incidence of complications to very acceptable levels. In addition to the systemic risks of nonoperative care already mentioned, the prolonged bed rest and immobilization (3 to 6 months) is not tolerable to most patients today, and it is accompanied by a significant incidence of malunion, nonunion, and permanent joint stiffness, particularly in the knee. In regions of the world where sophisticated intramedullary techniques are not available or where the risks of surgery are unacceptable, nonoperative management remains the mainstay; the techniques for it are discussed in detail in Chapter 10. In recent years, I have not used balanced suspension and skeletal traction as the sole method for treating a fracture of the femur in adults. I use functional cast braces combined with intermittent traction for supracondylar fractures of the femur in situations where surgery is contraindicated, such as in the presence of serious systemic illness in the elderly, coexisting infection in the region of the fracture, or comminution and severe osteoporosis. Using a well-molded cast-brace with intermittent tibial pin traction, it is possible to mobilize these patients to a chair at bedside within the first week after fracture and to obtain a reasonably good outcome in most cases (49,51).

EXTERNAL FIXATION

External fixation of closed fractures and of most open fractures of the shaft of the femur is rarely indicated today but still has a specific role in the armamentarium of the trauma surgeon (1,26,27,38). Indications for external fixation include the following:

- Patients with multiple injuries who are hemodynamically unstable or who have a particular combination of injuries in which rapid stabilization of the femur with minimal soft-tissue trauma is essential
- Some femoral-shaft fractures in children and adolescents (see Chapter 164)
- High-grade or severely traumatized open fractures where external fixation may be a temporary or definitive method of stabilization
- Some femur fractures with an associated vascular injury that requires repair, where internal fixation is either difficult or contraindicated
- The rare fracture in which systemic or local factors contraindicate internal fixation

OPEN INTRAMEDULLARY NAILING

The standard of care for the vast majority of fractures of the diaphysis of the femur today is locked intramedullary nailing utilizing closed percutaneous techniques. Direct open reduction of the fracture may be indicated in the following cases:

- The fracture is not reducible by closed technique, or a bone fragment is incarcerated in the canal, which precludes passage of a guide pin or the nail.
- The patient is a victim of multiple-system injuries and is on a regular operating table where convenience and speed are best facilitated by a modified open nailing (see Chapter 11, Chapter 12, and Chapter 14).
- The fracture is open, and irrigation and debridement of it exposes the fracture site.
Retrograde insertion of a femoral nail through the intercondylar notch has some advantages over antegrade nailing:

- somewhat more distal than standard nails, thereby increasing the range of supracondylar fractures that can be handled. All current designs use AP cross-locking found in the supine position on a regular operating table after general surgical procedures. Devices used for retrograde nailing have included specially designed short nails. The current technique of retrograde nailing through the knee has recently become popular because of the previously successful experiences nailing tibias through this site. When opening the fracture, it is usually possible to make an incision directly over it and then to dissect through the quadriceps where the femur has torn it, rather than make a separate independent approach. The incision need be only large enough to admit the fingers to facilitate passage of the guide pin across the fracture site. Once this has been achieved, and if good fluoroscopic visualization is available, it is usually possible to close the wound and proceed with nailing as one would for closed technique. This has the advantage of minimizing the amount of time the wound is open, and it allows the medullary contents and reamed bone to accumulate around the fracture site following reaming, which enhances union.

STANDARD NONLOCKED OR FLEXIBLE NAILS

Standard reamed or nonreamed nails, such as the original Kuntscher nail (76), are rarely used today in most developed countries, but because of the simplicity and low cost of the procedure, it can be performed open with either antegrade or retrograde technique in areas of the world where more sophisticated locking nail techniques under fluoroscopic control are not available. A typical case is illustrated in Figure 30.2. Flexible nonreamed nails such as the Ender nail (see Chapter 19) can be inserted both antegrade and retrograde, and either singly or multiply, and are used today most commonly in femur fractures in children or early adolescents who require internal fixation. The Ender nail did not provide enough control of malrotation and shortening to be used routinely in fractures of the diaphysis in adults. Its simplicity and low cost, particularly when combined with temporary skeletal traction and cast bracing, make it a very useful technique in less developed countries.

Figure 30.2. A: The classic indication for medullary nailing of a short, oblique, mid-isthmus fracture. B: A standard medullary nail is placed. C: After removal 16 months later, there is a smooth, well-remodeled callus, and the general shape of the bone is quite normal, with no significant varus or valgus and some maintenance of the normal neck in combination with distal locking are not indicated in the vast majority of diaphyseal fractures of the femur and are reserved for subtrochanteric fractures, some pathologic fractures in the proximal femur, and some concomitant ischial fractures of the hip and femoral shaft (see Chapter 19).

Brumback et al. (11,12,16) and Wiss et al. (78) have all shown that the best results come from interlocked nailing that maximizes bone apposition at the fracture site, with the use of closed techniques and no direct intervention at the fracture site by open means, and with static interlocking even in segmental fractures of the femur.

REAMED VERSUS NONREAMED, LOCKED, CLOSED INTRAMEDULLARY NAILING

It is interesting to see how history repeats itself. When Kuntscher and others first developed intramedullary nailing prior to World War II, nails were generally inserted without reaming. When all the advantages of using larger, reamed nails became apparent, unreamed nails for the femur nearly disappeared in developed countries. As we began to carry out early reamed, locked nailing of fractures of the femur in patients with increasingly severe multiple injuries, investigators at a number of important trauma centers in both Europe and North America raised the issue of whether embolization of the contents of the medullary canal to the lungs was a significant factor in increasing morbidity (discussed in detail in Chapter 11).

Nonreamed nailing is attractive because of the decreased operating time and decreased blood loss (24,72). In addition, the introduction of retrograde nailing through the intercondylar notch of the knee was particularly useful with nonreamed techniques. In a prospective randomized trial comparing unreamed to reamed nails, Clavworthy et al. (24) found that union was slower in the unreamed group, and a high incidence of implant failure in the nonreamed nails led them to discontinue the study early. Both they and Torretta and Tiburzi (72) found no advantage in fixing routine femoral fractures with nonreamed nails and recommended the routine use of reamed nails because of quicker union and fewer implant failures with the larger size. They did not believe that the quicker operating time and somewhat lower blood loss in the nonreamed groups was a sufficient advantage to justify their use. This remains controversial, however. Most surgeons recommend unreamed nails for severely and multiply injured patients with concomitant severe pulmonary compromise or injury (see Chapter 11).

RETROGRADE NAILING THROUGH THE KNEE

In North America, the group at Harbor View Hospital in Seattle (61,71) introduced retrograde nailing of the femur through a lateral epicondylar portal with the use of a Kuntscher-style nail, primarily as a means of fixing the femoral shaft in combined concomitant ischial fractures of the shaft and femoral neck. The technique has now been abandoned in favor of using an entry through the intercondylar notch of the femur, because the eccentric entry site made reduction difficult and resulted in persistent varus deformity (64,68,71).

The current technique of retrograde nailing through the knee has recently become popular because of the previously successful experiences nailing tibias through this same approach and the challenge of stabilizing a femur fracture in a quick, efficient manner in patients with multiple injuries, whom orthopaedic surgeons frequently found in the supine position on a regular operating table after general surgical procedures. Devices used for retrograde nailing have included specially designed short nails that provide additional screw fixation in the distal fragment and were not designed to penetrate beyond the isthmus (45), standard locked intramedullary nails designed for antegrade use (62), and long retrograde nails designed for this technique. These can be used reamed or nonreamed. The cross-locking screws are somewhat more distal than standard nails, thereby increasing the range of supracondylar fractures that can be handled. All current designs use AP cross-locking proximally, as most surgeons view it as technically easier to accomplish because of improved fluoroscopic visualization (30,32,35,37,52,53,58,63).

Retrograde insertion of a femoral nail through the intercondylar notch has some advantages over antegrade nailing:

- Elimination of the need for a fracture table in most cases
- A much easier starting point without the risks associated with proximal entry in the pyriform fossa, which include injury to the sciatic nerve, fracture of the femoral neck, avascular necrosis of the femoral head, comminution of the proximal femur due to eccentric entry, and heterotopic bone at the nail entry site
- Intercondylar retrograde insertion of nails requires arthroscopy of the knee and partial reaming of the articular cartilage at the roof of the intercondylar notch; therefore, potential risks include the following:
  - Early knee dysfunction
  - Patellofemoral pain
  - Loss of knee motion
  - Arthrosis of the knee
  - Knee sepsis
  - The tendency to use smaller nails, which could increase the rate of nonunion and risk of implant breakage
Subtrochanteric fracture at the proximal tip of the nail
Less secure fixation distally, particularly in osteoporotic bone, since the more recently designed nails tend to place cross-locking screws in the cancellous bone of the metaphysis rather than through cortical bone at the metaphyseal diaphyseal junction

As the following brief review of the literature will show, some of these concerns have been borne out through recent clinical experience, and others have not proven to be a problem. Large numbers of retrograde nails have been used only in the last 5 years. Only time will tell whether this technique will continue to be used for difficult fractures of the femur or, in the long run, replace antegrade nailing. ElMaraghy et al. (29) studied the effect of nail entry and reaming in the canine femur on arterial profusion of the anterior and posterior cruciate ligaments. They demonstrated that profusion in the anterior cruciate ligament is decreased by 52% and in the posterior cruciate ligament by 49% acutely. Whether this returns to normal with time and whether it has any significant clinical effects on either healing or function of these two ligaments is currently not known.

Morgan et al. (54) studied the effect of the entry site on patellofemoral contact area and pressures. When they used the intact femur for comparison, they found no differences unless the nail was left 1 mm proud of the cartilage and this resulted in statistically significant increases in the mean pressure at 120° of flexion, and in the maximum flexion of flexion. Their studies suggested that the intercondylar entry hole does not have any significant biomechanical effects on patellofemoral function as long as good surgical technique is followed. To this point, no study has been sufficiently large or long enough to state whether this entry site will increase the incidence of later arthritis, but, based on the experience in sports medicine with various intraarticular reconstructive procedures of the knee, this does not appear to be a problem.

Because of the popularity of proximal cross-locking in the anterior proximal posterior plane, Riina et al. (65) studied the relationship of the femoral artery and nerve to the proximal third of the femur. They demonstrated that the femoral artery that lies medial to the nail has up to 15 branches in the proximal third of the femur, but the closest lies 4 cm distal to the lesser trochanter. The femoral nerve lies medial but has multiple branches crossing the anterior femur, the first of which crosses 4 cm distal to the pyriform fossa; the fewest are above the lesser trochanter. Riina et al. recommended that AP cross-locking always be performed above the lesser trochanter to minimize risk to these structures.

A review of recently published larger studies (30,32,35,37,46,52,53,58) showed only one infection, which resulted in a septic knee, among 271 fractures followed for between 1 and 2 years. The infection responded to treatment and did not result in osteomyelitis. There were 10 nonunions (3.7%), which were more common with smaller unreamed nails and for the most part responded to reamed exchange nailing or local bone graft for bone deficiency. Only two rotary malunions were reported. When there was no concomitant injury to the knee, all authors reported that knee motion returned to normal or nearly normal, with minimal long-term complaints. No cases of arthritis were reported, but, of course the follow-up is quite short. Union seemed to be faster and the incidence of nonunion lower when reamed nails larger than 10 mm in diameter, with larger cross-locking screws, were used.

The results with retrograde nailing appeared to be comparable to those reported with antegrade nailing, but there is neither sufficient evidence nor a long-enough follow-up at the present time to state whether retrograde nailing will replace antegrade nailing as the method of choice for stabilization of fractures of the shaft of the femur. Considering the fact that the published series thus far had a higher incidence of open fractures and multiply injured patients, the results are quite encouraging.

There is no question that a role for retrograde nailing of the femur has now been firmly established. Current indications include the following:

- Multiple injuries, when nailing on a regular table in the supine position and use of an unreamed nail are advantageous
- Combination fractures of the femoral shaft and tibial shaft, when nailing of both fractures through the same entry site is possible
- Communicant ipsilateral fractures of the femoral neck and shaft, when independent fixation of the shaft and neck fractures is desired
- Ipsilateral fractures of the acetabulum and pelvis, when avoidance of a surgical wound about the hip makes surgery of the pelvis and acetabulum on a delayed basis less risky
- Pregnant or massively obese patients when proximal access to the hip or lateral decubitus positioning for nailing is difficult
- Periprosthetic fractures in the distal femur when retrograde nailing is superior to open fixation or antegrade nailing

PLATE FIXATION

For fractures of the diaphysis, from the lesser trochanter to 10 cm proximal to the knee joint, locked intramedullary nailing is the treatment of choice and has replaced plate fixation. Plating a mid-diaphyseal femur fracture involves a much larger surgical procedure, more blood loss, and a higher incidence of nonunion and loss of knee motion than medullary nailing (67). Plate fixation is indicated in the following cases:

- For femur fractures in settings where inadequate experience with intramedullary nailing or nonavailability of intraoperative fluoroscopy or instruments and implants makes medullary nailing impractical
- When a vascular repair has been done and plate fixation is feasible through the same surgical approach and/or is less risky to the vascular repair than intramedullary nailing
- In ipsilateral concomitant fractures of the femoral neck when retrograde nailing or antegrade nailing using reconstruction nails is not available or when there is preexisting knee pathology that prevents the knee from being flexed beyond the 45° angle that is necessary to obtain the proper entry site
- For nonunions or malunions of the femur when the medullary canal is obliterated or an open osteotomy and/bone graft is required, when nailing will be more difficult than plate fixation, or when the deformity is greater than plate correction (70)

OPEN FRACTURES

Acute open femoral fractures can be effectively treated by reamed or nonreamed medullary nailing without significantly increased rates of infection or nonunion (4,10,45,72,77). Perform an immediate, thorough, layer-by-layer irrigation and debridement, and institute appropriate bactericidal intravenous antibiotics as soon as possible. Then re-repair and re-drape so that a clean operative field is available for intramedullary nailing. Gustilo grades I, II, and IIIA and AO grades I0, I02, and I03 of open fractures may be routinely treated in this fashion. Individually assess Gustilo grade IIIb and AO grade IV0. If these more severe grades are highly contaminated, have marginal soft tissues that cannot be debrided at the initial debridement, or are neglected (more than 12 hours old), then consider primary external fixation if the patient needs to be mobilized immediately. If up to 2 weeks in skeletal traction is not contraindicated in isolated fractures, then this is an alternative.

Locked intramedullary nailing can be done when the wound is closed and there is no evidence of infection.

Early conversion from an external fixator to intramedullary nailing does not carry an increased infection rate as long as there has been no infection along the pin tracks. It may be prudent to remove the external fixator, debride the pin tracks, and close them (maintaining the patient in traction for a few days until these wounds are sealed) before carrying out intramedullary nailing. Gustilo grade IIIc and AO grades I04 and NV3–5 fractures can be initially stabilized with an external fixator, although plating may be preferred if little additional periosteal stripping is necessary.

After immediate nailing, close the elective portions of the wounds and leave the traumatic wound open, performing delayed primary closure within 5 days if the wound is ready. The huge muscle mass around the femur facilitates revascularization and provides excellent coverage of bone and implants; therefore, flaps are rarely if ever indicated except in fractures around the knee. More recent studies have shown no infections or nonunions in 28 patients with Gustilo grade I–IIIa open fractures (5), and no infections and only two delayed unions in a series of 56 patients with open fractures of the femur due to low-velocity gun-shot wounds treated with immediate interlocked reamed nailing (77). Routine bone grafting is not necessary to secure adequate rates of union in open femur fractures treated by nailing unless there is segmental bone loss.

Although unreamed nails have shown efficacy and decreased rates of infection in open fractures of the tibia, no data support their superiority over reamed nails for open fractures of the femur.

Williams et al. (75) compared primary treatment of proximal intramedullary nailing in 42 patients with open fractures, including 33% with grade III injuries, and had overall infection and nonunion rates of 2.4%, with no significant difference between the two groups (see Chapter 12 on open fractures).

Patients can be positioned in the lateral decubitus or supine position on a fracture table or on a radiolucent operating table for closed intramedullary nailing. Most

Timing

There is a major advantage to performing closed nailing as soon as possible in cases of multiple trauma and in isolated fractures. In addition to the physiologic
advantages of early fracture stabilization and patient immobilization, it is technically easier to nail a femur immediately after the injury. Muscle spasm, contracture, hemorrhage, and swelling are less prominent, making the closed reduction easier. The decreased length of hospitalization contributes to the cost-effectiveness of acute trauma care.

Preoperative Considerations

Thoroughly evaluate the patient, treat all of her injuries, and ensure hemodynamic stability. Obtain AP and lateral radiographs of the entire fractured femur, including the entire hip joint and knee joint. Look carefully for occult fractures of the femoral neck. This requires a high-quality AP radiograph taken with the hip in internal rotation to be certain that the femoral neck is in full profile (usually done under anesthesia in the operating room). Obtain a high-quality cross-table lateral view of the hip as well.

Place the fractured femur into skeletal traction as soon as possible, as this is important to maintain length and to stabilize the thigh, thereby reducing pain, reducing hemorrhage, and maintaining overall alignment and length, which facilitates later nailing. Two choices exist for skeletal traction. A transverse ¼-inch-diameter or larger pin placed at the level of the tubial tubercle is most frequently used. Its advantages are that it is not a potential contaminator of the femoral canal (if nailing is to be delayed over 24 hours) and does not interfere with the tip of the nail as it is driven to the distal end of the femur. Its disadvantages include a tendency to cause knee extension as traction is applied on the fracture table, and a limited ability to control a short distal fragment of femur.

A distal femoral pin, if placed anteriorly, can provide better control in distal fractures without interfering with nail placement. To position the traction pin, place a 0.062-inch or larger, smooth Kirschner wire (K-wire) just distal to the superior patellar pole, keeping it as anterior as possible. In this position, it is likely to remain out of the path of the approaching nail, particularly with nail designs that employ an anterior bow. For a distal fracture that is to be nailed with the patient in the lateral decubitus position, insert the traction pin somewhat obliquely so that it runs in a distal–medial to proximal–lateral direction. The resultant pull through a traction bow tends to counteract the valgus alignment caused by gravity.

The major disadvantage of a distal femoral pin, whether a K-wire or a Steinmann pin, is that if the distal fragment is not placed into appropriate position for nailing, the pin holds it in a fixed position, which can make reduction of the fracture and driving of the nail exceedingly difficult. It also interferes with distal cross-locking. The distal pin allows the distal femoral fragment to “float,” so alignment is simplified. This issue is addressed in more detail during the following discussion on fracture reduction. I prefer to use a proximal tibial Steinmann pin.

In rare cases in which the patient cannot be placed on a fracture table or cannot undergo countertraction from the perineal post, it is possible to apply traction and reduce the fracture by means of a modified femoral distractor (Fig. 20.3). The Synthes (Paoli, PA) Universal Femoral Distractor utilizes an accessory targeting device that attaches to the proximal targeting guide of their universal nail system. The targeting guide allows placement of the proximal Schanz pin into the lesser trochanter through a small stab incision (Fig. 20.3A). Place the distal Schanz pin parallel to the femoral articular surface, distal to the intended location of the nail tip, taking care not to traumatize the adjacent femoral artery, vein, or nerve (Fig. 20.3B). With the fixator in place, distraction can be achieved as well as control of flexion/extension, varus/valgus, and rotation (Fig. 20.3C). Utilize a radiolucent table and an image intensifier (Fig. 20.3D). Baumgaertel et al. (6) found the AO femoral distractor as efficacious as a fracture table and a better time saver. Some surgeons even advocate nailing fractures on a regular table, using hand traction and manipulation rather than the distractor, as they found the distractor to be technically challenging and time-consuming (23). This manual technique, however, requires a very experienced surgical team and is technically difficult, and the surgeon must be prepared to open the fracture if reduction cannot be achieved. I recommend against this technique for routine nailing in the hands of the average surgeon, and I advocate use of a tibial pin on a fracture table.

Positioning of the Patient

Patients can be positioned in the lateral decubitus or supine position on a fracture table or on a radiolucent operating table for closed intramedullary nailing. Most surgeons prefer a fracture table and use the supine position because they are most comfortable with this position, as they use it on a frequent basis for hip fractures. The only advantage of the supine position is easier positioning of the patient and assessment of rotation. Particularly for heavily muscled or obese patients, the supine position makes access to the nail entry point at the proximal end of the femur challenging, and impingement of the instrumentation against the table or the side of the patient makes fracture reduction and execution of the nailing much more difficult.

On the other hand, the lateral decubitus position is much more technically exacting, it requires the surgeon and usually two assistants to position the patient, and judging rotation can be more difficult. In addition, in multiply injured patients and in those with pulmonary injury or spine fractures, the lateral decubitus position is a greater threat to the spine and compromises pulmonary function. In the latter instances, the supine position is indicated. In addition, the supine position is much more convenient for bilateral fractures and carrying out simultaneous procedures. Because the nailing is much easier, I much prefer the lateral position.

Lateral Positioning

- For lateral positioning, I use a ¼-inch-diameter or stronger transverse Steinmann pin placed transversely through the proximal tibia and dressed with a circumferential sterile dressing. I use a Chick-Langren fracture table (Fig. 20.4).
Supine Position on a Fracture Table

- Before moving the patient to the fracture table, be certain that the table is level and properly located in the room with reference to the anesthesia equipment and lights, and that the C-arm has been placed on the appropriate side of the table. Make sure that all appropriate equipment is mounted on the table and in the appropriate position for the patient. Having everything “pre-prepared” greatly facilitates positioning.
- While the anesthesiologist controls the airway and positions the upper extremities, have an assistant control both lower extremities, roll the torso, and secure the patient to the table.
- Once the patient is in the lateral position, place the T-shaped pelvic perineal post and secure it so that the vertical portion lies just distal to the anterior superior iliac spine (Fig. 20.4A). Elevate the perineal post to help support the proximal fragment in a horizontal position and allow the genitalia to drape below the post. Make sure the groin and all bony prominences are well padded by the appropriate pads. Also be certain that the greater trochanter on the down side is supported by the table; the table is adjustable for this purpose.
- Secure the iliac pin into the iliac pin traction holder attached to the traction arm of the fracture table, and manually pull sufficient traction to stabilize the patient on the traction table. Maintaining the pin post and to bring the fracture out to length. In transverse fractures, slight distraction is an advantage initially. Place the femur parallel to the floor with the hip flexed approximately 20° to 25° and the hip internally rotated just enough to place the heel slightly above the patella, which is about 10° to 15°. This compensates for the fact that patients in the lateral decubitus position tend to slump somewhat forward during the nailing, which can induce an external rotation deformity. On the Chick-Langren table, the traction assembly provides sufficient support that it is not necessary to support the leg distal to the traction pin unless the bone quality is poor; in that case, fashion a sling to the overhead arm of the table to support the leg. Allow the knee to flex freely, as this permits flexion of the knee as traction is applied, thereby avoiding stretch on the sciatic nerve.
- Never apply traction through the foot with the knee extended and with the hip in the flexed position, because this will cause a sciatic nerve stretch injury even if used for as little as an hour. Excessive traction and inadequate padding cause pudendal nerve palsy. Maintain traction on the femur only until the guide pin is placed, and then loosen it as much as possible to avoid this problem.
- Secure the unoperated leg onto a well-padded leg holder, placing the leg holder just proximal to the knee to support it and padding the peroneal nerve well to avoid injury. I prefer circumferential tape over a blanket into which the leg is wrapped, as this provides good stability and can be a source of traction in the event of bilateral femur fractures. Initially, position the lower leg as close as possible to the upper, operated leg in all planes to facilitate use of the C-arm.
- Secure the upper extremities to double-airplane splints, securing the uppermost upper extremity to stabilize the thorax in a directly vertical position. After positioning the patient, check all bony prominences and neurovascular structures with the anesthesiologist to be certain that everything is padded and protected.
- Bring in the C-arm fluoroscope on the anterior side of the patient. Place it exactly at right angles to the femur and in a position where the entire length of the femur from the hip to the knee can be seen easily on both the AP and lateral views without repositioning the base of the C-arm.
- Prepare the injured thigh from the iliac crest to the iliac pin circumferentially, and drape it so that the buttocks and all but the most medial aspect of the thigh down to the iliac pin are available.
- Under fluoroscopic control, extend the down leg at the hip just enough so that the fracture site and proximal femur can be clearly seen on the lateral view. Lower the skin layers as close together as possible, pass the C-arm from the AP to the lateral position. Extending the uninjured hip permits better visualization of the fractured femur on the lateral view. The least extension is required for supracondylar fractures, and the most for subtrochanteric fractures.

Supine Position on a Fracture Table

- Place the patient in the supine position on the fracture table and secure the iliac pin into the traction apparatus on the table (Fig. 20.5). With the perineal post in place, reduce the fracture and secure the patient’s position on the table by applying manual traction. The difference from the lateral position is that the thigh is slightly abducted to expose the trochanter better (avoid excessive abduction, as this tightens the iliotibial band, which produces valgus malalignment of the fracture) and the leg is placed in neutral rotation. Raising the traction holder to flex the hip 15° to 20° greatly facilitates access to the entry site. To facilitate exposure of the hip, tilt the torso to the opposite side by using either a kidney rest or a tape-and-bolster arrangement. Avoid too much tilt, which also tightens the iliotibial band, which produces valgus malalignment of the fracture. On the Chick-Langren table, the support under the buttocks is in three sections, and the lateralmost section on the operative side can be lowered out of the way to facilitate exposure. The key to this positioning is the flexion of the hip, which allows the instrumentation to pass beneath the patient rather than impinging on his side, as occurs if the hip is flexed in extension. Place the opposite leg in a 90°–90° leg holder, making certain that the pelvis is stabilized to the table or to the vertical post of the leg-holding device. Bring the C-arm between the legs, and position it to be certain that AP and lateral views from the hip to the knee can be acquired without moving the base of the machine.

The Skin Incision and Trochanteric Starting Point

- Begin the incision at the tip of the trochanter, and extend it proximally in line with the fibers of the gluteus maximus and the femoral shaft (Fig. 20.6). The length of the incision is determined by the soft-tissue thickness. Continue dissection sharply through the gluteus maximus fascia, and then split the gluteus fibers bluntly. Stay posterior to the gluteus medius, palpate the trochanteric tip, and with your fingers pointing upward, glide a finger down the posterior medial border of the trochanter. You will encounter a sharp bump at the mid-portion of the trochanter. This represents the old physeal line of the trochanter and is known as the quadrate tubercle (Fig. 20.6A). Then slide your finger directly forward into a fossa located at the junction of the femoral neck with the underside of the posterior central aspect of the trochanter. By common usage this is called the pyriform fossa, which is actually nearest to the insertion of the obturator externus. This is the usual entry site for a femoral nail because it is directly over the medullary canal (Fig. 20.6B). (See the section on intramedullary nailing in Chapter 11.)

The Skin Incision and Trochanteric Starting Point

- In the past, a Küntscher awl was used to penetrate the cortex at this point. Some surgeons still prefer it, but most have now converted to using a guide pin over which is passed a reamer. This procedure is easier and can be done puncuately, and is more accurate and easily visualized under fluoroscopy. The danger of accidentally slipping off the posterior aspect of the trochanter into vital structures such as the sciatic nerve is eliminated. Most any guide pin combined with a reamer used for nailing hip fracture suffices. I use the 3.2-mm guide pin for the Alta hip screw (Howmedica, Rutherford, NJ) and drill it over with either a 14 mm or an 8 mm reamer, depending on the size of the patient.

Figure 20.5. Supine positioning with use of a distal femoral traction pin.

Figure 20.6. A: Posterior view of the buttocks with the posterior aspect of the greater trochanter exposed. a, quadrate tubercle, the origin of quadratus femoris; b, insertion of the obturator externus tendon; c, insertion of the pyriformis tendon. B: Top view of the femur. Note that the entry site is directly over the medullary canal and tucked up under the greater trochanter, encroaching only minimally on the femoral neck.
Reduction of the Fracture and Insertion of a Ball-Tipped Reaming Guide Pin

- Place the tip of the guide pin on the tip of your finger, palpating the pyriformis fossa, and hold the tip upward against the underside of the greater trochanter at its junction with the femoral neck. Control the guide pin with a guide pin holder or a T-wrench. The guide pin can be used to palpate the anterior and posterior aspects of the neck to be certain that you are central or slightly posterior. Then use a mallet to drive the guide pin into the soft bone on the underside of the greater trochanter at its junction with the neck to provide a reaming area of 10° to 20° in the distal 2.5 cm of the guide pin, as this facilitates manipulation of the guide pin around corners. Attach a T-handle to the proximal end of the guide pin.

- Now, under fluoroscopic control, place the appropriate-size reamer over the guide pin and ream through the outer cortex into the medullary canal. As soon as the proximal fragment is fully reamed, the guide pin will be distally across the fracture site. The guide pin is then inserted and driven with a mallet into the subchondral bone of the knee, ensuring that it is in both views. Place the guide pin directly in the center of the medullary canal on this view, then push it 2–4 cm into the proximal fragment. If your alignment is perfect, you will immediately feel crepitus as the guide pin encounters the rough endosteal surface of the medullary canal. With this feedback demonstrating that the guide pin is in the medullary canal, insert it down to subchondral bone at the knee, ensuring that it is in, on both views. Primarily, the guide pin should be used to palpate the extent of the fracture, the position of the guide pin, and the extent of bone loss. If the guide pin is not aligned with the distal fragment, the proximal fragment will be pulled distally. With the aid of fluoroscopy, push the guide pin past the proximal fragment to the point where it is flush with the fracture line and then push it 2–4 cm into the medullary canal. If the guide pin is not in the medullary canal, it is most likely that it is not in the correct position.

- With this feedback demonstrating that the guide pin is in the medullary canal, insert it down to subchondral bone at the knee, ensuring that it is in, on both views. Ensure that the guide pin is distally where you want the distal end of the nail to end. In most systems, nail length is determined by placing an identical second guide pin at the tip of the trochanter and then measuring from the top of the guide pin in the femur to the top of the second guide pin. Make adjustments if a shorter nail is desired.

- In the Altas system, the length of nail is measured directly off the fracture reduction tool, which for the Altas standard nail places the top of the nail flush with the top of the femoral neck rather than with the tip of the trochanter. This allows for some adjustment of the position of the nail if a more proximal position of the intertrochanteric screws is desired.

Measuring for the Length of Nail

- Ensure that the guide pin is distally where you want the distal end of the nail to end. In most systems, nail length is determined by placing an identical second guide pin at the tip of the trochanter and then measuring from the top of the guide pin in the femur to the top of the second guide pin. Make adjustments if a shorter nail is desired.

- In the Altas system, the length of nail is measured directly off the fracture reduction tool, which for the Altas standard nail places the top of the nail flush with the top of the femoral neck rather than with the tip of the trochanter. This allows for some adjustment of the position of the nail if a more proximal position of the intertrochanteric screws is desired.

Reaming the Medullary Canal

- To minimize pressurization of the canal, which leads to embolization of bone marrow, and to avoid overheating and jamming of the reamers, it is important to use a power reamer. The guide pin head is usually not necessary unless problems are encountered.

- Run reamers at the highest available RPM on a power reamer because this makes cutting most efficient, but push the reamer slowly down the medullary canal to minimize pressurization. Visualize the passage of the first couple of reamers across the fracture site to be certain that everything is going smoothly. Fluoroscopic imaging of the reaming process is usually not necessary unless problems are encountered.

- Begin with the smallest reamer in the set and progress in 1 mm increments until the first reamer contacts the inner cortex of the canal. Then progress in 0.5 mm increments until the desired diameter is reached. Once cortical contact is made, feel the reamer head with your hand as it is removed after each pass to be certain that you have not overheated. If you encounter any resistance, remove the reamer, extract reaming with a mallet, and clean the flutes of cortical bone to increase cutting efficiency and to avoid jamming the reamer when it is withdrawn. Do not allow the reamer to pull itself distally because this may cause it to screw down the medullary canal, which may cause the intertrochanteric screws to become loose. For each reaming of the reamer, reaming of 2 mm after initial reaming. Most surgeons prefer to reamers from apical to distal, rather than distal to apical, since this is most likely to be the case.

- After reaming the medullary canal, it is imperative that the guide pin be inserted and driven with a mallet into the subchondral bone of the knee. The guide pin should be used to palpate the extent of the fracture, the position of the guide pin, and the extent of bone loss. If the guide pin is not aligned with the distal fragment, the proximal fragment will be pulled distally. With the aid of fluoroscopy, push the guide pin past the proximal fragment to the point where it is flush with the fracture line and then push it 2–4 cm into the medullary canal. If the guide pin is not in the medullary canal, it is most likely that it is not in the correct position.

HINTS AND TRICKS

- Broken reamers or shafts are highly unusual but are usually easily removed by extracting the bullet-tipped guide pin along with the broken reamer.

- To ensure that the guide pin does not accidentally withdraw, hold it in the femur with a lat tape over the proximal end of the pin (do not use your gloved hand because, if the wire starts to turn with the reamer, it will tear the glove). When the back of the reamer obscures the guide pin, it may be necessary to insert a T-wrench into the back of the guide pin to hold it in place.

- After the length of nail has been measured, drive the guide pin farther with a mallet to lodge it into the subchondral bone of the knee often prevents accidental removal. This is particularly important in subtrochanteric fractures with a short distal fragment.

- In fractures of the femur, verifica the fragment has not proven to be of any value, because during reaming the medullary canal vents through the fracture site.

- At the completion of reaming, thoroughly irrigate and clean the buttocks wound to minimize the risk of heterotopic bone formation.

- Now insert a plastic tube over the reaming guide pin down the medullary canal, making certain that it is across the fracture site, and exchange the reaming guide pin for the nail guide pin.
ball-tipped guide pin for a driving guide pin.

Selecting and Driving the Intramedullary Nail

- In systems of reamed, locked nails manufactured from titanium alloys, an 11-mm-diameter nail for women and a 12-mm-diameter nail for men provide sufficient strength and stability. In stainless-steel systems, some manufacturers recommend a 12 mm nail for women and a 13 mm nail for men. Smaller nails may be necessary in very small people, and larger-diameter nails may be necessary in large men or in the elderly, where the medullary canal tends to be capacious. The relationship between the maximum diameter reamed and the size of the nail is based on the manufacturer's recommendations, but in most cases overreaming by 1 mm provides a suitable fit. Some manufacturers recommend overreaming even more, particularly in femurs that have a fairly marked anterior bow.

- Assemble the nail on the driver and drive the medullary nail down the medullary canal across the fracture site, using the driver provided by the manufacturer. At this point, only minimal traction should be necessary, and in fact, traction on the extremity should have been released as soon as the fracture was reduced and the guide pin passed, assuming that traction is not necessary to maintain overall alignment or length. A nail that drives hard can be the result of an eccentric entry site or insufficient reaming. Do not persist in driving the nail because of the risk of nail incarceration or comminution of the femur. Reassess the entry site; oval it if necessary, and consider re-reaming somewhat larger.

- In comminuted fractures where determination of length may be difficult, a good guide is to preoperatively measure the opposite extremity from the prominence of the trochanter to the lateral epicondyle of the femur and relate this to the length of nail to be used.

- Avoid distraction at the fracture site. If distraction occurs when you drive the nail, then drive it slightly deeper, cross-lock distally, and use the driver assembly to backsnap the nail to approximate the fracture ends; then lock proximally. In supracondylar fractures, be certain to provide support beneath the fracture site medially as the nail is driven to ensure that it is centered in the distal fragment and that alignment is good.

- Visualize the nail as it passes into the mouth of the distal fragment to ensure that it does not hook up on a cortex and cause comminution. Most nails today have a bullet-nose design, which minimizes the risk of comminution.

- In osteoporotic bone, if fixation is too distal, it will provide poor purchase because of the poor-quality cortical and cancellous bone in the very distal regions of the femur. This results in loss of purchase in the near cortex, but, when combined with a second screw, it provides adequate fixation on the opposite cortex as long as bone quality is good.

- In osteoporotic bone, if fixation is too distal, it will provide poor purchase because of the poor-quality cortical and cancellous bone in the very distal regions of the femur. This results in loss of purchase in the near cortex, but, when combined with a second screw, it provides adequate fixation on the opposite cortex as long as bone quality is good.

Cross-Locking the Nail

- In nearly all nail systems today, distal cross-locking is best accomplished by freehand cross-locking under fluoroscopic control (discussed in Chapter 11). The jigs now available for distal cross-locking have had mixed success. Hand-held fluoroscopic guides and laser-guided systems facilitate freehand cross-locking.

- Proximal cross-locking can be done with a jig or guide system in all nails.

- When cross-locking is completed, verify on a lateral view that the screws have passed through the nail. They can appear on the AP view to be in, and yet have missed the nail.

- If a screw misses the nail, then correcting it can be quite difficult because the drill point or screw tends to drop into the old screw hole. A quick and simple way to solve this problem is to expose the screw hole, widen it with a larger drill point so that the near hole in the nail is now exposed, and then insert the screw under direct intraoperative control. This results in loss of purchase in the near cortex, but, when combined with a second screw, it provides adequate fixation on the opposite cortex as long as bone quality is good.

- In osteoporotic bone, if fixation is too distal, it will provide poor purchase because of the poor-quality cortical and cancellous bone in the very distal regions of the femur. This results in loss of purchase in the near cortex, but, when combined with a second screw, it provides adequate fixation on the opposite cortex as long as bone quality is good.

- It is almost always advisable to have three to five threads of the screw extending through the opposite cortex, because this greatly facilitates removing the medial section of screw if the screw breaks.

- In osteoporotic bone, washers and backup nuts enhance fixation.

- In stable patterns such as Winquist-Hansen I and II, where there is good cortical contact at the fracture, a single screw proximally and distally usually suffices. This saves time and energy; it also reduces the risk of distal fixation mismatch that can cause you to insert a screw that is too long.

- When approaching the entry site for the nail, do not use a direct mid-lateral incision, but use the same incision as for lateral decubitus nailing, beginning at the tip of the trochanter and passing proximally in line with the fibers of the gluteus maximus. A direct lateral approach goes through the gluteus medius, damaging it. The thick muscle envelope in this area makes access to and visualization of the proper entry site extremely difficult. In addition, entry this far superior makes it exceedingly difficult to avoid injury to the base of the femoral neck because of the overlapping trochanter. A more posterior approach is better.

- In cases where the femur is broad and the trochanter is short, or when reaming through the pyriformis fossa, the guide pin tends to enter the fracture site rather than the pyriformis fossa, which is just a few millimeters lateral to the fracture line.

- In the guide pin directly into the tip of the greater trochanter. Ream the entry site into the greater trochanter and then use an instrument such as an Army-Navy retractor to push or pull the reamer medially while reaming, to create an oval entry hole that is centered directly over the medullary canal. This oval hole is larger than is needed for the nail, but I have seen no adverse consequences of this technique.

- Note that the trochanter is located at the femoral head and neck. This greatly facilitates manipulation of instrumentation and reduction of the fracture, as well as driving the nail. The only disadvantage is that it is awkward because of the inclination of the instrumentation toward the floor.

- Cross-locking distally in the supine position can sometimes be difficult because the locks on the C-arm prevent achieving appropriate alignment of the x-ray tube with the cross-locking holes in the nail. As long as the fracture is well impacted and rotationally stable, it is often easier to rotate the leg to bring the cross-locking holes in line with the central beam of the fluoroscope than to try to line it up using the fluoroscope mechanics.

- Always examine patients carefully in the operating room under anesthesia to be certain that alignment, particularly rotation, has been restored. Always try to achieve perfect alignment. Some asymmetry in rotation is acceptable as long as it does not exceed 15° and the patient can rotate in both directions beyond 15°. The jigs now available for distal cross-locking have had mixed success. Hand-held fluoroscopic guides and laser-guided systems facilitate freehand cross-locking.

- Visualize the nail fluoroscopically to be certain that it is in the appropriate location and that the fracture is both rotationally and axially in good alignment.

Special Considerations for Supine Nailing

The overall technique for supine nailing is very similar to that for lateral nailing, and the following guidelines are quite useful:

- When approaching the entry site for the nail, do not use a direct mid-lateral incision, but use the same incision as for lateral decubitus nailing, beginning at the tip of the trochanter and passing proximally in line with the fibers of the gluteus maximus. A direct lateral approach goes through the gluteus medius, damaging it. The thick muscle envelope in this area makes access to and visualization of the proper entry site extremely difficult. In addition, entry this far superior makes it exceedingly difficult to avoid injury to the base of the femoral neck because of the overlapping trochanter. A more posterior approach is better.

- In cases where the femur is broad and the trochanter is short, or when reaming through the pyriformis fossa, the guide pin tends to enter the fracture site rather than the pyriformis fossa, which is just a few millimeters lateral to the fracture line.

- In the guide pin directly into the tip of the greater trochanter. Ream the entry site into the greater trochanter and then use an instrument such as an Army-Navy retractor to push or pull the reamer medially while reaming, to create an oval entry hole that is centered directly over the medullary canal. This oval hole is larger than is needed for the nail, but I have seen no adverse consequences of this technique.

- In cases where the femur is broad and the trochanter is short, or when reaming through the pyriformis fossa, the guide pin tends to enter the fracture site rather than the pyriformis fossa, which is just a few millimeters lateral to the fracture line.

- In the guide pin directly into the tip of the greater trochanter. Ream the entry site into the greater trochanter and then use an instrument such as an Army-Navy retractor to push or pull the reamer medially while reaming, to create an oval entry hole that is centered directly over the medullary canal. This oval hole is larger than is needed for the nail, but I have seen no adverse consequences of this technique.

- Note that this is nearly identical to the lateral decubitus position. This greatly facilitates manipulation of instrumentation and reduction of the fracture, as well as driving the nail. The only disadvantage is that it is awkward because of the inclination of the instrumentation toward the floor.

- Cross-locking distally in the supine position can sometimes be difficult because the locks on the C-arm prevent achieving appropriate alignment of the x-ray tube with the cross-locking holes in the nail. As long as the fracture is well impacted and rotationally stable, it is often easier to rotate the leg to bring the cross-locking holes in line with the central beam of the fluoroscope than to try to line it up using the fluoroscope mechanics.

- Always examine patients carefully in the operating room under anesthesia to be certain that alignment, particularly rotation, has been restored. Always try to achieve perfect alignment. Some asymmetry in rotation is acceptable as long as it does not exceed 15° and the patient can rotate in both directions beyond neutral. Shortening up to 10 mm is either asymptomatic or easily compensated for by an in-the-shoe lift. Shortening of 15 mm or more, although nicely corrected with a shoe lift, is quite noticeable to most patients and is likely to be the source of complaints. Shortening over 20 mm is unacceptable to the vast majority of patients, and correction is required in most patients who have shortening over 25 mm. Except in distal supracondylar fractures of the femur, alignment in the sagittal plane is nearly always guaranteed by the contour of the nail. The most common malalignment in supracondylar fractures is recurvatum. Recurvatum of up to 10° or so is acceptable in most patients as long as they do not have lax joints or a preexisting hyperextension problem at the knee. Try to avoid varus or valgus malalignment of over 5°. Over 10° often requires correction.

- As soon as the patient will tolerate it, begin hip and knee range-of-motion and muscle-strengthening exercises for the entire extremity. Do not forget the hip abductors; persistent weakness in these due to the operative approach is common (3). It usually takes 6 weeks to gain enough joint motion and muscle rehabilitation that the patient can walk safely without assistive devices. In Winquist I and II stable patterns, full weight bearing can progress as quickly as possible, and most patients can bear full weight without assistive devices by 6 weeks. In Winquist III and IV patterns, bridging callus must be seen on two views before progression to full weight bearing is acceptable.

See Figure 20.7 for a typical case of locked, antegrade, closed intramedullary nailing.
**Antegrade Nailing on a Regular Radiolucent Table with a Universal Femoral Distractor**

- The lateral decubitus position with the fractured femur uppermost is preferable, although some use the supine position with bumps under the back and midsacrum to make the entry site for the nail available.
- Prepare and drape the extremity completely free, including the buttocks for the entry site.
- Apply the AO distractor (Fig. 20.3). Make the anterior insertion of a Schanz pin into the medial aspect of the femur at the lesser trochanter carefully to avoid injury to the femoral nerve and artery.
- Reduce the fracture and perform antegrade nailing as described previously.
- When you are cross-locking, the distractor may be in the way, particularly distally. If the fracture is sufficiently stable, remove the distractor and proceed with cross-locking as usual. In cross-locking with the leg free on a radiolucent table, it is useful to have the assistant position and stabilize the leg for cross-locking rather than shift the head of the C-arm to align it.

**Retrograde Intercondylar Nailing**

- Position the patient in the supine position on a fully radiolucent table. Place a 3–5 cm soft bump under the ipsilateral buttocks and a large bolster under the knee and thigh so that the knee sits flexed at approximately 45°.
- If a universal distractor will be used to gain length and aid reduction, apply a Schanz pin proximally just above the lesser trochanter and distally through the femoral condyles posterior to the nail entry site, attach the distractor, and make appropriate adjustments. Many fractures can be nailed without a distractor, particularly if an unreamed technique is used, which is discussed below.
- Make a midline longitudinal incision from the inferior pole of the patella to the intercondylar notch. Split the patellar tendon the full length of the incision, and reflect the fat pad inferiorly. Identify the intercondylar notch. One centimeter anterior to the anterior edge of the posterior cruciate ligament, insert a guide pin under fluoroscopic control (Fig. 20.8). On the AP view, make certain that this is in the midline and aligned with the femoral canal. Laterally, the guide pin must be aligned with the long axis of the distal fragment of the femur and be central in the canal. (This usually results in an entry hole that is 50% on nonarticular surface in the intercondylar notch and 50% into the articular cartilage.)  Over this pin, ream with an appropriate-size end-cutting reamer. In most cases, this will remove a few millimeters of articular cartilage at the superior edge of the intercondylar notch. Ream until the medullary canal is entered. Use a protector to prevent injury to the patellar tendon, and irrigate and suck during reaming to remove any loose reamings from the knee joint.

**HINTS AND TRICKS**

- The most important and sometimes challenging aspect of retrograde nailing is being certain that the top of the nail is countersunk below the subchondral bone of the intercondylar notch. It is important to understand the anatomy of your nail and driver as seen on fluoroscopy, so that there is no question where the most distal extent of the nail is. I always countersink the nail at least 10 mm below the subchondral bone to allow room for the cap screw and for any parallax error.

**For reamed technique, the method is identical to that already described for reamed nailing. The fracture manipulation tool for controlling the distal fragment is equally advantageous here.**

- Nail length is critical because the nail must be countersunk below the subchondral bone distally, the fracture must be at appropriate length, and the proximal cross-locking should be at the level of the lesser trochanter.

- First, cross-lock distally, using the cross-locking guide, then impact the fracture and cross-lock proximally, using either the Alta distal cross-locking guide or freehand technique.

- With the other leg lying flat on the table, visualization of the cross-locking holes at the lesser trochanter is easy because the two thighs are at different levels. Even if overlap occurs, with a good C-arm both femurs can be visualized and the femur with the nail in it is easily identified and targeted.

- When using systems that provide a cap screw, be certain to take this into account when setting the depth of the nail at the knee (Fig. 20.9).
IPSILATERAL CONCOMITANT FRACTURES OF THE HIP AND SHAFT

EXTERNAL FIXATION WITH AN AO FIXATOR OR WAGNER DEVICE

- After completion of the nailing, thoroughly irrigate the knee joint to remove any loose bone, do a meticulous interrupted closure of the patellar tendon, and close the subcutaneous fat and skin in a routine fashion.

Postoperative Care

Postoperative care is the same as that already described for antegrade nailing.

PLATE FIXATION OF THE FEMORAL SHAFT

Although a medullary nail is the preferred method of operative fixation for most diaphyseal femoral fractures, there are situations in which plate fixation is appropriate.

- Place the patient in the supine or lateral decubitus position on a radiolucent table. Make a midlateral longitudinal incision over the fracture, and sharply incise the iliotibial tract. Beyond this, the exposure is guided by the muscle disruption and periosteal stripping that are already present. Carefully clear the major fragment ends of soft tissue and the lateral or anterolateral surface where the plate will be located.

- Reduce the fracture, typically by means of traction on the distal fragment. Maintain the anterior bow by placing a bolster posterior to the femur as distraction is applied. This can be effectively accomplished by means of a femoral distractor, as described by Mast (Fig. 20.3). If small, comminuted fragments are present, do not strip them in an attempt to produce an anatomic reduction. Tease them into the best position possible, but do not worry about fixation. Fix large butterfly fragments anatomically by means of lag screws. Maintain correct rotation by using the lines aspera and fracture configuration as a guide.

- Apply a single, broad plate to the lateral or anterior surfaces, obtaining eight cortices of fixation in both proximal and distal fragments, preferably augmented with lag-screw fixation between the major fragments. Before fixation is completed, obtain compression if there is good cortical contact by using an articulated tensioning device. The resulting construct may leave several plate holes unfilled and some comminuted fragments unreduced, but it will have correct length and alignment (Fig. 20.10).

- Apply autogenous cancellous bone graft for medial comminution. If graft can be introduced through the fracture to the medial cortex before final reduction, less stripping of bone is required. Otherwise, carefully pack graft over the anterior cortex to rest medially and wherever comminution is extensive. Close the wound in layers over a suction drain.

- Postoperatively, begin immediate active-assisted range-of-motion exercises and mobilization identical to the postoperative program for patients with nailed fractures. Continue touchdown weight bearing for 6 weeks, and then advance to partial weight bearing once bridging callus seen on two views has developed. Begin full weight bearing when the fracture has healed.

Plate removal may be advisable in active young people, particularly if they engage in a sport or have a vocation in which heavy stress on the femur or trauma may occur. Usually, we wait at least 18 months after the time of plating, and remove the plate only if the bone is solidly healed and the callus has remodeled. (See Chapter 11 for advice on plate removal.) After removal, patients can progress to full weight bearing with crutches as soon as they can tolerate it, but they must limit their activities to just walking and nonimpact activities such as swimming and stationary bicycle until 6 months after removal to prevent refracture.

EXTERNAL FIXATION WITH AN AO FIXATOR OR WAGNER DEVICE

- Although not essential, the use of a fracture table is quite helpful in the application of external fixation. An image intensifier speeds up the procedure. Position the patient and reduce the fracture with traction. It is important to realize that, although small amounts of angular deformity can be corrected after the pins have been placed, rotational correction may be impossible to correct in some fixators. Therefore, the initial reduction should be as close to perfect as possible and should not be made with the expectation that the device can later be adjusted to compensate for an inadequate reduction.

- For an AO or Wagner fixator, use Schanz pins 6 mm in diameter, for which 4.5 mm holes are drilled in both cortices. To minimize tie-down of the quadriceps, apply the fixator laterally. Make a lateral stab wound over the femur at the level of the lesser trochanter. Carry it down through the deep fascia, then use a small elevator to slide posterior to the quadriceps and anteriorly to the lateral intermuscular septum. Elevate a small area on the femur.

- Drill the femur through a drill guide with a 4.5 mm drill point, and insert a Schanz pin bicortically. Place the fixator over the pin, adjust the fixator for length and alignment, and place the second Schanz pin through the distalmost hole of the fixator or through a guide if one is provided by the manufacturer. Place this pin at or just proximal to the lateral epicondyle.

- Adjust the fixator, confirm proper position of the fracture, and insert the two innermost pins. Some prefer to use three pins in each fragment.

- Achieve final reduction, lock the pin holders, and then apply compression across the fracture if possible.

- Follow the instructions for pin care outlined in Chapter 11. Regularly check the tightness of the clamps that secure the pins. Begin partial weight-bearing and active range-of-motion exercises immediately. At 8 to 12 weeks, the device may be replaced by a cast brace if callus has appeared and the fracture location and pattern are appropriate. Otherwise, the fixator can remain in place until the bony union is strong enough to eliminate the need for a cast brace, which is usually at least 4 months after fracture (Fig. 20.11) (28).

Plate fixation of a femur fracture.
Ipsilateral concomitant fractures of the hip and femoral shaft are unusual and pose a difficult treatment problem. Most of these are intracapsular fractures, with a high shear angle similar to a Pauwels type III fracture of the femoral neck. However, the fracture tends to begin distally in the base of the neck and extend across the neck, exiting in a subcapital location. Many of these are initially completely undisplaced and therefore are difficult to diagnose. In a review of the literature, Swiontkowski et al. (71) noted that in 10 articles on the subject, roughly one third of the femoral neck fractures reported were not detected initially. Casey and Chapman (19) postulated that most of the force in an ipsilateral femoral neck and shaft fracture is dissipated in the femoral shaft fracture, therefore often resulting in undisplaced or minimally displaced fractures of the femoral neck, which therefore have less soft-tissue damage and a much lower incidence of avascular necrosis of the femoral head than would be expected.

In every fracture of the shaft of the femur, an ipsilateral fracture of the femoral neck must be ruled out. Routine radiographs of the femur must include the hip joint with a good-quality AP and cross-table lateral views. From a practical viewpoint, many of these radiographs are taken in the emergency room under duress and do not give an ideal view of the femoral neck. For that reason, it is wise, prior to nailing a femoral-shaft fracture, to obtain a good-quality AP radiograph of the hip while it is in internal rotation, to throw the neck into full profile, with the patient on the fracture table and under anesthesia. A good-quality lateral must be taken as well, which the fracture table optimizes. If you detect a femoral neck fracture, you may need to alter treatment plans. When nailing is completed, repeat the radiographs of the hip, because hairline fractures not seen on initial films may appear after the vigor of a nailing. Any patient who has an unexpected proximal thigh or hip pain in the postoperative period should have these radiographs repeated because these fractures may appear even up to 6 weeks later in spite of good-quality initial films.

Computed tomography, magnetic resonance imaging, and bone scans are more sensitive than routine radiographs, but it is not practical and probably not economically feasible to order one or more of these studies on every patient with a femoral shaft fracture.

If the femoral neck fracture is picked up early, is not displaced, and is internally fixed in good position, the outcomes are usually good. Union rates approaching 100% and rates of avascular necrosis under 15% can be expected (71). Because of the risk of displacement of these fractures, which worsens the prognosis, they should be treated as surgical emergencies and internally fixed as soon as possible. Most are either undisplaced or can be reduced well on a fracture table with traction and gentle internal rotation despite an unstable shaft fracture. For that reason, fixation of the shaft is not always necessary to achieve a satisfactory reduction of the femoral neck. One can choose between fixation of the femoral neck or fixation of the shaft first, using independent fixation or a single device that provides combined fixation of both fractures. Alternatives for fixation include the following:

- Combined fixation with a gamma nail or reconstruction type nail
- Antegrade nailing of the femoral shaft with a standard nail or the AO “miss a nail,” followed by fixation of the femoral neck with independent screws in front of the nail

Use of gamma or reconstruction nails for such a combination can be quite challenging and requires considerable experience. For surgeons without extensive experience with these devices and this combination of fractures, independent fixation is probably easier and more reliable. In undisplaced fractures, multiple screw fixation, as described in Chapter 19 for the femoral neck, usually works well. If fractures are displaced, they tend to be much more unstable, and in young, vigorous individuals, a device such as a sliding compression hip screw, which provides better purchase on the shaft of the femur, may be indicated. In most cases, for the femoral shaft I now recommend a retrograde nail through the intercondylar notch at the knee, and occasionally plate fixation in select cases.

- Independent fixation of the hip with multiloop screws or a compression hip screw combined with independent fixation of the femoral shaft with an intercondylar retrograde nail or a plate
- Other possible combinations

HINTS AND TRICKS

- If the femoral shaft will be fixed first, particularly with an antegrade nail such as a reconstruction nail, achieve preliminary fixation of the femoral neck fracture with a suitable-size, smooth Steinmann pin placed from the lateral cortex up the femoral neck and head along the anterior cortex, where it will not be in the way of the medullary nail.
- Do not fix fractures in nonanatomic position, as this significantly increases the risk of nonunion and failure. In displaced fractures that will not reduce, open the fracture through a modified Watson-Jones approach to secure fixation in anatomic position.
- When using independent fixation, try to fix the hip first.
- When using intramedullary nails, overseam so that the nail can be driven gently, which avoids stressing the femoral neck fracture.

Postoperative care is determined by the healing of the femoral neck. This may require as long as 6 months, during which time the patient must not bear more weight than the weight of the leg, using assistive devices.

SIGNIFICANT CORTICAL LOSS

A substantial segment of cortex may be lost at the scene of injury or be completely detached from soft tissues at the time of initial debridement. Remove contaminated free cortical fragments when debriding open fractures, because they may become infected (Fig. 20.13). Although shortening of as much as 1.5 cm is usually tolerated, avoid larger discrepancies and maintain length with an interlocking nail. Many femurs heal even with a gap of several centimeters, particularly in patients under 20 years of age. Cortical losses of 3 cm or more are more likely to not heal. The initial nailing is not definitive and may be performed using a smaller-diameter nail with little reaming, because little weight bearing will be permitted. Several weeks after healing of the soft-tissue envelope, the patient may undergo a bone-grafting technique described by Chapman (see Chapter 30) (Fig. 20.13). Remove the initial nail and ream the canal to accept a larger nail of appropriate diameter. Using a chest tube, pass a slurry of iliac crest cancellous graft and reamings down the medullary canal into the fracture site, followed by placement of a new statically locked nail. The graft incorporates over several months, after which time weight bearing is progressively increased. Another alternative is a microvascularized fibula (49).
RESULTS
Since the introduction of interlocked intramedullary nails and current methods for irrigation and debridement of open fractures, the results in fractures of the shaft of the femur are truly remarkable. In closed fractures utilizing closed intramedullary techniques with reamed nails, reported union rates are from 96% to 100%, with infection rates only from 0% to 1% (4,6,12,17). In low-grade open fractures, Gustilo I through IIa, comparable results are achievable (3). In grade IIb open fractures, the infection rate after initial nailing approaches 11% (10). Therefore, a more sanguine and cautious approach is indicated for severe open fractures.

PITFALLS AND COMPLICATIONS
Complications specific to fractures of the shaft of the femur include malunion, nonunion, hardware breakage, infection, neurovascular injury, avascular necrosis of the femoral head, heterotopic ossification at the hip, and loss of joint motion.

MALUNION
With attention to detail, malunion can be avoided in the vast majority of cases. Varus or valgus malunion is most common in high subtrochanteric fractures, where varus is most commonly the result of an eccentric entry point, which, when combined with a large medial bone deficiency, results in loss of position of the proximal fragment during the nailing. Be certain that the entry site is correct. In some cases, it may be necessary to insert a Scharz pin into the proximal fragment to control it during nailing, or to open the fracture to reduce angulation. In supracondylar fractures nailed in the lateral position, varus may occur because of the angulation induced by gravity on the fracture, and recurvatum at the fracture can occur in the supine position. Keeping the guide pin centralized, and controlling the distal fragment as the nail is driven down into it, will usually prevent these problems. Control with a Schanz pin on a T-handle or opening the fracture may occasionally be necessary. Shortening most commonly occurs when there is significant comminution, which makes judgment of length difficult. Follow the recommendations in the section on “Selecting and Driving the Intramedullary Nail” to avoid leg-length discrepancy.

Rotational malunion is the most difficult to avoid. Preoperative evaluation of the range of motion of the opposite hip and attention to the angle of progression of the foot when the patient is lying in the supine position on the operating table often provides good guidelines as to how the rotational alignment of the fractured limb should be set. Yang et al. (89) recommend preoperative evaluation of the anteversion angle of the intact femur to provide more accurate assessment of rotation. With the advent of nonreamed small locked intramedullary nails, torsional distortion of these nails has been a new and unexpected cause of rotational deformity. This can be avoided by using either nonreamed or larger reamed nails (61). Careful postoperative examination of the patient on the operating table usually reveals any deformity, particularly in rotation. Plan to correct this at the time of the initial surgery rather than having to bring the patient back for repeat surgery or reconstructive surgery.

NONUNION
As mentioned earlier, nonunion is uncommon, and the treatment is addressed in Chapter 30. For the most part, nonunions occur in open fractures or in those with significant comminution. In segmental bone loss, angulation by any degree may be a problem in small proximal nails. Angulation of the fracture site, despite the tremendous healing capability of the femur, can also lead to nonunion. In segmental bone loss, early bone grafting, either open or with closed intramedullary technique, is indicated as soon as the soft-tissue envelope has recovered. In open fractures or where nonreamed nails were used, when no callus has formed by 12 weeks after injury, consider conversion to a large reamed locked nail. In delayed unions or nonunions where the problem seems to be distraction in the fracture site, dynamization may be sufficient if rotational stability will be maintained. Otherwise, exchange reamed locked nailing and compression are best.

NAIL OR SCREW BREAKAGE
Breakage may occur early in small-diameter nonreamed nails that use small screws, and late in larger reamed nails when the patient has continued to bear weight in the face of a nonunion. Removal of the side of a screw where the screw head is, presents little problem. Removal of the opposite segment of the screw may require an implant trephine, or occasionally, overreaming of the screw. Removal of the proximal end of the nail with the anterior fibular nerve palsy. Although direct surgical injury of a nerve in the incision in antegrade nailing is possible, it is exceedingly rare. In very small individuals, especially when the hip is flexed 20° or more, the sciatic nerve may drift quite close to the trochanter. If there is any question about the location of the sciatic nerve, lengthen the wound and explore it before placing screws. If the sciatic nerve is entrapped, division is indicated. Sciatic nerve division is caused by a combination of traction and excessive flexion of the hip with the knee in extension. Avoid this problem by never putting the foot into a traction stirrup but rather applying traction through a proximal tibial or distal femoral pin, allowing sharp instruments for entering the proximal femur. In most cases, sciatic nerve paresis is caused by a combination of traction and excessive flexion of the hip with the knee in extension. Avoid this problem by never putting the foot into a traction stirrup but rather applying traction through a proximal tibial or distal femoral pin, allowing the knee to flex freely to accommodate for stretch on the sciatic nerve.

AVASCULAR NECROSIS
Avascular necrosis of the femoral head secondary to antegrade femoral nailing is exceedingly rare but has been reported. It is most likely caused by interruption of the blood supply to the femoral head as a result of encroachment of the nail entry onto the superior aspect of the femoral neck (2). Avoid this complication by avoiding reamed nails in very small patients or in children with open physees. If antegrade nailing is indicated, use of flexible nails such as the Ender nail through the tip of the trochanter provides a good alternative.

HETEROTOPIC OSSIFICATION ABOUT THE HIP
In a review of 80 patients undergoing antegrade reamed nailing, Brumback et al. (13) found an incidence of 26% of heterotopic ossification. They found that irrigation with pulsatile irrigation did not affect either this incidence or the severity. Notably, the nail used in their study had an end cap that would permit flow of more contents into the hip region postoperatively. It is rare that this heterotopic ossification is sufficient to be symptomatic, but it is a significant impediment to nail removal, and infiltration into the gluteus medius musculature can result in significant damage to the muscle at the time of attempted removal of the ossification or of a medullary nail. It has been my experience that heterotopic ossification can be minimized by the following:

Figure 20.13. A: A grade III open fracture of the femur with approximately 10 cm of cortical loss at the scene of injury. The fracture was initially irrigated, debrided, and stabilized with a narrow-diameter, statically locked medullary nail. Local wound care consisted of dressing changes, with uneventful healing of the soft-tissue envelope. B: At 1 month from injury, the original nail was removed and the canal reamed to accept a 15 mm, statically locked nail. Simultaneously, a large amount of cancellous bone was harvested from the iliac crest and introduced into the fracture gap through a chest tube, using a technique described by Chapman (22). C: At 1 month from grafting, early callus can be seen forming across the fracture site. D: At 3 months from grafting, further callus formation is evident. E: At 15 months from fracture, the femur has completely reconstituted and hardware has been removed.

• Taking care to carefully protect the gluteus maximus and medius as well as other soft tissues about the hip during antegrade nailing
• Thoroughly irrigating and debriding the wound at the termination of the procedure, to remove any marrow contents or bone that might predispose to heterotopic ossification
• Using an intramedullary nail that has a cap screw that closes the nail off and prevents retrograde oozing of marrow contents postoperatively. If the heterotopic ossification is symptomatic, the treatment is removal of it after it has matured, which is usually at least 1 year after injury.

JOINT STIFFNESS AND MUSCLE WEAKNESS

Since the advent of modern techniques, loss of motion in the hip and knee after fractures of the shaft of the femur is uncommon unless there is concomitant ipsilateral injury of these two joints. It is important, however, to institute an early range-of-motion and muscle-strengthening program because neglect of rehabilitation can lead to stiffness and persistent weakness. A particular problem is weakness of the abductors in antegrade nailing, apparently due to the traumatic effect of the nailing on the gluteus medius and maximus muscles as well as a tendency to neglect those muscles during rehabilitation. Always include abductor strengthening exercises in the rehabilitation program.

AUTHOR’S PERSPECTIVE

For closed fractures of the shaft of the femur from just above the lesser trochanter to 2.5 cm proximal to the lateral epicondyle, and in both closed and open fractures grades I through IIIA, my preferred treatment is reamed locked nailing with an Allo titanium intramedullary nail—using an 11 mm nail in women and a 12 mm nail in men—which provides two transverse cross-locking screws proximally and distally. For routine diaphyseal fractures, I place two proximal transverse cross-locking screws proximally and distally, with two proximal transverse cross-locking screws at the level of the lesser trochanter.

In high subtrochanteric fractures, I move the rod more proximally, up to 1 cm proximal to the tip of the greater trochanter, and cross-lock into the femoral neck. In grade IIIB open fractures, when I feel that initial intramedullary nailing is the best approach, I use a nonreamed nail, planning conversion to a reamed nail as soon as the risk of infection has passed and the soft-tissue envelope has recovered. When I believe the risk of infection is too high, I use external fixation.

For retrograde nailing through the intracortylar notch of the knee, I prefer to use a standard Allo nail rather than a special retrograde nail, and I always try to use a nail 10 mm or larger so that the largest transverse cross-locking screws can be used. This is now my treatment of choice for patients with severe multiple injuries in whom rapid atraumatic fixation of the fracture in the supine position on a regular radiolucent table is necessary. I also prefer this technique for fixation of shaft fractures below the femoral neck fracture, using independent fixation of the femoral neck with either multiple screws or a sliding compression hip screw, depending on the configuration of the fracture. I rarely plate a diaphyseal fracture of the femur, reserving this technique for patients in whom the configuration of the femur or absence of a medullary canal precludes intramedullary nailing, or in whom a vascular repair has been done that is least threatened by plate fixation as opposed to nailing. I reserve single-plane half-pin external fixation for grade IIIB (and higher) open fractures and the occasional polytrauma patient in whom retrograde nailing is not possible.

B. PERIPROSTHETIC FRACTURES OF THE FEMUR

Fracture of the femur associated with a prosthetic implant is not unusual and is increasing in incidence (21,23,25,38,44,50,59,60,62,66,69,74). The second leading cause of revision hip arthroplasty at the Mayo Clinic is now periprosthetic fracture (44). The overall prevalence is between 0.1% and 1.1% of total hip prostheses. Periprosthetic fractures can occur acutely at the time of initial implantation of the prosthesis or later. Factors that predispose to periprosthetic fractures include the following:

• Intraoperative creation of cracks, defects, or windows in the bone that are not bypassed with a stem of sufficient length
• Extravasation of cement out of bone defects that results in an unhealed stress riser
• Severe cortical erosion from a loose femoral component
• Hip surgery prior to prosthetic replacement, because of weakening of the bone or because of holes left from previous implants

These fractures usually occur in elderly patients with osteoporosis who have had total joint replacement of the hip or knee. Because the bone is weak, and on one side of the fracture the medullary canal is occupied by the prosthesis, internal fixation becomes a major challenge. Many surgeons have recommended nonoperative treatment for these fractures, but experience has shown that nonoperative treatment leads to a high rate of local and systemic complications (39). Local complications include fracture nonunion, femoral shortening, femoral deformity, and prosthetic loosening. These complications require major secondary surgery for correction. Prolonged bed rest and immobilization can produce life-threatening complications. These risks for nonoperative treatment, combined with the high likelihood of the need for future revision arthroplasty, have led to a recommendation of internal fixation for all displaced fractures associated with femoral prostheses, whenever clinically possible.

CLASSIFICATION

Fractures of the femur associated with an implanted femoral prosthesis can be classified on the basis of type and location of prosthesis, the type and configuration of fracture line, and the status of prosthesis fixation (i.e., whether it is stable or loose).

TYPE AND LOCATION OF PROSTHESIS

The following situations may be encountered:

Surface Replacement of the Proximal Femur

Fractures associated with surface replacements of the hip usually occur at the femoral neck just distal to the prosthesis. Treat by converting the surface replacement to a standard total hip replacement arthroplasty. In the unusual case in which a fracture occurs at or distal to the intertrochanteric region, you may treat it by the usual operative methods for similar fractures not associated with a prosthesis.

Stemmed Replacement of the Proximal Femur

Stemmed prostheses of the proximal femur may be further subdivided into those in which the femoral stem and cement, or the stem alone occupies the entire medullary canal, and those in which the femoral stem occupies only a portion of the medullary canal. In fractures in which the entire medullary canal is filled with a prosthetic stem, with or without cement, placement of a new prosthesis with a longer stem provides intramedullary fixation (Fig. 20.14). An alternative method is to fix the fracture with a plate, supplemented with bone grafting (Fig. 20.15, Fig. 20.16). Secure the plate with bicortical screws in the femur distal to the prosthesis, and with unicortical or tangential screws proximally where the medullary canal is filled by the prosthetic stem (Fig. 20.16). Another method of securing the plate proximally is to use cerclage wires or cable systems (Fig. 20.17). If an uncemented stem occupies only a portion of the femoral canal, it is sometimes possible to gain adequate fixation by passing small flexible intramedullary rods, such as Ender or Rush rods, across the fracture site and into the medullary canal adjacent to the prosthetic stem (Fig. 20.16).
Figure 20.14. Use of a long-stemmed femoral prosthesis and cerclage wires to hold the reduction of a long oblique fracture.

Figure 20.15. Plate and screw fixation of a fracture at the tip of a proximal femoral prosthesis.

Figure 20.16. Three possible methods of plate and screw placement to be used if the intramedullary stem prevents central bicortical screw placement. The goal is to obtain a solid purchase on eight cortices on each side of the fracture.

Figure 20.17. Use of cerclage wires to secure fixation of a plate to the proximal femur segment.

Figure 20.18. A: Flexible small intramedullary rods are used to internally fix fractures of the femoral shaft distal to the tip of an uncemented proximal femoral prosthesis that fills the entire canal. B: Possible intramedullary placement if the prosthesis stem is not cemented and does not fill the entire canal.

Femoral Prosthesis Associated with Knee-Replacement Arthroplasty

Fractures around total knee prosthesis can include femoral prosthesis associated with knee replacement arthroplasty; distal femoral surface replacement without a stem; cemented distal femoral replacement with an intramedullary stem; and uncemented distal femoral replacement with an intramedullary stem. Fractures of the distal femur just proximal to a total knee replacement are most often associated with anterior notching of the femur caused by poor placement of the cutting guides during total knee arthroplasty. The notching causes weakening of the femur just above the prosthesis, and delayed fracture propagating from the stress riser is not an uncommon complication.

Distal femoral prostheses not associated with a femoral stem are essentially surface replacement prostheses. In fractures that occur proximal to a nonstemmed prosthesis, alternatives include a condylar blade plate or compression screw with side plate screws (Fig. 20.19), retrograde nails (Fig. 20.20), and antegrade nails (Fig. 20.21). In fractures associated with a distal femoral prosthesis that has an intramedullary stem, a revision can be done using a longer stem (Fig. 20.22) or a plate-and-screw fixation with tangential placement of the screws to avoid the stem.

**TYPE AND CONFIGURATION OF FRACTURE LINE**

**Proximal to or at the Tip of the Prosthetic Stem**

The most common fractures of the femur associated with femoral prostheses are transverse or short oblique fractures at, or proximal to, the tip of the femoral stem [Johansson type I (38)]. Long oblique or spiral fractures in this location are less common. The fractures usually result from trauma at a stress riser created by the transition between the stiff one-prosthesis segment and adjacent, less stiff bone. If the fracture is transverse or short oblique, there is a high risk of displacement, shortening, and nonunion. Internal fixation is recommended. If the fracture has a spiral or long oblique course, displacement may be minimal, and if there is no associated loosening of the prosthesis, treatment can be nonoperative, consisting of fracture bracing and crutches.

**Around the Prosthesis**

For fractures to occur around the prosthesis, a portion of the prosthesis must be loose. Johansson type II fractures occur around the prosthesis and extend to beyond the distal tip of the prosthesis with dislodgement of the stem from the distal canal. The prosthesis may have been loose before injury, or the fracture itself may break the prosthesis from its fixation to the surrounding bone. In these situations, the fracture must be reduced and internally fixed, and the prosthesis must be revised (Fig. 20.23).
Allografts in the Treatment of Periprosthetic Femoral Fractures.

Figure 20.25. Use of a long-stemmed proximal femoral prosthesis with cerclage wires to contain fragments around the stem.

At a Distance from the Prosthesis

Fractures that occur at a distance from the prosthesis (Johansson type III) may be treated by plate fixation. However, the interval of bone between the end of the plate and the tip of the prosthetic stem is subject to high stresses and is a potential site of future fracture.

STATUS OF PROSTHESIS FIXATION

If the prosthesis remains tight and well fixed to bone, aim fracture management at reestablishing bony alignment and achieving union. If the prosthesis is loose, fracture fixation is necessary, and the prosthesis must be reimplanted with a longer stem and recemented or, if a porous-coated long-stemmed prosthesis is used, bone-grafted. Frequently, cerclage wires or cables are required to “gather in” bone fragments or to oppose oblique fractures around the prosthesis (Fig. 20.23).

Chandler and Tigges (21) recommend reinforcing the fracture site with allograft when a proximal femoral fracture occurs at or distal to a well-fixed femoral stem, or proximal to a well-fixed knee replacement. They recommend the following techniques.

Fixation with Allograft Reinforcement

- Expose the fracture, reduce it anatomically, and temporarily stabilize it with cerclage wires or cables (Fig. 20.24A, Fig. 20.24B).
- Obtain an allograft femoral or tibial shaft of appropriate size, harvest the diaphyseal portion, and split it into two equal medial and lateral shells in the sagittal plane to provide biological bone plates. Fresh frozen allografts are preferred, but freeze-dried allografts are also thought to be effective (Fig. 20.24C).
- Machine the endosteal inside surfaces of the grafts with a high-speed burr to conform them to the outside contours of the recipient femur (Fig. 20.24D).
- Place these on the medial and lateral sides of the femur, preserving the soft-tissue attachments to the linea aspera, which contain the extraosseous blood supply to the femur. Make the struts long enough to extend at least 10 cm beyond the fracture both proximally and distally (Fig. 20.24E).
- Apply the allograft struts to the fracture, and compress them into place with commercial hose clamps (Fig. 20.24F).
- With a wire passer, pass double #16 stainless-steel cerclage wires around the struts at 2–4 cm intervals (Fig. 20.24G).
- Tighten the wires. I: The hose clamps have been removed, and the autologous graft has been applied. (Reproduced with permission from Chandler HP, Tigges RG. The Role of Allografts in the Treatment of Periprosthetic Femoral Fractures. In: Cannon WD, ed. Instructional Course Lectures, Vol. 47. Rosemont, IL: American Academy of Orthopaedic Surgeons, 1998.)
- With a wire passer, pass double #16 stainless-steel cerclage wires around the struts at 2–4 cm intervals (Fig. 20.24G).
- Tighten the wires with a Harris wire tightener (Johnson & Johnson, Raynham, MA) (Fig. 20.24H). When the allograft has been secured with the wires, remove the hose clamps.
- Use protected weight bearing to 60 pounds (27 kg) until 12 weeks, then advance weight bearing.

For femoral fractures distal to a well-fixed femoral stem or proximal to a well-fixed knee replacement, Chandler and Tigges (21) recommend retrograde intramedullary nails—assuming that the knee prosthesis permits insertion of the nail, and recognizing that in total hip replacement there is the potential for a stress riser between the proximal end of the medullary nail and the distal end of the stem of the prosthesis (21,56,65,70).

Where rods cannot be used, plate fixation is indicated. Pack autologous cancellous bone around the fracture site. However, comminution and the osteopenic bone frequently found in this group of patients result in poor screw fixation. To circumvent this problem, harvest an allograft from either a tibia or a femur (probably better from a comparable femur). Chandler and Tigges (21) back up the plate on the opposite cortex with an allograft strut harvested from the identical location on the allograft femur so that the strut fits the host femur accurately (Fig. 20.25). Their technique includes the following.

Figure 20.25. An allograft shell placed on the opposite cortex to reinforce the fixation and provide a structural bone graft. (From Chandler HP, Tigges RG. The Role of Allografts in the Treatment of Periprosthetic Femoral Fractures. J Bone Joint Surg Am 1997;79:1422.)
THE VANCOUVER SYSTEM

Duncan and Maeri (28) have modified Johansson’s (38) classification system to create the Vancouver System. Their classifications for fractures about a total hip prosthesis follow.

- Type A: Trochanteric fractures
- Type B: Fractures about the stem or tip
  - B1: Well-fixed stem
  - B2: Loose stem
  - B3: Associated bony deficiency or destruction
- Type C: Fractures distal to the tip

Lewallen and Berry’s (44) recommendations for these include the following:

- Type A: Treat simple avulsion fractures of the greater or lesser trochanter in the presence of a well-fixed stem nonoperatively. For severe periprosthetic osteolysis, replace the component that is the source of the microparticles.
- Type B1: These usually can be treated with internal fixation.
- Type B2: Revise the loose component.
- Type B3: Revise the component.
- Type C: Internal fixation usually suffices.

Lewallen and Berry (44) emphasize that in all types of fractures associated with a loose femoral component, the best treatment is revision unless medical problems or advanced age contraindicates this extensive surgery.

SURGICAL TECHNIQUES

Femur fractures in which a prosthesis is in place are long and difficult surgical cases requiring excellent support and careful preoperative planning. If possible, have autogenous blood and a cell saver available. A laminar flow unit or ultraviolet radiation may reduce the infection rate.

- Expose the distal femur and total knee through a medial parapatellar incision.
- Reduce the fracture, and temporarily hold it reduced with cerclage wires or a K-wire while the plate is fitted to one cortex and the allograft strut to the opposite cortex.
- Stabilize the plate and strut to the host femur with cerclage cables or wires in the area of an intramedullary stem, and use screws elsewhere (Fig. 20.17).

Their postoperative care is the same as that already described.

POSTOPERATIVE CARE AND REHABILITATION

Ideally, fracture fixation must be sufficiently solid so that the patient can be out of bed and ambulatory by the 4th or 5th postoperative day. In patients with good bone stock and strong intramedullary fixation, weight bearing can progress as with any fracture fixed with an intramedullary device. For patients who have had a trochanteric osteotomy and reattachment, use at least 6 weeks of touchdown weight bearing to avoid displacement of the trochanter. If the femoral prosthesis has been exchanged, the usual postoperative precautions associated with joint replacement to prevent dislocation and other complications are necessary.

RESULTS

Johansson et al. (38) reported on 35 patients with 37 periprosthetic fractures following total hip replacement after a follow up averaging 3.9 years (range, 2–9 years). Their results were dismal, with unsatisfactory outcomes in 22 fractures (99%). The most common problem was prosthetic loosening, which occurred in ten, followed by malunion with loosening in three, nonunion in three, massive heterotopic bone in one, infection in three, and two unsatisfactory outcomes in primary Girdlestone resections. Seven immediate postoperative fractures that were treated in traction all had unsatisfactory results. Johansson et al. had a total of 30 complications (60%) in their 22 patients. Improvement in techniques to handle these difficult problems have shown markedly improved results. Chandler et al. (29) in 1993 achieved anatomic union in 100% of periprosthetic fractures treated with their technique of onlay grafting, with all returning to their functional status prior to fracture.
PITFALLS AND COMPLICATIONS

Operative complications of treating fractures associated with femoral prostheses usually stem from difficulties of cement and prosthesis removal or inadequate preoperative planning. A variety of prosthetic alternatives, including cemented and uncemented devices of various stem sizes and lengths, must be available to deal with unexpected technical problems.

Always available a long-stemmed power burr and intramedullary reamers and cures for removal of cement. It is important to know the techniques for removal of broken hardware from the medullary canal, including the use of an image intensifier, to avoid cortical perforation during reaming. Preoperative planning should include careful silhouetting of the femur and fracture with appropriate templates to determine prosthesis size and to match components for the revision. Appropriate plates, screws, and intramedullary rods must be available. It is not uncommon to change techniques from those planned because of intraoperative findings at the time of surgery. Multiple options must be open to achieve optimal fixation.

Postoperative complications usually arise from inadequate prosthetic fixation or refraction. If cement fixation is insufficient, the prosthesis will become loose, particularly in patients in whom the original prosthesis loosened because of periprosthetic cortical lysis. In patients in whom a prosthesis is left in place and plates or screws or cerclage techniques are used to stabilize the fracture, fixation is always less than ideal. Take care to delay weight bearing until the fracture has united, because excessive and premature weight bearing may lead to loss of fixation, displacement, and nonunion, requiring reoperation. Patients who have a stress riser between the end of the prosthesis and an adjacent plate are always at risk of refraction and must be cautioned to avoid trauma to the leg.

ACKNOWLEDGEMENT

This chapter in the second edition was written by Sigvard T. Hansen, Jr., and David W. Lhowe. Portions of their original, excellent chapter are included here.

CHAPTER REFERENCES

+ Chandler HP, Danyuch K. Treatment of Distal Femoral Fractures Proximal to a Total Knee Replacement or Distal to the Stem of a Total Hip Replacement in Osteoporotic Patients. Presented as a poster exhibit at the annual meeting of the American Academy of Orthopaedic Surgeons, Atlanta, Georgia, February 25, 1996.
Fractures of the distal femur (i.e., the distal 15 cm of the femur) in the adult account for only 7% of all femoral fractures, but because of our modern lifestyles and high-velocity means of transportation, these injuries are being seen with increasing frequency. Fractures of the distal femur are often complex injuries that present the surgeon with numerous potential complications. Although there has been an increasing trend toward internal fixation of fractures of the distal femur, the management of these fractures remains controversial (4, 6, 16, 26, 31, 38, 40, 41, 46, 51, 52, 54, 55, 56, 70).

Among young patients, this injury is usually a component of multiple trauma due to high-velocity, high-energy incidents, such as motor vehicle accidents or falls from a height. In particular, motorcycle accidents are a prime cause for these fractures in the 17- to 30-year-old patient. The elderly patient may present with a fracture resulting from trivial trauma, such as falling on the flexed knee. Both groups benefit by early mobilization.

In the past, this injury was treated by skeletal traction for a variable duration, followed by some form of cast or brace immobilization (10, 11, 42). Complications associated with the closed management of this fracture have led to the proposal of a number of alternative methods of internal fixation. In 1966, Stewart (69) and, in 1967, Neer (45) and their associates reported large series of distal femur fractures treated by both open and closed methods. Most of the surgically treated patients required prolonged supplemental immobilization, negating the advantages of open reduction and internal fixation. This led both groups to recommend closed management strongly, despite their findings that this method results in significant problems—primarily varus and valgus angulation, internal rotation deformity, and inadequate recovery of knee motion.

Although early attempts at internal fixation of distal femur fractures frequently gave unacceptable high rates of malunion, nonunion, and infection, improved techniques of internal fixation have yielded results far superior to those achieved with nonsurgical management. Meticulous internal fixation has been shown to yield good to excellent results in 60% to 80% of cases and allows immediate mobilization of the patient and the extremity, minimizing the cardiopulmonary and other multisystem sequelae of long-term immobility (53). A number of excellent devices are now available that provide improved techniques for fixation of these fractures. These include, but are not limited to, the 95° angled blade plate, the 95° condylar screw, the cloverleaf condylar plate, combined medial/lateral and anterior double plates, the antegrade interlocking intramedullary nail, the Green-Seligson-Henry (GSH) and other retrograde intramedullary nails, wound closure and postoperative care, external fixation, phalas and complications, and chapter references.

Fractures of the distal femur (i.e., the distal 15 cm of the femur) in the adult account for only 7% of all femoral fractures, but because of our modern lifestyles and high-velocity means of transportation, these injuries are being seen with increasing frequency. Fractures of the distal femur are often complex injuries that present the surgeon with numerous potential complications. These include, but are not limited to, the 95° angled blade plate, the 95° condylar screw, the cloverleaf condylar plate, combined medial/lateral and anterior double plates, the antegrade intramedullary (IM) nail, and the retrograde supracondylar nail.

**CLINICAL ASSESSMENT**

Fractures of the distal femur often occur in patients who have sustained multisystem trauma, usually characterized by injuries of the head, chest, abdomen, and other parts of the skeletal system. The immediate objective is to identify and treat life-threatening problems and initiate protocols to achieve and maintain cardiovascular and cardiopulmonary stability. Although these fractures rarely are life-threatening, they do contribute to the hemodynamic response to trauma and may involve neurovascular structures to the extent that limb viability is jeopardized. Always include careful clinical and radiographic assessment of the pelvis and bilateral lower extremities in the initial trauma workup. Assessment of the implications of these fractures and planning for surgical intervention should be done during the early resuscitative period. Ordinarily, internal fixation can be completed initially and certainly by the third post-trauma day, depending on the extent of other injuries. Look for local swelling, painful crepitus with motion, and deformity of the thigh. Apply hand traction and bend gentle when realigning the deformity before splinting it. Carefully assess the soft tissues. A small puncture wound over the distal thigh or suprapatellar pouch area may represent an open fracture. Suspect neurovascular damage if there is distal coolness, pallor, diminished pulses, or increased fullness in the popliteal space. Immediate arteriography may be indicated if evidence of circulatory impairment is present or neurologic compromise is possibly due to a vascular lesion.

Take a complete series of good-quality radiographs of the entire limb and pelvis, if indicated. Identify ipsilateral as well as contralateral fractures or dislocations of the pelvis, hip, knee, and lower leg. These associated injuries are often missed in the initial assessment.

**CLASSIFICATION**

The classification of fractures traditionally serves to organize approaches to treatment and provides a basis for comparing results of various treatments. Developing a workable classification system for fractures of the distal femur is problematic because the fractures have an infinite number of configurations and the injury is always associated with other considerations such as injury of the soft tissues that play an important role in determining the approach to treatment and its outcome. I recommend using a combined system that accommodates both the anatomic characteristics of the fracture and its “personality.”

The AO/ASIF classification developed by Müller and associates (45) is excellent. A1, A2, and A3 are fractures proximal to the condyles with the condyles intact. B1, B2, and B3 are variations of a single condylar fracture. C1, C2, and C3 are the more complex multicondylar fractures combined with associated supracondylar fractures (Fig. 21.1). Other factors that establish the fracture’s personality include...
serve as a warning of the difficulty of surgical treatment of distal femur fractures. A study revealed that if the requirements of accurate reduction and stable fixation are met, good results can be achieved in most cases. Furthermore, this study should emphasize the importance of strict adherence to the basic recommendations. Good results can be expected in most cases when basic AO/ASIF principles are followed. In a classic article in 1979, Schatzker and Lambert demonstrated the importance of diligent preoperative planning, meticulous intraoperative technique, and comprehensive postoperative management is important. Support. A knowledge of closed methods of treatment is essential and should always be considered as the decision for operative management is weighed.

If the above-mentioned criteria are met, the following may be considered indications for surgery:

- Extraarticular fractures in which acceptable reduction cannot be obtained or maintained.
- Displaced intraarticular fractures. Distal femoral fractures combined with ipsilateral (floating knee) or contralateral fractures to begin early mobilization of the knee and to facilitate control of the limb. Fix bilateral femoral fractures internally to facilitate general care.
- Supracondylar femur fractures in patients with multiple system injuries.
- Obesity. Extremely obese patients are best managed by internal fixation because of the difficulty in treating them with skeletal traction or a cast-brace.
- Vascular repair. A distal femur fracture associated with vascular damage should be stabilized to protect the vascular repair.

RELATIVE INDICATIONS

The management of elderly patients must be individualized. Advanced age alone should not be considered a contraindication to internal fixation. In 1982, Mize et al. introduced the ambulatory cast-brace. In 1974, Mays and Neufeld introduced roller traction, which when combined early with a cast-brace, allowed early mobilization of the patients and early restoration of knee motion.

If the above-mentioned criteria are met, the following may be considered indications for surgery:

- Extraarticular fractures in which acceptable reduction cannot be obtained or maintained.
- Displaced intraarticular fractures. Distal femoral fractures combined with ipsilateral (floating knee) or contralateral fractures to begin early mobilization of the knee and to facilitate control of the limb. Fix bilateral femoral fractures internally to facilitate general care.
- Supracondylar femur fractures in patients with multiple system injuries.
- Obesity. Extremely obese patients are best managed by internal fixation because of the difficulty in treating them with skeletal traction or a cast-brace.
- Vascular repair. A distal femur fracture associated with vascular damage should be stabilized to protect the vascular repair.

CONTRAINDICATIONS

The contraindications to surgical fixation of fractures of the distal femur are patients with massive, severe comminution; severe osteopenia; or the presence of infection or severely contaminated soft tissues that cannot be adequately debrided.

PRINCIPLES OF TREATMENT

The AO/ASIF has developed principles of management that are central to successful surgical intervention:

- Good preoperative planning.
- Gentle handling of soft tissue.
- Accurate anatomical reduction.
- Rigid, stable internal fixation.
- Bone grafting of any defects.
- Early, active rehabilitation of the limb and the patient.

Good results can be expected in most cases when basic AO/ASIF principles are followed. In a classic article in 1979, Schatzker and Lambert demonstrated the importance of strict adherence to the basic recommendations. They used AO instruments and implants, and when they evaluated their results, two distinct groups emerged. When the basic principles of accurate reduction and stable fixation were followed, good to excellent results were achieved in 71% of the cases. In the other group, despite using the same instruments and implants, the basic principles were not followed, and only 21% of this group showed good to excellent results. This study revealed that if the requirements of accurate reduction and stable fixation are met, good results can be achieved in most cases. Furthermore, this study should serve as a warning of the difficulty of surgical treatment of distal femur fractures.
PREOPERATIVE MANAGEMENT AND PLANNING

Unless immediate surgery is indicated, place the injured limb in balanced suspension with tibial pin traction. Perform surgery immediately or within 24 to 48 hours after the injury. A radiograph of the opposite normal femur is helpful for preoperative planning. A tunnel view of the intercondylar notch is helpful in judging the displacement of vertical fractures into the joint. Use templates to draw the outlines of the femur and fracture lines. Determine the type, size, and position of the implants and the need for a bone graft. Select all necessary instruments, implants, and back-up devices. The chief surgeon must review and discuss the procedure step by step with the assistant surgeons and surgical staff. This type of careful preoperative planning is important to smooth surgical technique and a successful outcome.

INTERNAL FIXATION

FIXATION DEVICES

Fractures of the distal femur may be repaired using cancellous screws, a dynamic condylar screw system, a 95° angled blade plate, a cloverleaf-type condylar plate, combined medial/lateral or lateral/anterior double plates, an antegrade interlocking IM nail, or a retrograde supracondylar nail, depending on the type of fracture, available instrumentation, and the surgeon's experience and skill. I prefer the AO/ASIF system.

Lag Screws

Interfragmentary compression using AO 6.5 mm cancellous, or similar, screws may suffice for simple stable intra-articular unicorticar fractures (Müller type B1 or B2). Washers are usually necessary, and one screw should always be in a buttress position.

AO 95° Angled Blade Plate

The angled plate has been one of the most commonly used devices in the past for internal fixation of fractures of the distal femur (Fig. 21.2A). Because of its one-piece construction and the broad, flat blade, the blade plate provides stable fixation for most fracture types, but the one-piece characteristic of the blade plate also accounts for the difficulty in using it. Precision and correct alignment in all three planes is required for the insertion of this device.

Dynamic Condylar Screw

The dynamic condylar screw (DCS) system (Fig. 21.2B), is a supracondylar plate combined with a lag screw (16,18,30,49,52,53,56,71). This two-piece device is more forgiving and allows correction in the sagittal plane after the lag screw is inserted. Precise seating is also easier because the channel is precut directly over a guide wire. The cannulated triple reamer used for cutting the hole for the screw has less risk of disrupting split condyles than the seating chisel, especially in young, hard, cancellous bone. The DCS also has an advantage in that it provides interfragmentary compression of condylar fragments (57).

SURGICAL APPROACHES

For internal fixation, the distal femur can be exposed through a straight lateral, anterolateral, anteromedial, or straight medial approach. These surgical approaches are described in Chapter 3. Complex intraarticular fractures are best exposed through an anterolateral approach such as that used for total knee arthroplasty, displacing the patella medially. This approach provides access for lateral implants and permits access to the articular condyles.

SURGICAL TECHNIQUES

OSTEOTOMY OF THE TIBIAL TUBERCLE

Only rarely is osteotomy of the tibial tubercle necessary, but it is described here for completeness.

- To reflect the tibial tubercle, extend the incision to a point about 15 mm distal to the tuberosity. Extend the retinacular dissection along the lateral margin of the patellar tendon. At this point, the tibial tuberosity should be fully exposed so that the exact center can be identified.
- Make a 3.2 mm drill hole through this center and continue it carefully through the posterior cortex. Overdrill the hole in the anterior or near cortex with a 4.4 mm drill. Measure the distance between the anterior and posterior cortices so the appropriate-length 6.5 mm cancellous screw can be used later to stabilize the bone block.
- Tap the near cortical hole with a 6.5 mm tap.
- Identify the four cortices of the tibial tuberosity and make a drill hole at each corner through the near part of the cortex using a 3.2 mm drill.
- Carefully remove a block of cortical and cancellous bone consisting of the entire tibial tuberosity with the attached patellar tendon. To accomplish this, connect the four corers holes by osteotomies made with a narrow, straight osteotome or small sagittal saw, and lift the block out using 1/8-inch (1.3 cm) curved osteotome. The block should be about 1.5 cm thick.
- Reflect the bone block, with attached tendon and patella, medially to give complete exposure to the anterior and articular surfaces of the distal femur (Fig. 21.3).

Figure 21.3. After the tibial tuberosity is elevated, a good exposure of all components of the fracture is achieved. (Redrawn from Mize RD, Buchloz RW, Grogan DP. Surgical Treatment of Displaced, Comminuted Fractures of the Distal Femur. J Bone Joint Surg 64-A:978, 1982, with permission.)
FRACTURE REDUCTION

- Following the surgical exposure, clean the fracture fragments of hematoma and inspect the entire knee joint. Then reduce and stabilize the intraarticular condylar fragments. For purposes of this discussion, the Müller type C1, which is a T or Y fracture with split condyles, will be used (Fig. 21.4).

**Figure 21.4.** The Müller type C1, the so-called T or Y condylar fracture with split condyles.

- With the knee flexed at 90°, reduce the condyles anatomically and restore the articular surface and patellofemoral groove. Secure the reduction with large sharp pointed tenaculum bone-holding forceps. Provisionally fix the condyles with Kirschner wires (K-wires). Do not place the K-wires where they will interfere with fixation.
- Stabilize the condyles by placing two 6.5 mm cancellous screws with washers (Fig. 21.5). Choose the sites for screw placement carefully to avoid the entry site of the condylar lag screw or seating chisel. Insert the screws slightly proximal to the proposed site of the primary fixation device, and posterior and anterior to the middle of the shaft, well away from the anticipated path of the slide plate.

**Figure 21.5.** A: The articular surface and split condyles have been restored and fixed with two 6.5 mm cancellous screws with washers. B: The screws are inserted slightly proximal to the proposed entry site of the large condylar screw, and posterior and anterior to the middle of the shaft, well away from the anticipated path of the side plate.

- Reduce the supracondylar component of the fracture. When there is minimal comminution in the metaphyseal area, reduce the condyles directly to the proximal fragment and temporarily fixed with multiple crossed K-wires or better stabilize with one or more 4.5 mm cortical lag screws inserted using lag technique.

**HOFFA FRAGMENT**

A coronal split in the femoral condyles, either medial, lateral, or both, particularly of the posterior part, may produce a Hoffa fragment. This is very difficult to manage because the entire fragment may be covered by articular cartilage and is devascularized. These fractures must be recognized, anatomically reduced, and solidly stabilized when traction is between the femur and tibia. The same principles apply to metaphyseal fractures.

**INDIRECT REDUCTION**

- Indirect reduction techniques use tension on the soft-tissue attachments to the bony fragments to pull and guide them back into their proper alignment (Fig. 21.6). This process, also known as ligamentotaxis, has often been equated with the sails of a ship because the lines are pulled taut, and wind fills the sail and holds it in the desired position. This technique is indicated in severely comminuted intraarticular fractures of the distal femur, one of the most difficult types to align and stabilize when traction is between the femur and tibia. The same principles apply to metaphyseal fractures.
- Strip soft tissues only in area where the plate will lie. Next, insert the blade plate or condylar screw (Fig. 21.6A). Insert two Schanz pins, one proximal to the side plate and one into the condyles through the most distal plate hole (Fig. 21.6B). Through distraction of the soft-tissue attachments, pull and guide the bony fragments into reasonable alignment. A small periosteal elevator or dental pick can be helpful to tease and guide fragments. By overdistracting, it becomes easier to tease fragments into better alignment (Fig. 21.6C). With the fragments restored to their proper alignment, turn the nuts on the distractor counter clockwise to "slightly compress" the comminuted zone (Fig. 21.6D).

**Figure 21.6.** Indirect reduction of a supracondylar fracture of the femur. A. Reduce and fix the intraarticular fracture and insert a blade plate or condylar screw. B. Insert Schanz screws distal and proximal to the fracture and attach the distractor. C. Overdistract the fracture and tease comminuted fragments into position. D. Now slightly compress the comminuted zone to complete the reduction. E,F. Selectively insert screws to complete the fixation.

- After axial and rotational alignment have been verified, attach the proximal end of the plate to the femoral shaft, skipping the comminuted zone. Selectively insert lag screws to increase both the stability and fixation of the construct (Fig. 21.6E, Fig. 21.6F). With this technique, medial bone grafts are not necessary and are not recommended because they require stripping of the medial soft tissues for placement. Maintenance of soft-tissue attachments usually promotes rapid healing of the fracture because the blood supply to the comminuted fragments is maintained.

**DYNAMIC CONDYLAR SCREW SYSTEM**
The DCS has two major components connected with a small compressing screw. It has a 95° angle between the screw and the side plate, and both the screw and side plate are available in a variety of lengths. The condylar screw must be inserted parallel to the knee joint on the anteroposterior view and on the lateral side of the femoral condyle so that the plate will lie flat on the lateral midshaft. Proper alignment may prove difficult until the technique, which involves the use of K-wires and the plate are available in a variety of lengths. The condylar screw must be inserted parallel to the knee joint on the anteroposterior view and on the lateral side of the femoral condyle so that the plate will lie flat on the lateral midshaft. Proper alignment may prove difficult until the technique, which involves the use of K-wires and the available aiming devices, is mastered. With practice in a motor skills workshop, experience with simple fractures, and good preoperative planning with close attention to detail, the technique can be mastered. Determine the position of the condylar screw by placing three K-wires (Fig. 21.7A, Fig. 21.7B, Fig. 21.7C, Fig. 21.7D and Fig. 21.7E).

![Figure 21.7. Placement of the three directional guide wires.](image)

- With the knee bent to 90°, insert a 2 mm K-wire transversely through the soft tissues of the anterior knee joint and parallel to the joint axis (Fig. 21.7A, wire 1). Insert a second wire (Fig. 21.7A, wire 2) anteriorly over the lateral and medial condyles to show the inclination of the patellofemoral joint. The distal femur is rhomboid-shaped; therefore, this wire will slope from anterolateral to posterior medial.
- The location of the site for insertion of the screw, and for a blade plate as well, must be precise if the side plate is to lie on the midportion of the lateral aspect of the femoral shaft. To determine this, measure 2 cm proximal to the articular surface and draw a line with a marking pen at right angles to the axis of the femoral shaft (Fig. 21.7C, line a). Then divide this line in half (line b). Draw a cross line (c) at the halfway point of the anterior half of line a. This will generally result in proper positioning of the guide pin for the screw. Verify with direct visualization.
- The DCS angle guide is a mirror image of the side plate and is used in placing the guide wire through the lateral condyle (Fig. 21.7D, Fig. 21.7E). Use a standard 9 inch or 230 mm guide wire. The guide pin must be parallel with the first and second guide wires. It is the definitive guide for the triple reamer and the subsequent placement of the large condylar lag screw. Insert it under fluoroscopic visualization until the medial cortex is reached. When the correct position of the guide pin has been verified, remove the first and second K-wires (Fig. 21.8A).

![Figure 21.8. A: Slip the cannulated condylar screw over the guide wire and into the reamed hole. B: Insert the dynamic compressing screw. C: Tighten the compressing screw, resulting in interfragmentary compression between the split condyles.](image)

- Slip the direct measuring device over the guide wire and read the length of the guide pin that has been inserted into the femur (Fig. 21.8B). Reverse calibration on the measuring device allows direct measurement of the guide pin depth. After taking the measurement, advance the guide wire a few millimeters to further engage the medial cortex to help prevent inadvertent removal of the guide wire with the triple reamer. Note that because of the rhomboidal shape of the femoral condyles, the guide pin should appear short on the AP view (Fig. 21.7B). Overpenetration will result in prominence of the point of the lag screw in the knee joint, which is painful.
- Assemble the triple reamer (Fig. 21.8C), which allows you to set the depth in 5 mm increments and has a locking nut to prevent slippage of the depth setting during the reaming procedure. Always verify that you have the correct triple reamer. To distinguish the condylar triple reamer from the one used for the hip, it is labeled DCS. Set the depth setting to about 10 mm less than the measurement taken from the direct measuring device. The reamed channel will end about 10 mm from the medial cortex. Slip the cannulated triple reamer over the guide wire to ream the channel. Occasionally, the guide wire will be inadvertently withdrawn with the triple reamer (Fig. 21.9A, Fig. 21.9B, Fig. 21.9C and Fig. 21.9D). If this happens, reinsert the wire; otherwise, there is a risk of misplacing the lag screw. This danger is especially great in elderly patients with osteopenic bone. To reposition the guide pin, first insert the short centering sleeve and then insert a lag screw backward into the sleeve (Fig. 21.9C). Reinsert the guide pin through the cannulated lag screw and correctly reposition it (Fig. 21.9D). Verify its correct position on the image intensifier.

![Figure 21.9. A: The guide wire is inadvertently withdrawn with the triple reamer. B: To reinsert the guide wire, first insert the short centering sleeve. C: Next, insert a lag screw backward into the sleeve. D: Insert the guide wire into the cannulated lag screw and position it correctly.](image)

- If the patient has hard cancellous bone, tap the reamed channel for the lag screw threads. Use the DCS tap with a short centering sleeve to tap to the same depth as the reamed channel. Do not pretap the channel in patients with osteopenic bone.
- Assemble the DCS and place it onto the wrench using the long centering sleeve. Position the assembly over the guide pin and insert the centering sleeve into the reamed hole (Fig. 21.10A). Insert the screw until the zero mark on the wrench reaches the lateral cortex. At this point, the tip of the lag screw is about 10 mm from the medial cortex, and the proximal end of the lag screw is even with the lateral cortex. In porotic bone, insert the lag screw to the 5 mm mark, which allows the tip of the lag screw to cut itself 5 mm beyond the prereamed channel. With the lag screw properly inserted, the T handle of the insertion wrench should be parallel with the shaft of the femur, otherwise, the slide plate cannot be slid onto the lag screw.
If the fracture is not accurately reduced before this implant is introduced, distal fragment displacement into valgus alignment may result. In addition, the cloverleaf plate is not as strong as the heads of the screws and the plate; therefore, any deficiency of the medial cortex usually results in varus malalignment at 4 to 6 weeks postoperatively. If the fracture is considered unstable, the AO cloverleaf condylar plate is technically easier to apply, it should not be used indiscriminately. A major problem with this device is its lack of rigid interface between the lateral condyle and the screws. Precision and correct alignment in all three planes is required for the insertion of this device. Owing to its one-piece construction and broad flat blade, the blade provides stable fixation for most fracture types. However, the one-piece configuration allows direct measurement of the guide pin depth if a standard 9-inch or 230 mm wire is used. C: The depth setting of the triple reamer should be 10 mm less than the measurement from the direct measuring device. The triple reamer is cannulated. Slip it over the guide wire.

- Remove the wrench with its centering sleeve and slide the appropriate-length side plate over the lag screw. Withdraw the guide pin. While an assistant surgeon applies firm counterpressure medially, use the impactor to seat the side plate gently. Insert the dynamic condylar compression screw (Fig. 21.10B, Fig. 21.10C). When fixing a T or Y fracture with split condyles, interfragmentary compression can be achieved with the compressing screw. Do not compress with the compression screw in osteopenic bone because the lag screw may pull out of the bone.
- Achieve supplemental fixation of the side plate to the distal fragment by inserting one or two 6.5 mm cancellous screws through the plate immediately proximal to the large condylar lag screw. Ensure that the proximal component of the fracture is well reduced. Use a tension device to achieve axial compression. After tension is applied to the plate, check the reduction and stability of the fixation. If both are satisfactory, complete screw fixation of the plate to the femoral shaft.

BONE GRAFTS

After the fracture has been stabilized, assess the condition of the medial cortex. Stability requires good cortical contact in compression. I advocate autologous bone grafting of most fractures of the distal femur that have medial defects (Fig. 21.11):

- Augment fixation of the condyles by placing two 6.5 mm cancellous screws through the round holes directly above the large condylar screw. Secure the side plate to the shaft with 4.5 mm cortical screws. Fill the medial defect with cancellous bone graft.
- The exception to this would be the severely comminuted fracture, in which the technique of indirect reduction is used. Out of 68 cases, I have found that bone grafting was necessary in 59 (59). The medial side of the fracture is subject to compression forces with activity. If the medial side defect is present because of comminution, it will collapse under cyclic axial loading and create bending forces on the plate exactly opposite the defect. If the fracture does not heal in the usual time, the plate will break, often very quickly if the forces are great. Use autologous cancellous bone grafting to fill and buttress the medial defect. Failure to graft these defects can lead to implant failure, loss of reduction, and delayed union or nonunion. I prefer the anterior iliac crest as the donor site (Fig. 21.12).

**Figure 21.10.** A: Make the point of entry for the condylar lag screw about 2 cm from the knee joint and in line with the middle of the femoral shaft or slightly anterior. Place the third wire parallel with the knee joint axis and with the tip just penetrating the medial cortex. B: Reverse calibration on the measure device allows direct measurement of the guide pin depth if a standard 9-inch or 230 mm wire is used. C: The depth setting of the triple reamer should be 10 mm less than the measurement from the direct measuring device. The triple reamer is cannulated. Slip it over the guide wire.

**Figure 21.11.** Augment fixation of the condyles by placing two 6.5 mm cancellous screws through the round holes directly above the large condylar screw. Secure the side plate to the shaft with 4.5 mm cortical screws. Fill the medial defect with cancellous bone graft.

**Figure 21.12.** The progression of a medial instability to varus deformity.

**95° ANGLED PLATE BLADE**

The condylar plate is a one-piece angled blade plate with a 95° fixed angle between the blade and the plate. The blade is U shaped, which contributes to the strength of this device. Owing to its one-piece construction and broad flat blade, the blade provides stable fixation for most fracture types. However, the one-piece configuration of the plate also makes it difficult to use. Precision and correct alignment in all three planes is required for the insertion of this device. The technical aspects for the use of this device can be found in Müller and associates’ Manual of Internal Fixation Technique Recommended by the AO Group (44).

**CLOVERLEAF CONDYLAR PLATE**

The AO cloverleaf condylar plate is a one-piece device with a heavy proximal side plate configured like the broad dynamic compression plate and a cloverleaf-shaped distal portion precontoured to correspond to the lateral condylar surface of the distal end of the femur (Fig. 21.2C). The distal condylar section has six round holes to accommodate 6.5 mm cancellous screws. Never begin surgical fixation of the distal femur without having this implant or a similar plate for backup. For example, if the lateral condyle is comminuted or if there are multiple articular fracture lines in both the sagittal planes and the coronal planes, both the DCS system and the angled blade plate may be impossible to use. The cloverleaf condylar plate is an excellent device to salvage a failed DCS system or a 95° angled blade plate. Although the cloverleaf condylar plate is technically easier to apply, it should not be used indiscriminately. A major problem with this device is its lack of rigid interface between the heads of the screws and the plate; therefore, any deficiency of the medial cortex usually results in varus malalignment at 4 to 6 weeks postoperatively. If the fracture is not accurately reduced before this implant is introduced, distal fragment displacement into valgus alignment may result. In addition, the cloverleaf plate is not as strong...
as either the condylar screw system or the blade plate.

**MEDIAL/LATERAL OR LATERAL AND ANTEROMEDIAL DOUBLE PLATES**

A solution for the fracture with severe deficiency on the medial side is the use of double plates (7). If a lateral approach is used, a separate medial incision is usually required to apply a medial plate. An anterolateral approach is used, a second plate can be applied at right angles to the lateral plate by placing it on the anterior cortex near the medial side through the same incision. Always bone graft any deficits on the medial side. Sanders et al. (53) have discussed the use of double plating for unstable fractures of the distal femur. Some of the disadvantages to medial/lateral double plating include multiple surgical exposures, longer operating time, increased stripping of the soft-tissue attachments with decreased blood supply to bone fragments, and increased risk of infection. Chapman and Finkemeier (6) have shown improved results in nonunions using the anterolateral approach and lateral and anterior plates. The use of indirect reduction techniques has decreased the indication for double plate fixation.

**ANTEROGRADE INTERLOCKING INTRAMEDULLARY NAILING**

In 1984, Winquist et al. reported using closed intramedullary nailing for femoral shaft fractures (65). The well-known advantages of an IM device have been extended to include selected fractures of the distal femur (1,3,5,6,12,13,14,15,16,17,18,22,24,25,27,28,29,32,33,43,48,57,61,62,63,66,67 and 68). Antegrade nailing is limited to very specific cases for the distal femur because at least 10 cm of intact bone above the intercondylar notch is normally required. Essential to success is the ability to secure the two distal screws into intact bone. The surgical technique and indications are discussed in Chapter 20.

**THE SUPRACONDYLAR NAIL**

The supracondylar nail developed by Zickle et al. (70) is a retrograde IM nail designed to be inserted through the medial and lateral condylies. The nail is then anchored to the condyles with large compression screws. The screws need to facilitate fixation for the opposite condyle for minimal fixation. In the case of Y or T condylar fractures, the condyles must be reduced and fixed with lag screws before the insertion of the nails.

This nail is most useful in the elderly with osteopenia. It controls rotation and allows axial impaction. This feature can be desirable in the elderly because it yields an increased union rate, although it results in some shortening (34,69). It is not suitable for younger patients because of the frequent complications of shortening (34,70). Since the development of retrograde interlocked IM nails, it is little used.

**THE GREEN-SELIGSON-HENRY (GSH) AND OTHER RETROGRADE INTRAMEDULLARY NAILS**

Developed by Green, Seligson, and Henry, this nail is a cannulated, single-piece, stainless steel implant that is available in 11 and 12 mm diameters. It was initially designed for the elderly with a fracture of the distal femur. However, results were so good in the elderly that they have applied it to younger patients with the same good results (23,33). Suggested advantages of the GSH nail include a reduction in operating time and blood loss, and a reduction of devascularization of fracture fragments. All of these factors combine to create a lower incidence of complications (22). This technique is discussed in Chapter 20.

**WOUND CLOSURE AND POSTOPERATIVE CARE**

- Insert tubes for suction drainage to prevent the formation of a hematoma. Close the synovial tissue and iliotibial band subcutaneous fat and skin in layers. If an anterolateral suprafascial approach is used, a meticulously layered closure is important to prevent adhesions and to permit early vigorous knee motion. Do not suture the vastus lateralis to the intermuscular septum; doing so may retard knee motion. Meticulous closure of the skin is recommended. Apply a sterile dressing and splint the knee.
- As soon as the drains are removed, begin knee rehabilitation. Continuous passive motion (CPM) helps to regain knee motion in the immediate postoperative period. The AO group advocates positioning the limb on a frame, with the hip and knee flexed 90°. This position, combined with CPM, prevents quadriceps contracture, helps decrease swelling, and enhances knee motion if the patient can tolerate it. CPM is not recommended until the patient has initiated and then intermittently after gait training is started. If CPM is unavailable, maintain the limb in the 90°/90° position for 4 to 6 days. While the limb is on the frame, begin gentle, active, assisted range-of-motion exercises. Because of the risk of a flexion contracture, many surgeons prefer that the rest position be in full extension.
- If the fracture is fixed rigidly, the patient may begin immediate partial weight bearing of about 10 kg. The patient who remains completely non-weight bearing with the hip and knee flexed may develop circulatory stasis and rapid disuse osteopenia.
- Maintain weight bearing to the weight of the lag using two crutches until there is clinical and radiographic evidence of healing of the fracture, which usually requires 12 to 16 weeks, at which time progressing gradually to full weight bearing. Supplemental external support is usually not required, but a functional cast-brace may be desirable for the elderly patient with tenuous fixation, the patient with marked comminution, or the unreliable patient.

**EXTERNAL FIXATION**

External fixation is rarely used today for the definitive treatment of supracondylar fractures of the femur because the transfixation pins tend to lie down the quadriceps mechanism and interfere with regaining knee motion (59). The primary indication for external fixation today is high-energy type II, IIIb, and C open supracondylar fractures of the femur. In such fractures, the initial primary external fixation of the metaphyseal portion of the fracture is thought to be too risky because of the potential for infection, or the fracture has occurred in the presence of other severe multiple injuries and the time required for definitive internal fixation is inadequate. In the instance in which the fracture has occurred along with other injuries, a simple anterior single bar frame, bridging from the femur to the tibia to provide temporary stability and alignment of the extremity until definitive internal fixation can be done, may be indicated. This can be a life-saving procedure because it stabilizes the limb and allows early mobilization of the patient.

In severe open fractures from crushing injuries such as being hit by the bumper of a high-speed vehicle, the soft-tissue envelope may be severely compromised and the injury extends across the knee joint into the tibial plateaus. In these cases, many surgeons prefer to perform limited internal fixation of the articular surface of the femur with lag screws and wires. The metaphyseal portion of the fracture is then managed with an external fixator from the shaft of the femur to the reassembled condyles or bridging to the tibia. When only the femur is fixed, use a hybrid circular fixator using tensioned wires in the articular fragments and half pins in the shaft.

Although the fracture can be managed definitively in an external fixator, if the degree of comminution and bone quality allows, most trauma surgeons today convert to plate fixation after the condition of the soft tissues has stabilized and the risk of infection has been minimized (see Chapter 32).

**PITFALLS AND COMPlications**

Complications associated with the surgical management of fractures of the distal femur include neurovascular injury, thromboembolic disease, delayed union or nonunion, malunion, infection, joint contracture, knee instability, posttraumatic arthritis, implant failure, refracture after removal of the implant, and others. Although many of these problems cannot be avoided, the occurrence of some can be diminished by recognizing potential pitfalls in the various phases of treatment.

During the initial assessment, have a high index of suspicion for associated injuries to the head, chest, abdomen, and spine. Carefully evaluate the pelvis and all extremities for possible occult injuries. Ligamentous instability of the knee can occur with fracture of the distal femur and often cannot be determined until after the fracture is stabilized. Carefully evaluate the neurovascular function; if vascular injury is suspected, arteriography is indicated.

Good preoperative planning is essential and can minimize many of the intraoperative and postoperative complications. During this planning phase, determine the best surgical approach; the type, approximate size, and position of the implants; and the possible need for a bone graft. Making these decisions before surgery allows preparation of the appropriate instrumentation and implants, and a smoother surgical procedure with less wound exposure time.

Atraumatic surgical technique with minimal soft-tissue stripping, accurate anatomic reduction, stable fixation, and grafting of any bony defects cannot be overemphasized. Strict adherence to these principles will decrease the incidence of infection, implant failure, malunion, delayed wound and fracture healing, and nonunion. Accurate reconstruction of the articular surfaces is essential.

A common technical error while using the angled blade plate or the DCS is failure to appreciate the rhomboid shape of the distal femur. The blade or condylar screw must be directed somewhat posteriorly and be of proper length to avoid penetration of the anterior surface of the medial femoral condyle.

Considerable judgment is required in dealing with the fractures with severe osteopenia or comminution. Occasionally, these fractures are impossible to stabilize.
surgically with any type of implant and surgery may not be indicated.

During the postoperative phase, early, active rehabilitation will serve to decrease swelling, avoid muscle contracture, enhance knee motion, and diminish the incidence of thromboembolic disease. During this phase, stress patient education. Early excessive weight bearing can lead to implant failure, resulting in deformity or delayed healing and the need for repeat surgery.

CHAPTER 22

PATELLAR FRACTURES

Timothy J. Bray

PATHOPHYSIOLOGY

Fractures of the patella are not uncommon and often result in residual patellofemoral arthralgia, quadriceps weakness, restricted knee motion, and degenerative arthritis. The goals of surgical treatment are to reestablish continuity of the extensor mechanism and to restore a smooth articular surface using stable internal fixation to permit early knee motion.

BIOMECHANICS OF THE PATELLOFEMORAL JOINT

Despite early conclusions to the contrary, the patella has an important role in both quadriceps and knee joint function (6,14,20,22,26). By increasing the lever arm of the quadriceps mechanism, the patella improves extensor power, particularly during the last 30° of extension. Maquet's proposal that the patella reduces tibiofemoral contact stresses has been established in experimental animal studies (7,17). Excision of the patella can cause pain, extensor weakness, extensor lag, knee instability, and decreased flexion arc. In one series, as many as 90% of patients undergoing patellectomy following fracture had continued pain, and 60% complained of instability (34).

MECHANISMS OF INJURY

Fractures of the patella result from both indirect and direct forces (28). Unexpected falls can generate violent contractions of the quadriceps muscle as a result of the effort to regain balance, and patellar fracture may occur. Failure of the patella secondary to an imposed tensile load can result in a displaced transverse fracture associated with tearing of the medial and lateral retinacula. A direct blow to the patella transmits compressive forces that can cause a longitudinal, stellate, or comminuted fracture of the patella. These injuries are usually not widely displaced because of preservation of the quadriceps expansions. Abrasions or lacerations of the skin may be seen in fractures caused by direct forces.

Lateral dislocation of the patella can generate shearing forces that produce an osteochondral fracture of the articular surface of the medial facet of the patella or of the lateral femoral condyle. These fragments are usually less than 1 to 2 cm in diameter, but larger fragments occasionally occur. More recently, patellar fractures are occasionally seen as complications of total knee arthroplasty or are secondary to the harvest of a patella graft for reconstruction of the anterior cruciate ligament (41).

DIAGNOSIS

Displaced patellar fractures are readily apparent from the history and physical examination. Conspicuous findings include a history of direct trauma or an unexpected fall, with resulting pain and swelling about the anterior knee; inability to extend the leg actively against gravity; and a palpable defect between the patellar fragments and in the extensor retinacula. Nondisplaced fractures may have a similar history but lack impressive physical findings, demonstrating only tenderness to palpation and pain with resisted motion of the knee. A patellar dislocation is suggested by a history of a noncontact, valgus, external rotation injury to the knee with sudden collapse, requiring extension of the leg to relieve the incurred pain and deformity. Subsequent giving way, locking, catching, and swelling suggest an osteochondral fracture.

The radiographic examination for a patellar fracture should include anteroposterior and lateral views. A tangential patellar view with the knee in 30° of flexion is helpful in evaluating longitudinal fractures of the patella and in locating osteochondral fractures following patellar dislocation. Comparison radiographs of the opposite knee may be helpful in cases of bipartite patella, which can usually be distinguished by its superolateral location and well-rounded margins.

CLASSIFICATION

No comprehensive classification scheme exists to account for all patellar fractures. Traditionally, they have been categorized by degree of displacement and fracture line configuration, but this system may fail to assess the degree of articular surface injury, which significantly influences the outcome. Bostman classified comminuted and displaced fractures by the degree of articular stepoff and by vertical and horizontal displacement of major fragments in an effort to evaluate the results of various treatment regimens (4).

We define displaced patellar fractures by the amount of displacement, the anatomic portion of the patella involved, the fracture line configuration, the amount of comminution, and the amount of articular incongruity. For this discussion, we recognize four groups of patellar fractures (Fig. 22.1):
although most authors recommend patellectomy when less than half of the articular surface of the patella remains intact (Satisfactory results have been reported with use of the tension band wire and its modification in treating comminuted and displaced patellar fractures (EXTENSIVELY COMMINUTED AND DISPLACED FRACTURES can be excised with advancement of the patellar tendon (the patella can be preserved, whether it is intact or restored with interfragmentary screw fixation, then small comminuted intraarticular fragments about the distal pole fragments are large enough, use interfragmentary screw fixation, which is performed and supplemented with a tension band. If more than half of the articular surface of With Comminution of the Distal Fragment

In significantly displaced fractures, there is usually an associated tear of the medial and lateral retinacula. Repair of the retinacula provides additional stability to the 

In displaced transverse fractures with comminution of the distal fragment, make an effort to preserve as much of the patellar articular surface as possible. If the fracture fragments are large enough, use interfragmentary screw fixation, which is performed and supplemented with a tension band. If more than half of the articular surface of the patella can be preserved, whether it is intact or restored with interfragmentary screw fixation, then small comminuted intraarticular fragments about the distal pole can be excised with advancement of the patellar tendon (I, 18-39). 

EXTENSIVELY COMMINUTED AND DISPLACED FRACTURES

Satisfactory results have been reported with use of the tension band wire and its modification in treating comminuted and displaced patellar fractures (Fig. 22.2), although most authors recommend patellectomy when less than half of the articular surface of the patella remains intact (4). Techniques for patellectomy include
The basic principles of this technique are described in Chapter 11.

- Prepare and drape the patient in the routine fashion. I usually use a tourniquet.
- Make a midline vertical incision beginning 2 inches above the superior pole of the patella and extend it distally to the middle of the patellar ligament. Using sharp dissection, divide the subcutaneous tissue down to the quadriceps retinaculum, preserving the patellar ligament periaticenon.
- Raise medial and lateral skin flaps to explore the medial and lateral extensions of the retinacular tear. Using gentle curettage, remove the clotted blood and fibrous tissue from the fracture surfaces to help ensure anatomic reduction.
- Dissect the retinaculum and periosteum free from the fracture edges on the anterior border of the patella. Using the 2.0 mm drill guide, place two parallel 0.062 inch K-wires retrograde through the superior patellar fragment. The wires will exit the superior pole of the patella and extend through the extensor retinaculum (Fig. 22.3). Place the wires in the midpatella to allow appropriate mechanical stability for the tension band principle. If they are placed too close to the articular surface, compression forces will be neutralized during knee flexion (Fig. 22.4).

Next, use a medium-pointed reduction forceps to obtain an anatomic reduction of both fragments (Fig. 22.3D). Then, drill the previously placed K-wires through the inferior fragment to exit near the patellar ligament (Fig. 22.3E). Using 18-gauge wire, with a small loop on one side, secure the superior and inferior patellar fragments to the 0.062 inch K-wires with an oval or figure-of-eight configuration (Fig. 22.3F). Ensure that the 18-gauge wire is in direct contact with the bone of the superior pole of the patella and the exiting K-wire. The tendency of allowing the quadriceps tendon and the patellar ligament to interpose between the K-wire and the 18-gauge wire leads to loosening of the tension band and failure of fixation. Often, small vertical incisions are required along the line of the tendon fiber to allow the loop of 18-gauge wire to fit snugly against the exiting K-wire. Tighten the figure-of-eight tension band wire on both the medial and lateral sides to apply an equal distribution of tension on the wire. An alternative is to place the tension band wire through transverse drill holes in the patella.

Remove the reduction forceps and bring the knee into full extension. Patinate and inspect the articular reduction through the medial or lateral retinacular tears. Once the fixation is determined to be stable and anatomic, trim the excess wires. Bend the ends of the wire proximally to a 180° loop, and drive the wire into the
bone fragment to trap the K-wire. Be certain that the K-wires distally are long enough to prevent the 18-gauge wire from dislodging, but not so long that they will irritate the patellar tendon.

Next, repair the medial and lateral tears of the quadriceps retinaculum. Begin at the apex of the tears medially and laterally and use figure-of-eight sutures of #0 to #2 weight. Reproximate the tear but do not shorten it too much or the result may be loss of knee flexion. Close the subcutaneous fat and skin. A small drain left in the knee joint for overnight may prevent a hemarthrosis.

After surgery, apply a long leg bulky dressing, and elevate the leg for 24 to 48 hours before the patient is discharged from the hospital. Place the extremity in a universal hinge brace with Velcro straps but allow no motion until the wounds are completely healed and dry. After 10 days, begin active flexion to between 20° and 40° and gradually advance it over the next 6 weeks. The patient can begin isometric exercises immediately if the fixation is secure and if he bears full weight on the site using crutches with the hinges on the brace locked in full extension. Most fractures heal by 6 to 8 weeks, at which time protection can be discontinued and full rehabilitation instituted.

**SCREW FIXATION**

- If the fracture is not conducive to tension band wiring alone, screw fixation using 4.0 mm cancellous screws can be done with or without a supplementary tension band wire (Fig. 22.5A, Fig. 22.5B). Screw fixation is more applicable to stellate fractures in which tension band principles are more difficult to apply.

**Figure 22.5.** A, B: Interfragmentary compression screw and tension band wire for a comminuted fracture. C, D: Fixation with interfragmentary lag screws.

- Use the same approach for joint irrigation and retinacular repair. Use the pointed reduction forceps for temporary reduction before screw placement or retrograde technique can be used as described in Fig. 22.3A, Fig. 22.3B, Fig. 22.3C, Fig. 22.3D and Fig. 22.3E.

- Using a 2.0 mm drill bit, stabilize the two fragments using the lag technique with 4.0 mm cancellous screws placed perpendicular to the fracture surface (Fig. 22.5C, Fig. 22.5D). Screw fixation provides stability and compression, but it is not nearly as reliable as when a tension band is present. I try to use a tension band in all cases.

- Cannulated screw fixation with tension band wire techniques has gained popularity recently (Fig. 22.6). Applying the advantage of compression screw technique and tension band principles enhances stability and helps prevent failure of fixation at higher loads.

**Figure 22.6.** Two different methods for combining cannulated screws with tension band wires through the screws.

- Stabilize the fracture using 4.0 mm cannulated screws, as described above.
- Pass an 18-gauge wire through the holes in the screws in a crossed wire fashion or separately for each screw. Bend the wire twists away from the anterior skin to prevent irritation as with all tension band techniques. Combinations of transverse or longitudinally placed screws are acceptable, depending on the fracture classification or direction of fracture lines. This technique does not apply to comminuted fractures in osteoporotic bone but rather to young patients with large fixable fracture fragments.

**PARTIAL PATELLECTOMY WITH REATTACHMENT OF THE PATELLAR LIGAMENT**

Often, the inferior half or less of the patella is so severely comminuted that internal fixation or tension band fixation cannot be used (Fig. 22.7); in such a case, partial patellectomy is required (15).

**Figure 22.7.** Marder (27) technique for partial patellectomy and repair of the patellar tendon. See text for details.

Previously, it was recommended that the patellar tendon be reattached to the posterior aspect (articular surface) of the remaining portion of the patella. Recent studies of the patellofemoral contact areas and pressures in human cadavers following partial patellectomy with reattachment of the patellar tendon at anterior, middle, and posterior positions on the remaining patellar fragment have been performed. These studies have demonstrated that regardless of the position of reattachment, there is a decrease in patellofemoral contact area and an increase in mean patellofemoral contact pressure following partial patellectomy (27). An anterior position of reattachment of the tendon significantly minimizes this effect, however (27). An adequate result requires strict attention to detail.

- Prepare the extremity in the usual fashion. Make a vertical longitudinal incision as described previously and identify the fracture. Raise skin flaps medially and laterally to identify the apex of the retinacular tear.
- Shell out the fragments of the inferior pole of the patella while protecting the patellar tendon.
- On the proximal pole, remove all articular cartilage fragmentation to provide a congruent, smooth patellofemoral joint preventing the later migration of loose osteochondral fragments into the patellofemoral joint.
- Using a 2.0 or 3.2 mm drill, make three longitudinal parallel holes in the anterior third of the patella, exiting the quadriceps tendon at the superior pole of the patella (Fig. 22.7A, Fig. 22.7B and Fig. 22.7C). Place one hole in the center of the patella on the frontal view, and place the medial and lateral holes parallel to and at the normal width of the patellar tendon remaining in solid bone.
- Place two 5-0 Tevdek sutures, or similar-weight sutures, into the patellar ligament, beginning at the tibial tubercle; weave them in Bunnell fashion to exit the most
superior edge of the disrupted patellar tendon. Use a suture passer or wire inserted from the superior pole of the patella through each of the drill holes to pull the suture through the holes in the patella, thereby securing the patellar tendon to the fractured surface of the patella. Pass the two central sutures through the central drill hole. Tie the two sutures to secure the patellar tendon to the fractured patella. Avoid trapping the quadriceps tendon between the superior pole of the patella and the suture.

- Then repair the medial and lateral retinaculum as described above for the technique for tension wire fixation of the patella. Irrigate the wound copiously, close it in layers over a suction drain, and place the leg in a long leg bulky dressing with splints.

- Allow 20° of motion (0° to 20°) in a universal brace with hinges; after 6 weeks, advance motion by 20° per week until full flexion and extension are obtained at 12 weeks. Encourage isometric quadriceps exercises early. Muscle electrical stimulation may help prevent quadriceps atrophy. Full weight bearing is possible with the hinges of the brace locked in extension.

HINTS AND TRICKS

The anterior half or more of the knee joint can be inspected through this limited anterior approach. Use this opportunity to look for loose osteochondral fragments and to deal with associated injuries.

- Approach the knee and expose the fracture as described above.
- Shell out the comminuted fragments with a #15 blade, preserving the soft-tissue attachments as much as possible.
- Repair the retinacular tears as described above and carry the figure-eight sutures across the area of the patellectomy. Oppose the torn surfaces with nonabsorbable sutures or biodegradable, self-reinforced polyglycolide tension bands have been used to replace the traditionally used wire to eliminate the need for later wire removal. These methods have proven to be equally efficacious.
- Shield out the two fragments, preserving all soft-tissue attachments. Ensure hemostasis.
- Repair the retinacular split in the longus retinaculum with interrupted #1 or #2 figure-of-eight sutures. Close the subcutaneous tissues and skin.
- Wound management and rehabilitation are as described above.

ELECTIVE TOTAL PATELLECTOMY

If repair of a fractional patella is unsuccessful or patellectomy is required for primary (rare) or painful posttraumatic patellofemoral arthritis, use the following technique:

- Expose the quadriceps mechanism and patella through an anterior midline longitudinal incision.
- Incise the quadriceps retinaculum longitudinally in the midline over the patella with an electrocautery knife.
- Split the patella longitudinally by first cutting through the anterior three quarters with an oscillating saw and then completing the fracture with an osteotome by prying the two fragments apart. A lamina spreader can be used as well. Avoid injury to the articular surface of the femur.
- Shell out the two fragments, preserving all soft-tissue attachments. Ensure hemostasis.
- Repair the retinacular split in the longus retinaculum with interrupted #1 or #2 figure-of-eight sutures. Close the subcutaneous tissues and skin.
- Immediate protected knee motion, weight bearing, and muscle rehabilitation are usually possible because the quadriceps mechanism is in continuity.

RESULTS

Unfortunately, the vast majority of published results on the outcomes and results from treatment of patellar fractures are retrospective studies and there is very little standardization of the methods used to analyze results. Bóasustam et al. (4) have used the most comprehensive clinical grading scale published so far, which includes evaluation of pain, stair-climbing, giving way, use of aids for walking, return to work, and evaluation of range of motion, atrophy, and presence of an effusion. They looked at 219 patients treated nonoperatively for nondisplaced fractures. All patients had less than 4 mm of residual articular incongruity. Fifty-four percent had excellent results. Their results with those showing that the nonoperative treatment of nondisplaced fractures gives excellent results with failure rates under 5%. Although open reduction and internal fixation gives better results in displaced fractures, even widely displaced fractures of the patella can be treated nonoperatively with reasonable outcomes if surgery is contraindicated.

Of the various surgical techniques for internally fixing transverse fractures of the patella and more comminuted fractures, anterior tension band wiring, particularly when combined with cannulated screws, gives the best results. Accumulated results from several studies show 57% excellent results, 29% good results, and 14% poor results. Berg (3) in 10 patients showed 70% excellent or good results based on the hospital for special surgery knee score utilizing figure-of-eight tension band wiring through parallel cannulated compression screws. Recently, nonabsorbable sutures or biodegradable, self-reinforced polyglycolide tension bands have been used to replace the traditionally used wire to eliminate the need for later wire removal. These methods have proven to be equally efficacious.

Partial patellectomy with reanastomoses of the patellar tendon to the remnant fragment produces somewhat less favorable outcomes than restoration of the normal anatomy of the patella. Sutton et al. (38) showed that excision of one-third of the inferior pole of the patella resulted in an overall loss of 18° of motion. Partial patellectomy reduces the contact area between the patella and trochlea groove. This results in an increased incidence of anterior knee pain. However, retention of landmark staples (making up 50% or more of the patella) improves quadriceps function compared to patellectomy and, overall, has reasonably good outcomes of 70% or so combined good and excellent results when a number of reports are summarized. Total patellectomy may be necessary in very comminuted fractures but gives poorer results than partial patellectomy or operative repair. Comparision is difficult, however, as these three different treatments are applied to three entirely different fracture patterns, each involving different levels of energy of injury. Sutton et al. (38) showed that total patellectomy resulted in a 40% reduction in the strength of the extensor mechanism. This causes significant loss of ability to support body weight while stair-climbing. Wilkinson (41) examined 31 patients with 4.5 to 13 years of follow-up after total patellectomy and found that less than 25% of patients had an excellent result. He noted that knee function continued to improve for approximately 3 years before stabilizing. Einola et al. (18) followed 28 patients for an average of 7.5 years after total patellectomy and found good results in only 6 patients. Atrophy of the quadriceps was common, and he found that quadriceps power was within 75% of that of the normal knee in only 7 patients. He advised saving as much of the patella as possible. Scott (34) found only 47 of 71 patients who were pleased with the long-term outcome of their total patellectomy. Gaglani et al. (19) found that the results of total patellectomy could be substantially improved by advancing the vastus medialis obliquus.

In comminuted fractures of the patella, my current practice is to fix internally the patella and retain as much patella as possible as long as the articular surface can be reduced anatomically or with an incongruity of less than 2 mm. If the fixation fails or the patient has unacceptable symptoms after healing and rehabilitation, then elective patellectomy usually gives a result similar to that of total patellectomy done initially.

In open fractures of the patella, the outcomes depend primarily on the degree of soft-tissue injury. Catalano et al. (8) treated 70 open patellar fractures—the majority of which occurred in patients with multiple injuries—with irrigation and debridement, open reduction, and primary internal fixation with reconstruction of the extensor mechanism. They performed no wound washout. They had only three failures of initial fixation and one asymptomatic nonunion. Using a modified Hospital for Special Surgery knee score they found good to excellent results in 17 of 22 patients at an average follow-up of 3 years. In these severe injuries, they advised thorough irrigation and debridement with primary reconstruction of the patella and extensor mechanism restricting total patellectomy as a salvage procedure. Torchia and Lewallen (40) reviewed 57 open patella fractures. They experienced somewhat less good outcomes particularly since their rate of deep infection was 10.7% which correlated directly with the magnitude of soft-tissue injury. They had no infections in Type I and Type II open fractures.
fractures. Their final recommendations for treatment were similar to those of Catalano et al.

POSTOPERATIVE CARE AND REHABILITATION

Immediate postoperative care and rehabilitation have been described with each of the previously described procedures. Certain general principles apply to all of these procedures:

- After the repair is completed and while the wound is still open, gently carry the knee throughout range of motion to determine what the safe range is that does not place excessive stress on the repair.
- Passive range of motion exercises including continuous passive motion can begin as soon as the condition of the wound permits. Motion helps prevent intraarticular adhesions and tightness of the quadriceps retinaculum.
- As long as the quality of the bone and soft tissue is good and the repair solid, most patients can begin quadriceps isometric exercises immediately and can bear full weight in a brace with the knee locked into full extension.
- The hinge of the brace can be adjusted to permit increasing range of motion as healing advances.
- By 6 to 8 weeks, most patients should have good control of their quadriceps and hamstrings, be able to raise the leg straight against gravity, and flex the knee to 90°. If so, full, unprotected weight bearing can begin.
- By 12 weeks, patients should be 70% to 90% rehabilitated and have good strong quadriceps function and flexion to 135°.

Bone repairs are slower to heal than soft-tissue repairs and are less predictable from the standpoint of stability. They require more cautious rehabilitation until bone union occurs, usually between 6 and 10 weeks.

PITFALLS AND COMPLICATIONS

Loss of motion is one of the most common complications. Minor degrees of loss of terminal flexion after patellar fixation have little effect on functional outcome of the knee. Adherence to the guidelines for rehabilitation and a cooperative patient will minimize the risk of knee stiffness.

Inferior positioning of the patella, “patella baja,” is a well recognized, but rare, complication of inferior pole patellectomy and reconstruction of the patellar ligament. Patients with the condition have pain, loss of full flexion, and occasionally loss of terminal extension. Prevent it by avoiding overshortening of the quadriceps mechanism at the time of repair. Reconstruction requires preoperative comparative radiographs of the contralateral flexed knee to assess the appropriate lengthening required. The patellar tendon can be lengthened by a Z-lengthening procedure. It is usually preferable to a tubial tubercle osteotomy.

Loss of reduction due to failure of fixation may be related to poor-quality tissues, poor fixation techniques, poor patient compliance, and too rigorous a postoperative rehabilitation program. As with articular reductions, the joint accommodates small degrees of gap; however, stepoff of more than 2 mm or complete disruption may require repeat fixation or patellectomy.

Infection has been reported in 3% to 10% of cases and occurs most frequently with open fractures or fractures associated with deep, neglected abrasions. Acute infections may be salvaged with debridement, maintenance of fixation hardware, and appropriate antibiotics. Late infections with knee-joint involvement require aggressive debridement, removal of hardware, and an attempt at late reconstruction. Outcomes are often poor.

Nonunion is a rare problem that can result in a stable fibrous union requiring no treatment. Repair or patellectomy may be required (see Chapter 30).

Partial and total patellectomy decrease quadriceps mechanism strength but most patients function well (23,28,30,32).

AUTHOR’S PERSPECTIVE

In young patients with repairable fractures, I make every effort to preserve the patella. I prefer to use cannulated screws with supplemental tension band wire fixation. I am more likely to perform partial or complete patellectomy in complex fractures in sedentary middle-aged or older patients or where osteoporosis is present. Success depends on direct supervision of the rehabilitation program by the surgeon.

MECHANISM OF INJURY

Fractures of the tibial plateau were originally described as “the fender fracture” (10) because they resulted primarily from low-energy pedestrian versus car bumper accidents (Fig. 23.1). The majority of tibial plateau fractures reported in the recent literature have resulted from high-speed motor vehicle accidents and falls from a height (7, 21, 48, 50). Fractures of the tibial plateau are caused by direct axial compression, usually with a valgus (more common) or varus (less common) moment and indirect shear forces. The anterior aspect of the femoral condyles is wedge shaped; with the knee in full extension, the force generated by the injury drives the condyle into the tibial plateau (47). The direction, magnitude, and location of the force, as well as the position of the knee at impact, determines the fracture pattern, location, and degree of displacement.

Figure 23.1. The classic mechanism of injury in tibial fractures is shown.

When a single compartment is involved in fractures of the tibial plateau, it is usually the lateral plateau (7, 16, 27, 32, 44, 47, 51, 52). This is because the anatomic axis at the knee joint (which is normally in 7° of valgus) as well as the mechanism of injury usually causes a direct force from lateral to medial (30). Patient factors such as age and bone quality can also influence the fracture pattern. Elderly individuals with osteopenic bone are more likely to sustain depression-type fractures (4) because their subchondral bone is less likely to resist axially directed loads (Fig. 23.2). In contrast, younger individuals with denser subchondral bone are more likely to sustain cleavage-type fractures and have an associated ligamentous disruption (Fig. 23.3) (26, 81, 52).

Figure 23.2. In pure depression fractures, the cancellous bone absorbs the energy, thus sparing the medial collateral ligament of injury.

Figure 23.3. In split fractures, the cancellous bone does not compress, thus imparting the energy to the medial collateral ligament.
INITIAL EVALUATION

A tibial plateau fracture should be considered in the differential diagnosis any time a patient complains of pain and swelling about the knee following major or minor trauma. Decision making regarding the treatment of periarticular fractures about the knee depends on knowledge of the mechanism of injury, clinical stability, radiographic findings, and associated injuries. Initial evaluation of the knee following trauma includes palpation to elicit tenderness over a potential fracture or site of ligamentous disruption. Generally, hemarthrosis is present; however, significant capsular disruption may lead to dispersion into surrounding soft tissues.

Careful neurovascular examination of the extremity should follow documentation of the skin condition and presence of swelling. Because many of these injuries are produced by high-energy forces, the presence of compartment syndrome must be ruled out. If pulses are not palpable, perform Doppler studies. If the clinical signs of an impending compartment syndrome (pain out of proportion to the injury, pallor, pain on passive stretch of the toes, or impaired neurologic status) are present, compartment pressures must be measured. Pressures should also be measured in the unconscious patient with a tense, swollen leg.

Associated injuries of the supporting ligamentous structures around the knee have been well documented with tibial plateau fractures. Injury to the collateral ligaments have been reported to occur in 7% to 43% of cases (2,7,12,20,21,51,52), and ruptures of the anterior cruciate have been reported in up to 23% of high-energy injuries (23). Furthermore, meniscal injuries have been reported in up to 50% of tibial plateau fractures; the meniscus may be incarcerated within the fracture site (21,40,41,48). Ligamentous injuries may be difficult to diagnose on initial examination during the acute phase. Varus and valgus stress testing of the knee in near full extension can be performed under general anesthesia if one is unable to assess the knee properly in the emergency room (19). Split fractures of the lateral plateau have a high incidence of associated ligamentous injury, because the dense cancellous bone associated with split fractures does not compress. Energy is therefore not dissipated, and the force is imparted to the medial collateral ligament.

Open fractures about the knee are particularly problematic; thus, any open wound should be evaluated for the possibility of an open joint injury. Because an open joint injury is an absolute indication for surgical intervention (2,3,30), it is incumbent on the treating physician to make the diagnosis. If you are unsure as to whether the open wound communicates with the joint, instill at least 50 ml of sterile normal saline into the knee away from the wound. If fluid extravasation is noted, the diagnosis is confirmed (30). It should be stated that a negative injection test does not exclude the possibility of an open joint injury. Exploration of the knee in the operating room is indicated any time the suspicion for an open joint wound is significant.

Following the clinical examination, perform radiographic evaluation. The standard knee trauma series includes an anteroposterior (AP) view, a lateral view, and two oblique views. Owing to the 10° to 15° posterior slope of the articular surface of the tibia, a 10° to 15° caudally tilted plateau view provides more accuracy in assessing articular stepoff (Fig. 23.4) (19,37). In addition to providing an assessment of the fracture patterns, radiographs often provide evidence of associated ligamentous injury. Avulsion of the fibular head, the Segund sign (lateral capsular avulsion), and Pellegrini-Stieda lesion (calcification along the insertion of the medial collateral ligament) are indicative of associated ligamentous injury (12,17,18). Stress views may be helpful as well but take care not to displace the fracture further.

Computed tomography (CT) has virtually replaced plain tomography for the evaluation of displaced tibial plateau fractures. CT scanning with sagittal reconstruction has increased the diagnostic accuracy in tibial plateau fractures and is indicated in cases of articular depression (Fig. 23.5) (15,43). CT scans have been shown to increase the interobserver and intraobserver agreement of the classification of tibial plateau fractures (3). Furthermore, these studies are excellent adjuncts in the preoperative planning of lag screw placement when percutaneous fixation is to be undertaken. Magnetic resonance imaging (MRI) has recently been suggested as a method for evaluation of these injuries as an alternative to CT scan and arthroscopy. MRI theoretically evaluates both the osseous as well as the soft-tissue components of the injury (6). Currently, however, no clear indication exists for the use of MRI in tibial plateau fractures.

Use of arthroscopy has become more prevalent in the evaluation of tibial plateau fractures (16,23,40). With arthroscopy, one can examine the articular surface, menisci, and cruciates directly (Fig. 23.6). In addition, one can irrigate the joint of any loose debris and hematoma. However, development of compartment syndrome (related to the extravasation of arthroscopy fluid) has been reported in the literature (16,23,40).
treatment of displaced tibial plateau fractures (operative treatment of displaced tibial plateau fractures, however, vary widely in the literature. Numerous authors have reported excellent results with nonoperative treatment of displaced tibial plateau fractures (1,11,14,18,24,48,49), whereas others advocate anatomic restoration of the articular surface (7,51,52,53). The degree of

INDICATIONS

It is generally accepted that nondisplaced or minimally displaced fractures can be treated nonoperatively (7,18,32,45,52). The indications for nonoperative versus operative treatment of displaced tibial plateau fractures, however, vary widely in the literature. Numerous authors have reported excellent results with nonoperative treatment of displaced tibial plateau fractures (1,11,14,18,24,48,49), whereas others advocate anatomic restoration of the articular surface (7,51,52,53). The degree of

CLASSIFICATION

Numerous classification systems have been proposed to describe tibial plateau fractures (1,17,18,36,39,47,51,52). The majority are very similar, with each system recognizing wedge, compression, and bicondylar types. The Hohl classification was the first widely accepted description of tibial plateau fractures (17), classifying these fractures into displaced and undisplaced. Under the displaced category, he recognized local compression, split compression, total condyle depression, and comminuted fractures.

Moore expanded Hohl's concepts, taking into account higher-energy injuries and resultant knee instability (38). His classification of fracture subluxations of the knee is divided into five types: Type 1 is a split fracture of the medial tibial plateau in the coronal plane; Type 2 an entire condyle fracture with the fracture line beginning in the opposite compartment and extending across the tibial eminence; Type 3 is a rim avulsion fracture (these fractures are associated with a high rate of associated neurovascular injury); Type 4 is another type of rim fracture, a rim compression injury, usually associated with some type of contralateral ligamentous injury; and Type 5 is a four-part fracture with the tibial eminence separated from the tibial condyles and the tibial shaft (Fig. 23.7) (38).

Schatzker's classification of tibial plateau fractures (Fig. 23.8) is currently the most widely used and was the first to make the distinction between medial and lateral plateau fractures (51,52). Type I is a pure cleavage fracture of the lateral tibial plateau that results in a wedge-shaped fracture fragment. Type II is a cleavage fracture of the lateral tibial plateau in which the remaining articular surface is depressed into the metaphysis. Type III is a pure central depression fracture of the lateral tibial with an intact osseous rim. Type IV involves the medial tibial plateau and is divided into two subtypes: type A is a split fracture and type B is a depression fracture. Either type may be combined with a tibial spine fracture. Type V is a bicondylar fracture with the fracture line often forming an inverted Y; the metaphysis and diaphysis remain intact. Type VI is a tibial plateau fracture in which there is dissociation between the metaphysis and the diaphysis; these fractures may have varying degrees of comminution of one or both tibial condyles and the articular surface (51,52). Honkonen and Jarvinen have recently modified Schatzker's classification to take into account residual limb alignment. They divide type VI fractures into medially and laterally tilted fractures to take into account functional results in treated fractures with residual angulation (21).
