The Arbeitsgemeinschaft für Osteosynthese Fragen (AO) classification is divided into three main categories (Fig. 23.9) and is most useful as a research tool. Type A fractures are extraarticular. Type B fractures are partially articular and are subdivided into three main categories: B1 fractures are pure splits, B2 fracture are pure depression, and B3 fractures are split depression. Type C fractures are complete articular fractures and are also subdivided into three subtypes: (a) being articular and metaphyseal simple, (b) articular simple and metaphyseal multifragmentary, and (c) articular multifragmentary (39).

INDICATIONS

It is generally accepted that nondisplaced or minimally displaced fractures can be treated nonoperatively (7,18,32,45,52). The indications for nonoperative versus operative treatment of displaced tibial plateau fractures, however, vary widely in the literature. Numerous authors have reported excellent results with nonoperative treatment of displaced tibial plateau fractures (1,11,14,18,24,48,49), whereas others advocate anatomic restoration of the articular surface (7,51,52,54). The degree of

Figure 23.6. Arthroscopic view of a split fracture of the lateral tibial plateau. One can obtain good visualization of the articular surface, femoral condyles, and meniscus.

Figure 23.8. Schatzker's classification of tibial plateau fractures is shown. Types I to IV are defined as follows: I: A split fracture of the lateral tibial plateau. II: A pure depression fracture of the lateral tibial plateau. III: A split-depression fracture of the lateral tibial plateau. IV: A fracture of the medial tibial plateau. V: A bicondylar fracture of the tibial plateau. VI: A fracture of the tibial plateau with metaphyseal-diaphyseal dissociation.

Figure 23.9. The AO classification of tibial plateau fractures is shown.
articular depression that can be accepted has varied and ranges from less than 2 mm to 1 cm (11,18,45,51). Most authorities today believe that more than 2 mm of offset in the weight-bearing portion of the articular surface is not acceptable in active patients. The need for surgery on tibial plateau fractures can also be based on instability of more than 10° of varus or valgus in the nearly extended knee compared with the contralateral side (32,44,45). This potential instability depends on the status of the rim of the tibial plateau. Split fractures are more likely to be unstable than pure depression fractures in which the rim is intact. Open fractures and fractures associated with vascular injury or compartment syndrome require urgent surgical intervention.

NONOPERATIVE MANAGEMENT

Nondisplaced and stable fractures are best treated nonoperatively. Protected weight bearing and early range of knee motion in a hinged cast-brace are the authors’ preferred method of treatment. Initiate isometric quadriceps exercises and progressive passive, active-assisted, and active range of knee motion exercises as the stability of the fracture permits. Allow partial weight bearing for 8 to 12 weeks, with progression to full weight bearing as tolerated thereafter.

Treatment with a long leg cast is primarily of historical interest. Significant quadriceps atrophy and restricted range of knee motion are likely to result from prolonged joint immobilization (18,19). Reserve treatment in a long leg cast for unreliable patients who cannot be trusted to bear partial weight; in this instance, the cast should be applied with the knees flexed to 45°. Cast immobilization may also be necessary in unstable fractures in which a cast brace is insufficient and, for some reason, surgery is contraindicated. Apley described the use of skeletal traction to provide alignment of displaced tibial plateau fractures yet allow for range of motion of the knee joint (1). This method involves the use of a Steinmann pin inserted transversely through the tibia, usually in the distal third below the fracture. Patients are restricted to bed rest for 6 weeks but allowed active range of motion exercises of the knee. The major limitations of this form of treatment include inadequate reduction of the articular surface and ineffective control of limb alignment (19). Furthermore, the extended period of hospitalization and recumbency are not cost-effective in today’s health care environment. If the criteria for operative treatment are not met, cast bracing has provided excellent results (11,12,14,50).

SURGICAL TECHNIQUES

PREOPERATIVE PLANNING

One should understand the exact nature of the fracture before attempting any type of surgical intervention. Preoperative planning is essential for any complex injury because it forces the surgeon to understand the “personality” of the fracture and to prepare an operative strategy mentally. Radiographs of the contralateral extremity should be reviewed. An initial AP and lateral tibial plateau view should be taken and followed by reestablishment of tibial alignment. Buttress securely with bone graft or a bone graft substitute to support depressed articular fragments. Fracture fixation should be applied with the knee flexed to 45°. Cast immobilization may also be necessary in unstable fractures in which a cast brace is insufficient and, for some reason, surgery is contraindicated. Apley described the use of skeletal traction to provide alignment of displaced tibial plateau fractures yet allow for range of motion of the knee joint (1). This method involves the use of a Steinmann pin inserted transversely through the tibia, usually in the distal third below the fracture. Patients are restricted to bed rest for 6 weeks but allowed active range of motion exercises of the knee. The major limitations of this form of treatment include inadequate reduction of the articular surface and ineffective control of limb alignment (19). Furthermore, the extended period of hospitalization and recumbency are not cost-effective in today’s health care environment. If the criteria for operative treatment are not met, cast bracing has provided excellent results (11,12,14,50).

Figure 23.10. An example of preoperative templating is illustrated.

The basic goals and principles for the treatment of tibial plateau fractures follow those of other articular fractures. First should be reconstruction of the articular surface, followed by reestablishment of tibial alignment. Buttress securely with bone graft or a bone graft substitute to support depressed articular fragments. Fracture fixation can involve the use of plates and screws, screws alone, external fixation, or combinations of these methods. Finally, adequate soft-tissue reconstruction that includes preservation or repair, or both, of the meniscus and ligaments may be required (54).

SURGICAL EXPOSURE

Exposure of the tibial plateau can be gained through a variety of approaches. The surgical approach should provide maximum visualization, combined with preservation of all vital structures as well as minimal soft-tissue dissection and osseous devitalization (52).

- Make the skin incisions for tibial plateau fractures longitudinal and as close to the midline as possible. Because the majority of plateau fractures involve the lateral compartment, a lateral parapatellar incision and arthrotomy is often used. Medial fractures use a medial parapatellar approach. In either case, plan the incisions so that implants do not lie directly below the skin incision. Any flaps that are raised should be full thickness down to the crural fascia and retinaculum and include the subcutaneous fat. We favor midline skin incisions in bicondylar fractures to allow access to both knee compartments and facilitate any future reconstructive procedures.
- Once the level of the capsule has been reached, make an arthrotomy. The arthrotomy can be submeniscal (52,54) (Fig. 23.11) or vertical, with division of the anterior horn of the lateral meniscus (19,25,41,42); division of the anterior horn of the meniscus near its origin has been shown to heal reliably at follow-up arthroscopy (25,41,42). With either approach, the split fracture component can be displaced open, and depressed fracture fragments can be elevated. In any case, all efforts should be made to preserve the meniscus.

Figure 23.11. The technique of submeniscal arthrotomy is shown. ITB, iliotibial band.

- Posterior medial fractures of the plateau can be approached through a separate incision, between the medial gastrocnemious and semitendinosus and then between the medial collateral ligament and the posterior oblique ligament (22,53).
- Occasionally, it is necessary to obtain better exposure of severely comminuted bicondylar fractures. If the tibial tubercle is a separate fragment and free, it can be reflected along with the patellar tendon to afford excellent exposure of both compartments. Because of the difficulties of repair, avoid actual osteotomy of the tibial tubercle. If the tubercle is intact, incise the patellar tendon in a Z-plasty fashion with the same resultant exposure (19,52). Following the completion of surgery and repair of the extensor mechanism, protect the patellar tendon using a tension band.

PATIENT POSITIONING

- Position the patient supine, with a bolster under the knee or on a table where the foot of the table can be dropped.
- Prep and drape the ipsilateral iliac crest if a need for autogenous bone graft is contemplated.
- Furthermore, the patient's position should take into account the need for intraoperative image intensification, with the ability to obtain AP, lateral, plateau, and...
oblique views. A fully radiolucent table is preferred.

- If arthroscopy is to be used, either a well-padded leg holder or post should be available.

### REDUCTION TECHNIQUES

- Reduction of tibial plateau fractures can be attained either by direct or indirect means. Direct reduction of the articular surface and tibial metaphysis can be performed either open (6,7,51,53) or by semipenis means (16,23,45).
- Indirect reduction techniques have been described in the literature (14,15,27,29,35). These methods use ligamentous and capsular attachments to the fracture fragments to indirectly reduce the joint surface and align the tibial shaft (Fig. 23.12). Indirect reduction techniques have the advantage of minimal soft-tissue stripping, thus protecting the blood supply to the bone fragment (35). However, ligamentotaxis does not work on centrally depressed articular fragments. For badly comminuted fractures, use of a femoral distractor with threaded pins placed into the femoral condyles and the tibial shaft can aid in fracture reduction (29,35,53).

![Figure 23.12. The use of the femoral distractor to provide indirect reduction of a split fracture component.](image)

- For unicondylar fractures, place the femoral distractor on the side of the fracture. For bicondylar fractures, use two femoral distractors or one distractor and an external fixator. Keep the threaded pins parallel to the joint surface.
- An alternative method for severe bicondylar fractures is to place the pins anteriorly, superior to the patella on the femoral side and distal to the fracture in the tibia. With this technique, however, the knee cannot be flexed (35). Spanning external fixators can be used in much the same way as the femoral distractor (67). The key is to place the pins far enough away from the fracture site so as not to compromise future reconstructive options (35).
- If segments of articular surface remain depressed following attempted indirect reduction or in a pure depression fracture, make a cortical window in the metaphysis, the site of which depends on the location of the depression (Fig. 23.13). Elevate the entire osteochondral segment en masse using bone tamps and punches (15,29,51,52).

![Figure 23.13. Depressed segments of articular surface can be elevated using a curved tamp inserted through the anterior fracture line as shown here or through a cortical window.](image)

- Following articular surface elevation, fill the void left by impacted cancellous bone with either autogenous bone graft, allograft, or bone graft substitute (27,29,51-57).

### ARTHROSCOPY

The use of arthroscopy has increased steadily since the early 1980s. Arthroscopic management of tibial plateau fractures is generally indicated for Shatzker Type I, II, and III fractures (16,29,45). The role of arthroscopy in these fractures is twofold: (a) as a diagnostic tool to assess the articular surface, menisci, and the cruciate ligaments accurately and (b) as an adjunct to treatment. For Type I fractures, pure splits that may be treated with closed reduction and percutaneous screw placement, arthroscopy permits debridement of loose joint fragments and repair of meniscal damage in addition to direct assessment of the articular reduction. For Type II and III fractures, depressed segments can be elevated through a cortical window under image intensification and confirmed visually with the arthroscope (16,29).

### FRACTURE FIXATION

#### Plates and Screws

Plates have two functions when they are used for the treatment of tibial plateau fractures. They can act as a buttress against shear forces or function in a capacity to neutralize rotational forces. Owing to the tenuous soft-tissue envelope around the proximal tibia, thinner plates have been advocated. Recently, percutaneous plating, which is a more biologic approach, has been described (30a,47a) (Fig. 23.14). In this technique, the plate is slid subcutaneously without soft-tissue stripping. Some authors advise against double plating of the tibial plateau due to an increase in soft-tissue complications (55). These complications are more likely caused by the higher energy injury, resulting in greater soft-tissue injury than from double plating (55). One may need to use double plates for a bicondylar fracture if the far cortex has an unstable fracture pattern; the use of low-profile plates with minimal soft-tissue devitalization through a separate incision is recommended. In such cases, plan to use the major plate on the most unstable or displaced side, using a much smaller plate and very limited dissection on the opposite side. An alternative is to use adjunctive external fixation on the opposite side rather than a plate; however, pin tract infection is a risk.

![Figure 23.14. A 45-year-old woman who sustained a Schatzker type VI fracture in addition to a closed femur fracture. A: Initial radiograph. B: CT scan. C: The swollen limb with evidence of healing blisters. D: Reduction of the articular surface and placement of 7.3 cannulated screws. E: A femoral distractor is used to align the tibial shaft followed by subcutaneous insertion of a tibial buttress plate. F: Screws are placed percutaneously under image intensification. G: Final appearance of the limb after placement of a second plate subcutaneously on the medial side. H: Postoperative radiographs.](image)
External Fixation

External fixation can involve either half-pins or thin wire, or a combination of the two (hybrids). External fixators may be placed across the fracture such that thin wires, with or without olive beads, capture fracture fragments or across the knee joint in a bridging fashion to make use of ligamentotaxis (38). The key is placement of the pin or wire 10 to 14 mm below the articular surface to avoid penetration of the synovial recess posteriorly. This approach will help minimize the development of a septic joint from a pin tract infection (46). Anatomic studies have shown cadavers to have some communication between the tibial-fibular joint and the knee joint. Thus a transfibular wire could potentially seed the knee joint if a pin tract infection were to develop (46). Place smooth wires parallel to the articular surface and below any percutaneously placed screws (Fig. 23.15). If an Ilizarov construct is used, place half pins and wires into the intact tibial diaphysis below the fracture (13,16,38-57) (Fig. 23.16).

Figure 23.15. Example of thin wires placed below percutaneously inserted lag screws.

External fixators that span the knee joint may be either half-pin or smooth wire. These constructs can be used temporarily to allow the soft tissue envelope time to heal (Fig. 23.17). In certain situations, however, spanning external fixators used in conjunction with limited internal fixation may be considered definitive fixation and left on for a longer period of time.

Figure 23.16. The use of an Ilizarov external fixator to stabilize a Schatzker VI fracture.

Figure 23.17. A patient with an open tibial plateau fracture with extensive comminution is shown. A bridging external fixator was applied for 10 days until the soft tissues allowed for definitive fixation.

OPEN REDUCTION AND FIXATION OF A TYPICAL SPLIT-CENTRAL DEPRESSION FRACTURE OF THE LATERAL PLATEAU

- Position the patient supine on a radiolucent table, as described earlier.
- Make a longitudinal skin incision just lateral to the midline from 2 cm proximal to the joint line and long enough to expose the distal extent of the fracture.
- Make an inframensical incision through the meniscotibial ligament and continue this longitudinally distalward along the anterior border of the anterior compartment to identify the vertical fracture in the lateral condyle.
- Expose the lateral condyle just enough to apply the smallest buttress plate that will be strong enough to support the plateau.
- Open the fracture site through this exposure and hinge the lateral condylar fragment laterally enough to visualize the depressed central fragment.
- Elevate the central fragment to slightly higher than an anatomic position and pack an appropriate graft beneath it to maintain its position. Preliminary fixation with Kirschner wires may be necessary.
- Now reduce the main condylar fragment into anatomic position and secure it with a bone holding forceps. The central fragments should now be aligned anatomically because they tend to subside slightly during these maneuvers. If not, make adjustments as necessary.
- Now apply a buttress plate of your choice with cancellous lag screws through the superior most holes and cortical screws more distally. Confirm the result with radiographs (Fig. 23.18).

POSTOPERATIVE CARE

Following surgical treatment, protect the knee in a hinged brace. Many authors have reported the benefits of early range of motion to the knee following tibial plateau fracture (1,18,47). Continuous passive motion from 0° to 30° may be started on postoperative Day 1 and increased as tolerated. Physiotherapy should consist of active and active-assisted range of motion to the knee, isometric quadriceps strengthening, and protected weight bearing. Progressive weight bearing depends on fracture healing. Some authors allow full weight bearing in cases in which there is an isolated lateral plateau fracture and in which a well-molded cast-brace is used to unload the affected compartment (11,49). For patients treated with external fixation, dynamization may be delayed 4 to 6 weeks following surgery and the fixator may be removed on radiographic evidence of fracture healing.

PITFALLS AND COMPLICATIONS

Complications in the treatment of tibial plateau fractures can occur whether operative or nonoperative management is chosen. Complication rates of 10% to 12% (14,51,52) have been reported for patients treated nonoperatively and 1% to 54% (5,24,47,57) for those treated with surgery. Most complications that occur with nonoperative treatment are related to prolonged recumbency and include thromboembolic disease and pneumonia (14,47,47). In addition, peroneal nerve palsy has been reported to occur with cast-brace treatment (14). Finally, pin tract infection can occur in patients if tibial pin skeletal traction is chosen.

The most severe complication that occurs with operative treatment of tibial plateau fractures is infection. Infection rates range from 1% to 38% (5,24,31,57) depending on which technique is employed. Superficial infections occur in 3% to 38% of cases (5,24,47,57) and deep wound infections from 2% to 9.5% (5,24,57). Skin slough is a risk factor for late infection and is of particular concern in the proximal leg because of exposure of ligaments, bone, and implants. Factors relating to skin slough include the severity of the initial injury, poor surgical timing and improper soft-tissue techniques with extensive osseous devitalization and use of biocompound implants (58).

Thromboembolic complications can occur following operative treatment of tibial plateau fractures (4). Deep vein thrombosis rates are reported to be 5% to 10% (5,31), with pulmonary embolus occurring in 1% to 2% of patients (5,24,31). Deep vein thrombosis prophylaxis includes the use of compression stockings, low-molecular weight heparin or coumadin; aggressive treatment of suspected pulmonary embolus is critical.

Late complications include painful hardware, loss of fixation, posttraumatic arthritis, and malunion. The most common late complication following operative treatment of tibial plateau fractures is so-called symptomatic hardware. The reported incidence is between 10% to 54% (4,27,57). Hardware may be removed usually 1 year following initial treatment. Loss of fixation is a complication that can be avoided by proper preoperative planning. Improper use of implants and the failure to use bone graft or bone graft substitutes adequately to buttress the articular surface may lead to loss of reduction or backout of hardware (loosening of screws or failure of fixation) (30,51). Posttraumatic arthritis may result from the initial chondral damage or be related to residual joint incongruity (56). Good functional results can be obtained in the face of poor radiographic results, however, and they may be due to the preservation of the meniscus and its ability to bear a substantial portion of the load of the lateral compartment (12,20,27,32,56). Malunion can occur either intrarticularly because of inadequate reduction or loss of reduction or with respect to the articular surface to the tibial shaft. Patients with malunions with residual varus or valgus of greater than 10° have been shown to have a higher incidence of poor long-term functional results (21). Rare complications include popliteal artery lacerations, osteonecrosis, and nonunion (19,53).

AUTHORS' PERSPECTIVE

We prefer to use the Schatzker classification to determine the choice of treatment. Our indications for surgery in addition to the absolute indications of open fracture, compartment syndrome, and vascular injury include instability of the nearly extended knee of greater than 10° compared with the uninvolved knee and unacceptable articular incongruence. The timing of surgery depends on the condition of the soft tissue. Early postinjury swelling represents hematoma. Within 8 to 12 hours following injury, the soft tissues become edematous. Fracture blisters may develop and are an indication of soft-tissue compromise. Earlier surgery in high-energy injuries through compromised soft tissues is inadvisable and may lead to a higher incidence of wound problems. Whenever possible, we prefer to use indirect reduction techniques with pointed bone forceps, a femoral distractor, and cortical bone windows, as described above.

Type I split fractures can generally be reduced closed with a large tenaculum forceps (29,52,54). Once reduced, we stabilize this fracture pattern with percutaneous 6.5 to 7.3 mm cancellous lag screws with washers (Ep. 23.19) (30,51). Recent biomechanical studies have shown no advantage to the addition of a buttress plate or an antigrade screw in the treatment of this fracture pattern in nonosteopenic bone (28). A thin plate may be helpful in patients with osteopenia.

Figure 23.19. A: Schatzker type I fracture is shown. B: Reduction of the split component with a tenaculum clamp. C: Placement of partially threaded lag screws across the fracture site.

Type II fractures have a depressed articular segment in addition to the split fragment. We have generally been dissatisfied with the quality of reduction achieved with indirect reduction and percutaneous fixation and usually perform a formal open reduction, as described above. We place 6.5 to 7.3 mm lag screws across the reduced split fracture fragments. Biomechanical testing has shown that subchondral Kirschner wires positioned as a horizontal array or cluster significantly enhance the load-bearing capacity of the articular surface (3). Therefore, we place three to four 3.5 mm cortical screws in the subchondral region, spread from anterior to posterior like leaves of a raft to support the articular surface. Because type II fractures tend to occur in older patients, these fractures may also require a thin buttress plate (30,52,54).

Type III fractures are pure depressions that we treat by elevation through cortical fenestrations (Figs. 23.20) and support with subchondral screws and bone graft. We view the articular reduction with an arthroscopy.
For type IVa and V fractures we use indirect reduction using a femoral distractor. We usually reduce type IVb fractures open. Internal fixation of fracture types IV to VI generally requires the use of plate and screws. Type IV fractures require a medial buttress plate to counteract the shear forces acting on the medial plateau. We stabilize low-energy type V fractures with medial and lateral plates (13, 34, 57). Type VI fractures have metaphyseal-diaphyseal dissociation. Following articular reconstruction, we stabilize the tibial shaft using either a single plate, double plates, a single plate and a contralateral two-pin external fixator or a thin wire fixator. If the fracture is transverse, a single plate will suffice. Oblique fracture lines exiting the opposite cortex require a second plate or external fixator to resist shear forces. When we use a second plate we use minimal dissection (Fig. 23-21) and a thin plate (one half or one third tubular).

Figure 23.20. A Schatzker type III fracture treated by elevation of the depressed segment through a cortical window. In this case, the fenestration was made medially to facilitate placement of the curved tamp.

For higher-energy injuries with a compromised soft-tissue envelope, we prefer to use a temporary spanning external fixator. The spanning external fixator is used to allow the soft tissues to heal in the critically ill patient and in those with severe soft-tissue injuries. This can be converted to internal fixation or a hybrid frame as soft tissues allow or maintained as definitive treatment.

We thoroughly debride and irrigate open joint fractures to reduce bacterial contamination, and then perform open reduction and limited internal fixation of the articular surface. We perform repeat irrigation and debridement at 48 hours and as often as necessary thereafter. Injuries with extensive soft-tissue devitalization are temporarily spanned with an external fixator and converted later to a hybrid fixator or definitive internal fixation once the soft tissues have healed. There is no consensus on how long antibiotics should be continued following open joint injury, but we continue antibiotics for 48 hours following final debridement and wound closure over suction drainage tubes.

Figure 23.21. Treatment of a Schatzker type VI fracture with either a plate (for a transverse shaft fracture) or a plate and a 2-pin ex-fix (for an oblique shaft fracture).

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Springer-Verlag, 1995:118.

Combination of loading mechanisms can occur. In nearly all cases, direct trauma results in worse injuries than indirect trauma. If it is possible to obtain a good history, energy absorption prior to fracture, thereby leading to explosive-type fractures that cause much more soft-tissue trauma and resultant severe comminution.

Slow rates of loading are characteristic of low-energy injuries and result in limited soft-tissue injury and simple fracture patterns. High rates of loading result in more high-speed motor-vehicle accidents and high-velocity missiles cause direct trauma and severe injury due to the high absorption of energy.

Most fractures from indirect trauma, such as twisting injuries occurring in sports, generally result in low to medium absorption of energy, whereas trauma, where the force is transmitted through the bone by twisting or bending, or by direct forces from direct impact against an object or from a penetrating missile. They can also be a result of amputations caused by massive, high-energy direct trauma, such as occurs in motorcycle accidents. Fractures can be caused by indirect trauma, including the extent of soft-tissue injury, associated injuries of the thigh, knee, and foot, and the pattern of injury to the bone itself. Treatment is equally varied, ranging from simple walking-cast immobilization through complex procedures required to replace lost bone, soft tissues, and neurovascular structures.

Of all the long bones, the tibia and fibula have the highest incidence of diaphyseal fractures. These fractures are often caused by high-energy trauma. Because the shaft of the tibia is subcutaneous throughout its length and may have a diminished blood supply, severe complications and major disability are common outcomes, particularly when the fractures are open.

Fractures of the tibia and fibula can range from completely undisplaced fractures with minimal soft-tissue damage, to traumatic amputations. For this reason, the decision tree for treatment is complex. It must take into account many factors, including the patient’s overall health, associated injuries, and the multiple factors bearing on the fracture itself, including the extent of soft-tissue injury, associated injuries of the thigh, knee, and foot, and the pattern of injury to the bone itself. Treatment is equally varied, ranging from simple walking-cast immobilization through complex procedures required to replace lost bone, soft tissues, and neurovascular structures.

It will not be possible in the context of this chapter to explicate all available techniques, but the general principles of soft-tissue management, closed treatment, external fixation, intramedullary nailing, and plate and screw fixation will be covered in such a way that the reader will be able to pursue other variations in treatment not discussed in this text. There is much material available in other chapters in Orthopaedic Surgery, as will be noted.

GOALS OF TREATMENT

In the treatment of closed and open fractures of the shaft of the tibia and fibula, patients and physicians would like to achieve complete union in a reasonable period of time (less than 6 months) without complications. Alignment should be maintained. In nearly all patients, as much as 1 cm of shortening and 5° or less of angular deformity or malrotation are not significant. Preexisting tibia vara or valgum or toe-in or toe-out influence the significance of greater degrees of malalignment. External rotation is better tolerated than internal rotation.

As much as 10° of malalignment is compatible with good function in most patients. Merchant and Dietz (191), in a long-term follow-up (average, 29 years) of fractures of the tibial and fibular shafts, found no predisposition to arthritis in the knee or ankle, regardless of the degree of residual angulation. As the location of the deformity approaches the ankle or knee, however, malalignment results in maldistribution of articular surface pressures that may predispose a patient to premature osteoarthrosis (137, 138).

MECHANISM OF INJURY AND PATHOPHYSIOLOGY

Fractures of the tibia can result from minor repetitive trauma below the threshold of injury required for fracture, resulting in a stress (fatigue) fracture (see Chapter 96). They can also be a result of amputations caused by massive, high-energy direct trauma, such as occurs in motorcycle accidents. Fractures can be caused by indirect trauma, where the force is transmitted through the bone by twisting or bending, or by direct forces from direct impact against an object or from a penetrating missile.

The prognosis is determined as much by the severity of soft-tissue injury as by the type of fracture, and both depend on the amount of energy absorbed by the limb at the time of injury. Most fractures from indirect trauma, such as twisting injuries occurring in sports, generally result in low to moderate absorption of energy, whereas high-speed motor-vehicle accidents and high-velocity missiles cause direct trauma and severe injury due to the high absorption of energy.

Slow rates of loading are characteristic of low-energy injuries and result in limited soft-tissue injury and simple fracture patterns. High rates of loading result in more energy absorption prior to fracture, thereby leading to explosive-type fractures that cause much more soft-tissue trauma and resultant severe comminution. Combinations of loading mechanisms can occur. In nearly all cases, direct trauma results in worse injuries than indirect trauma. If it is possible to obtain a good history,
a thorough knowledge of the mechanism of injury is important in classifying the fracture, which may bear directly on the choice of treatment.

Spiral fractures are caused by indirect loading in torsion, such as occurs in skiing. These are generally low-energy injuries with a good prognosis. High-energy, high-velocity torsional injuries result in comminution, which signals a worse prognosis, particularly if marked displacement is present. Short oblique and transverse fractures are generally caused by bending, which requires direct contact with the bone at or near the fracture site. These generally are worse injuries than spiral fractures and are often the result of high-energy trauma.

Crush injuries from direct trauma such as in motorcycle accidents or in the case of pedestrians being struck by vehicles are nearly always high-energy injuries with severe soft-tissue injury and severe comminution. In the absence of a good history, the mechanism of injury can often be inferred by the pattern of the fracture. Transverse or short oblique fractures, or comminuted fractures associated with fractures of the fibula with wide displacement, indicate disruption of the interosseous membrane and severe soft-tissue injury (22).

**CLASSIFICATION**

Classification systems of fractures enable us to communicate more accurately with each other and to make better diagnostic and therapeutic decisions, and they facilitate comparison of clinical and laboratory research results. The difficulty with classification schemes is that to be truly useful they must take into account many different and occasionally unrelated factors, some of which may be difficult to quantify. More important, interobserver reliability is questionable, making the comparison between studies somewhat unreliable (21).

Using the Gustilo and Anderson classification for open fractures, probably the most widely understood and accepted classification for fractures in the world today, Brumback (21) asked the attendees at the 1992 meeting of the Orthopaedic Trauma Association (OTA), a group of highly experienced and skilled trauma surgeons, to classify 12 open tibial fractures. The interrater reliability was only 60%. It is useful to keep this fact in mind while reviewing various classification schemes.

In classifying fractures of the tibia, various authors have listed the factors in Table 24.1 as important to the treatment and outcomes in tibial fractures. Ellis (36) in 1958, and Nicoll (100) in 1964 both used a number of these factors to establish simple classification systems that predicted the time of union and incidence of delayed union and nonunion (Table 24.2, Table 24.3). They, as well as Edwards (35), identified the severity of the soft-tissue injury as probably the most important prognostic factor in the outcome of fractures of the tibia and fibula.

**Table 24.3. Factors Affecting Rate of Union, Used by Nicoll for Classification**

Henley (54) used the Winquist and Hansen classification system for femur fractures (151) to provide indications for different patterns of cross locking in the use of interlocking nails (Fig. 24.1). I disagree somewhat with Henley’s recommendations in that fracture types I, II, and III all have the propensity to be rotationally unstable and to require static locking. In addition, undetected hairline fractures can become displaced, resulting in an unstable pattern that can either shorten or cause malrotation. This issue is addressed in more detail in the discussion under intramedullary nails in this chapter.
The American Society of Internal Fixation (AO/ASIF) classification, as developed by Müller et al. (99), has enjoyed worldwide acceptance; it was modified by Johner and Wruhs (64), taking into account the mechanism of injury, the initial displacement and comminution, and the severity of soft-tissue injury (Fig. 24.2). This classification was applied primarily to open reduction with plate and screw fixation.

In determining prognoses, Johner and Wruhs (64) found that initial displacement was unreliable, as the first radiography was often done after initial reduction and splinting of the fracture, whereas the fracture pattern and degree of comminution had significant influence. Spiral fractures were found usually to be due to lower-velocity indirect injuries and therefore were associated with less soft-tissue injury, whereas bending fracture patterns tended to be associated with higher-energy direct trauma with worse soft-tissue injury. Oni (105) confirmed these observations in a study of manually produced fractures in the rabbit tibia.

The OTA, in cooperation with the AO group, has recently published their classification, which is required for articles published in the *Journal of Orthopaedic Trauma* (106). In the OTA classification, the tibia is divided into its proximal, middle, and distal thirds, and a distinction is made between articular and extraarticular fractures (Fig. 24.3).

Gustilo and Anderson (48) in 1976 proposed their three-level classification of open fractures, which they subsequently modified to include five levels (47,49). Their classification system is critical to understanding the treatment of open fractures of the tibia and is discussed in detail in *Chapter 12*. Grading of the degree of soft-tissue injury in closed fractures of the tibia is equally important, because the deep soft-tissue injury may be much more severe in a fracture, as a result of crushing of the midshaft tibia, compared with a minor type I open fracture occurring from indirect trauma, such as a spiral fracture in skiing. Tscherne and Gotzen (144) developed a classification of closed injuries, which is helpful in looking for potential complications and in deciding treatment (Table 24.4).

Trafton (142) has attempted to pull all of these classifications together into a simple system that incorporates nearly all factors. To make it easy to use and clinically practical, he modified the systems of Ellis (36) and Edwards (35) with Leach's (77) modification and incorporated the soft-tissue grading systems of Gustilo (48) and Tscherne and Gotzen (144) (Fig. 24.4). This classification has not been verified by published clinical trials. Prior to surgery, it is often difficult to determine the soft-tissue grade; displacement of the tibial fracture itself is not reliable, as has already been pointed out. The pattern of fracture, however, is highly suggestive of the category in which Trafton would classify the fracture. This finding correlates rather well with expected problems or success in healing (Fig. 24.5).
PRINCIPLES OF TREATMENT

A wide variety of nonsurgical and surgical methods of treatment are available. They can be used in isolation or in interesting combinations involving two or more methods, depending on the particular fracture at hand, the age and health of the patient, and other imperatives that might be imposed by associated injuries (Table 24.5).

Table 24.5. Methods for Treating Fractures of the Tibia and Fibula

Regardless of the method chosen, the surgeon must attain the goals listed in Table 24.6 to achieve a satisfactory outcome. Two algorithms for the treatment of shaft fractures of tibia and fibula are seen in Figure 24.6A, Figure 24.6B.

Table 24.6. Treatment Goals

Figure 24.6. A: Management of soft tissues in open tibial fractures. B: Stabilization of adult fractures of the shafts of the tibia and fibula.
NONSURGICAL TREATMENT

Nonsurgical treatment includes closed reduction and application of various types of casts or fracture braces, either with or without regional or general anesthesia (60-63). Pins in plaster can be included, although functionally this method is a form of external fixation. Ten key articles are detailed in Table 24.7.

Table 24.7. Results of Treatment of Open and Closed Fractures of the Tibia and Fibula

The modern era of physiologic treatment of fractures of the tibia with early weight bearing and joint range-of-motion and muscle-strengthening exercises began with experiences of the military during and after the Korean War. Denier (27.28.29) and (30) and Brown and Urban (20) advocated early weight-bearing treatment of both closed and open fractures of the tibial shaft, applying a total-contact, well-molded, long-leg, weight-bearing cast. Sammarino (120,121,122,123,124,125 and 126) recognized the advantages of the total-contact socket used for below-knee prostheses and applied these principles to fracture treatment, thus allowing early use of a cast that does not immobilize the knee. He further refined his method to employ custom-built and subsequently off-the-shelf prefabricated fracture braces that could be applied early in stable fractures and later in treatment of less stable patterns.

In his 1995 paper, Sammarino reported on his experience treating 943 closed tibial shaft fractures with functional braces. He had only a 1% rate of nonunion and a 10% incidence of malunion. Other investigators (Table 24.7) showed nonunion rates of 0% to 4% and malunion rates of only 4% to 5%. This experience confirms closed reduction as the treatment of choice for stable fractures of the tibia (see Fig. 24.68).

Unstable fractures patterns (Fig. 24.1, Fig. 24.2, Fig. 24.3, Fig. 24.4, Fig. 24.5, Fig. 24.6B) are more difficult to treat by closed means, and recent comparative studies between closed treatment and intramedullary nailing (Table 24.7) show superior results with locked intramedullary nailing (18,57). Bone et al. (19) in 1997, in a prospective randomized series, showed only a 2% incidence of nonunion and malunion in their nailing group as compared with 10% nonunion and 25% malunion rates in their cast group. Hallmarks of instability that would favor locked intramedullary nailing in adults and external fixation in children include comminution precluding less than 50% contact between the ends of the proximal and distal fragments, diastasis of the tibia and fibula indicating complete rupture of the interosseous membrane, widely displaced segmental fractures, and fractures with segmental bone loss (Fig. 24.5).

Extremely comminuted fractures in patients who are at high risk for operative intervention, however, or those who could not be expected to cooperate in postoperative care—perhaps in particular those who have fracture patterns that preclude external fixation without bridging the knee—may be best treated by nonsurgical means. Most grade I open fractures with stable patterns can be treated with casts, as care of the wound does not require the access permitted by internal or external fixation.

Achieving successful outcomes with cast and fracture brace management is as demanding of the surgeon as operative treatment, and it requires a cooperative patient (108). Frequent follow-up with radiographic and frequent cast adjustments or changes may be necessary to permit healing with acceptable alignment and minimal shortening. The details of closed treatment are outlined later in this chapter and in Chapter 10.

EXTERNAL FIXATION

External fixation has waxed and waned in popularity for the treatment of tibial fractures throughout most of the 20th century. Refinements in external-fixation pin technique, and frame designs with improved mechanics made it popular beginning in the late 1960s through the mid to late 1980s. During that period, external fixation was the stabilization method of choice for open fractures of the tibia (11,11,19,26,32,33,34 and 35,37,38 and 39,42,45,67,68,69 and 70). External fixation is indicated in or without a cast. The fracture, which has not yet healed, becomes displaced and often the screw breaks or the fracture becomes distracted, resulting in nonunion and frequently malposition. This situation then requires operative intervention. Therefore, I try to avoid combining interfragmentary screw fixation with external fixation in diaphyseal fractures. Early weight bearing is possible and the surgeon can use both radiographic and clinical criteria to judge when the external fixator can safely be removed.

Conversion of External Fixation to Other Types of Internal Fixation

Table 24.7 lists five articles describing conversion of external fixation to intramedullary nailing, either early or late (13,65,85,140), and in the case of Siebenrock et al.
A review of the literature in

...normalcy by 11 weeks after reaming. In animal models, osteotomy of the tibia as well as reaming increase blood flow in the muscle and skin surrounding the fracture... canine fracture model demonstrated that overall tibial blood flow was reduced by 63% with limited reaming, as opposed to 83% with full reaming. All blood flow... of blood supply from the periosteum and surrounding soft-tissue envelope, which is compromised in open fractures. This situation may predispose patients to infection... The reaming, however, stimulates a strong hyperemic reaction, which in experimental animals reaches a level several times normal by 2–4 weeks after fracture... of the diaphysis of the tibia is indicated, the fixation of choice today is a locked intramedullary nail (see Chapter 25). When internal fixation of a fracture of the diaphysis of the tibia is indicated, the fixation of choice today is a locked intramedullary nail (see Chapter 25).... Intramedullary nailing of the tibia, particularly with nonreamed nails, was popularized by Lottes (1970, 1974, and 1977; see Table 24.7). He described his blind nailing technique in 1952 (1970, 1974, and 1977; see Table 24.7). The technique that the technique was more widely used. Their results were remarkably good, with acute infection rates of only 3%, and a low incidence of nonunions (2% to 2.5%). Because the Lottes nail could not be locked, fixation was always supplemented by a long-leg cast, and in spite of that, D'Aubigne reported a 16% incidence of malunions—the main reason the Lottes nail did not gain widespread use. The orthopaedic community did not seem to pay attention to the excellent results with the Lottes nail in open fractures until Velazco et al. (2017) showed a remarkably low acute infection rate of only 2% in 50 consecutive fractures, of which 65% were grade III (Table 24.7). In the early 1980s, the flexible solid medullary nails developed by Ender for the femur were downsized and applied to the tibia. The Ender nail experienced brief popularity and is still used by some (86-92,125). The advantage of the Ender nail over the Lottes nail is that its smaller cross section, shape, and flexibility allow it to be more easily inserted, and the nail can be used to reduce the fracture. Because two nails are typically introduced, one from medial and one from lateral, and they are spread in a similar fashion distally, they offer better rotational control than the Lottes nail. Levy et al. (79) found Ender nails to be superior to plaster-cast treatment in preventing varus deformity in tibia fractures with an intact fibula. Holbrook et al. (56), in a prospective randomized study that compared Ender nails to external fixation in the treatment of open fractures of the tibia, found Ender nails to be as effective as external fixation in types I and II open fractures. In a similar retrospective study, Whitelaw et al. (149) found Ender nails to be superior in a similar group of fractures. In my experience, Ender nails work well, especially when combined with plaster cast or cast-brace immobilization in unstable fracture patterns. I no longer use Ender nails in adults, however, because they do not provide the stability of locked intramedullary nails, and most fractures heal with some posterior angulation. Although they can be locked on one end by inserting screws through the hole in the nail provided for the inserter, they do not provide adequate control against shortening. We keep a set of tibial Ender nails in our operating room for the rare situation when we want to place an intramedullary nail in a child with an open fracture of the tibia for which external fixation is not suitable, or in the occasional extremely unstable fracture for which external fixation is not suitable. With careful technique, the nail can be inserted without injury to either the proximal or the distal growth plates. When internal fixation of a fracture of the diaphysis of the tibia is indicated, the fixation of choice today is a locked intramedullary nail (54,134,153). In closed fractures, most surgeons prefer to place a nail that uses transverse cross-locking screws of 4.5 mm or larger. Nails generally are 10 mm or larger in diameter, reaming is often necessary. In open fractures, most surgeons prefer to use nails that do not require reaming, because in severe open fractures, the soft-tissue envelope around the tibia has been stripped and the outer cortex devascularized. Reaming has been demonstrated to devascularize the inner two thirds of the cortex or more (71,73,111). The reaming, however, stimulates a strong hyperemic reaction, which in experimental animals reaches a level several times normal by 2–4 weeks after fracture (41,107). This revascularization of the diaphysis by reaming of the normal centrifugal blood supply of the cortex to a centripetal blood supply depends on the adequacy of blood flow from the periosteum and surrounding soft-tissue envelope, which is compromised in open fractures. This situation may predispose patients to infection and failure to heal the fracture. The revascularization is influenced by the presence of an intramedullary nail. Nails that fit tight against the cortex interfere with revascularization, whereas fluted nails, or smaller-diameter nails that have limited contact with the endosteal cortex, allow more complete and rapid reestablishment of the blood supply to the cortex (43,44,62,107,143). Reaming also increases strength of union in an osteotomy. In the nailing of open fractures, early full-thickness soft-tissue coverage, preferably with muscles, is therefore of great value. A review of the literature in Table 24.7 shows that the results with nonreamed locked intramedullary nails are excellent, but that delayed union rates are as high as...
48%. For the most part, this delay results from the fact that these series involve high-energy open fractures, and unreamed nails tend to be flexible and relatively weak. Comparisons to use of external fixation, however, in particular the series of Santoro et al. (119) and Torretta et al. (139), show results comparable or superior to those of external fixation. Unreamed or minimally reamed locked nails are therefore preferable to external fixation in open fractures. The major disadvantage of unreamed locked nails is that because they are small, there is an increased incidence of delayed union and broken hardware. Secondary procedures to convert to larger reamed locked nails or bone graft occur in 10% to 20% of fractures.

The results from reamed, locked intramedullary nails are excellent. Rates of infection, delayed union, nonunion, and malunion are low, with the best series reporting rates of less than 5% for all of these complications. Because acute reamed nailing of open fractures has higher rates of infection, however, initial nonreamed nail fixation or external fixation with subsequent conversion to a reamed nail, as discussed previously, is preferable in high-grade open fractures.

PLATE AND SCREW FIXATION

Müller et al. (95,96.67 and 98) advocated open reduction and the use of interfragmentary lag-screw and compression-plate fixation in displaced fractures of the tibia and fibula. Ruedi et al. (116) reported good to very functional results in 98% of 323 closed fractures. There was less than a 1% incidence of late osteomyelitis and a similarly low incidence of nonunion. There were three fixation failures and one refracture. Plate and screw fixation of open fractures is far more hazardous, as reflected by results in 101 open fractures, in which the overall rate of complications was 32%, including a 12% incidence of infection and a 7% incidence of nonunion (23,100,101,103).

The difficulty with plate fixation is that the complications of infection can be devastating, leading to osteomyelitis and even amputation. Since the development of closed intramedullary nailing with locking screws, the indications for plate fixation for diaphyseal fractures are rare. Fractures at the metaphyseal–diaphyseal junction are difficult to treat with intramedullary nails. Lange et al. (74), in 32 extraarticular fractures of the proximal third of the tibia treated with locked intramedullary nails, reported 84% with greater-than-acceptable angulation and advise consideration of plating or external fixation for these fractures. I often place unstable fractures in the proximal third or distal fourth of the tibia when nonoperative treatment does not suffice.

OPEN FRACTURES

The worst open fractures encountered by most orthopaedic surgeons involve the tibia and fibula (which are often crushed in high-speed motor-vehicle accidents). It is extremely important to follow all the basic principles in the treatment of open fractures outlined in Chapter 12, including appropriate emergency care, early administration of appropriate intravenous bactericidal antibiotics, meticulous layer-by-layer wound irrigation and debridement, appropriate fracture stabilization, delayed wound closure, and early full-thickness soft-tissue coverage (86,75,68). Figure 24.6A presents the protocol for management of the soft tissues in open tibial fractures, and Figure 24.6B the protocol for stabilization of open tibial fractures.

In 1993, when the second edition of this book was published, numerous trauma centers were just beginning to use nonreamed intramedullary nailing. It has now become the method of choice for grade I, II, and IIIA open fractures. As noted in Table 24.7, it can be satisfactory for grade IIIB and C open tibial fractures as well, but the risk of infection is significant. For that reason, some surgeons still prefer initial external fixation for high-grade open tibial fractures. As discussed earlier in this chapter, many now have adopted the practice of passing one or two reamers gently to increase the medullary canal size to allow insertion of a 10 mm nail, which permits the use of larger transverse cross-locking screws. Laboratory evidence indicates that this method has less impact on the circulation to bone than full reaming, and clinical outcomes appear to be acceptable.

The more challenging decision is what to do after placement of small, unreamed locked nails or external fixation. In the case of the former, many fractures will go on to successful union, but delayed union with early failure of screws, and occasionally nails, can occur in up to 48% of cases (17). In fractures fixed with unreamed nails less than 10 mm in diameter, I delay weight bearing and keep a close watch on the fracture. If by 12 weeks there is no callus formation or evidence of progression toward union, or if there is evidence of impending hardware failure, I convert to a larger reamed locked intramedullary nail, on occasion combining its use with an open bone graft if there is segmental bone deficiency.

In the case of external fixation, if the patient tolerates the fixator well and there are no significant pin complications, the fracture can often be followed until union in the external fixator, particularly if the fixator allows early joint motion, muscle rehabilitation, and weight bearing. On occasion, I convert external fixation to a reamed intramedullary nail if the patient is unable to tolerate the external fixator or if there are socioeconomic reasons. I will not make this conversion in the case of pin-track infection. In most cases, I remove the external fixator and place the leg in a cast until pin-track healing has occurred, usually in 2–3 weeks, and then carry out nailing.

As with the small unreamed locked intramedullary nails, if by 12 weeks there is evidence of delayed union, I intervene surgically to hasten union. Choices include conversion to a large reamed intramedullary nail, or bone grafting of the fracture in the fixator, usually through a posterolateral approach, except in proximal fractures, where a posteromedial approach is utilized. I handle fractures with segmental bone deficiency in a similar manner by doing large posterolateral bone grafts spanning from tibia to fibula to produce a tibial–fibular synostosis, effectively bypassing the area of missing bone.

Success of these techniques requires a good-quality, full-thickness soft-tissue envelope. I make liberal use of local muscle flaps and free microvascular flaps to achieve muscle coverage of the fracture by 10 days, if possible.

I do not have enough experience with early conversion of external fixation to reamed locked medullary nailing in high-grade open fractures to comment; the articles listed in Table 24.7, however, support this as an alternative and effective technique.

Some surgeons have converted entirely to the use of ilizarov-type ring fixation with half-pins, tension wires, or combinations thereof. I have used ilizarov-type fixation in cases that called for primary shortening of the limb through the fracture site to achieve bone apposition and early soft-tissue closure (utilizing proximal or distal distraction osteogenesis to restore length to the limb). I also have used this method where the normal length of the limb has been maintained and a segment has been transported to fill a bone defect. These techniques are discussed in more detail in Chapter 32.

Because of the highly managed health care economy in the Sacramento region, I have not found ilizarov techniques to be as suitable for our patients as the other methods discussed. The patients are often quickly transferred to other surgeons after their initial care, or they live a considerable distance from my hospital. For that reason, if I feel that an ilizarov methodology is applicable, I am more likely to apply a simple unilateral fixator initially and then later convert the patient to an ilizarov device when it is apparent that I will be carrying out the full course of treatment and the patient is an appropriate candidate for the method selected. In addition, I find the use of circular external fixators time consuming and technically demanding and therefore difficult to use in emergency situations, particularly in patients with multiple injuries. I find it better to apply these devices on an elective basis.

AMPUTATION

Perhaps one of the most important decisions is whether to amputate a severe open fracture of the tibia (61). It is destructive and wasteful to invest two or more years in an attempt to salvage a limb that is finally amputated because it is painful and dysfunctional. Over the past decade or so, clinical researchers in major trauma centers dealing with massively traumatized limbs have attempted to develop scoring systems to assist clinicians and patients and their families in the decision-making process. The surgeon and patient must decide whether early amputation is indicated for a mangled limb, or whether the major repeated surgeries required to salvage the limb would leave the patient with an extremely more useful than a below-knee prosthesis (Table 24.8).

Table 24.8. Mangled Limb Scoring Systems
The most frequently studied of these is the mangled extremity severity score (MESS) (Table 24.9), and the most recent and most complete is the NISSSA (for nerve injury, ischemia, soft tissue injury, skeletal injury, shock, and age of patient) (Table 24.10). The literature on the reliability of these indices is mixed, however. In looking at the outcomes of free microvascularized flaps to the tibia, Laughlin et al. (78) in 14 open fractures, 8 grade IIIB, and 6 grade IIIC, experienced one related death and four early amputations. Of the remaining nine, six became infected, but all cleared with treatment and all of the fractures healed. Eight of the nine patients eventually returned to work, six to their preinjury occupations.

Trabulsky et al. (141), in a study of 45 grade III open tibial fractures, performed free flaps in 78% with a 97% success rate of the flaps and overall salvage rate of 98%. There is little question that most limbs are salvageable using modern surgical techniques. Slauterbeck et al. (133), in a retrospective study of 43 severe open fractures, found the MESS to be accurate, as all nine limbs with a MESS greater than 7 went on to amputation and 34 with a score of less than 7 were salvaged.

Robertson (114), in a retrospective review of 152 open fractures, also found the MESS to be accurate in predicting the need for amputation but found that the score was not as reliable in predicting outcomes in young people with moderate injuries who had experienced no shock and who had an arterial injury requiring repair. Survival of the limb in this group was higher than the score would predict.

Studies by Georgiadis et al. (40) and Bonanni et al. (15) illustrate the problems with these scoring systems. Georgiadis et al. (40) compared 16 limbs salvaged with a free flap, with 18 that were treated early with below-knee amputation. In the salvaged group, he found an increased incidence of complications, an increased number of operative procedures, and an increased length of stay in the hospital. Furthermore, these patients were more likely to report themselves as severely disabled, and they reported less satisfactory performance in their occupational and recreational activities. Bonanni et al. (15) did a retrospective review of 89 severe open tibial fractures of which 58 were salvaged and 31 went on to primary amputation. They evaluated the MES, MESS, predictive salvage index (PSI), and limb salvage index (LSI) and found no predictive value in any of these measuring tools. Of the 58 that were salvaged, 31% eventually went on to delayed amputation.

It is often difficult to determine in the emergency room, or for that matter at the time of initial surgery, the full extent of injury to a limb. For that reason, I prefer to follow the simple guidelines of Lange et al. (74), erring on the side of preservation rather than amputation unless the limb is obviously nonsalvageable, or unless the limb presents a threat to the patient’s life. It is critical, however, to take an early second look at the limb, at which time a definitive decision can usually be made. It is important to involve patients and their families as much as possible in this decision-making process.

The surgeon must make every effort to avoid discharging a patient from initial admission with a severely mangled limb that in the long run is not going to be salvageable or function better for the patient than a below-knee prosthesis. Lange et al. (74) have developed guidelines for primary amputation. In type IIIC fractures (i.e., those with a vascular injury requiring repair), primary amputation is indicated when the posterior tibial nerve is transected, or in crush injuries where the warm ischemia time is greater than 6 hours. Relative indications are serious associated polytrauma, severe ipsilateral foot trauma, or an anticipated protracted course to obtain soft-tissue coverage or tibial reconstitution. Consider primary amputation if one of the absolute indications or two or three of the relative indications are present. These criteria and the decision-making variables are listed in Table 24.11.

The most important variable in determining the outcome of a limb is the patient’s ability to accept the result. Most patients who are amputated are not able to return to work or to their preinjury occupation. The family also has to accept the results, as the burden of care falls on them, and the patient is often left feeling devastated. It is critical that the patient and family be involved in all decisions. The patient must make an informed decision based on all the available information.

Caudle and Stern (24) have emphasized the importance of making the decision to amputate early. They eventually amputated in the cases of seven of nine type IIIC open fractures because of pain, sepsis, nonunion, or failure of the vascular repair. The results in the two that were salvaged were poor.
After addressing life- or limb-threatening emergencies, take a complete history and perform a physical examination. Carefully examine the involved extremity. In particular, look for any evidence of open injury, compromise of neurovascular function, or evidence of impending compartment syndrome. Record your findings.

Gently restore the leg to grossly normal alignment, control hemorrhage from wounds with a compression dressing, and dress all open wounds with povidine-soaked sterile dressings. Apply a long-leg, well-padded splint. Elevate the limb on a pillow 10 cm above the level of the heart. Take anteroposterior (AP) and lateral radiographs that include the knee and ankle.

**SKELETAL TRACTION**

Treatment of tibial fractures in traction was popularized by Böhler (14). Traction may be indicated to overcome unacceptable shortening that cannot be corrected by closed reduction, particularly in neglected fractures, although modern external fixators that provide distraction have limited the usefulness of this technique. Traction is most commonly used to maintain length when severe soft-tissue injury or other considerations make immediate incorporation in a cast or splint or performance of internal fixation impossible. Because traction may be followed by internal fixation, it is important to avoid pin-track complications.

- Place a transverse, smooth, Kirschner wire through the distal tibia (Fig. 24.7). Place povidine-soaked or dry sterile gauze pads over the wire, using enough to prevent the wire from sliding. If internal fixation of the tibia is planned, place the wire in a similar fashion through the calcaneus.

**Figure 24.7.** Kirschner wire traction for fractures of the tibia and fibula. (From Chapman MW. Fractures of the Tibial and Fibular Shafts. In: Evarts CM, ed. *Surgery of the Musculoskeletal System*. New York: Churchill-Livingston, 1983, with permission.)

- Apply a traction bow that is large enough to fit around the foot.
- Support the fracture on a Böhler-Braun frame, a suspended Thomas splint, or a pillow (see Chapter 10).

**Postoperative Care**

Institute physical therapy immediately to encourage movement of the ankle and avoid equinus contraction. Isometric exercises of the muscles in the lower extremity and limited knee motion are often possible in traction. As soon as length is regained or the soft-tissue problem is resolved, discontinue traction and implement other methods of stabilization.

**CLOSED REDUCTION AND CAST IMMOBILIZATION**

Closed reduction and the application of a plaster cast is the most commonly used method for treating fractures of the tibia and the fibula. Weight-bearing methods were popularized by Dehne (27,28) and 29, Brown (20), and Sarmiento (120,121,122,123,124,125,126). I almost never use non-weight-bearing casts. The technique of applying an immediate weight-bearing cast is demanding and requires as much motor skill as internal fixation.

Initially, use a long-leg cast. Change to a Sarmiento cast or brace as soon as early axial and translational stability are present, usually about 4–6 weeks after injury.

Closed reduction and cast application usually do not require a regional or general anesthetic if the patient is cooperative. Medicate him well, and use local anesthesia. Place a padded crutch or board beneath the thigh and secure it to the table. Gently place hand traction on the leg and position it as illustrated in Figure 24.8.

**Figure 24.8.** Position for application of a Sarmiento, short-leg, or the initial portion of a long-leg plaster cast for a fracture of the tibia. (From Chapman MW. Fractures of the Tibial and Fibular Shafts. In: Evarts CM, ed. *Surgery of the Musculoskeletal System*. New York: Churchill-Livingston, 1983, with permission.)

**Application of a Removable Ankle Traction Bandage**

A traction bandage and gentle traction are used to stabilize the tibia (Fig. 24.9).

**Figure 24.9.** Removable ankle traction bandage. (From Chapman MW. Fractures of the Tibial and Fibular Shafts. In: Evarts CM, ed. *Surgery of the Musculoskeletal System*. New York: Churchill-Livingston, 1983, with permission.)
Cut a strip of muslin 65 cm in length and 2.5 cm wide, and bring the ends together. Make a second strip.

Place one strip over the instep and one over the heel, and connect them with 12 mm tape level with the bottom of the foot. Locate the junction of the strips directly below the malleoli. Apply a thin layer of petroleum jelly beneath each strip to ease removal.

Tie a bucket of water to the strips or use a foot loop. Apply enough traction (add water or increase foot pressure) to stabilize the fracture and achieve alignment.

After cast application, cut the tape, remove the strips completely, and seal the cast. Do not leave the traction bandages in the cast, as they can cause pressure sores.

**Application of a Long-leg Weight-bearing Cast**

Note the anatomic molding in Figure 24.10.

![Figure 24.10. Long-leg weight-bearing cast. (From Chapman MW. Fractures of the Tibial and Fibular Shafts. In: Evarts CM, ed. Surgery of the Musculoskeletal System. New York: Churchill-Livingston, 1983, with permission.)](image)

- Apply the short-leg section first up to the mid patella.
- Place a 15–20 cm piece of tubular stockinet at each end of the cast for trimming.
- Apply a double layer of cast padding with a triple layer over bony prominences. It must be free of wrinkles.
- Dip one 10 cm roll and three 15 cm rolls of plaster into 72°F water. Apply the 10 cm roll about the foot and ankle and follow with the 15 cm rolls. Apply rapidly and smoothly. Place tucks posteriorly.
- Mold the cast as it sets. Mold in the transverse and longitudinal arches of the foot and about the malleoli. The malleolar molding produces a posterior bulge for the Achilles tendon. Smooth the cast along the entire anteromedial border of the tibia. As the plaster sets, mold posteriorly to push the leg anteriorly to fit against the smooth anterior aspect of the cast. The cast should assume a triangular shape with a slight bulge for the sharp anterior border of the tibia and relatively flat surfaces over the posterior and anterior compartments and medial surface. Fit the cast to the medial and lateral flares of the proximal tibia.
- When the cast has set, extend the knee. Remove the ankle bandage. Trim the proximal end of the cast.
- Apply the thigh portion of the cast. Support the cast at the fracture site with an assistant’s chest (or use a leg holder). Keep the knee flexed 5° short of full extension. Wrap on two layers of cast padding. Apply three or four 15 cm rolls of plaster. Extend proximally to the greater trochanter.
- Mold the cast above the medial and lateral epicondyles. This molding technique causes posterior bulging, which creates a channel for the hamstring tendons. Proximally, mold the cast over the anterior and lateral surfaces to produce a quadrilateral socket. This molding produces a snug fit over the greater trochanter and femoral triangle, which creates a channel for the adductor and hamstring tendons.
- Trim the ends of the cast, reinforce the foot, and apply a walker or walking boot.
- In acute fractures where swelling is a risk, place a single longitudinal cut along the full length of the anterior aspect of the cast over the muscle of the anterior compartment and spread the cast as needed. Reseal when the swelling resolves.

**Application of a Sarmiento-type Cast**

- After applying the below-knee cast as just described, carry the padding and plaster 5 cm proximal to the patella. Mold the leg portion of the cast and extend the knee to 45° of flexion.
- Mold the plaster to the flares of the tibia and over both femoral epicondyles. Mold the cast to gently grip the epicondyles, thereby creating an anterior channel for the patella and patellar tendon and a posterior channel for the hamstrings. Flatten the popliteal fossa to keep the leg against the anterior aspect of the cast.
- Trim the cast (Fig. 24.11). Notice that it is above the patella to avoid patellar impingement and give good support. Trim out the popliteal fossa to allow the amount of flexion desired. You may choose to limit flexion to 45° initially and then gradually increase it as fracture stability increases.

![Figure 24.11. Sarmiento type cast. (From Chapman MW. Fractures of the Tibial and Fibular Shafts. In: Evarts CM, ed. Surgery of the Musculoskeletal System. New York: Churchill-Livingston, 1983, with permission.)](image)

**Postoperative Care**

Provide crutches or a walker and encourage the patient to be out of bed within 1–2 days and to bear weight as tolerated. The typical patient requires at least 3 weeks and up to 6 weeks to achieve full, unsupported weight bearing. The patient should strive to be independent of crutches by 4 weeks. Begin isometric exercises for all muscle groups immobilized in the cast. It is important to follow the patient at weekly intervals for the first 4–6 weeks when weight-bearing methods are used. Loss of reduction must be corrected early to avoid malunion.

Change casts at 4- to 6-week intervals, depending on the stability of the fracture. Stable fracture patterns and those that gain stability early may be converted to a Sarmiento cast or fracture-brace as early as 4 weeks. Protect tibial fractures for at least 12 weeks. The average healing time is 16–24 weeks. Fracture instability after 24 weeks is considered a delayed union.

**FRACTURE BRACING**

Fracture bracing, popularized by Sarmiento et al. (126), is very useful, particularly with prefabricated braces (Fig. 24.12). Although the description of this technique is beyond the purview of this text, it is fully described in the literature (120,121,122,123,124,125 and 126).
PINS AND PLASTER

With the availability of single-bar, half-pin external fixators, I almost never use the pins-and-plaster technique. When pins in plaster are used, at least three pins, two of which must be full pins, are required. External fixation requires only four half-pins and is much quicker and more versatile, so there is no reason to use pins in plaster. However, as it is a simple and inexpensive method, it continues to enjoy wide use, particularly in underdeveloped countries. I prefer a three-pin technique using a short-leg cast.

**Fig. 24.13.** Pins in plaster—two pin technique. (From Chapman MW. Fractures of the Tibial and Fibular Shafts. In: Evarts CM, ed. Surgery of the Musculoskeletal System. New York: Churchill-Livingston, 1983, with permission.)

- When pins are used in plaster, at least two proximal pins are needed to control the proximal fragment, and then only a short-leg cast is needed.
- Insert one large transverse Steinmann pin just distal to the tibial tubercle. Insert a second pin from anterior to posterior, slightly distal to the first pin. Engage the posterior cortex, but do not penetrate the soft tissues because of the risk of neurovascular injury. Leave the pins protruding 5 cm, and incorporate them into the cast. Use a distal transverse pin if necessary for the distal fragment.

**Postoperative Care**

Pin loosening is a common problem with pins and plaster, so weight bearing is usually contraindicated. Some patients can perform partial weight bearing with crutches if a distal pin is not used. If a distal pin is used, weight bearing is contraindicated. When this method is properly applied, and in the absence of complaints from the patient, inspection of the pin sites is unnecessary until cast removal. In stable patterns with rapid healing, remove the pins by 4–6 weeks and convert to a weight-bearing cast. In unstable patterns, prolonged immobilization may be necessary. Prolonged immobilization in pins and plaster is often complicated by delayed union and nonunion, and it may necessitate bone grafting.

**EXTERNAL FIXATION**

Chapter 11 covers in detail the basic principles of insertion of external fixation pins and application of simple fixators, as well as pin care and the general postoperative regimen for external fixation. The focus in this section will be on external fixation of the shaft of the tibia.

Complex fractures involving the tibial plateaus and proximal quarter of the tibia or the ankle joint may require special fixators, especially those using tensioned wires or hybrid fixators (see Chapter 23 on fractures of the tibial plateau, and Chapter 25 on ankle fractures). Other than Ilizarov fixators (Chapter 32), the most commonly used external fixators for the diaphysis of the tibia are those in which half-pins are inserted along a rigid, single-piece bar or tube, or into which pins are inserted either individually or as clusters through articulating pin holders that are mounted on an adjustable tube or bar or series of bars. Many interesting and useful combinations are commercially available.

In the second edition, we discussed in detail Hoffmann-type external fixators, which used through-and-through pins in clusters of up to four. Modern external fixators make such pin designs obsolete and therefore will not be described here. I still use some through-and-through pin fixator configurations for the tibia—in particular, a type of delta frame for pylon fractures (Chapter 25).

The simple single-bar systems are inexpensive and versatile. With their components, complex fixators can be built to meet almost any challenging combination of problems. The major disadvantage of fixators where the half-pins are mounted on a single bar is that the fracture must be nearly anatomically reduced during the application of the fixator; after application, there is minimal opportunity to make adjustments and achieve anatomic position. In addition, it is very difficult to “dynamize” these fixators when weight bearing across the fracture site becomes desirable.

To some extent, dynamization can be obtained by removing fixation rods, assuming more than one were initially applied, or by removing frames in other planes, assuming more than one plane was used. Adjusting the pin length also can achieve some element of dynamization, but the result is a type of cantilevered motion. The most recent designs, based mostly on tubes, incorporate mechanisms for allowing controlled dynamization of the fracture site over given amounts of compression at different spring-loads.

**ANATOMIC CONSIDERATIONS**

Fixation pins are much less likely to loosen if inserted through cortical bone. For biomechanical reasons, it is desirable to have one set of pins in the proximal and distal fragment, as far from the fracture as practical, and a second set as close to the fracture site as practical. In the former, I always try to keep the pin at the metaphyseal–diaphyseal junction, so that the pin is transgressing some cortical bone rather than being placed in pure cancellous bone.

In the region of the fracture, I generally place the pins approximately 25–30 mm away from the fracture site or the area of nearest fracture line, to avoid accidentally inserting the pin through an unseen crack, and to minimize the risk of communication of the pin with the fracture hematoma. Because of the neurovascular structures in the leg, it is important to be aware of the safe anatomic corridors of pin insertion along the length of the tibia. These have been well described by Stuart Green (45), who divides the leg into four segments—A, B, C, and D—each representing a quarter section of the leg.

**Fig. 24.14.** Sarmiento type fracture brace with free ankle hinge. (From Chapman MW. Fractures of the Tibial and Fibular Shafts. In: Evarts CM, ed. Surgery of the Musculoskeletal System. New York: Churchill-Livingston, 1983, with permission.)
In zone A, the risk of injury to nerves and vessels is small, as they lie posterior to the tibia. The common peroneal nerve divisions and anterior tibial artery and vein lie close to the fibula.

In zone B, pin placement in the usual locations does not threaten the neurovascular bundles unless the soft tissues are penetrated too deeply posteriorly or the pin angle is incorrect. Be cautious with 30° medial half-pins.

In zone C, transverse pins are reasonably safe. Pins entering the medial subcutaneous border threaten the anterior tibial artery and vein, and the deep peroneal nerve. A direction more anterior to posterior, engaging the posterior cortex, is safest for a half-pin in this section.

In zone D, the anterior tibial artery and nerve are closely applied to the tibia and pass from mid tibia to anterior tibia as they travel distally. Transverse pins in the proximal third of this section are contraindicated. Place other pins with caution.

Insert pins through the middle of the medullary canal and avoid the anterior cortex if possible (Fig. 24.15). Driving pins through the solid anterior cortex can cause overheating and bone necrosis, which is often followed quickly by pin-loosening infection and osteomyelitis.

The configuration of the fracture may dictate the selection of the frame. The configuration must offer sufficient strength to adequately immobilize the fracture and should use the least injured soft tissue and bone for the pin sites. The frame must be constructed to allow optimal access for subsequent surgical debridements and reconstructive procedures, such as local, rotational, or free soft-tissue flaps.

MECHANICAL CONSIDERATIONS

Behrens and Searls (12) have pointed out that the sagittal bending moments in the leg are about two to five times larger than those in the coronal plane. For that reason, the primary frame is best located as close as possible to the anterior–posterior plane. To maximize the initial stiffness of the frames, they advise increasing the spread of pins in each main fragment, reducing the distance between the bone and longitudinal rod, adding a second rod to the same pins, or adding a second half-frame as close as possible to 90° to the plane of the first frame.

The configurations they recommend for different tibial fractures are illustrated in Figure 24.16. They studied 69 fractures, of which 54 were open, and found that simple, one-plane frames were adequate for over 80%. In their series, 5 mm stainless-steel pins were used. Further stiffness can be obtained by using 6 mm pins. They encouraged their patients to try early partial weight bearing, progressing to full weight bearing as the fracture healed. They increased the load transmission across the fracture by the techniques previously described, including loosening the central pin articulations in their half-frames.

UNILATERAL SIMPLE AO FIXATOR

With the single-bar frame, place the pins at right angles to the subcutaneous surface of the tibia, through the center of the bone. At the junction of the middle and distal thirds, avoid injury to the anterior tibial neurovascular bundle. If two half-pin frames will be used, place the first frame about 1 cm posterior to the anterior ridge of the tibia and close to the sagittal plane. Place the second frame 1 cm anterior to the posterior border of the tibia in the lateral plane. The angle between
Place the first pin just distal to the tibial tubercle using appropriate technique with predrilling as described in Chapter 11. (For purposes of this discussion, assume the fracture is mid diaphyseal.) Insert the distalmost pin about 5 cm proximal to the ankle joint, in alignment with the proximal pin. Assemble four universal pin holders on the appropriate-length AO carbon fiber bar and secure the outermost holders to the two pins in place (Fig. 24.17).

Figure 24.17. Application of anteromedial half-pin single-plane AO external fixator. All four universal clamps are on the fixator bar. Place the most proximal and distal Schanz screws first. Align the fractures.

Anatomically reduce the fracture. Secure the bar to the pins with the bar about 2.5 cm from the skin, unless greater distance is needed for wound care. While maintaining reduction, insert a second pin into the proximal fragment and the last pin into the distal fragment. Insert the pins through the universal pin holders, which act as guides, using the drill sleeve assembly. Place the pins about 2.5 cm from the fracture site, assuming there are no bone or skin problems to contraindicate this location.

If the reduction is imperfect, loosen all universal clamps slightly and achieve a reduction as close to anatomic as possible. Tighten the pin clamps. If the fracture configuration allows, place it in compression, using hand pressure or the compression device (Fig. 24.18). Once the first half-pin frame is in place, application of a second frame is far simpler, because the fracture is already reduced. Follow the same technique. When two frames are used, use bars that are long enough to attach cross-connecting bars at each end.

Figure 24.18. Final configuration of single-plane AO external fixator. Place the two additional Schanz screws using the universal pin clamps as guides. Achieve compression across the fracture if possible.

HOFFMANN II

The Hoffmann II (Howmedica, Rutherford, NJ) is a versatile external fixation system that represents the evolution of external fixation frames from the original design to a more sophisticated system. It allows use of single pins or clustered pins in almost any arrangement. Although it is always a good idea to have the limb roughly aligned as the initial fixator is applied, the frame allows reduction of the fracture after application of the fixation pins. Fracture manipulation tools are provided that apply to the frame (Fig. 24.19).

One-step Apex (Howmedica, Rutherford, NJ) pins are 4 or 5 mm, self-drilling, self-tapping pins, and 6 mm blunt pins that require predrilling. A pin-to-rod coupling provides connection to the frame for a single pin with allowances for full three-dimensional rotation, and it accommodates 4 and 5 mm Apex pins. The spring-loaded mechanism allows snap-fit fixation and attaches to 8 mm rods. The pin coupling is locked through an easily accessible four-sided bolt mounted on its end. The pin clamp shown holds multiple pins, as in the original Hoffmann system.

HINTS AND TRICKS

- Open the rod-to-rod and pin-to-rod couplings until the mechanical stop is reached, to guarantee proper snap fit of the component. 
- Face all 7 mm square-head screws upward or to the outside of the fixator to facilitate adjustment. 
- Do not bend connecting rods. 
- Always use Apex pins with this device. 
- Carefully think through the frame configuration to be used before applying it. Take into consideration the size of the patient, bone quality, fracture configuration, and need for soft-tissue reconstructive procedures.

UNILATERAL FRAME FOR FIXATION OF TIBIAL SHAFT FRACTURES

The components required are two 8 mm connecting rods, two pin-clamp assemblies without posts, four 30° posts, four 8 mm rod-to-rod couplings, and four 5 mm one-step Apex pins (Fig. 24.19B).

- Obtain and maintain approximate alignment of the fracture. 
- Insert the most proximal and most distal 5 mm pins through a small stab wound on the anterior surface of the tibia, as close as possible to the AP plane. Avoid
the thick anterior ridge of the tibia.

- Insert the pins with the hand-powered drill brace and appropriate-sized chuck. Use firm pressure; avoid excessive insertion speed to avoid overheating the pin and bone.
- Apply a pin clamp assembly to the proximal pin. Use it as a guide to insert the second pin as close as practical to the fracture site through the outside pin site.
- Repeat this procedure on the distal fragment.
- Insert 30° angled posts in an inverted V position (they can be assembled before you apply them to the pins).
- Connect the two pin-clamp assemblies together using four rod-to-rod couplings and 8 mm connecting rods of appropriate lengths and material.
- Hint: Keep rod-to-rod couplings on the inside of the frame and connecting rods as short as possible to increase stability of the frame.
- If the fracture is not anatomically reduced or not in the desired position, the rod-to-rod couplings can now be loosened and final position obtained either by direct manipulation of the fracture or with the use of the reduction wrench.

**SEMICIRCULAR FRAME FOR PROXIMAL TIBIAL SHAFT FRACTURES**

The semicircular frame (Fig. 24.19C) is applicable to fractures of the proximal shaft at the metaphyseal–diaphyseal junction, where an array of pins parallel to the tibial plateau and at different angles is desired to improve the strength of proximal fixation.

The components required are one curved aluminum semicircular rod; two 8 mm connecting rods; three 8/4, 5 mm pin-to-rod couplings; four 8/8 mm rod-to-rod couplings; one pin clamp assembly with no post; two 30° angled posts; and five 5 mm one-step Apex pins.

- Using the semicircular rod as a guide, insert three pins into the proximal tibia in a unilateral bicortical fashion.
- Connect the single pins to the semicircular rod using the pin-to-rod couplings.
- Place a classical parallel pin assembly with two 30° angled posts in an inverted V position as illustrated in Figure 24.19C and as described for the previous unilateral frame.
- Reduce the fracture and connect the pin-clamp assembly to the semicircular aluminum rod using four rod-to-rod couplings and manipulating the fracture either directly or with the assistance of the reduction wrench.

**Independent Pin Placement Frame for Distal/Tibial Shaft Fractures**

The independent pin placement frame fixator is recommended for extraarticular fractures of the shaft at the metaphyseal–diaphyseal junction (Fig. 24.19D).

The components required are two 8 mm connecting rods, one pin-clamp assembly with no post, two 30° posts, two 8/8 rod-to-rod couplings, two 5 mm 8/4 pin-to-rod couplings, and four 5 mm pins.

- Achieve approximate reduction of the fracture.
- Place a classical parallel pin assembly in the proximal fragment as illustrated in Figure 24.19D and as described previously.
- Independently, insert a 5 mm Apex pin into the medial surface of the tibia in the transverse plane, proximal and parallel to the ankle joint. Place a similar pin in the AP plane.
- Connect the proximal pin clamp assembly to the distal pins using pin-to-rod couplings and rod-to-rod couplings; use connecting rods of appropriate length and material.
- Achieve final reduction of the fracture if necessary by loosening the couplings to the rods and retightening after reduction.

**Orthofix Dynamic Axial Fixation**

The Orthofix (Richardson, TX) Dynamic Axial Fixation (DAF) has been employed widely for limb lengthening as well as fracture fixation. It uses half-pins for cortical and cancellous bone, with tapered threads that are designed to offer more uniform fixation in both the near and far cortex. Pins are inserted in parallel arrays through clustered pin holders like those the Hoffmann II uses, and the body of the fixator has ball joints for reduction of the fracture and final alignment. It provides for distraction and compression and dynamization as well. The pins can be placed transversely for the management of fractures at either end of the shaft of the tibia with the potential configurations seen in Figure 24.20. The components and instrumentation are illustrated in Figure 24.21.

**Figure 24.20.** Configurations for Orthofix Dynamic Axial Fixator (DAF). See text for details. A: Proximal tibial fracture using the T-pin clamp proximally. B: Midshaft tibial fracture with standard DAF. C: Pylon fracture of the distal tibia and ankle joint with articulated pin holder using pins in the talus and calcaneus. D: Severely comminuted fracture of the tibial plateau with a fixator bridging the knee joint.

**Standard Longitudinal Fixator**

- Obtain approximate reduction of the fracture and lay a template or fixator along the subcutaneous border of the tibia to determine the approximate location of the incisions for the screws, which will be placed first. Orient the fixator into either the anterior or medial/lateral plane as desired.
At the location of the proximal screw, make a longitudinal incision sufficient to accept the screw guide. Cut down to the periosteum, and gently elevate it at the screw site with a small elevator.

Insert a trocar into the correct-length screw guide under fluoroscopic control, making sure that the guide is perpendicular to the longitudinal axis of the bone. Make a pilot hole with the trocar. Withdraw the trocar from the guide, maintaining pressure on the screw guide handle. Using a mallet, tap the screw guide lightly to engage the cortex with its teeth (Fig. 24.22A).

D: Application of the template to the first screw. E: Insertion of the remaining screws. F: Application of the DAF and reduction of the fracture. G: Compression of the fracture. (Courtesy of Linda Krugman, Orthofix, Richardson, TX.)

Drill the cortex using a 4.8 mm drill for cortical screws and a 3.2 mm drill for cannulated screws. Avoid overheating the drill bit. The drill stops can be used to avoid overpenetrating the soft tissues beyond the far cortex (Fig. 24.22B).

Remove the drill bit and drill guide while maintaining pressure on the screw guide handle. Insert the selected screw into the screw guide using the T-wrench. Under fluoroscopic control, insert the screw until at least two threads protrude beyond the second cortex. Since these screws areaperositioned by turning counterclockwise without loosening the screw (Fig. 24.22C).

Adjust the template body to the correct length and place drill sleeves into the second hole to be used in the proximal template clamp and into two holes in the distal. Place the screws as widely separated as the clamps will allow. In good-quality bone where the fixator will be reasonably close to the limb, two screws are usually sufficient. A third screw can be added when bone quality is poor or the fixator body is to be mounted at a significant distance from the limb. Note that to permit final adjustment at the fracture site, the body of the fixator must not be either fully compressed or fully extended. Although the ball joints of the fixator allow for final adjustment of position, and the body allows for additional compression or distraction, it is important to reduce the fracture as close to anatomic as possible while applying the fixator. Adjustments will be easier if the body is kept parallel to the long axis of the diaphysis (Fig. 24.22D).

Next, insert the most distal screw and then the two inner screws using the technique just described.

Remove the template and attach the Orthofix DAF. Be certain that the body-locking screw is on the outside. Have the dot and arrow on the cam mechanism and the screws on the clamps facing upward to facilitate adjusting and locking the fixator. Position the fixator at least 1 cm from the skin and tighten the clamp screws using the Allen wrench (Fig. 24.22F).

Achieve final reduction using the manipulation forces, and then lock the clamps and body-locking screw. Final locking of the clamps employs the torque wrench that should be tuned until the first click (Fig. 24.22G).

Compression and distraction can be achieved by using the compressor distractor unit (Fig. 24.22G).

**POSTOPERATIVE CARE**

Several different pin-care regimens work well. As long as the pins remain tight in bone, and skin necrosis does not occur, infection rarely becomes a problem. When swelling decreases, skin tension will sometimes develop on one side of a pin. Incise the skin on the tension side (where the skin is gathered against the pin) to relieve pressure. Dress the pins with sterile dressings. Light pressure on the skin limits skin motion and decreases the infection rate.

After 7–10 days, let patients shower but not bathe. Ask them to wash the frame and skin around the pin sites daily with mild soap, using a soft toothbrush on the skin around the pin sites and a soft surgical brush on the frame. All exudate must be removed from the skin. After showering, they should dry the frame and skin with a freshlaundered towel and then place x-inch dressings on the pin sites with clips to minimize skin motion on the pins (Chapter 13). Advise patients to wear pants to protect the frame and skin.

If good contact of the major bone fragments has been achieved, the patient can begin partial weight bearing with crutches. Start with the weight of the leg. Once some fracture stability is achieved, usually between 6 and 12 weeks, allow the patient to progress to full weight bearing if the fracture and type of fixator permit. If weight bearing is not possible, the frame and pins remain tight and no displacement of the fracture occurs. Give your patients a wrench and ask them to check all fittings on a daily basis.

Stable, closed, or low-grade open fractures in good contact, as well as those that have been bone-grafted, can be expected to unite in the external fixator. As fracture stability increases, after the frame design or use adjustments allowed by the frame design to reduce its stiffness to allow more weight bearing through the bone. In double half-pin fixators, the most medial frame can often be removed in 6–12 weeks. The same is true for delta frames, which can be reduced to the single anterior frame. Initially, a second bar can be mounted on the single-bar frame to increase its rigidity; the second bar is removed later. Further flexibility can be achieved by moving the bar farther away from the skin.

After the first 8–12 weeks, loosen the fixator and check the fracture for stability at 4- to 6-week intervals. When clinical stability is present, remove the fixator and place the patient in a short-leg fracture brace. If you question the adequacy of stability, leave the pins in place and the frame off for 1 week to be certain the fracture does not change position. Reapply the frame if it does.

Some surgeons prefer to remove external fixators early. Patient preference and pin problems can also precipitate early removal. If the fracture is unstable at the time of removal, shortening and deformity are common. Good immobilization in an appropriate cast or brace is important. In some cases, conversion to internal fixation may be desirable, but be advised that the infection rate is higher when internal fixation is preceded by external fixation.

The safest method to use is nonreamed intramedullary nails and closed technique. In these cases, remove the fixator, immobilize the fracture with a cast until the pin tracks are clean and dry, and then proceed with internal fixation. Do not use intramedullary nailing if the external fixator pins have been infected. Some surgeons advocate using external fixators only until soft-tissue problems in open fractures are resolved with early conversion to an intramedullary nail (Table 24.7).

**PITFALLS AND COMPLICATIONS**

The most common and troublesome complication is pin-track drainage or infection. If a pin persistently drains, or is painful, most likely it is infected and loose. Loosen the clamp holding the pin and gently wiggle the pin back and forth. Usually it is loose in the near cortex. A radiograph may show a radiolucent zone around the pin.

Loose pins must be removed. Place a pin in a new site at least 15 mm away from the loose pin. If you cannot do so, try to get along with fewer pins, or remove the frame. If the pin is tight, then soft-tissue care with debridement, drainage, and local antibiotics or antiseptics is appropriate. Oral antibiotics are occasionally useful as well.

**INTRAMEDULLARY NAILING**

**POSITIONING OF THE NAIL**

Regardless of the type of nail to be inserted, the positions used are similar. I prefer to use a fracture table with skeletal traction through the calcaneus. This setup (Fig. 24.23) offers the best opportunity to reduce the fracture before inserting the nail. More important, it allows the reduction to be maintained during the procedure. It also facilitates fluoroscopic visualization of the extremity.
SETUP FOR INTRAMEDULLARY NAILING OF THE TIBIA ON A CHICK-LANGREN FRACTURE TABLE

- On a Chick-Langren fracture table (Kirshner Medical, Greenwood, SC), place the uninjured lower extremity with the hip and knee flexed to 90° and abducted to give access for the C-arm.
- Position the injured extremity over a well-padded thigh support placed on the distal thigh. Avoid the popliteal fossa to avoid neurovascular injury.
- Secure the foot in a well-padded foot holder, if distal cross locking is not to be done. Alternatively, place it into a tibial pin traction device attached to a quarter-inch threaded Steinmann pin. The pin is placed transversely under sterile conditions through the calcaneus to permit adequate access to the distal tibia for cross locking.
- Bring the C-arm into place (Fig. 24.23). It must be able to rotate unhindered from the AP to the lateral position, and you must be able to visualize the full length of the tibia.
- Prepare and drape the tibia so that full access is available from the knee joint to the ankle joint with the sheets draping down from the leg to cover the lower head of the C-arm. When the C-arm is brought into the lateral position, the head should remain beneath the drapes, preserving the sterile field. Sterility drape the uppermost head of the C-arm.

NAILING ON A REGULAR OPERATING TABLE

If a regular operating table (preferably with a radiolucent top) is used, three alternatives are available for positioning and maintaining reduction. Using any of these positions, either open or closed nailing can be carried out with all of the intramedullary nails with which I am familiar. If closed nailing is to be carried out, I highly recommend the use of a fracture table.

- You may place an arthroscopic leg holder about the thigh and position it to support the lower extremity, with the knee flexed to 90° and the foot supported on the operating table (Fig. 24.23).
- Alternatively, abduct the thigh, flexing the knee to 90°, allowing the foot and tibia to hang vertically off the side of the operating table. If you use this method, pump the table up so that the foot is just below your waist.
- The third alternative is to prepare and drape the extremity and then place a large sterile bolster under the thigh. Insert one transverse Schanz pin into the proximal tibia and a second one into the distal tibia or calcaneus. Attach to these an AO distractor and use it to apply traction to align the fracture.

LOTTE'S NAILING

The Lottes nail is little used today, but because it is simple and inexpensive it is still popular in underdeveloped areas (10). Lottes nails can be inserted by open or closed technique, unless the fracture is open, always try to use closed technique.

- Position the patient and drape the limb in the usual manner for lower extremity surgery. A tourniquet can be used.
- Make a 5 cm longitudinal incision, beginning at the level of the tibial tubercle, one fingerbreadth medial to the tubercle, and extend it proximally to the joint line. Split the patellar tendon or go to its medial side. Directly beneath this incision, expose the cortex of the tibia. Perforate the cortex with either a Küntscher awl or a half-inch drill point just proximal to the tibial tubercle. Avoid encroaching on the tibial tubercle or the articular surface. Lottes advocates a large drill point, but I have found it easier to use Küntscher awls. The disadvantage of the awl is that in a young patient with dense cancellous bone, sometimes the hole cannot be placed deep enough to actually enter the medullary canal, and a drill or a reamer may be necessary.
- Direct the entry hole straight down the medullary canal. The most common mistake is to perforate posteriorly. Press the handle of the awl or drill against the knee to achieve alignment with the medullary canal (Fig. 24.24). In the medial-lateral plane, follow the line of the anterior crest of the tibia.

- Next, select the appropriate-size Lottes nail. Although it is possible to determine the size preoperatively by measuring radiographs, it is unnecessary to do so unless the patient is unusually small or large. Determine nail length by laying the nail on the leg. Place the proximal end of the nail against the entry site. The distal end should be within 2.5 cm of the ankle joint, depending on the level of fracture being treated. Of the two diameters available, 5/16 inch (8 mm) and 3/8 inch (9.5 mm), select the appropriate diameter based on appraisal of the radiographs.
- Flex the knee to 90° or greater. With an assistant supporting the leg, drive the rod into the proximal fragment, taking care to maintain proper alignment.
- Avoid perforating the posterior cortex. The nail must move easily with each blow of the mallet. Impending impaction of the nail in the proximal fragment is characterized by an increase in the pitch of the sound of the mallet and by lack of forward movement of the nail. In the event of impaction, extract the nail and use a smaller nail.
- Drive the nail until it is at the fracture site. Ensure that the fracture is well reduced, and drive the nail into the distal fragment (Fig. 24.25). Drive the nail until the proximal end is level with bone. Because of the subcutaneous location of the entry site, too long a nail will result in a painful bursa. If a nail is found to be too short, extend it by adding the appropriate-size extension (5/16 inch (13 mm), 3/8 inch (19 mm), or 1 inch (25 mm)).

Figure 24.23. Setup for intramedullary nailing of the tibia. A: Chick-Langren fracture table set up for tibial nailing. The foot is in a foot holder. The thigh bolster is above the popliteal fossa. B: Setup on a regular radiolucent operating table using an arthroscopic leg holder.

Figure 24.24. Entry site for intramedullary nailing of the tibia.
The tibia on the fracture table is shown in difficult to pass the guide pin, and radiologic control is poorer. Refer back to the discussion on positioning the patient; the position for reamed intramedullary nailing of reamed nailing is easier and more trouble free when done on a fracture table. It is possible to perform reamed nailing on a regular operating table, but it is more unreamed nail.

As the general principles for insertion of most nails are similar, only the technique for the Alta system will be described. The nail can be inserted as a reamed or an

REAMED TECHNIQUE

proximal fractures and undisplaced fractures of the tibial plateaus where proximal fixation is desired.

Some nail designs such as the Alta (Howmedica, Rutherford, NJ) offer add-on tabs or extensions at the proximal end of the nail. These extensions provide the opportunity to vary the length of the nail. They also allow for the addition of extra cross-locking screws in a very proximal location, which may be useful for high longitudinal curvature, and configuration of the cross-locking screws; but the general principles in their insertion and application are very similar. Cross locking is offered with round holes, which provide rigid locking, and oval holes with the capability for spontaneous compression at the fracture site while maintaining rotational control.

Nearly every manufacturer of bone fixation equipment in the world today has a locking nail for the tibia. Nails vary in the curvature, cross-sectional shape, cannulation, longitudinal curvature, and configuration of the cross-locking screws; but the general principles in their insertion and application are very similar. Cross locking is offered with round holes, which provide rigid locking, and oval holes with the capability for spontaneous compression at the fracture site while maintaining rotational control.

Some nail designs such as the Alta (Howmedica, Rutherford, NJ) offer add-on tabs or extensions at the proximal end of the nail. These extensions provide the opportunity to vary the length of the nail. They also allow for the addition of extra cross-locking screws in a very proximal location, which may be useful for high proximal fractures and undisplaced fractures of the tibial plateaus where proximal fixation is desired.

REAMED AND NONREAMED LOCKED INTRAMEDULLARY NAILING

As nails with locking capabilities can be used without locking, nonlocking nails are now obsolete. Except for the cross-locking procedure, the techniques for all nails are nearly identical.

Postoperative Care

At the time of discharge from the hospital, or at 1 week postoperatively, remove the splints and apply either a long-leg cast, Sarmiento cast, or functional brace, depending on the stability of the fracture. If axial stability is present, allow weight bearing; otherwise, delay weight bearing until 6 weeks. In most cases, by 6 weeks there is enough stability that immobilization is no longer necessary and the patient can continue with crutches and weight bearing as tolerated. Continued instability at 6 weeks may necessitate further immobilization and delayed weight bearing. Begin joint and muscle rehabilitation as soon as possible.

ENDER NAILS

The preoperative and intraoperative preparation for Ender nails is identical to that for Lottes nailing. The Ender tibial nail is 4.0 mm in diameter. At least two nails are necessary for adequate stability; if the canal will accept more, they can be placed.

■ Insert the Ender nails through 2.5 cm stab wounds located about 2 cm medial and lateral to the patellar tendon on the proximal tibial flare, about 2 cm below the joint line.

■ Perforate the cortex with a Kuntscher awl or a drill point. Insert the medial or lateral nail first, depending on the configuration of the fracture. If the fracture tends to angulate into varus, place the lateral nail first. In difficult fractures, it is sometimes helpful to drive both nails simultaneously, alternating the driving from one side to the other.

■ The nail can be used to reduce the fracture. More or less curve can be bent into the tip to facilitate the reduction. Use the bend of the nail to fish the tip into the mouth of the distal fragment by twisting the nail, and then use the nail to reduce the fracture.

■ Then drive the nails to the subchondral bone of the tibia distally, spreading the tips.

■ Leave the flat of the proximal end of the nail lying against the cortex above the entry hole (Fig. 24.27).

Insert both Ender and Lottes nails with closed technique. If necessary, the fracture can be opened, but opening is discouraged as it increases the risk of infection and the rate of delayed union. In comminuted fractures, avoid the temptation to place cerclage wires for butterfly fragments, which would further devascularize the fragments and is nearly always unnecessary.

Postoperative care is identical to that described for Lottes nails.

REAMED AND NONREAMED LOCKED INTRAMEDULLARY NAILING

As nails with locking capabilities can be used without locking, nonlocking nails are now obsolete. Except for the cross-locking procedure, the techniques for all nails are nearly identical.

Nearly every manufacturer of bone fixation equipment in the world today has a locking nail for the tibia. Nails vary in the curvature, cross-sectional shape, cannulation, longitudinal curvature, and configuration of the cross-locking screws; but the general principles in their insertion and application are very similar. Cross locking is offered with round holes, which provide rigid locking, and oval holes with the capability for spontaneous compression at the fracture site while maintaining rotational control.

Some nail designs such as the Alta (Howmedica, Rutherford, NJ) offer add-on tabs or extensions at the proximal end of the nail. These extensions provide the opportunity to vary the length of the nail. They also allow for the addition of extra cross-locking screws in a very proximal location, which may be useful for high proximal fractures and undisplaced fractures of the tibial plateaus where proximal fixation is desired.

REAMED TECHNIQUE

As the general principles for insertion of most nails are similar, only the technique for the Alta system will be described. The nail can be inserted as a reamed or an unreamed nail.

Reamed nailing is easier and more trouble free when done on a fracture table. It is possible to perform reamed nailing on a regular operating table, but it is more difficult to pass the guide pin, and radiologic control is poorer. Refer back to the discussion on positioning the patient; the position for reamed intramedullary nailing of the tibia on the fracture table is shown in Figure 24.23A.

Figure 24.25. AP (A) and lateral (B) radiographs of a Lottes nail fixing an open Gustilo grade II fracture of the tibia. Circlage wires were used to secure a butterfly fragment. This further devascularizes the fracture and is best avoided if the fragment is in reasonable apposition.

Next, complete impaction of the fracture and examine for stability. If the fracture is unstable, additional stability can be obtained by plating a fracture of the fibula (Fig. 24.26) (B). Some surgeons feel that plating promotes delayed union of the tibia, but my experience with this combination in open fractures has been reasonably good, with results comparable to those with external fixation.

Figure 24.26. AP and lateral radiographs of a Lottes nail fixing an unstable fracture of the tibia. The fibula has been plated to gain additional stability. Plating of the fibula may lead to delayed union of the tibia. Consider early bone graft of the tibia if callus formation is delayed.

After wound closure, place the extremity in long-leg, well-padded splints to maintain the knee in 15° of flexion and the ankle at a right angle. See Figure 24.25 and Figure 24.26 for sample cases.

Postoperative Care

At the time of discharge from the hospital, or at 1 week postoperatively, remove the splints and apply either a long-leg cast, Sarmiento cast, or functional brace, depending on the stability of the fracture. If axial stability is present, allow weight bearing; otherwise, delay weight bearing until 6 weeks. In most cases, by 6 weeks there is enough stability that immobilization is no longer necessary and the patient can continue with crutches and weight bearing as tolerated. Continued instability at 6 weeks may necessitate further immobilization and delayed weight bearing. Begin joint and muscle rehabilitation as soon as possible.

Figure 24.27. AP (A) and lateral (B) radiographs of a fracture of the tibia and fibula stabilized with Ender pins. Notice the mild posterior angulation on the lateral view. This is a common problem with Ender nails. (From Chapman MW. Fractures of the Tibial and Fibular Shafts. In: Evarts CM, ed. Surgery of the Musculoskeletal System. New York: Churchill-Livingston, 1983, with permission.)

Insert both Ender and Lottes nails with closed technique. If necessary, the fracture can be opened, but opening is discouraged as it increases the risk of infection and the rate of delayed union. In comminuted fractures, avoid the temptation to place cerclage wires for butterfly fragments, which would further devascularize the fragments and is nearly always unnecessary.

Postoperative care is identical to that described for Lottes nails.

REAMED AND NONREAMED LOCKED INTRAMEDULLARY NAILING

As nails with locking capabilities can be used without locking, nonlocking nails are now obsolete. Except for the cross-locking procedure, the techniques for all nails are nearly identical.

Nearly every manufacturer of bone fixation equipment in the world today has a locking nail for the tibia. Nails vary in the curvature, cross-sectional shape, cannulation, longitudinal curvature, and configuration of the cross-locking screws; but the general principles in their insertion and application are very similar. Cross locking is offered with round holes, which provide rigid locking, and oval holes with the capability for spontaneous compression at the fracture site while maintaining rotational control.

Some nail designs such as the Alta (Howmedica, Rutherford, NJ) offer add-on tabs or extensions at the proximal end of the nail. These extensions provide the opportunity to vary the length of the nail. They also allow for the addition of extra cross-locking screws in a very proximal location, which may be useful for high proximal fractures and undisplaced fractures of the tibial plateaus where proximal fixation is desired.

REAMED TECHNIQUE

As the general principles for insertion of most nails are similar, only the technique for the Alta system will be described. The nail can be inserted as a reamed or an unreamed nail.

Reamed nailing is easier and more trouble free when done on a fracture table. It is possible to perform reamed nailing on a regular operating table, but it is more difficult to pass the guide pin, and radiologic control is poorer. Refer back to the discussion on positioning the patient; the position for reamed intramedullary nailing of the tibia on the fracture table is shown in Figure 24.23A.
Two entry sites are possible: through the patellar tendon or medial to the tendon. I much prefer to go through the tendon, as I have seen no significant morbidity from splitting the tendon, and positioning the nail is greatly simplified (Fig. 24.28).

Figure 24.28. Surgical approach and entry hole for intramedullary nailing of the tibia. See the text for a full description.

- If you choose to go through the tendon, make a longitudinal skin incision from 1 cm proximal to the distal pole of the patella, to 1 cm proximal to the tibial tubercle. Reflect the infrapatellar fat pad in a proximal direction. Perforate the cortex with a Küntscher awl just above the tibial tubercle. Maintain good alignment with the intramedullary canal of the tibia, taking care not to angulate posteriorly or laterally. Avoid impingement on the articular cartilage of the tibial plateau.
- Penetrate the cancellous bone of the metaphysis into the medullary canal. Insert the reaming ball-tipped guide pin into the proximal fragment, reduce the fracture by manual manipulation, and pass it into the distal fragment. Manipulation of the fracture is greatly assisted by placing a manipulator into the proximal fragment; this technique usually eliminates the need for an assistant. With appropriate-size reamers, ream the medullary canal throughout its isthmus to the size appropriate for the nail to be used. Usually 1.0 mm of overreaming is necessary.
- Determine nail length by comparative measurement of two identical guide pins, or measure directly by laying a nail on the tibia.
- Use a plastic tube to exchange the reaming guide pin for a driving guide pin.
- Select a nail of the appropriate length and diameter, and drive it into position, taking care to maintain good fracture alignment. In most cases, select the nail that will reach to within 1 cm of the ankle joint and will sit slightly below the level of the cortex at the entry point. This technique, using Alta instrumentation, is shown in Figure 24.29.

Figure 24.29. Reamed intramedullary nailing using the Alta system. A,B: Driving the Alta tibial nail using the anvil as a crossbar to control rotation. C: Proximal cross locking with a jig. Insert drill sleeves down to bone (usually medially). Tap an appropriate-size drill point into the bone with a mallet to anchor its point and then drill through the nail and opposite cortex. Measure for screw length with a depth gauge off the outer drill sleeve. Then insert a transverse cross-locking screw through the sleeve. D: In the Alta system a tab (shown here) or cylindrical extender can be attached to the top of the rod. These provide holes for cross locking with up to two additional screws under direct vision. They are angled at 45° to the sagittal plane. Here the tab is secured to the nail with a screw. E: Transverse cross-locking screw being inserted into the tibia through one of the holes in a tab. F: Distal cross locking of a tibial nail is most easily accomplished from medial to lateral. Freehand technique is commonly used. (Courtesy of Howmedica, Rutherford, NJ.)

- If indicated, perform distal and proximal cross locking with the special guides provided, or by using freehand technique. The Alta nail is supplied in diameters from 6 to 14 mm. The 6 and 7 mm nails are solid and cannot be locked. The 8 and 9 mm nails are solid but have holes for cross locking with 3.7 mm transverse cross-locking screws. The 10 to 14 mm nails are cannulated for a guide pin and take 5 mm locking screws. (Figs. 24.30, Figs. 24.31, Figs. 24.32 and Figs. 24.33 demonstrate sample cases.)

Figure 24.30. Alta locked intramedullary nailing using closed technique. A: Lateral radiograph of a transverse displaced tibial shaft fracture. B: Postoperative AP radiograph showing anatomic reduction and static locking with a reamed nail. Since there was 100% cortical contact in compression, the patient was permitted to bear weight as tolerated. C: Lateral view.

Figure 24.31. Proximal shaft fracture of the tibia fixed with an Alta nail using the tab. A: AP radiograph showing a fracture in the proximal third. This fracture requires at least two screws in the proximal fragment to achieve adequate stability. Since this earlier design of the nail had only one proximal cross-locking hole, the tab and screw were added. B: Lateral radiograph.
Figure 24.32. Comminuted segmental fracture of the tibia treated with a locked Alta intramedullary nail and supplemental plate proximally. A: AP and lateral radiographs of a multisegmental fracture. B: Postoperative AP radiograph. On this film it can be seen that there were four separate fracture sites resulting in five major fragments. The proximal fracture was opened medially and stabilized with a 3.7 mm reconstruction plate, and the remainder of the fractures were stabilized by closed intramedullary nailing with static cross locking.

Figure 24.33. Distal-third fracture of the tibia treated with a statically locked AO nail. A: AP radiograph showing the fracture. This could have been treated in a Sarmiento cast or cast-brace as well. B: AP radiograph taken postoperatively. C: Lateral radiograph.

UNREAMED TECHNIQUE

A nail of any size can be driven unreamed as long as it will fit into the medullary canal and can be driven with reasonable ease.

- Position the patient, reduce the fracture, prepare and drape the leg, and perform the surgical exposure and create the entry site for the nail as described for reamed nailing.
- Use sounds or a tibial nail to determine the diameter of the canal.
- Select a nail equal to, or 1 mm in diameter smaller than, the largest sound that will pass easily through the isthmus of the canal.
- Insert the nail while pressing the driver toward the knee to ensure proper alignment of the nail; direct the nail down the canal until it is at the distal end of the proximal fragment.
- Using the nail and driver as a lever, and with an assistant directly manipulating the fracture, drive the nail across the fracture into the distal fragment. Drive the nail to approximately 15–20 mm proximal to the ankle joint.
- The remainder of the procedure, such as cross locking, is identical to that for reamed nails.
- When locking, I usually cross-lock distally first, then adjust the position of the fracture by back-slapping on the driver to be certain that the bone fragments are in good contact. Then I lock proximally.

Postoperative Care

Apply a well-padded long-leg dressing with splints. Have patients wiggle their toes and begin isometric exercises in the splint. Three to 7 days after surgery, remove the splint and begin full rehabilitation.

Avoid a tight heel cord and equinus contracture with a rigorous physical therapy program. Use of a cast-brace that prevents equinus or a removable posterior night splint may be necessary in the first few weeks after surgery.

With stable fracture patterns and dynamic cross locking, allow the patient to progress to full weight bearing, with or without a brace, as tolerated. With static cross locking in stable patterns, I like to impact the fracture intraoperatively with the driver. In these cases, full weight bearing is usually possible immediately. In unstable fracture patterns, delay full weight bearing until callus can be seen bridging the fracture on radiographs.

Take caution with smaller nails that use transverse cross-locking screws 4 mm or less in diameter. Incidence of screw fracture with weight bearing on unstable fractures is as much as 30%. Removal of cross screws to dynamize the nail is usually necessary only in delayed unions with short oblique fractures.

SCREW FIXATION

The indications for open reduction with only lag screw fixation are limited. The most common indication is a spiral or oblique fracture in the distal third of the tibia with an intact fibula, where unacceptable varus angulation of the distal fragment is present. These types of fractures are very difficult to control by closed means and respond well to interfragmentary screw fixation.

Many surgeons attempt to place lag screws percutaneously using cannulated screws. Intramedullary locking nails can often be used as well. The length of the fracture must be at least 3 times the diameter of the tibia at the level of the fracture. Approach the tibia through an anterior longitudinal incision, 1 cm lateral to the anterior crest of the tibia. Expose only the edges of the fracture fragments by subperiosteal dissection. Perform lag screw fixation with three or more screws.

A comparable fracture presenting a similar problem can be seen in the proximal third of the tibia, with or without an intact fibula, which may have persistent gapping and unacceptable angulation. Treat it in a similar manner. Interfragmentary screw fixation alone rarely provides sufficient stability; external protection is always necessary. In both of these fractures, a functional non-weight-bearing brace is recommended. Because these fractures are through cancellous bone, bone grafting is usually unnecessary.

Interfragmentary screw fixation alone for diaphyseal fractures is rarely, if ever, indicated. These fractures are better treated with a locked intramedullary nail. An occasional type I or low-grade type II open fracture with exposed fracture fragments will benefit from screw fixation. The fracture must be oblique or spiral and must be three times in length the width of the tibia at the site of the fracture (Fig. 24.34). In this circumstance, interfragmentary screw fixation combined with a single-bar external fixator might be indicated. Precise technique is critical. Details for this technique are discussed in Chapter 11.
Coverage of the middle and distal thirds of the tibia by local tissue is more difficult. In the middle third, the soleus will suffice. In the distal third, the flexor digitorum
split-thickness skin-grafts to the muscle pedicle as necessary. With full-thickness tissue is often necessary. Done directly on the periosteum. Although direct split-thickness grafting provides early coverage, it often does not provide durable long-term coverage, and replacement major neurovascular structures can be handled either by primary closure or by split-thickness skin grafting. If periosteum is present, split-thickness skin grafting can be
Delay reconstructive surgery to gain coverage until you are certain that further necrosis will not occur and infection is not present. Skin defects without exposed bone or
Progressive necrosis can lead to loss of both skin and underlying soft tissue, particularly if compartment syndrome intervenes. Early full-thickness soft-tissue coverage
Loss of skin and soft tissues is a common problem in open fractures of the tibia. The skin and soft-tissue injury in closed fractures can be substantial as well.
Figure 24.34. A: Interfragmentary lag-screw fixation. The fracture is at least three times as long as the diameter of the bone. Insert three 4.5 mm cortical screws to lag the fracture together using a gliding hole in the near cortex. B: Keep the screws at right angles to the fracture. Accurate placement is guaranteed by using gliding-hole-first and threaded-hole-first techniques (see Chapter 11).

PLATE FIXATION
The indications for plate fixation are intraarticular fractures, metaphyseal fractures requiring a buttress or neutralization plate to support interfragmentary screw fixation, and an occasional diaphyseal fracture for which intramedullary nailing or external fixation is not feasible (12). Because of the risk of infection, soft-tissue complications, and delayed union, plate fixation of fractures of the diaphysis of the tibia is the treatment of last choice. Broad or narrow 4.5 mm plates can be used, but the narrow plates are preferable (Fig. 24.35). Semitubular plates are too weak. Specialized L and T plates and spoon plates are available for the metaphyseal/epiphyseal regions.

Figure 24.35. Plate fixation of the tibia. A comminuted intra-articular fracture of the tibia and fibula seen on an AP radiograph showing plate and screw fixation.

Technically, it is easiest to place plates on the anteromedial subcutaneous border of the tibia. This is the location of highest risk, as skin problems or infection may result in exposure of the plate. It is much safer but technically more difficult to place plates on the lateral surface of the tibia. Plates may also be placed posteriorly on the tibia, but this approach is reserved for severely injured extremities, where the anterior soft tissues are unsuitable for surgery. The techniques are the same as those described in Chapter 11. I routinely bone-graft all diaphyseal fractures of the tibia subjected to plate fixation to accelerate and ensure union. With excessive swelling, do not close the deep fascia; in some cases, fasciotomy may be indicated. Skin closure must be without tension and atraumatic.

POSTOPERATIVE CARE
Postoperatively, place the limb in a short- or long-leg Robert Jones dressing with splints. Elevate it on two pillows with the knee flexed to help control edema. As rigid internal fixation is usually achieved with plate and screw fixation, immediate touch-down weight bearing, mobilization, and rehabilitation of joints and muscles is possible. Weight bearing must be delayed until fracture union occurs.

In rigidly internally fixed fractures of the tibia, union may be difficult to judge, as minimal or no callus may form. Fractures of the diaphysis in adults rarely heal well enough to sustain weight bearing before 16 weeks. At 16 weeks or later, take AP, lateral, and two oblique radiographs to establish the presence of union. If union is judged to be present, begin careful, progressive weight bearing with crutches, and monitor frequently, to ensure that displacement does not occur.

PITFALLS AND COMPLICATIONS
Fractures of the tibia present more problems and complications than in any other long bone of the body and are discussed in detail in multiple chapters. The most common acute complications directly related to the injury are infection (Chapter 132 and Chapter 135), loss of skin and soft tissues (Chapter 8 and Chapter 35), neurovascular injury, compartment syndrome (Chapter 13), and amputation (Chapter 120). Also discussed elsewhere are late complications such as delayed union, nonunion, and malunion (Chapter 31), and sympathetic dystrophy (Chapter 7).

INFECTION
To eliminate infection with minimal morbidity, it must be recognized early, and irrigation and debridement must be done as expeditiously as possible. It is far better to explore a few too many suspicious-looking wounds than to miss an acute infection. Stability of the fracture is critical, and in most cases best achieved with external fixation. If plate and screw fixation is stable, leave it in place; it can be removed after union occurs.

Remove all acutely infected intramedullary nails, and in the tibia convert to external fixation. In mild infection with sensitive organisms, it is worthwhile in some cases to debride the tibia with reaming and to replace the nail with a larger one. In general, however, this method works best in the femur and does not have a high success rate in the tibia. It has been suggested that cannulated intramedullary nails may harbor organisms in their interiors, but a study by Singer and Seligson (122) showed that this is not true. Antibiotic-impregnated beads are useful.

LOSS OF SKIN AND SOFT TISSUES
Loss of skin and soft tissues is a common problem in open fractures of the tibia. The skin and soft-tissue injury in closed fractures can be substantial as well. Progressive necrosis can lead to loss of both skin and underlying soft tissue, particularly if compartment syndrome intervenes. Early full-thickness soft-tissue coverage is important to reduce the incidence of infection and delayed union. At the time of original debridement of an open fracture, do not close the traumatic wound.

Delay reconstructive surgery to gain coverage until you are certain that further necrosis will not occur and infection is not present. Skin defects without exposed bone or major neurovascular structures can be handled either by primary closure or by split-thickness skin grafting. If periosteum is present, split-thickness skin grafting can be done directly on the periosteum. Although direct split-thickness grafting provides early coverage, it often does not provide durable long-term coverage, and replacement with full-thickness tissue is often necessary.

For skin and soft-tissue defects in the proximal third of the tibia, swing the medial head of the gastrocnemius muscle on its vascular pedicle for coverage. Apply split-thickness skin-grafts to the muscle pedicle as necessary.

Coverage of the middle and distal thirds of the tibia by local tissue is more difficult. In the middle third, the soleus will suffice. In the distal third, the flexor digitorum
NEUROVASCULAR INJURY

The nerve most often injured in tibial fractures is the common peroneal nerve. This nerve injury is most often the result of the original trauma and is usually a neuropaxia or axonotmesis due to stretch. It can be difficult to detect in the limb with severe muscle injury. Direct severe injury to muscle looks similar. Examine the limb carefully at the time of initial injury, recording any evidence of sensory loss or motor weakness. Frequent repeat examinations are important. A laceration directly over the main bundle of the nerve requires exploration; otherwise, treatment is limited to observation, prevention of an equinus contracture, and muscle rehabilitation.

Because three arteries supply the lower extremity distal to the knee, vascular repair of a single artery laceration is rarely necessary. The limb does fairly well with just a posterior tibial artery, and in most healthy limbs, with just an anterior tibial and peroneal artery. If only the anterior tibial or peroneal artery is functional, some late symptoms caused by lack of blood supply to the posterior compartment muscles may occur. For that reason, lacerations of the posterior tibial artery are often repaired, particularly if the fate of the other two arteries is unknown. Good arteriography is necessary to establish the patency of these arteries in severely injured legs.

COMPARTMENT SYNDROME

In the severely traumatized limb, intramedullary nailing may contribute to compartment syndrome (13). Perform careful monitoring in these cases. Diagnosis and treatment are described in Chapter 13.

FRACTURES OF THE SHAFT OF THE FIBULA

In the absence of dislocations of the proximal or distal tibiofibular joints, fractures of the fibula accompanying a tibial fracture require no special treatment other than that described for the tibia. Isolated shaft fractures are usually the result of direct violence. Although treatment can be symptomatic, most such fractures are painful and do better if immobilized in a long-leg walking cast for 2–3 weeks, followed by a brace or Sarmiento-type cast until 6 weeks. If symptoms allow, a soft supportive dressing and crutches may be adequate. Always look carefully for associated disruptions of the proximal and distal tibiofibular joints.

AUTHOR’S PERSPECTIVE

For closed fractures of the shaft of the tibia that have less than 1 cm of shortening, minimal displacement, and 50% or more cortical contact between the main proximal and distal fragments, I prefer closed reduction, application of either a Sarmiento or long-leg cast, and early weight bearing with a vigorous rehabilitation program. However, if there is a contra indication, I treat all other unstable fractures of the tibia with reamed, statically locked intramedullary nailing using a fracture table. I use a medullary nail 10 mm or larger in diameter so that I can take advantage of large transverse cross-locking screws.

In these cases, I use either a CAM walker or a night splint for symptomatic relief and to protect against an equinovarus contracture. I start the patient on a vigorous joint and muscle rehabilitation program. Because the majority of these fractures have unstable patterns, I delay weight bearing, other than the weight of the leg, until I see bridging callus on at least one view. I progress toward full weight bearing depending on the progression of healing. I persist with nonoperative treatment when there is a systemic or local contra indication to nailing.

For me, a relative contra indication to intramedullary nailing is a displaced fracture of the tibia at the proximal metaphyseal—diaphyseal junction. If for some reason this fracture is treated with intramedullary nail fixation, I take special precautions to be certain that the fracture remains anatomically reduced during the nailing. I may add extra fixation screws or a small unicortical plate, applied with minimal dissection, to prevent displacement of the fracture (Fig. 24-32).

Similar problems can be encountered in short oblique fractures of the distal tibia within 5–7 cm of the ankle joint. These are often better handled by either external fixation or open reduction and plate fixation, but they can be treated with locked intramedullary nails as an extended indication if special precautions are taken as described previously.

In open fractures of the tibia, I try to use unreamed locked intramedullary fixation in all fractures at the time of initial debridement. To avoid premature nail or screw failure, I always try to use a 10 mm or larger titanium nail, which permits insertion of the strong 5 mm transverse cross-locking screws. In smaller patients, I may have to pass one or two reamers gently to get up to 10 mm. I find this technique to be acceptable in the majority of cases. I leave the traumatic wound open in all cases and try to achieve full-thickness, good-quality soft-tissue closure by 10 days.

I use external fixation for open fractures and on occasion for closed fractures in the presence of multiple injuries where external fixation is more practical and expedient. I often convert these to reamed nailing early. In high-grade contaminated grade III B and C open fractures, I often begin with external fixation. After successful soft-tissue closure, and in the absence of any evidence of infection, I convert to a reamed intramedullary nail. In fracture patterns unsuitable for intramedullary nailing, I continue with the external fixator until fracture union.

I cannot recall having used interfractionary screw fixation alone for a fracture of the diaphysis of the tibia in the past 10 years. In fractures that can be reduced anatomically closed, or with minimal open incisions, I use interfractionary cannulated screws in the cancellous bone of the metaphysis, or epiphysial region, which are not suitable for nailing.

I reserve plate fixation for intraarticular fractures of the proximal and distal ends of the tibia and for an occasional metaphyseal fracture that is not suitable for nailing or external fixation. I place the vast majority of plates on the lateral border of the tibia to take advantage of the better soft-tissue coverage. I take great pains to protect the blood supply to bone using “biological” fixation techniques. I use a much larger number of plates for the treatment of nonunions of the tibia, which I apply posteriorly along with a bone graft. This technique is discussed in Chapter 33. In treating compartment syndrome of the tibia, I always use single-incision, lateral four-compartment fasciotomy rather than dual lateral and medial incisions.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and *, clinical results/outcome study.

The superiority of internal fixation over closed treatment for displaced fractures and dislocations of the ankle has been thoroughly demonstrated in the literature (14, 22, 32, 33, 37, 38, and 40, 43, 47, 53, 56, 60). In this chapter, we devote little attention to closed methods of treatment and discuss in detail modern internal fixation techniques. See Chapter 10 for more detail on closed treatment.

MECHANICS AND ANATOMY

The ankle joint consists of the articulation between the tibia and the talus, the talus and the fibula, and the tibia and the fibula, along with the capsule and stabilizing ligamentous structures, and distal projections from the medial side of the tibia and from the distal fibula, which form the malleoli. Together, these structures form a geometric constraint to transverse movement of the talus (13, 41, 48, 49, and 51, 57). The ankle joint is commonly referred to as a mortise-and-tenon joint because of its appearance on the frontal radiograph (Fig. 25.1). This carpentry term describes a technique in which wood is joined by the insertion of a square peg into a square hole, thus offering great rigidity and stability. This particular geometry is best suited to resist rotation of the talus within the ankle mortise.

Figure 25.1. carpenter’s mortise-and-tenon joint, showing the squared-off appearance of the ankle joint seen on the mortise view.

The articular surface of the talus is somewhat wider anteriorly than it is posteriorly and, depending on the shape of the talus, requires a small amount of spreading of the malleoli during dorsiflexion of the foot. In many ankles but not all, any loss of this spreading motion can cause a loss of dorsiflexion. This shape of the articular surface offers some restraint toward posterior subluxation of the talus, but the greater restraint is the cup-shaped distal tibia, which projects distally at its posterior margin.

The ankle owes its soft-tissue stability to the capsule and its ligamentous condensations (Fig. 25.2). The medial ligamentous complex, called the deltoid ligament, consists of a superficial and a deep portion. The superficial portion is large and fan shaped and extends from the medial malleolus to a wide attachment on the talus, calcaneus, and navicular (Fig. 25.2A). The deep portion is a transverse ligamentous connection between the deep surface of the medial malleolus and the talus. This ligament inserts into the axis of rotation of the talus and is one constraint against lateral subluxation of the talus. This portion of the ligament is very short.
**Figure 25.2.** A: Ligamentous anatomy at the ankle, from the medial side. The fan-shaped deltoid ligament extends distally from the medial malleolus to the calcaneus, talus, and navicular. B: Lateral ligamentous anatomy, showing the anterior and posterior talofibular ligaments and the calcaneofibular ligament, extending distally and posteriorly. C: Anterior view of the ankle, showing primarily the anterior tibiofibular ligament. D: Posterior view showing the posterior tibiofibular ligament.

The lateral ligamentous complex consists of the anterior and posterior talofibular ligaments and the calcaneofibular ligament (Fig. 25.2B). These three ligaments are helpful in preventing the tilting of the talus within the mortise. The tibia and fibula articulate with each other distally and are held together by a system of ligaments, including the interosseous membrane and the anterior and posterior tibiofibular ligaments (Fig. 25.2C, Fig. 25.2D). These ligaments allow the elastic widening of the ankle mortise during dorsiflexion and, to a certain degree, rotation of the fibula.

The sum of bony and ligamentous stability of the ankle joint results in motion best described as a simple hinge whose axis is parallel to the floor and externally rotated between 15° and 20° from the frontal plane (Fig. 25.3). The range of movement averages 20° of dorsiflexion and 40° of plantar flexion.

**Figure 25.3.** The true axis of the ankle joint is externally rotated 15° from the axis of the foot. A radiograph through the axis of the foot will not give a true tangential view of the ankle joint.

### RADIOGRAPHIC ASSESSMENT

Proper radiographic examination of the ankle requires anteroposterior, lateral, and mortise views. The anteroposterior view is taken with the beam centered on the ankle joint and directed in the sagittal plane (Fig. 25.4A). The lateral view is taken with the beam centered on the ankle joint and directed in the frontal plane (Fig. 25.4B). The mortise view is taken with the leg internally rotated about 15° so the x-ray beam passes perpendicular to the axis of movement (Fig. 25.4C). The anteroposterior view combined with the mortise view allows detection of avulsion fractures of the malleoli, vertical fractures of the medial malleolus, and lateral subluxation of the talus. The lateral view is most helpful in outlining the configuration of the lateral malleolar fracture and in detecting anterior and posterior tibial fractures.

**Figure 25.4.** A: A true anteroposterior view along the axis of the foot. B: The true mortise view with the foot internally rotated 15° clearly shows the entire joint space extending from the tip of the medial malleolus to the tip of the lateral malleolus. C: The lateral view of the ankle joint, showing the fibula line posterior to the tibia.

Diagnosis of occult instability of the distal tibiofibular syndesmosis requires careful interpretation of the radiographs, particularly for torsional injuries (Fig. 25.5). Stress views, particularly under anesthesia, may be helpful. Marginal impaction fractures, particularly in the anterolateral plafond of the tibia, can often be seen on plain radiographs but may require tomograms or CT scans. Full delineation of the various fracture fragments, particularly those involving the articular surface in pylon fractures, often requires CT with sagittal and frontal plane reconstructions. Comparison views of the opposite side occasionally prove useful for preoperative planning. Plain radiographs taken in traction are particularly useful in pylon fractures, as the traction achieves a rough reduction, restores length, and makes the fracture configuration easier to understand.

**Figure 25.5.** A: Anteroposterior projection of an ankle joint: a, lateral border of the lateral malleolus; b, lateral border of the anterior aspect of the tibia; c, medial border of the fibula; d, lateral border of the posterior aspect of the tibia. B: Rupture of the anterior syndesmosis with external rotation of the fibula does not affect the apparent width of the syndesmosis (c–d) or the intermalleolar distance (a–e). However, the amount of overlap of the anterior portion of the tibia on the fibula, distance a–b and distance b–c, change. Distance a–b increases, and b–c decreases. In most ankles, distance b–c is over 50% of a–c on anteroposterior projections. Comparison radiographs of the normal ankle are very helpful. (Modified from Chapman MW. Fractures and Fracture-Dislocations of the Ankle (Chapter 34). In Mann RA, Coughlin MJ, eds. Surgery of the Foot and Ankle, 6th edition. Philadelphia: Mosby, 1992:1448.)

### CLASSIFICATION

---

**Figure 25.3.** The true axis of the ankle joint is externally rotated 15° from the axis of the foot. A radiograph through the axis of the foot will not give a true tangential view of the ankle joint.
ANKLE FRACTURES

A classification system is useful as it helps to determine the proper treatment or predict the outcome [18,21]. Two classification systems stand out in any discussion of ankle fractures because they address these issues.

The first, devised by Lauge-Hansen, encompasses well over 95% of all ankle fractures [19,58]. It divides ankle fractures into categories by mechanism of injury and secondarily into groups of increasing severity. Lauge-Hansen determined the mechanisms of injury in various fracture types by cadaveric experiment in which he created these fractures in a laboratory setting. He classified ankle fractures into four categories determined by the position of the foot at the time force is applied (pronated or supinated) and by the direction that force is applied (external rotation or straight) (Fig. 25.6). An external rotation force applied as the patient's body twists over the planted foot causes a supination–external rotation or pronation–external rotation injury. Straight forces, such as when the supinated foot is forced into further adduction, result in the injuries described as supination–adduction. The opposite is the pronation–abduction injury. Each of these four categories is subdivided into stages indicating increasing severity of injury. The higher the stage, the greater is the severity of the injury and, thus, the poorer the prognosis.

A second and equally popular classification scheme is that devised by Weber of the AO group [35]. This classification scheme includes three major fracture types, depending primarily on the level of the fibular fracture.

In the Weber type A fracture, the fibula is avulsed distal to the syndesmotic ligaments, and the medial malleolus is fractured vertically (Fig. 25.7A). This fracture type, which roughly corresponds to Lauge-Hansen's supination–adduction type, is usually unstable, requiring internal fixation. There is often a small compression of the articular surface of the tibia, which should be elevated for complete reduction of the medial malleolus.

![Figure 25.7. The Weber classification of ankle fractures. A: Fracture of the fibula below the level of the tibial plafond and vertical fracture of the medial malleolus. B: Avulsion fracture of the medial malleolus and fracture of the fibula, beginning at the level of the tibial plafond. The posterior rim may also be fractured, as shown. C: An avulsion fracture of the medial malleolus or ruptured deltoid ligament with a short oblique fracture of the fibula, well above the level of the tibial plafond. Also, a posterior rim fracture of the tibia may be seen.](image)

The Weber type B (Fig. 25.7B) includes an oblique fracture of the fibula, beginning at the level of the tibial plafond and extending proximally and posteriorly through the fibular shaft. The posterior lip of the tibia is usually fractured; the fragment may be large or small. Also included is an avulsion of the medial malleolus or rupture of the deltoid ligament. This category corresponds to the supination–external rotation type of Lauge-Hansen. When undisplaced, according to criteria to be detailed below, these can be treated by immobilization alone.

The Weber type C (Fig. 25.7C) is characterized by a fibular fracture that is entirely above the level of the tibial plafond. A large or small posterior lip fracture often accompanies this injury, as does a medial malleolar avulsion or deltoid ligament rupture. This category corresponds to Lauge-Hansen's pronation–external rotation type. The syndesmosis is always ruptured; the need for repair of this part of the injury is detailed later.

Both the Lauge-Hansen and the Weber classifications are well known and widely used. The Lauge-Hansen classification is of greater value in comparing the results of treatment because it accurately describes the severity of the injury. The Weber classification is more useful in deciding on the appropriate form of treatment.

PYLON FRACTURES

A pylon fracture is one involving not only the articular surface but also the metaphysis. On occasion, it extends into the distal diaphysis as well. Most pylon fractures in urban trauma centers result from higher-energy vertical compressive forces during a fall from a height or a motor vehicle accident. Lower-energy injuries, often incorporating a torsional component, may result from activities such as snow or water skiing. The extent to which pure compressive loads are responsible for the injury is related to the final outcome. High-energy injuries not only produce greater comminution and compression of the fracture fragments but also produce greater soft-tissue damage, worsening the eventual outcome [53]. (Note: The term pylon is from the French word “pilon” meaning to ram or hammer, referring to the mechanism of injury of this complex fracture.)

Foot position during impact in compressive-type injuries heavily influences the fracture pattern of the articular surface [7]. Foot dorsiflexion during impact produces anterior articular impaction and comminution, whereas a plantarflexed foot is associated with posterior articular damage. Loading a supinated or pronated foot produces a characteristic pattern of articular damage, referred to in the European literature as medial or lateral gap patterns, respectively.

The most commonly used pylon classification is by Ruedi and Allgöwer [42] (Fig. 25.8). Type A fractures describe an intrarticular cleavage-type fracture without joint displacement. Type B fractures demonstrate intrarticular displacement with limited comminution. Type C fractures have intrarticular displacement with marked comminution. The classification has been further subdivided using the AO classification scheme (Fig. 25.9).
safe wound healing. Patients with diabetes mellitus, particularly if they have peripheral neuropathy, have a much higher-than-average occurrence of infection and other

Contraindications to operative treatment include medical conditions precluding safe operative intervention and vascular insufficiency or other skin conditions preventing

the risk of pain and loss of motion. Noncongruent ankles can quickly progress to severe degenerative arthritis.

stable internal fixation, and early range-of-motion exercise (15,26,69). Failure to restore the anatomic relationships and articular congruity of the ankle joint increases

the risk of pain and loss of motion. Noncongruent ankles can quickly progress to severe degenerative arthritis.

Internal fixation is indicated for all fractures of the articular surface of the ankle with displacement greater than 2 mm lateral or posterior at the lateral or medial

malleolar (18). In the absence of a medial malleolar fracture, widening of the medial clear space greater than 2 mm must be considered an unacceptable displacement.

Some surgeons would not accept widening of more than 1 mm in young active individuals.

LOW-VELOCITY INJURIES

Low-velocity injuries typically result in simple minimally comminuted fracture patterns with mild to moderate soft-tissue injury. Lower-energy ankle fractures commonly

occur in an elderly population with osteopenic bone, so fixation may be compromised. Although judicious soft-tissue handling and appropriate surgical timing are still

necessary to avoid wound breakdown and infection, surgery usually can proceed immediately after presentation to the emergency room and preparation of the patient

for surgery (6).

HIGH-VELOCITY INJURIES

High-energy ankle fractures resulting from motor vehicle collisions and falls from significant heights pose problems in the management of the bony and soft-tissue

injuries. Early closed reduction of these fractures is important to minimize further soft-tissue compromise and to decrease the risk of fracture blister formation.

Soft-tissue swelling, as well as abrasions and blisters, may make early open reduction and fixation hazardous. Sometimes temporary external fixation may be

advisable, but usually incorporation in well-padded long-leg splints or a cast with elevation of the limb suffices until the soft tissues recover sufficiently to permit fixation.

OPEN FRACTURES

For open fractures, administer appropriate intravenous antibiotics to the patient as soon as possible. Open ankle and pylon fractures require immediate and thorough

irrigation and debridement of nonviable tissue (10) (see Chapter 12). Whereas grade 1 injuries may be primarily closed following a thorough debridement, grade 2 and

grade 3 injuries usually require repeated irrigation and debridement to minimize the risk of infection. Open injuries do not necessarily dictate the type of fixation that

should be used to stabilize a fracture because both internal and external fixation principles can be applied, assuming thorough debridement and early soft-tissue

coverage are performed. In severe open grade 3 pylon fractures, generally the soft tissues will not tolerate extensive internal fixation of the comminuted metaphyseal

portion of the fracture. Most authorities treat these with limited fixation of the articular surface and hybrid or other external fixation (3,29). In some cases, conversion to

biological internal fixation, once the soft tissues have recovered, is appropriate (3,49).

ASSESSMENT

Perform a history and physical examination, including a thorough neurovascular examination and evaluation for compartment syndrome. If the patient has a history of

vascular insufficiency or clinical findings suggestive of distal arterial compromise, perform noninvasive arterial Doppler studies preoperatively and consider vascular

consultation to insure that the wound will have the capability of healing.

Gently palpate along the osseous and ligamentous structures, including the proximal fibula, lateral and medial malleoli, syndesmosis, and lateral and medial ligaments, to

totally delineate all aspects of the injury. Carefully palpate the hindfoot, midfoot, and forefoot to rule out associated injuries.

SURGICAL INDICATIONS

Minimally displaced (less than 1 to 2 mm) stable fracture patterns without disruption of the ankle mortise do not require operative treatment (59). The most common

fractures treated closed are Weber A and B fractures without medial injury. All other displaced fractures about the ankle are optimally treated with anatomic reduction,

stable internal fixation, and early range-of-motion exercise (15,26,69). Failure to restore the anatomic relationships and articular congruity of the ankle joint increases

the risk of pain and loss of motion. Noncongruent ankles can quickly progress to severe degenerative arthritis.

Contraindications to operative treatment include medical conditions precluding safe operative intervention and vascular insufficiency or other skin conditions preventing

safe wound healing. Patients with diabetes mellitus, particularly if they have peripheral neuropathy, have a much higher-than-average occurrence of infection and other
Severe displacement in an ankle injury, particularly dislocation, can lead to skin necrosis as a result of tension over bony prominences as well as increased swelling and neurovascular compromise. For that reason, markedly displaced ankles should have a provisional reduction performed before radiography unless it will be performed immediately.

After radiographic evaluation, place the provisionally reduced ankle injury in a well-padded cast that has been univalved or in gutter splints, which will hold the provisional reduction. A long-leg cast or splint is required for most ankle fractures. Those that are rotationally stable can be immobilized in a short-leg device. Elevate the limb 10 cm above the heart. Perform surgery as soon as practical. Delay of surgery more than 24 hours may lead to excessive swelling and fracture blisters, which may preclude surgery for a week or more, and that delay could compromise the ability to achieve an anatomic reduction.

PREOPERATIVE PLANNING

If a full range of one-third tubular plates or their equivalent as well as screws are available in the operating room, then templating of routine ankle fractures is rarely necessary. Complex or very long lateral malleolus fractures may require templating to ensure that appropriate implants are available for fixation. Pylon fractures require detailed radiographic assessment of the articular surface of the tibial plafond and the fracture. For complex fractures, draw out the fracture lines on a line drawing traced from plain radiographs of the opposite normal side and use templates to sketch in the implants you plan to use. If staged open treatment following fixation of the fibula and external fixation is planned, radiographs following fibular reduction and provisional tibial–calcaneal fixation are useful in planning the definitive internal fixation.

NONOPERATIVE TREATMENT

Extrarticular fractures of the distal tibia and fibula with stable patterns and all nondisplaced fractures of the ankle are suitable for nonoperative treatment. Usually a well-molded short-leg cast suffices, and immediate weight bearing is possible. Univalve all circumpatellar casts applied acutely and have patients elevate the injured limb 10 cm above their heart until swelling subsides. Fracture braces can be used for some stable lateral malleolus fractures (59).

Displaced fractures of the medial malleolus, with the exception of avulsion fractures of the nonarticular tip of the malleolus, require open reduction and internal fixation (ORIF) because they have a significant incidence of nonunion as a result of soft-tissue interposition.

Fractures of the articular portion of the lateral malleolus with displacement of 2 mm or more require operative treatment.

In patients with systemic or local contraindications to surgery, displaced fractures can be reduced, closed, and managed in well-molded long-leg casts. Precise fixation is necessary. Complex or very long lateral malleolus fractures may require templating to ensure that appropriate implants are available for fixation. Pylon fractures require detailed radiographic assessment of the articular surface of the tibial plafond and the fracture. For complex fractures, draw out the fracture lines on a line drawing traced from plain radiographs of the opposite normal side and use templates to sketch in the implants you plan to use. If staged open treatment following fixation of the fibula and external fixation is planned, radiographs following fibular reduction and provisional tibial–calcaneal fixation are useful in planning the definitive internal fixation.

Perform ORIF in a conventional operating room under general or regional anesthesia. Give appropriate antibiotics intraoperatively before the tourniquet is inflated, and continue them for 24 hours (three total doses). Tourniquets are useful when bleeding interferes with visualization of the reduction. Because of the rebound edema that occurs after tourniquet use, we now prefer to use good surgical hemostasis and operate without a tourniquet, if possible. Avoid prolonged tourniquet time and under no circumstances exceed a total of 2 hours. Generally, the supine position with a bump under the ipsilateral hip to facilitate lateral exposures suffices. The prone position is useful for some difficult trimalleolar fractures requiring posterior-lateral exposure of the ankle. Gently prepare and drape the extremity from the toes to the upper thigh. Use adhesive, povidone-impregnated plastic drapes where incisions will be made. Expose no bare skin or toes to the operative field.

Surgical exposures of the ankle and the skin incisions are described in Chapter 3. Some additional advice is appropriate here, however. In general, skin incisions should be longitudinal, straight, and located directly over the fracture. The posterior ankle can be exposed through the medial or lateral incisions by making them longer and shifting them somewhat posteriorly. A gentle curve in their distal portion may be helpful, but avoid creating flaps.

The utilitarian incision for a pylon fracture is a straight anterior approach just lateral and parallel to the anterior tibial tendon. If the fracture pattern allows, rather than curve it medially distally, a straight incision carried well out into the neck of the talus facilitates complete exposure of the anterior tibial and syndesmosis.

Use a separate incision for the lateral malleolus and a separate short incision directly over the tip of the medial malleolus, if necessary, to insert malleolar screws (Fig. 25.11).
Avoid injury to subcutaneous sensory nerves.
- Carry dissection directly down to the periosteum. Expand exposure at the level of the periosteum.
- Minimize stripping of the periosteum. Expose only a 1- to 2-mm edge along the fracture lines.
- Thoroughly clean the fracture surfaces of hematoma.
- Explore the ankle as possible through the available surgical exposure and thoroughly irrigate to identify chondral injury and osteochondral fractures, and remove any loose fragments.
- In bimalleolar or trimalleolar fracture, consider exposing all of the fractures before inserting any internal fixation because this permits better inspection and irrigation of the ankle as well as facilitating ORIF.
- Obtain anatomic reductions and render them stable with one or more double sharp-pointed bone reduction forceps of appropriate size.
- Use completely stable fixation.
- Always obtain postoperative radiographs intraoperatively prior to wound closure.
- Close wounds in three layers: the periosteum if possible, subcutaneous tissue, and skin. Use atrumatic skin closure technique. Use 1/8-in. suction drains in pylon fractures and severe trimalleolar fractures or when there is enough bleeding to justify their use.
- Obtain postoperative dressing and well-padded splints or a Robert-Jones dressing with splints (Fig. 25.12).

**Figure 25.11.** Surgical incisions around the ankle.

**Figure 25.12.** The postoperative dressing. A: The dressing is well padded with cotton before plaster application; a foot plate is made of plaster splints, and a plaster stirrup on both medial and lateral sides covers the foot plate. The foot plate is then reversed over the stirrup for further strengthening. B: Close-up view showing the posterior aspect of the plaster. Plaster does not contact the patient’s heel. C: A light coating of cotton is placed over the plaster to prevent the compression dressing from sticking to the plaster and becoming ineffective. Then it is wrapped with an elastic bandage. The foot is in neutral position.

**MEDIAL MALLEOLUS FRACTURES**

Most medial malleolar fractures occur in conjunction with a lateral injury and should be approached after the lateral malleolus has been exposed. It is usually better to fix the lateral side first.

- Make an appropriate incision. Develop exposure utilizing dull retractors (Ragnals, Langenbecks), taking care to avoid damage to the saphenous nerve and vein.
- Strip the thick periosteal layer overlying the medial malleolus only enough to allow for visualization and reduction. It is imperative to visualize the anterior aspect of the fracture to insure an anatomic reduction.
- Inspect the medial gutter of the ankle joint to assess the talus for osteochondral injuries and to ensure that no loose fragments or infolded soft tissue is blocking the reduction. This is best accomplished by distracting the distal fragment with a dental pick.
- After anatomically reducing the fragment with a towel clip, sharp-tipped bone forceps, or dental pick, provisionally hold the reduction with a large Weber (two-point reduction) clamp (Fig. 25.13). Occasionally two small Weber forceps are required. Check for stepoffs between the fragments using a dental pick.

**Figure 25.13.** Provisional reduction of medial malleolar fracture utilizing a large two-point reduction clamp.

- Screw fixation is usually optimal for most medial malleolus fractures. Place two parallel screws in lag fashion directed perpendicular to the fracture place. Screw diameter (4.0 mm, 3.5 mm, 2.7 mm) can be varied to accommodate the size of the distal fragment. The sharp-tipped triple drill guide depicted in Fig. 25.14 is useful to provide preliminary fixation with drill points and to assure that the screws are parallel (Fig. 25.15).

**Figure 25.14.** This drill guide enables the operator to drill parallel holes to facilitate parallel screw placement. One hole can be drilled, and the drill bit left in place while the second drill bit is used to complete the procedure.
LATERAL MALLEOLUS FRACTURES

The methods for reduction and fixation of lateral malleolus fractures are dependent on the fracture pattern and mechanism. For most fractures about the ankle, reduce and fix the lateral malleolus first, restoring length and rotational alignment.

- Approach the majority of lateral malleolar fractures using incision 4 in Figure 25.11. If posterior fixation or concomitant posterior malleolar reduction is anticipated based on preoperative planning, use incision 6, which is posterior.
- Consider the anatomic variations of the sural and superficial nerves to avoid inadvertent injury.

Weber A lateral malleolus, transverse–avulsion fractures are optimally treated with tension-band fixation because the fragment is usually too small for screws and a plate. This can be accomplished with Kirschner (K-) wires and malleable wire. Occasionally, a one-third tubular plate and screws work well. An intramedullary screw can be used as well but provides less rotational stability (Fig. 25.16).

Weber B oblique fractures in the coronal plane ending at the level of the plafond can be stabilized with either a posterior antiglide plate (Fig. 25.17) or a lateral interfragmentary lag screw and a buttress plate (Fig. 25.18). Even though antiglide plating shows some biomechanical advantage [46], it should be reserved for short, oblique noncomminuted fracture patterns. For antiglide plating, a one-third tubular plate is optimal.

Weber C, D, and E fractures require more extensive ankle reconstruction. In these cases, a custom femoral condylar plate, tibial plate, and other custom implants are used along with external fixation. The ankle mortise is restored with anatomic reduction using image intensification. Residual instability is supplemented with ligamentous repair (e.g., tenodesis). The fixation must be strong enough to allow early weight bearing.

Rehabilitation begins with early range of motion and progressive weight bearing. Because of the complex nature of these injuries, return to athletic activities is delayed for at least 6 months.
Posterior Antiglide Plate

- Minimally strip the posterior soft tissue extraperiosteally. Insert a 3.5-mm screw through the posterior antiglide plate from posterior to anterior just proximal to the fracture line. As the screw is tightened, the plate will reduce the fracture.
- Fine-tune the reduction with small Weber clamps until an anatomic reduction is achieved.
- With the fracture held anatomically reduced, place a 3.5-mm or 2.7-mm distal-posterior to proximal-anterior lag screw though the plate across the fracture. The 2.7-mm screw head is less prominent for the peroneal tendons and can be angled perpendicular to the fracture line.
- Place a 3.5-mm bicortical screw through the plate proximally to serve as a derotation screw (Fig. 25.17).

Lateral Buttress Plate

For lateral plating of these fractures, a one-third tubular plate, stacked one-third tubular plates, or 2.7-mm reconstruction plates provide satisfactory fixation.

- Mallet a one-third tubular plate flat distally and contour and rotate it to match the contours of the distal fibula. In cases where distal fixation is problematic, a hook can be fashioned out of the distal screw hole and impacted into the bone as an additional point of fixation (26). Do this by cutting the distal end of the plate off through the screw hole and then bending the resulting sharp ends toward the bone.
- Rather than placing a short unicortical 4.0-mm cancellous screw in the distal holes, 2.7- or 3.5-mm cortical screws can be angled proximally or distally to obtain additional cortical purchase and still avoid penetrating the articular surface in the lateral gutter.
- Two proximal bicortical screws and an anterior-to-posterior interfragmentary screw complete the fixation (Fig. 25.18). Additional screw fixation proximal to the fracture is rarely necessary and results in unbalanced fixation.

For shortened comminuted fractures or fractures operated on in a delayed fashion, indirect reduction techniques are helpful in gaining the appropriate length and rotation.

- After fixing the plate distally, place a bicortical screw proximal to the plate and in line with it (24). This is known as a “push-pull” screw. Use a bone spreader between the push-pull screw and the plate to distract the distal fragment.
- After anatomic length has been achieved, correct rotational discrepancies before placing proximal screws.

Webber C Fracture

Webber C distal fibula fractures require correction of length and rotational deformities of the distal fragment of the fibula as well as anatomic reduction and fixation of the syndesmosis (1). In a few of these injuries the anterior and interosseous ligaments of the syndesmosis are torn, but the posterior ligaments remain intact. Anatomic reduction and plate fixation of the fibula alone then restores the syndesmosis and renders it stable. Independent fixation of the syndesmosis then is unnecessary. Indirect reduction techniques are ideal for restoring appropriate length. Single one-third tubular plates are usually not strong enough to allow for distraction through the plate. Stacked one-third tubular or 3.5-mm dynamic compression plates (DCP) function well for this task. These plates require precise contouring, as they are too stiff to assume the contour of the lateral fibula when the screws are tightened.

- Following a lateral approach to the distal fibula, dissect along the anterior fibula to expose the anterior syndesmosis. Careful preoperative and intraoperative planning is required for precise placement of a screw from lateral to medial across the syndesmosis parallel to and 2 to 3 cm above the joint line.
- After fixing the plate to the distal fragment along the posterosuperior aspect of the fibula, place a push-pull screw proximal to the plate. Distract through the plate until anatomic length, rotation, coronal plane alignment, and anatomic reduction of the syndesmosis have been accomplished. If there is cortical continuity between the distal and proximal fragments, the fracture can be loaded through the plate using the push-pull screw and a small Verbrugge clamp (24).
- Secure the plate proximally with two 3.5-mm bicortical screws.
- Then fix the syndesmosis.
- Position the hindfoot in slight inversion and the ankle in neutral dorsiflexion and hold the syndesmosis reduced with a two-point reduction forceps. The screw should parallel the joint and be directed from posterolateral to anteromedial at approximately a 15° angle (Fig. 25.19).

![Figure 25.19. A: Radiographs demonstrating a pronation type ankle fracture with syndesmotic disruption. Notice the avulsion fracture at the medial joint line. B: Radiographs following ORIF of the fibula and open reduction of the syndesmosis with transsyndesmotic fixation. C: Radiographs following union of the fracture. Radiolucenty around the syndesmotic screw without failure is evident.](image)

- Use a fully threaded 3.5-mm cortical screw across all four cortices of the fibula and tibia to secure fixation. In larger individuals, two 3.5-mm screws may be necessary. The fully threaded screw functions as a “positioning” screw by holding the reduced position, avoiding excessive compression of the syndesmosis.

POSTERIOR MALLEOLUS FRACTURES

Posterior malleolus fractures often are small enough not to require fixation (28). Fractures can involve only the nonarticular portion of the posterior malleolus, and fragments that are attached to the fibula by the posterior distal tibiofibular ligaments are well reduced and stable after fixation of the fibula. If the fracture involves 25% or more of the articular surface, the talus tends to subluxate posteriorly, so fixation is indicated (8,31). Because the fracture can be oblique, there is a tendency to underestimate the size of the fragment. Computed tomography (CT) is useful in delineating the size and location of the fragment.

- Posteromedial fragments can usually be fixed through incision 3 on Figure 25.114, which is used to fix the medial malleolus as well. Lengthen it as needed to gain adequate exposure. Posterolateral fragments can be approached in a similar way laterally through incision 6 on Figure 25.116. Use the interval between the peroneal tendons and the flexor hallucis tendon. This incision must be large enough to permit tension-free exposure. The prone position is very helpful for this exposure and fixation.
- Use a dental tool, large Weber double-pointed forceps, or spiked ball-tip pusher to reduce the fragment. Lock the proximal edge of the fractured fragment into place first and then close the articular surface. Hold it securely with the reduction forceps.
- After provisional K-wire fixation, obtain definitive fixation with percutaneous anterior-to-posterior 3.5-mm or 2.7-mm lag screws placed through anterior stab wounds. Do not overtighten the screws because this may cause the posterior fragment to displace proximally and anteriorly (Fig. 25.20).

![Figure 25.20. A 26-year-old woman was involved in a high speed motor vehicle accident sustaining multiple injuries including this comminuted intraarticular pylon fracture of the left ankle. ISOLATED DISRUPTIONS OF THE DISTAL TIBIOFIBULAR SYNDESMOSIS

Disruptions of the syndesmosis require open reductions to insure anatomic restoration of the syndesmosis.

- Expose the syndesmosis anteriorly as previously described.
- Before reducing the distal tibial–fibular joint, confirm that the distal anterior tibial–fibular ligaments have not “buttonholed” into the joint, blocking the reduction. Clean out the syndesmosis but do not disturb the articular cartilage or curette the bone in order to prevent a synostosis from forming.
- Reduce the syndesmosis using a large pointed reduction forceps. Be certain that the fibular slides posteriorly into the sulcus in the tibia and is anatomic.
- Proceed with screw placement as described for Weber C fractures (8). A two-hole one-third tubular plate on the fibula may be used as well, particularly if two screws are placed (Fig. 25.21).

**Figure 25.21.** A: Radiographs following pronation injury resulting in a medial ligamentous injury with syndesmotic disruption. B: Stress radiograph demonstrating syndesmotic disruption with comparative stress view of the uninjured ankle. C: Intraoperative radiograph with compression across the reduced syndesmosis. D: Radiographs following open reduction of the syndesmosis and internal transsyndesmotic fixation. E: Follow-up radiographs demonstrating maintenance of the syndesmotic reduction and development of (asymptomatic) intramembranous calcification.

- Repair of the anterior distal tibia–fibula ligaments can be performed with a nonabsorbable suture, although this is less important than anatomic reduction with stable screw placement.
- Repair of a concomitant rupture of the deltoid ligament is unnecessary. If the medial side is explored for other reasons, repair the ligament.

FRACTURES OF THE TUBERCLE OF CHAPUT

- Use the lateral incision for lateral malleolar fixation to reduce and stabilize the tubercle of Chaput. Dissect anteriorly with a periosteal elevator along the anterior tibial–fibular ligament to provide access to the tubercle of Chaput.
- Use a dental pick, spiked pusher, or Weber clamp for reduction.
- Provisionally stabilize the fracture with K-wires and then place a lag screw from lateral to medial, securing the fragment.

LIGAMENT INJURIES

Ligamentous injuries about the ankle that fail to disrupt the integrity of the ankle mortise and that fail to block anatomic reduction rarely require repair. Deltoid ligament tears in combination with lateral malleolar fractures do not require open treatment unless they prevent an anatomic reduction of the ankle mortise (12).

PYLON FRACTURES

PRINCIPLES OF TREATMENT

The goal of surgery is to achieve a precisely reduced joint surface maintained by stable internal fixation. If this can be achieved, functional postoperative treatment with early use of the muscles of the leg and physiologic activity of the joint can be instituted (34,35). Early use of the muscles prevents atrophy, and motion helps to repair injured cartilage (34). The fixation maintains the fracture in the correct position through the period of bone healing. Operatively achieved anatomic reduction and stable internal fixation can produce results impossible to achieve with other therapeutic approaches (2).

Operate on the fracture as soon as possible after injury. This window for intervention extends to about 10 to 12 hours after injury. If more time passes, interstitial edema increases, the skin loses its pliability, and fracture blisters appear. During this later period, surgery is contraindicated.

A closed reduction, external splinting incorporating a compression dressing, and elevation of the extremity may salvage the situation if it is too late to operate. Proper management during this period enables operative intervention when the skin starts to wrinkle, at about 8 to 10 days.

An alternative approach is to place a patient too unstable for emergent surgery into calcaneal pin traction on a Boehler frame and allow the traction to regain length and alignment of the limb. Elevation, reduction, and time allow the posttraumatic inflammatory period to pass. An idea of the relative ease of open reduction and internal fixation may be obtained by viewing radiographs of the reduction obtained by pure distraction during the traction period (23,24) (Fig. 25.22).

**Figure 25.22.** A: Anteroposterior (AP) radiograph of a type C pylon fracture. Notice the shortening that contributes to displacement of the diaphyseal and articular fracture fragments. B: An AP radiograph of the same fracture with 10 kg (22 lb) of skeletal traction applied through the calcaneus. Notice how simple distraction has reduced most of the diaphyseal and epiphyseal fracture displacements. This is a good prognostic sign, indicating that indirect methods of reduction during surgery can allow an atraumatic reduction of the fracture, which then may be fixed by standard methods of internal fixation. C: Another AP projection of a type C pylon fracture. Although this fracture is more comminuted than the previous example, a more important indicator of problems in reduction during surgery is shown by its failure to reduce or improve with skeletal traction. D: Ten kilograms (22 lb) of traction applied to the calcaneal pin have not markedly improved the radiographic situation. Failure to improve during skeletal traction can be attributed to the interposition of soft tissue. In this fracture, the flexor hallucis and neuromuscular bundle have been displaced into the joint and block reduction of the posterior fragment.
Carry out surgery after the acute effects of the injury have subsided. This does not represent the ideal situation, however. Surgical intervention is rendered more difficult by the passage of time because the soft tissues are less pliable and the bony fragments become softer and somewhat adherent.

The severity of the injury plays the most important role in determining the final outcome. In high-energy injuries, impaction of the subchondral bone, fragmentation of the epimetaphyseal cortex, and irreparable abrasion of the cartilage of tibia and talus may dictate a poor result regardless of the surgeon's experience. Under these circumstances, the condition of the soft-tissue sleeve becomes critical.

If surgical intervention is attempted, the operative approach and surgical tactic for the reduction and fixation must be carefully planned. In these fractures, a preoperative drawing may be very enlightening. If the key fragments to be reduced and fixed cannot be identified and drawn, it may be that at surgery they cannot be reduced and fixed (43). A misguided attempt at anatomic reduction and internal fixation under circumstances in which stable fixation cannot be achieved can deteriorate into a lengthy struggle, resulting in frustration for the surgeon, intraoperative acceptance of malreduction, unstable fixation and ensuing skin slough, wound dehiscence, bone and tendon necrosis, and infection. Worse, the patient may be deprived of delayed reconstructive procedures that could produce an acceptable result.

Although indirect reduction techniques are useful in enacting a reduction, pylon fractures, like all articular fractures, should be reduced directly. Regardless of which operative approach to pylon fractures is employed, distraction techniques are required to restore alignment and reduce compressed articular fragments.

### LIMITED INTERNAL FIXATION

Limited internal fixation as an isolated fixation technique should be reserved for undisplaced or anatomically reducible articular fracture patterns without metadiaphyseal extension that are potentially unstable and require additional stabilization. Isolated percutaneous screw fixation of perarticular fragments rarely provides sufficient stability to allow for early range of motion and likely necessitates cast immobilization to provide stability. This technique is best combined with external fixation, which is described below.

### EXTERNAL FIXATION

External fixation techniques include large pin fixators, small wire fixators, and hybrid fixators (3, 29). Reduction via external fixation relies on traction and resulting ligamentotaxis to help reduce the fracture fragments. Without direct visualization of the articular surface via open or arthroscopic means, treatment by external fixation relies on radiographic joint reduction, which is subject to errors. Although some small wire hybrid techniques do not cross the ankle joint, most large pin fixators rely on fixation that spans the ankle and often the subtalar joints, precluding early joint motion. If external fixation is used as a temporary treatment regimen while soft tissue swelling is allowed to subside, ensure that pin placement does not compromise future open treatment. Specific surgical techniques vary, depending on the type of external fixation employed. Correction of angular, rotational, and length discrepancies is accomplished by distracting through the fixator after connecting the fixator to proximal and distal pins and/or wires. Regardless of the fixator, it is essential that pins and wires be placed without causing thermal necrosis to the bone and soft tissue, which leads to infection and ring sequestrum formation (see Chapter 11 for more details).

### EXTERNAL FIXATION WITH LIMITED INTERNAL FIXATION

Treatment by this method involves limited fixation to stabilize the articular fractures followed by “connecting” the restored joint to the tibial shaft with external fixation. Indirect reduction techniques aid in repositioning of fragments via ligamentotaxis (49).

- Before attempting reduction of the articular fracture fragments, connect a universal distactor to tibial and talar or calcaneal Schanz screws and correct for length and rotational and angular malalignments. Alternatively, some fixation systems allow for distraction through the fixator.
- Utilize limited well-planned incisions and stab wounds near the plafond to reduce fracture fragments under fluoroscopic radiographic control. Small elevators, dental picks, pushers, and K-wires are helpful in positioning fragments in a reduced position.
- After obtaining anatomic reduction and provisional stabilization with K-wires or guide wires for cannulated screws, secure the articular and perarticular fragments with interfragmentary screws.
- Following reduction and stabilization of the articular fragments, use the external fixator to secure the ankle and distal tibia to the tibial diaphysis.

A variety of small-wire, hybrid, and large pin fixators are available. Small-wire or hybrid fixator fixation that provides stable fixation without spanning the tibial-talar or talocalcaneal joints is preferable when technically feasible because it allows for early ankle (and subtalar) motion, satisfying one of the goals of operative pylon treatment (Fig. 25.23).

![Figure 25.23. Radiograph of a pylon fracture in a hybrid or Orthofix fixator with percutaneous screws. A,B: AP and lateral radiographs demonstrating an AO C type pylon fracture with marked metadiaphyseal comminution. C,D: Radiographs with a tibial-calcaneal spanning external fixator, reducing the fracture via ligamentotaxis with limited internal fixation of the major articular fragments.](image)

### OPEN REDUCTION AND INTERNAL FIXATION

Open reduction and internal fixation performed well gives the best results (25, 38, 42). Poor soft-tissue handling, inappropriate surgical timing, excessive soft-tissue stripping, and use of excessively large implants, however, can lead to disastrous results.

Timing of pylon ORIF is based on basic soft-tissue injury principles. The safest time periods for open treatment are within 6 hours of the injury or at least 6 days from the injury (34). Staging of open treatment takes advantage of both these “windows of opportunity,” provisionally stabilizing the fracture to aid in soft-tissue healing and allowing for careful radiographic evaluation and preoperative planning.

As soon as possible after a patient with a pylon fracture presents to the trauma center, preferably within 6 hours from time of injury, perform ORIF of the fibula and provisional tibial-calcaneal external fixation:

- Carefully plan the fibular incision to allow for a 7-cm skin bridge between this and the future anterior tibial incision. Approach the distal fibula fracture essentially the same as for routine lateral malleolar fractures. Direct the incision slightly posteriorly to insure a safe skin bridge. Fibula fractures associated with pylon fractures typically occur proximal to the ankle mortise, but varying patterns may occur.
- Shortened fibulas from lateral compression modes of failure reduce well with indirect means. Following fixation to the distal fragment, place a 3.5-mm bicortical push-pull screw proximal to the plate. After distracting the fracture out to anatomic length with a bone spreader and correcting rotational malalignments, secure the plate to the proximal fragment. If cortical continuity exists, the fracture can be loaded using the push-pull screw.
- Place a 5.0-mm Schanz screw in the medial aspect of the tibia and calcaneus perpendicular to the ankle joint using standard techniques. Make sure the tibial pin is far enough proximal to avoid communication with the future tibial incision.
- Connect the pins to a single medial carbon fiber bar and distract the distal tibia out to length using the compression device (Fig. 25.24). Do not place any pins into the talus because this may compromise any incision required for definitive open treatment in the future.
Definitive open treatment should be delayed until soft-tissue swelling diminishes. This usually occurs within 7 to 10 days but may take up to 3 weeks.

- Make an anterior tibial incision (Fig. 25.11C), leaving a 7-cm skin bridge between it and the fibular incision. This will vary somewhat based on the fracture pattern.
- The standard incision starts just lateral to the crest of the tibia and courses just anterior to the tibialis anterior tendon at the distal limb (54). A posterior (European) approach may occasionally be preferable to accommodate open fracture wounds, but this approach provides limited exposure of the articular surface.
- Dissect directly down to bone just lateral to the anterior tibial tendon and develop the exposure medially and laterally at the level of peristemeum. Incise the anterior compartment fascia just lateral to the tibial crest and reflect the flap medially in an extraperiosteal manner, exposing the medial face of the tibia. Avoid violating the paratenon of the anterior tibial tendon at the distal aspect of the incision. Should the skin slough anteriorly, the paratenon will accept a split-thickness skin graft. In the absence of the paratenon, the tendon will desiccate, leading to infection and other problems.
- Make an anterior ankle arthrotomy and carry the exposure out onto the neck of the talus to visualize the reduction. Perform minimal periosteal striping of the fracture fragments.
- Additional distraction through the medial fixator may aid in the reduction (23).
- Use a variety of dental pits, reduction forceps, and pushers to tease the fragments into anatomic alignment. Forceful reduction maneuvers are rarely beneficial and increase the risk of further fracture fragmentation. Thoughtful, methodic, fragment-by-fragment reduction and provisional fixation are essential.
- After reducing the fragments, perform provisional fixation with K-wires. If significant crush of metaphyseal bone exists, place autologous bone graft into the osseous defect to prevent collapse of the reduction and promote osseous union.
- After confirming an anatomic articular reduction visually and radiographically, replace the provisional K-wires with limited lag screw fixation.
- Various small and minifragment plates may additionally be contoured to adequately stabilize the perarticular fracture fragments and stabilize the metaphyseal component to the distal diaphysis of the tibia (Fig. 25.25). It is rare that a plate larger than 3.5-mm limited-contact DC plates is required.

If skin closure is difficult because of tension, try to close all deep tissues over the bone and implants, leaving the fibular incision open, allowing for primary closure of the tibial wound with delayed closure or split-thickness skin grafting of the fibular incision. Delayed closures under sterile conditions are far safer than attempting to primarily close an overly tight wound.

POSTOPERATIVE CARE

During the early postoperative period, keep the limb in a well-padded compression dressing and splints to prevent the foot from dropping into equinus. Elevate the limb until swelling subsides. Gentle range-of-motion exercises can begin as tolerated if the surgeon feels the fixation is stable. On the first postoperative office visit, apply a removable below-knee cast. Keep patients touch-down weight bearing but remove the cast or brace daily to perform active, active-assisted, and gentle passive ankle and subtalar range-of-motion exercises. Patients with persistent swelling despite stable internal fixation and an anatomically reduced fracture often benefit from a knee-high medium compression stocking. Based on the fracture pattern, continue limited weight bearing for at least 6 weeks. Most fractures require limited weight bearing and protection for 12 weeks.

PITFALLS AND COMPLICATIONS

Complications may be loosely grouped into intraoperative (or technical) errors and early and late postoperative complications.

Technical mistakes typically involve failure to achieve anatomic reductions and failure to adequately stabilize the fracture. Articular incongruity and inability to restore the anatomic relationships of the ankle mortise increase the probability of postoperative pain and early posttraumatic arthritis (52). Failure to achieve stable fixation allowing for early range of motion leads to "fracture disease" and chondrolysis. Malreductions that have yet to result in significant levels of joint destruction are amenable to restorative osteotomies (55). Advanced ankle joint destruction often requires arthrodesis as a salvage procedure. Early total ankle arthroplasty results from newer generation ankle prostheses are an encouraging alternative to joint fusion.

Wound healing delays, nonunions, and infection following operative treatment of ankle and pylon fractures present a difficult challenge to the orthopaedic surgeon. Frequently, these postoperative complications stem from decisions made before and during operative treatment. Proper surgical timing, avoidance of undue soft-tissue and osseous devascularization, utilizing appropriate-sized implants, and adhering to principles of treatment of open fractures prevent the majority of these potentially disastrous complications. Even though operative treatment utilizing external fixation is usually considered safer than open techniques, complications can result from either treatment protocol. Superficial wound infections and breakdowns may be amenable to local wound care and oral antibiotics. Deep infection and full-thickness wound sloughs must be treated with aggressive debridements of devitalized tissue, full-thickness soft-tissue coverage, and intravenous antibiotics. Salvage following these grave complications may require extraordinary techniques such as free tissue transfer or bone transport procedures in order to achieve osseous union and restore limb length and function. Failure to eradicate deep infection or achieve union may necessitate a below-knee amputation.

AUTHORS' PERSPECTIVE

The complexity of surgery of ankle and pylon fractures is frequently underestimated, leading to pitfalls in treatment. Although various surgical modalities (internal fixation, external fixation) may be employed in the operative treatment of ankle fractures, ideal surgical treatment should produce anatomic restoration of the articular congruity of the tibial plafond and restoration of the ankle mortise with sufficient stability to allow for early joint motion. Each surgeon will choose different treatment
modalities in order to accomplish these goals. We routinely treat ankle and pylon fractures by open reduction and internal fixation. By protecting the soft tissues, operating during safe periods, preserving the osseous vascular supply, and utilizing appropriately sized implants, we have been able to avoid the majority of complications associated with ORIF. Other, less-invasive techniques may potentially minimize the risk of morbidity, but they often preclude anatomic restoration of the articular surface and prevent early restoration of ankle and subtalar motion.

A. NONUNIONS

DELAYED UNION

A healing fracture becomes a delayed union when it does not heal within the expected time after treatment. This very general definition reflects the multiple factors involved in determining when a fracture has become a delayed union. For example, a stable fracture of the distal radius in a healthy 33-year-old patient treated in a short-arm cast would be expected to heal by 6 weeks; if it does not heal by 12 weeks, it might be regarded as a delayed union. On the other hand, a displaced subcapital fracture of the femoral neck in a 70-year old treated with percutaneous cannulated screw fixation would be expected to heal in 6 months; it would be regarded as a delayed union if it had not healed by 6 months. Factors influencing the rate of union are the same as those that can lead to nonunion and are listed in Table 26.1.

Table 26.1. Causes of Nonunion

Clinical signs of delayed union are persistent pain, tenderness, and motion at the fracture site. Radiographic hallmarks of delayed union are persistence of the fracture line, hypertrophic callus with a persistent fracture line, and minimal or no callus production (Fig. 26.1). If internal fixation is present, fracture lines may be persistent or show evidence of resorption; there may be evidence of failure of fixation in the form of halos around screws, or there may be evidence of implant breakage.

The second most common cause of nonunion is loss of blood supply to the bone ends at the fracture site or in the surrounding soft-tissue envelope. High-energy trauma resulting in severely displaced fractures, particularly if they are open, can devascularize the bone ends by severe stripping of soft tissues from the bone, as well as by interruption of the medullary and extramedullary blood supply. Certain fractures have a higher incidence of nonunion due to anatomic factors in the vascular supply to bone that result in loss of blood supply to one or more of the major bone fragments. Typical examples are displaced subcapital fractures of the femoral neck, which result in avascular necrosis of the femoral head and nonunion of the femoral neck; fractures at the waist of the carpal scaphoid, which result in avascularity of the proximal pole and nonunion; and fractures of the neck of the talus, which can result in loss of blood supply to the body of the talus, particularly if associated with a...
Fracture treatment today, particularly in the multiply injured patient, involves the routine use of various methods of internal fixation for long-bone fractures, particularly in the lower extremity, and in periarticular and displaced intraarticular fractures. Inappropriate surgical techniques can lead to further devascularization of the bone through excessive soft-tissue stripping; obliteration of the intramedullary blood supply through reaming or the insertion of implants; necrosis of bone by overheating with power instruments; surgical interruption of major vessels that are critical sources of blood flow to bone, such as the medial circumflex femoral artery at the hip; and, finally, excessive coverage of bone surfaces with metallic implants, such as large double plates and intramedullary nail and plate combinations, which precludes revascularization of the bone. For the most part, these factors are under the control of the surgeon.

Infection, per se, does not cause nonunion, as union has been shown to occur in the presence of active infection (31). Uncontrolled infection, however, causes nonunion, predominantly because purulent material dissects under pressure within the intramedullary canal and along the subperiosteal surfaces of bone, resulting in bone necrosis. The inflammatory response to the infectious process may also lead to an excessive remodeling response causing osteolysis, which further slows the rate of union.

An anatomic cause of nonunion is the occurrence of a major gap in the fracture site, which precludes bridging by healing callus. Such gaps are most commonly caused by interposition of soft tissue, in particular muscle, as well as periosteum, tendons, and nerves. Gaps can also result from the wide displacement of intercalary fragments in closed fractures and actual loss of bone substance in open fractures, particularly from close-range or high-velocity gunshot wounds.

Many general and systemic factors affecting general health play a role in fracture union but are not causal factors per se. Evidence suggests that excessive intake of nicotine through tobacco consumption may, by its effect on the microvasculature, play a significant factor in predisposing to delayed union or nonunion. Other important factors include a fracture in a previously irradiated extremity, severe malnutrition, and the use of medications such as anticoagulants, steroids, and anticonvulsants. Age is a factor insofar as it leads to rapid and nearly always successful union in patients with open physeal lines and in particular in newborns where fractures can heal in a matter of days.

**CLASSIFICATION**

Factors that must be considered in the treatment of nonunions (Table 26.2) include the time elapsed since the original fracture or previous treatment, whether the nonunion is mobile or stable, and whether it is a synovial pseudarthrosis. The site, whether diaphyseal or metaphyseal, and the coexistence of shortening and angular or rotational deformity greatly influence treatment decisions, as does the presence of intact or broken internal fixation. It is, of course, critically important to know whether the nonunion is infected.

Whether the fracture is producing callus is a good indicator of its blood supply and potential for union, which is reflected in the Weber-Cech classification (101). This classification, proposed by Weber and Cech in 1976, is still the most useful system, although the presence of internal fixation, in particular intramedullary nails, makes it more difficult to use. They classified nonunions into two major groups based on whether the bone ends at the fracture site are vital—that is, whether they have a good blood supply. They examined plain radiographs to determine the amount of callus formation and correlated this with radioisotope studies to demonstrate the degree of blood supply (Fig. 26.4 and Fig. 26.5). Figure 26.4 shows vital nonunions, which have a good blood supply to both bone fragments and demonstrate various degrees of callus formation. Figure 26.4A is a hypertrophic, or elephant’s foot, nonunion, which is usually caused by mechanical instability. Increasing the mechanical stability of the fracture is often the key to healing. In addition, they are usually responsive to electrical stimulation. It is important, however, to differentiate hypertrophic nonunions from true synovial pseudarthroses. Plain tomodiography or computed tomodiography (CT) scans with sagittal or frontal plane reconstruction will often show a cyst in the center of the hypertrophic nonunion. An excellent test is a technetium bone scan, which will show increased uptake throughout the fracture site, but the center will be cold, as seen in the pseudarthrosis of a mid-shaft humerus fracture (Fig. 26.6). The other two types of vascular nonunions are the horse’s hoof (Fig. 26.4B) and oligotrophic nonunions (Fig. 26.4C). These nonunions form less bone, in part because of their lack of vitality, but this is also influenced by the bone they occur in and their location in the bone. The oligotrophic nonunion can be difficult to differentiate from the atrophic nonunion. This differentiation is important as the former has a much better prognosis as a result of its reasonably good blood supply.

**Figure 26.4.** Weber and Cech’s classification of pseudarthrosis. These are the vascularized, or vital, nonunions, which have the biological potential to heal. A: Elephant’s foot hypertrophy. B: Horse’s hoof. C: Oligotrophic (often mistaken for atrophy). (From Weber BG, Cech O. Pseudarthrosis. Bern: Hans Huber, 1976.)

**Figure 26.5.** Weber and Cech’s classification of pseudarthrosis. These are the dysvascular, or nonvital, nonunions, in which lack of blood supply, a gap, or another factor limits their ability to heal without biological intervention. A: Dystrophic (torsion wedge with butterfly). B: Necrotic (comminuted fragments). C: Defect (gap). D: Subtalar or ankle dislocation.

**Figure 26.5** shows avascular or nonvital nonunions. Weber and Cech (101) characterized two nonunions occurring in comminuted diaphyseal fractures as dystrophic or torsion wedge nonunions with a butterfly fragment (Fig. 26.5A), and necrotic (Fig. 26.5B) due to comminuted fragments. In both, there is a devascularized butterfly fragment, which in the first instance heals to one side of the fracture and then is partially revascularized. The opposite side then has a vascularized main fragment abutting a necrotic surface on a comminuted fragment. The intervening gap is usually filled with fibrous tissue. In the necrotic nonunion, the healing process fails on both sides of the comminuted fragment, which produces a devitalized gap. Both of these nonunions require efforts to induce revascularization of the devascularized areas, as well as good mechanical stability for revascularization, and bone grafting to bridge the fracture site.

A defect or gap nonunion (Fig. 26.5C) is caused by loss of bone from the fracture site. In children with open physes and in some adolescents who are just nearing the end of growth, large gaps may bridge through periosteal new bone formation. In adults, however, even gaps 5 mm or less may lead to nonunion, particularly in the presence of intramedullary nails. To achieve union, gaps must be filled with bone or bone apposition achieved. Alternatives include Ilizarov segment transport, direct autologous bone grafting, allografts, or osteoconductive materials such as coralline hydroxyapatite, usually combined with a bone-inductive medium such as bone marrow, stem cells, or bone-inductive proteins.

The atrophic nonunion (Fig. 26.5D) is particularly difficult to treat because not only does it have a poor blood supply but a gap is often present. Bone quality may be poor, and it would appear that there is an active osteoclastically mediated resorption process, which in some cases is related to an underlying systemic disorder such as neurofibromatosis. This is the most common type of congenital nonunion. Dysplastic tissues in the nonunion site preclude successful long-term formation of bone capable of withstanding mechanical stress.

Infected nonunions must be recognized. A history of prior infection is important, but if the nonunion site shows no local signs of infection and there has been no active drainage for 6 months or more (particularly if the previous infection was caused by an antibiotic-sensitive organism that was successfully eradicated), then operative intervention can usually proceed. Nonunions with active signs of infection, however, usually require eradication of the infection first, with thorough irrigation and debridement, removal of all devitalized bone, good stability (usually with an external fixator), and achievement of good-quality, full-thickness soft-tissue coverage. It is possible to achieve union in the presence of active infection, but usually it must be eradicated before proceeding with treatment (54).

**PRINCIPLES OF TREATMENT**

**OBJECTIVES AND RATIONALE**

The primary objective in the treatment of nonunions is to achieve solid union of the fracture site, one that will endure and allow the patient to regain a good level of function. The latter requires that the limb be left with little or no shortening or malalignment, and that sufficient joint range of motion, muscle strength, and neurovascular function be restored that the limb is useful to the patient. If these objectives are reached, but the patient continues to have chronic disabling pain, then treatment may have been fruitless. The primary source of pain in most cases, however, is the nonunion itself. Healing of the nonunion usually resolves any pain problems. Reflex sympathetic dystrophy may be a problem in some patients, particularly if there is an associated neurologic injury, and especially one involving the brachial or lumbosacral plexus.

Longstanding nonunions subjected to repeated surgeries can lead to permanent long-term disability in the limb resulting from muscle atrophy and joint stiffness. If this interferes with the patient's return to work and resumption of a normal lifestyle, significant socioeconomic consequences can occur. This must be taken into account when proposing treatment for nonunions. Listen carefully to the wishes and needs of each patient, and understand his treatment objectives. For example, the best solution for a sedentary individual with a longstanding, infected nonunion of the tibia with shortening and deformity and poor function of the foot might be a below-the-knee amputation, if a good-quality, satisfactory stump can be obtained.

**DIAGNOSIS**

Take a meticulous history of the present illness to characterize the nature of the original injury and the initial treatment, as well as all subsequent efforts to repair the nonunion, including the outcomes of these procedures, and complications. Particularly important is to establish whether infection has occurred at any time. Rule out any potential systemic aggravating factors that could possibly be treated, and review habits—in particular, tobacco use. There is substantial evidence that tobacco interferes with fracture healing and may predispose to nonunion, so it is prudent to try to persuade smokers with nonunions to stop smoking. Social history is important, as many operative procedures require a responsible, cooperative patient who will follow instructions and engage vigorously in a rehabilitation program.

The most typical complaint about the nonunion itself is pain in the fracture site, which is often severe and aggravated by motion or weight bearing. Ask patients whether they feel motion in the fracture site, as this may be an important clue. The direction in which they feel that motion or the mechanism of producing it may also be helpful. Perform a thorough physical examination, with a complete review of systems, to be certain that the patient can handle the major surgery often required for nonunions. Evaluate the other components of the musculoskeletal system to discover other disorders that must be treated prior to, or concomitantly with, the nonunion to obtain a successful outcome.

In the physical examination, the pathognomonic sign of nonunion is motion in the fracture site, occasionally accompanied by crepitus. Some nonunions are grossly fluid, but with internal fixation in place the detection of motion may be subtle. It is important to look for just a jiggle of motion in the fracture, which may occur in only one plane. This requires careful, meticulous, delicate examination with the fingertips, trying to elicit motion in all planes. If elicited, this is diagnostic regardless of the radiographic appearance. Extremely stable fibrous nonunions, and some nonunions in the presence of internal fixation, may have no motion in the fracture site.

Thoroughly evaluate limb alignment, joint range of motion, muscle strength, and neurovascular status. Accurately document shortening. This information is essential to planning an operative approach that will address all problems and provide the maximum opportunity for returning function to the limb.

**IMAGING**

Plain radiographs in the anteroposterior (AP) and lateral planes, including the joints above and below the fracture site, are the minimum required. Oblique views are useful for detecting nonunions that are not in the plane of AP and lateral radiographs (Fig. 26.7). The key to diagnosis on plain films is placing the nonunion in line with the central beam of the radiograph. This often requires examination under fluoroscopy, rotating the limb until the fracture site is clearly seen and then taking a plain film. Tomograms are less useful today because of the x-ray scatter produced by often-present implants. CT scans with reconstruction in various planes are very useful, particularly for fractures in metaphyseal and juxtaarticular areas. I do not use magnetic resonance imaging (MRI) often in the evaluation of nonunions, but it is occasionally useful in intrarticular nonunions. Use technetium bone scans to rule out synovial pseudarthrosis in hypertrophic nonunions for which you are contemplating treatment with either electrical stimulation or closed intramedullary nailing (23). The former is not useful in the presence of synovial pseudarthrosis, and
the latter may cause you to open the fracture and perform a bone graft in addition to placing the intramedullary nail. I rarely use other types of scintigraphy to rule out infected nonunions, as this does not change my surgical approach in the vast majority of cases.

**Figure 26.7.** Nonunion of the lateral condyle of the femur. This series of radiographs shows how difficult it is to detect some nonunions, and it demonstrates the importance of having the central beam of the x-ray exactly in line with the axis of the nonunion. A: AP view suggests the presence of a problem because there is partial unhealed fracture in the epicondylar area. Nonunion cannot be seen. B: Lateral view demonstrates apparent union. C: Oblique view likewise appears to show union of the condyle. D: Opposite oblique view shows clearly a well-established, stable fibrous nonunion of the medial condyle.

### NONOPERATIVE TREATMENT

#### CAST AND BRACE IMMOBILIZATION

There is little role today for cast and brace immobilization alone in the treatment of nonunions, although a functional, weight-bearing cast or brace may be useful for a delayed union of a closed tibial shaft fracture (83). Simple, continued application of a well-fitted cast or brace combined with functional weight bearing in the absence of a prematurely healed fibula, which is preventing compression of the fracture site, may suffice. An oblique osteotomy of the fibula may be useful in some circumstances to allow the fracture to compress with weight bearing.

#### ELECTRICAL STIMULATION

Yasuda (105) first demonstrated that electricity can induce or stimulate new bone formation. He observed that 1 microampere (µA) of constant direct current applied to a rabbit's femur by Vitalium needle electrodes inserted through the cortex into the medullary canal produced new bone formation, particularly in the vicinity of the negative electrode, or cathode. Since that first report, many investigators have demonstrated that electricity in its various forms—direct current, inductive coupling or pulsed electromagnetic fields (PEMFs), and capacitive coupling—can induce new bone formation using the proper electrical parameters (2,4,7,13,28,29,32,46,55,63,94). In tissue and bone cells, the initial response to electricity is increased bone cell proliferation and no change in or decreased matrix production and alkaline phosphatase activity (13,26,27,47,61,62,66,85,86,93). Later, matrix production increases and matrix calcification is stimulated or increased (18,27,66).

The actual cellular mechanism of electrically induced osteogenesis is not completely understood. Intracellular calcium and cyclic adenosine monophosphate (cAMP) have been shown to increase in some studies, but the results are neither significant nor consistent enough for intracellular calcium or cAMP to be considered the primary intracellular messenger of an extracellular electrical signal (12).

The physics involved in electrically stimulating bone formation is different for each of the three methods. The direct current method is the most complex, possessing electric, chemical, and mechanical effects, all of which may stimulate new bone formation. A constant direct current of 20 µA is applied to the electrodes, with the cathode located in the bone site and the anode located in the adjacent soft tissue or on the surface of the skin (Fig. 26.8). The electric current flowing between the electrodes probably is the predominant stimulus of the new bone formation. However, a chemical reaction also occurs at the electrodes, in which molecular oxygen is consumed and hydroxyl ions are produced, given the proper parameters of current and voltage (8,11):

\[
2H_2O + O_2 + 4^e \rightarrow 4OH^- 
\]

This lowers the local microenvironmental Po<sub>2</sub> (6,7) and raises the local pH. Both of these changes favor bone formation. Bone grows best in low Po<sub>2</sub> (6,7) (35–40 mm Hg) and when the pH at the bone–cartilage junction in the growth plate is alkaline (pH 7.7), which favors calcification (14,15,39). Mechanical effects from the trauma of inserting the cathode and postinsertion movement of the cathode may also stimulate osteogenesis in the direct current method (26).

In inductive coupling or PEMFs, there are an electric effect and a magnetic effect. A time-varying electric field is applied to a pair of matched coils placed on opposite sides of the extremity of interest, or to a single, flexible coil bent to conform to the extremity. The time-varying electric field applied to the coil(s) induces a time-varying magnetic field between the coils, and this induces a secondary time-varying electric field in the tissues, including bone, placed between the coils (Fig. 26.9). The configuration of the PEMF used for nonunions is shown in Fig. 26.10.

**Figure 26.8.** Application of direct current (DC) to the fracture site of a nonunion. The negative electrode or cathode is inserted percutaneously.

**Figure 26.9.** Application of inductive coupling or pulsed electromagnetic fields to the fracture site of a nonunion.
Technique for Pulsed Electromagnetic Fields

Relative contraindications include the following:

- Nonunion of the humerus, because of the high incidence of synovial pseudarthrosis and the difficulties in achieving adequate immobilization of the fracture
- Nonunion of the diaphysis of the radius or the ulna, if prolonged immobilization in a long-arm cast will result in permanent loss of functional motion
- Nonunion of the shaft of the femur, because of the high incidence of synovial pseudarthrosis and the difficulties in adequately immobilizing the femur
- Any nonunion with unacceptable deformity that requires surgery for correction

**Technique for Pulsed Electromagnetic Fields**

- Apply a well-molded cast to immobilize the nonunion.
- Position the flexible coil over the nonunion site so that the entire site is within the “window” of the coil.
- Confirm the location of the coil with radiographs and secure it with Velcro straps. Incorporate the coil into the cast with an additional wrap of casting material if the patient is likely to be noncompliant (Fig. 26.12).

---

**Figure 26.10.** The inductively coupled signal used for treating a nonunion. **A:** Dimensions of a single pulse. **B:** Dimensions of a pulse burst.

In capacitive coupling, there is only an electric effect; the magnetic field associated with capacitive coupling is negligible. A time-varying electric field is applied to a pair of electrodes placed on the surface of the skin on opposite sides of the injured extremity. The time-varying electric field applied to the electrodes produces a time-varying electric field in the tissues, including bone, between the electrodes (Fig. 26.11). The signal used in treating nonunions is a symmetrical sine wave with a peak-to-peak amplitude of 5 V and a frequency of 60 kHz. This produces in the fracture callus an average electric field of 80 mV/cm, with a range of 20 to 150 mV/cm, depending on the size of the limb and amount of fat in the extremity. The corresponding values for the current densities in the callus average 160 µA/cm², with a range of 40 to 300 µA/cm². These values for the electric field and current density produced in the fracture callus with capacitive coupling are probably similar to those generated by inductive coupling.

**Figure 26.11.** Application of capacitive coupling to the fracture site of a nonunion.

The only effect all three treatment modalities have in common is the electric effect, and it is assumed to be the dominant effect in each of the methods of treating nonunion with electricity.

Noninvasive electrical stimulation is indicated for any delayed union or nonunion in which operative intervention is not absolutely required to obtain adequate reduction and fixation, to remove a synovial pseudarthrosis, or to fill a large bone defect (e.g., a gap at the fracture site that is greater in width than the radius of the bone at that level). If a delayed union or nonunion is already held in good position and in alignment from a previous internal fixation, or if the delayed union or nonunion can be held adequately in good position and alignment by appropriate cast immobilization, and if there is no large gap or synovial pseudarthrosis, treatment with noninvasive electrical stimulation may be indicated.

In my practice, the most common indication for electrical stimulation is a delayed union in good position, particularly of the diaphysis of the tibia or femur. Most typically, these are fractures that occurred in patients with multiple injuries, or they were open fractures that were treated initially with nonreamed, locked, intramedullary nail fixation. For that reason, they are in good position, but the magnitude of the initial injury, combined with the less stable fixation offered by a small nonreamed nail, leads to delayed union. If at 12 weeks after injury, there is no evidence of callus formation and the fracture site is still clearly visible, then the chances of going on to a nonunion are significant. This could lead to implant failure, angulation, and the necessity for surgery. At that time in the treatment, I typically offer my patients the opportunity for operative intervention, usually in the form of an exchanged, reamed, locked nailing or noninvasive electrical stimulation if they do not wish to undergo surgery.

Other indications for electrical stimulation include fractures in acceptable alignment, which can be adequately immobilized in functional casts or braces in patients who have significant contraindications to surgery, such as coexisting infection, poor-quality soft tissues, or severe systemic illness.

Contraindications to noninvasive electrical stimulation for treating nonunion include a large gap at the fracture site and synovial pseudarthrosis (25). Brighton (16) states that a large gap occurs in approximately 5% of all nonunions, and synovial pseudarthrosis in approximately 12%, particularly in the humerus and radius. He defines a large gap as one that is equal to or larger than the diameter of the cortex at the site of the nonunion. He cites severe osteoporosis as a relative contraindication, as it lowers the union rate with electrical stimulation to 25% or less. He defines osteoporosis as occurring when the combined thickness of both cortices adjacent to the fracture site is equal to less than 20% of the diameter of the bone at that level as measured from plain radiographs. Osteomyelitis in the nonunion site is not a contraindication, as Brighton (15) reported a 58% union rate in 102 nonunions in the presence of osteomyelitis.

Relative contraindications include the following:

- Nonunion of the humerus, because of the high incidence of synovial pseudarthrosis and the difficulties in achieving adequate immobilization of the fracture
- Nonunion of the diaphysis of the radius or the ulna, if prolonged immobilization in a long-arm cast will result in permanent loss of functional motion
- Nonunion of the shaft of the femur, because of the high incidence of synovial pseudarthrosis and the difficulties in adequately immobilizing the femur
- Any nonunion with unacceptable deformity that requires surgery for correction

---

**Figure 26.12.** Dimensions of a pulse burst.
Connect the cable from the coil to the control unit, which can be worn on a belt or carried with an adjustable shoulder strap.

- Ideally, treat for 10 hours daily. The minimum use per day is 3 hours, but fracture healing will be slower.
- Encourage full function of the limb within the limits of the cast, including full weight bearing, unless motion of more than 5° of angulation will be induced at the fracture site.
- Examine and x-ray the fracture at 6-week intervals. If at 12 weeks the fracture is not yet healed but is showing evidence of progressive healing, continue treatment until healed. If at 12 weeks or later there is no evidence of progress toward healing, then change treatments. If a bone graft is done, consider combining it with an implantable stimulator.

Technique for Capacitive Coupling

- Apply an appropriate plaster or fiberglass cast to immobilize the nonunion. At the level of the nonunion site, cut two 1/2-inch-square windows in the cast opposite each other with a cast saw. Place the windows 180° ± 20° to each other at the level of the nonunion, ±4.5 cm. Exact alignment of the windows on radiographs is necessary.
- Cut out the padding and stockinet under the windows. Peel the backing liner off each electrode, and place them on the skin centrally, one in each of the windows. Depending on the thickness of the cast, place an appropriate spacer over one or both of the electrodes to fill the gap in the cast to prevent window edema. To prevent a pressure sore, do not extend the spacer above the surface of the cast (Fig. 26.13A).

Implanted Bone-Growth Stimulator

- Place an adhesive-backed fastener strip along the long axis of the cast between the windows. Apply a cast wrap around the cast over the fastener strip, and secure it with a cast wrap fastener (Fig. 26.13B). Extend the leads from the electrodes to the power supply, fastened to the cast itself or to a belt clip to be worn on a belt at the waist (Fig. 26.13B, Fig. 26.13C).
- Monitor the power supply with the appropriate test meter, initially and at each office visit. Have the patient replace the 9 V alkaline battery daily and change the electrodes weekly.
- If the nonunion is in the lower extremity, use a weight-bearing cast unless there is more than 5° of motion at the fracture site. If there is more than 5° of motion, use a non-weight-bearing cast until motion is less than 5° (13), at which time a weight-bearing cast can be used.

Identify a site for the generator, which must lie at least 5 cm away from the cathode and beneath the deep fascia. Sometimes this can be placed percutaneously through the surgical site of the nonunion. If not, make a 3-cm-long skin incision over the desired location for the generator, incise the deep fascia, and then use an obturator or a Metzenbaum scissors to dissect between the nonunion and the generator site. Place the generator into the wound beneath the deep fascia and pass the lead wire down to the nonunion site. Be certain that this route is straight, as it simplifies eventual removal, but leave some laxity in the line so that motion of the joints adjacent to the operative site does not cause tension on the wire (Fig. 26.13B, Fig. 26.13C).

Using the cylindrical plastic guide provided with the stimulator, measure the width of the defect in the tibia and wind the titanium electrode around the guide to produce a helix big enough to completely bridge the width of the canal at the point of the nonunion. Place the generator into the wound beneath the deep fascia and pass the lead wire to the nonunion site. Be certain that this route is straight, as it simplifies eventual removal, but leave some laxity in the line so that motion of the joints adjacent to the operative site does not cause tension on the wire (Fig. 26.13B, Fig. 26.13C).

- Connect the lead to the coil, placing the connector away from the bone so that it will disconnect when the generator is later removed.
- Postoperatively, if internal fixation has not been used, immobilize and proceed as discussed for noninvasive electrical stimulation. If implants are present, follow the postoperative treatment appropriate for the implant used. This device cannot be used with intramedullary implants, as there would be no place to locate the cathode. The generator usually remains active for up to 1 year. After that time, remove the generator by making an incision directly over it and pulling gently in

Figure 26.12. Inductive coupling. A: The connector mounting assembly is positioned near the coil. (Newer models do not require this.) B: The flexible coil and mounting assembly can be incorporated into the cast.

Figure 26.13. Capacitive coupling. A: One self-adhering, flexible electrode is in place on the skin in one window, and the backing is partially removed from another electrode before its placement on the skin through the second window. B: After the electrodes are in place and connected to the appropriate leads, a cast wrap is placed around the cast and secured over a self-adherent fastener strip. C: The leads extend from the electrodes to the power supply.

General surgical techniques that apply to plate fixation and bone grafting in all sites are as follows: autologous bone graft is applicable to all types of nonunions. Conductive as freshly harvested graft; therefore, I harvest iliac crest bone graft in the vast majority of nonunions that I plate. Plate and screw fixation combined with either to correct deformity or to create a site for the plate, often provides sufficient bone graft. This bone is frequently sclerotic and not nearly as bone inductive or bone that I treat with plate and screw fixation. In hypertrophic nonunions and in the occasional horse’s hoof nonunion, reduction of the bony callus for cosmetic reasons, (PLATE FIXATION WITH OR WITHOUT BONE GRAFT)

The type and location of bone graft harvest is determined by the needs of the nonunion. The bone graft required may vary from a small amount of pure cancellous posteromedial or posterolateral approach, using continued weight-bearing cast immobilization for stabilization. This approach is discussed in detail in Chapter 8, Chapter 35, and Chapter 36. The thought process applied to each of the implant possibilities and bone grafting are discussed next.

SURGICAL TREATMENT

PREOPERATIVE PLANNING

The first step in preoperative planning for the treatment of nonunions is a thorough evaluation of the patient, and of the nonunion and the alignment of the limb segment involved, which together lead to the decision to operate. If there is coexisting malalignment, shortening, or joint stiffness that requires surgical treatment as well, then the preoperative planning can be fairly complex, as the methods for correcting each of these deficiencies must be taken into account. The basic principles in reestablis...
Position the patient so that the appropriate iliac crest or other bone graft can be harvested without having to reposition or reprep and redrape the patient. When large amounts of graft are needed, the best source is the posterior iliac spine, which is most easily harvested in the prone position but can also be harvested from the uppermost crest in the lateral decubitus position. When the nonunion must be treated in the supine position, the graft of necessity will need to be harvested first.

When exposing nonunions for plate fixation and bone grafting, try to minimize subperiosteal stripping of the bone in order to preserve its blood supply. Application of a plate and bone graft usually requires exposure of only 50% of the overall circumference of the bone. Try not to use retractors that result in additional stripping.

Once the nonunion is exposed, remove any existing hardware, which will interfere with treatment of the nonunion.

In very stable, fibrous nonunions where there appears to be good blood supply to the bone ends [as demonstrated by punctate bleeding (paprika sign) when the cortex is shaved with an osteotome], a takedown of the nonunion site is usually unnecessary, as the fracture will normally heal with compression plate fixation combined with onlay bone grafting.

Where there is a synovial pseudarthrosis, if deformity needs to be corrected, or if there is an unstable, loose, fibrous union, remove all scar tissue in the fracture site, freshen the bone ends, and shape them to optimize cortical contact. Open the medullary canal fully on both the distal and proximal fragments.

When debridging fracture sites, take appropriate soft-tissue and bone cultures. Unless frank purulence is encountered, I have not found Gram stains to be useful. Do not administer preoperative antibiotics until these cultures are taken. Once cultures are taken, administer appropriate intravenous antibiotics.

Apply a plate to the fracture, incorporating interfragmentary screw fixation across the fracture site if possible. Whenever possible, I try to use an independent interfragmentary lag screw so that interplanar fixation is obtained. In the diaphysis of the large long bones such as the humerus, femur, and tibia, use broad plates; such as the forearm and fibula, use a 3.5 mm plate or the equivalent.

For nonunions, I tend to use plates somewhat longer than I would for the initial fracture, placing at least four solid bicortical screws in each fragment.

After the initial plate and interfragmentary screw fixation have been completed, carefully stress the fracture site under direct vision and examine for micromotion. If gaping in the fracture site occurs with stressing of the plate with your hand in the plane of the plate, supplemental fixation is needed. If the surgical situation precludes the addition of a second plate, then plan to use cast or brace immobilization postoperatively. In most cases, I apply a second plate at right angles to the initial plate, which is smaller in overall dimensions and shorter than the primary plate to avoid excessive stress protection at the fracture site, and to avoid a stress riser at the end of the plate. These supplemental plates can usually be applied with minimal additional exposure because they serve as tension bands to eliminate micromotion in the fracture site and therefore do not need to be large.

Petel the cortex with a small osteotome for a distance at least equal to the diameter of the cortex on that point on the proximal and distal fragment, and then apply a solid layer of cancellous and/or cortical cancellous iliac crest bone graft along this exposed surface. It does not good to apply a bone graft over the top of the plate. Try to apply it on both sides of the plate construct if this can be done without excessive soft-tissue stripping.

Perform a meticulous closure of the wound. A suction drain is nearly always advisable.

Prior to closure, carefully examine the nonunion site and the joints above and below to determine how much motion can be allowed without placing excessive stress on the nonunion site.

POSTOPERATIVE CARE

Take this assessment of allowable motion into account when designing the postoperative rehabilitation program. In a femur, for example, if full extension and flexion to 90° cause micromotion at the fracture site, plan to place the patient immediately after surgery into a functional brace that will limit extension to 10° and flexion to 80°. Continue this protection until bridging callus is seen across the nonunion site and it is stable and non tender to clinical examination.

In extensive procedures, swelling can be a problem, resulting in blistering of the skin and even compartment syndrome. In most cases, a bulky, well-padded splint postoperatively is important to allow for swelling. Elevate the limb 10 cm above the heart and observe it closely for swelling, which may require intervention.

After the risk of swelling has abated and the patient is more comfortable, replace the bulky dressing with a light dressing or functional cast or brace as indicated. Begin a joint range-of-motion and strengthening program as soon as possible, taking into account the limitations of the strength of the construct used to repair the nonunion. In all cases of plate fixation in the lower extremity, weight bearing must be limited to the weight of the limb until bridging callus across the nonunion site is seen on two radiographic views.

Continue intravenous or oral bacteriocidal antibiotics until the cultures are negative. If cultures are positive, continue antibiotics for at least 6 weeks. I find consultation with an infectious disease specialist helpful in determining the type and length of antibiotic therapy.

INTRAMEDULLARY NAILING

Intramedullary Nailing as a Primary Procedure

Locked intramedullary nailing is most useful for nonunions in the mid diaphysis in the tibia and the femur, however, it has been used in many bones including the malleoli (55). It is not technically feasible in the femur and does not work nearly as well as plates in the humerus. Closed technique is particularly advantageous, but it is usually difficult to perform in nonunions because the medullary canal is sealed and callus at the fracture site makes aligning the canal without opening the fracture exceedingly difficult. Primary intramedullary nailing, therefore, usually requires that the nonunion site be opened and the intramedullary canal reestablished and realigned.

Use an AO distractor in compression, or another device to compress the fracture site and lock the nail statically in compression. This eliminates micromotion in the fracture site and results in immediate relief of pain. If there is contact of 50% or more of the cortical surface between the proximal and distal fragments, weight bearing can progress rapidly if a large nail with 4.5 mm or larger transverse locking screws is used. I no longer treat nonunions with dynamic nails, as they tend to leave instability in the fracture site, particularly in rotation, which lowers the likelihood of union in spite of weight bearing. If a nonunion is opened for reamed intramedullary nailing, collect the reaming materials and apply them around the fracture site for a bone graft. Bone defects and avascular nonunions require autologous bone graft from the ilium as well.

Nail Dynamization

Nonunions can occur with intramedullary nails in place. Since the advent of interlocking nails, most of these occur in the presence of static interlocking. The nonunion occurs either because of the severity of the original injury, or because some factor in the original nailing resulted in devascularization of the fracture site, or because the fracture was nailed with a gap as a result of either bone loss or inadvertent distraction of the fracture site. In some atrophic nonunions, it appears that an osteoclastic response at the fracture site results in resorption of bone, which also produces a gap.

Dynamization of the nail—that is, removing the cross-locking screws from one or both ends of the nail and then allowing the patient to bear weight on the nail—has been advocated as a method to eliminate the gap and stimulate union. Although this is a very simple method and can lead to union in a significant percentage of cases, it may not work in the tibia if the fibula has healed and maintains distraction, or if weight bearing does not stabilize the fracture and rotary instability continues. Another concern pertains to the risk of moving a screw that is already controlled by a cross-locking mechanism. With the opposite cortex, assuming that this will not cause painful soft-tissue impingement in the event that removal of a broken screw is required. If the broken section of screw is buried, then removal requires overdrilling the broken segment with a hollow mill-reamer designed for screw removal under fluoroscopic control. This often leaves a fairly large hole in the bone. When repeat nailing is done, try to place the nail beyond this hole to avoid a stress riser at the end of the nail.

Exchange Nailing

Today, small diameter nails are frequently placed, either without reaming or with minimal reaming, to fix fractures of the tibia, the femur, and occasionally the humerus, particularly in patients with severe multiple injuries or open fractures. Occasionally, the result is a nonunion with breakage of the nail or screws. In these cases, exchange nailing is more difficult, and special techniques for removal of broken nails and screws are required.

Removal of Broken Screws

The section of the screw with the screw head is easily removed with the appropriate screwdriver. To remove the opposite side of the screw, make an incision directly over the tip of the screw and expose it. If sufficient screw tip is exposed, it can be removed with commercially available screw removal instruments or grasped with a pair of locking pliers when performed from the contralateral limb. Then perform a subchondral osteotomy from the opposite cortex, assuming that this will not cause painful soft-tissue impingement in the event that removal of a broken screw is required. If the broken section of screw is buried, then removal requires overdrilling the broken segment with a hollow mill-reamer designed for screw removal under fluoroscopic control. This often leaves a fairly large hole in the bone. When repeat nailing is done, try to place the nail beyond this hole to avoid a stress riser at the end of the nail.
Removal of Broken Nails

The difficulty encountered in removing broken nail segments depends on the type of nail—whether cannulated or solid—and where the break occurs. In the femur, typical locations for nail failure are (a) through the proximal cross-locking holes at the distal end of the two proximal cross-locking holes where transverse locking screws are present, (b) in the midportion of the nail at the fracture site, or (c) in supracondylar fractures through the more proximal of the two distal transverse cross-locking holes. If failure occurs through the proximal half of the nail, then removal of the proximal portion is easily accomplished with the standard nail removal instrumentation. An “easy out” (a T-handled instrument with a tapered, spiral-threaded tip), if it is long enough, can be used to remove the distal portion after removal of the distal cross-locking screws.

Another technique that also works well is to place a ball-tipped reaming guide into the distal segment of the nail, with the ball-tip outside the tip of the nail, and then to drive a second guide down the inside of the nail to jar the first guide. Alternatively, a vice-grip pliers or a T-handled pin holder facilitates removal. A third technique, one that I have used successfully on a number of occasions, is to fashion a hook from a coat hanger at home in my workshop using a duplicate of the nail to make certain that the hook is ideally shaped for hooking the distal end of the nail. This is sterilized and then used in a fashion similar to the jammed guide pin technique. As a last resort, a small window can be made in the bone just below the distal end of the nail, the broken nail segment is then driven proximalward to be grasped and removed. Usually, the plan is to place a larger reamed nail for fixation. In this case, it is quite helpful to first ream the proximal canal to a larger diameter to facilitate manipulation of the instruments and removal of the broken nail segment.

When doing reamed exchange nailing, I always try to use the largest nail feasible for the bone involved to ensure adequate strength of the implant, to improve cortical contact and therefore stability, and to produce as much reaming material around the fracture site as possible.

As discussed in the next chapter on nonunions in the upper extremity, I no longer use intramedullary nails for the treatment of nonunions of the humerus. The simple exception is when there is a nonunion with an intramedullary nail already in place. In these cases, closed reamed interlocked intramedullary nailing avoids opening the fracture site; in the few cases I have done this, it has worked 100% of the time. A contraindication to this technique is severe osteoporosis because of the high risks of fracture of the humerus and failure to obtain an adequate hold with cross-locking screws.

Ilizarov Techniques

Ilizarov techniques are discussed in detail in Chapters 132. Therefore, this discussion about the use of distraction compression techniques for the treatment of nonunions will be brief.

Ring fixators with tensioned wires and half-pins are indicated for nonunions that are accompanied by severe shortening and require concomitant lengthening; nonunions in which there is major bone deficiency that can be replaced only by segment transportation; and nonunions where there is severe bone deformity and/or soft-tissue contractures, which are best treated by Ilizarov techniques (17,36,37,38 and 39,90).

Ilizarov demonstrated that distraction at the appropriate rate and frequency results in osteogenesis, which can induce fibrous nonunions to heal. This will not work in metaphyseal pseudarthroses, which must be ruled out by a technetium bone scan, and it does not appear to be efficacious in atrophic nonunions. The technique utilized at the nonunion site to distract the nonunion approximately 5–10 mm and then to compress it, and to repeat this sequence until new bone formation is elicited, at which time the nonunion site is placed into compression. Throughout this process, the patient is encouraged to bear full weight to induce physiologic stress across the nonunion site, which also helps stimulate bone formation. This rate of distraction in North America has been sufficiently low so that for most surgeons it is not the distraction rate that is the major factor in nonunion healing, but rather the bone stock and the surgical approach. Several surgical techniques are not suitable or are contraindicated, as discussed previously. In addition, in gap nonunions where segment transport is used to close a gap, union at the site between the transported segment and the static segment tends to be quite slow; therefore, most surgeons bone graft the junction site to accelerate union.

Postoperative Care

Postoperative care differs considerably with the technique, so it is discussed in detail with each of the techniques in the next three chapters. In general, however, the most difficult decision to be made with regard to the patient’s rehabilitation program, particularly with the manipulation of joints, resistive exercises to build muscle strength, and weight bearing, because all three rehabilitation activities stress the implants and nonunion site. Active range of motion protected by braces is not used in North America, although this technique has produced good results in South America. However, for all procedures, some kind of passive range of motion is necessary, which can be initiated immediately postoperatively. The choice of whether to use a brace, tourniquet, or both is dependent on the fracture site and the surgeon’s preference. For example, in the above-the-knee procedures, the tourniquet is usually used; the patient’s leg is placed on a small table, and the thigh is encircled with an elastic bandage. Active range of motion is performed at regular intervals, and the speed and range are gradually increased. When the patient is able to perform a full range of motion without pain and has regained some of the strength of the involved extremity, the patient is allowed to begin active range of motion exercises, which are gradually increased.

Union at the nonunion site can often be very difficult to judge, particularly with plates, because if the reconstruction has been done well the fracture site can often not be seen on the immediate postoperative films. It can be helpful to establish intraoperatively which particular view shows the fracture site best by examining it under fluoroscopy. This view can then be used postoperatively to monitor trabeculation and obliteration of the nonunion site. Otherwise, monitoring the consolidation of the onlay bone graft usually provides the best guide to union. Early union is heralded by bridging callus along the surface of the nonunion seen on at least two 90° opposed views. Full union is characterized by obliteration of the fracture line, and increased maturation and density in the periosteal new bone to resemble that of the nearby cortex. In any case, stable union usually requires a minimum of 3 months and often 6 months or more. This is particularly the case in closed intramedullary exchange nailing and where previous plate fixation has been converted to an intramedullary nail.

HINTS AND TRICKS

With plate fixation, obtaining secure purchase of screws in bone that is osteoporotic in longstanding nonunions or in the elderly can be difficult. I have found the following techniques to be useful:

- In cancellous bone with an overlying thin cortical shell in metaphyseal and epiphyseal areas, place large cortical screws without tapping, to compress the cancellous bone around the screw and provide more threads for purchase in the cortical bone than cancellous screws do.
- In metaphyseal areas, use small-fragment double plates placed at 90° to each other to provide a sandwich effect, which adds stability.
- Avoid excessive periosteal stripping, as this has the risk of excessive devascularization.
- When inserting cortical screws in this application, run the screws from the two 90° plates close to each other so that the threads of the screws cross-engage; this often provides purchase where it would otherwise be nonexistent.
- When these measures fail, and the screws still have inadequate contact and therefore stability, inject liquid methylmethacrylate into each screw hole and then reinsert the screw while the cement is soft. This usually provides solid fixation. Do not allow the cement to enter the fracture site or the joint.
- In the diaphysis, injecting cement into the screw hole usually does not work well, because the cement tends to run into the medullary canal or into the fracture planes and not into the bone. As a technique to keep the cement from running out in an exchange nailing for bone transport, I will pack cement that is in the doughy phase into the medullary canal where the screws will be placed, keeping it well away from the fracture site. Once the cement is set, it can be drilled and tapped. Screw fixation is usually superb.

Another technique that is markedly devascularizes the cortex and absolutely precludes restoration of the medullary blood supply.

- Heating in these cases is totally dependent on the periosteum and surrounding soft tissues. It cannot be assumed that the fracture itself will heal, so a copious onlay bone graft must be done in the hope that this will result in good union. If this fails, then prosthetic replacement with a specialized prosthesis may become necessary.

- Other alternatives include the intramedullary plate discussed in Chapter 30 and the use of autologous or allograft cortical struts. The latter are more successful and more readily available. Place these struts in the intramedullary canal, or better yet, on the cortex opposite the plate, and insert the screws into the allograft. Backup nuts and washers can also be used, but they tend to crush osteoporotic bone unless an allograft strut is utilized.

Infected Nonunions

The principles of treatment and management of infection and management of acute and chronic osteomyelitis, pyarthrosis, and infected implants is discussed in detail in Chapters 133, Chapter 134, and Chapter 135. Always attempt to control infection before treating the nonunion, unless it is obvious that this is not possible. In an infected nonunion of the tibia, for example, perform a thorough debridement of the nonunion site, including the fistula tract and scarred soft tissue, and remove all necrotic and infected tissue and bone. Stabilize with external fixation and monitor with appropriate laboratory tests. If infection cannot be controlled, soft-tissue procedures such as local rotation musculofascial flaps or free microvascularized flaps may be necessary to revascularize the nonunion site and to provide a good environment for future operative intervention (44,76,102,103). In 8–12 weeks, if there are no systemic or local signs of infection and the wound has been clean and dry for at least 6 weeks, decide whether treatment of the nonunion will be carried out with an external fixator or by conversion to internal fixation with bone grafting.
Bone grafting in the presence of continued positive cultures in a wound that is under control is possible, but this is the exception rather than the rule. If the patient has a difficult organism, such as a drug-resistant enterococcus, treatment of the nonunion in the external fixator is indicated. Copious bone graft should be applied and the external fixator checked and revised if necessary to ensure excellent stability. If conversion to internal fixation is deemed necessary, it is usually advisable to remove the external fixator and to apply an appropriate cast to allow the pin tracks to heal prior to surgery.

B. MALUNIONS

DEFINITION OF MALUNION

Theoretically, any bone that does not heal in an anatomic position is a malunion. Minor deviations of the alignment of bones from anatomic, however, usually cause no symptoms or functional deficit. The term malunion, therefore, applies to fractures that heal with either shortening, malrotation, or angulation, which produces unacceptable functional deformity or significant functional deficit, or alters the contact stresses in adjacent joints such that degenerative arthritis is more likely. There is considerable controversy as to what constitutes malunion. Merchant (53), for example, showed in a long-term study that considerable angulation in the tibia is compatible with good function and does not predispose to arthritis in the knee or ankle.

In today’s sports-oriented, active population, however, even minor malalignment may lead to functional complaints, particularly in high-performance athletes. What constitutes sufficient malalignment to justify surgical correction will be addressed on a bone-by-bone basis in the following chapters.

Shortening rarely presents a problem in the upper extremities, but it can be a significant problem in the lower extremities. Walking with a shortened extremity produces a pelvic tilt and angulation at the lumbosacral junction, which can lead to chronic low back pain. This can be corrected by wearing a shoe lift; however, lifts over 15 mm in thickness usually must be applied, at least in part, to the outside of the shoe. This is expensive and often cosmetically unacceptable, and it cannot be done to some types of shoes. The lifts stiffen the soles and increase the weight of the shoe, which is a problem in sports wear. In addition, the increased height of the ankle off the floor predisposes to sprains of the ankle. Shortening of less than 2.5 cm in the lower extremity can usually be managed by shoe lifts, whereas shortening of 2.5 cm or more may require correction, particularly in active young people.

GOALS OF TREATMENT

The goals of treatment are to restore limb alignment and, in the lower extremity, to reestablish an anatomic mechanical axis of weight bearing between the hip and ankle joints (34, 45, 50, 56, 58, 69, 74, 72, 73, 93-106). Sometimes the goal may be to actually overcorrect alignment to redistribute the contact stresses in the knee as treatment for posttraumatic degenerative arthritis. Even if alignment is well corrected, the patient will not be happy if she has continued joint dysfunction, particularly stiffness. Concomitant arthroscopy to treat internal derangement of joints, to reconstruct ligaments, and soft tissue procedures to restore motion, must be considered. The ultimate goal is to restore as much function as possible.

DEFINING THE DEFORMITY

Angular deformities are nearly always in a single plane. Occasionally, a segmental fracture will result in a dual-plane deformity, as when a proximal fracture heals with deformity in one plane and the more distal fracture heals with deformity in another plane, and independent correction of deformity at each fracture site is necessary (36). The vast majority of malunions, however, are single fractures with angulation in a single plane. In the past, we considered these to be two-plane deformities, because angulation seen on the AP and lateral views. However, they are really single-plane deformities that are greater than can be seen on the AP and lateral radiographs alone.

Radiographic analysis provides crucial information, however. Take plain AP and lateral radiographs of both the affected and the normal extremity, making certain that both are aligned with the central beam of the x-ray. Use as long a tube distance as possible and incorporate a radiographic ruler to assist in measurements. Either include in those views the joints above and below, or take separate views. In the lower extremity, determine the mechanical axis by taking weight-bearing AP and lateral radiographs, using long cassettes to include the hip and ankle joints. When trying to compare the axis of the knee joint relative to the ankle joint, it is often helpful to take independent AP films with the central beam at right angles, or with a 10° caudal tilt at the knee and AP at the ankle.

The detailed history and physical examination for evaluation of nonunions described earlier in this chapter applies also to malunions. Try to measure the degree of angulation and establish the plane in angular deformities. Compare rotation in the affected limb to that in the abnormal limb: This is often the best guide to malrotation. The same is true for shortening, which is discussed below.

Establishing the true degree of shortening can be difficult, particularly if there are contractures of the ankle, knee, or hip joint. I use all of the following methods before deciding on how much to equalize leg length.

- Measure leg lengths from the anterior/superior iliac spines to the medial malleoli and bottom of the feet.
- Measure leg lengths at the medial malleolus by marking the malleoli with a felt tip pen whose mark will transfer easily. With the pelvis level, pull down on both feet and touch the malleoli together, noting the leg-length discrepancy between the two marks.
- Slant the patient and place measuring blocks under the short side until the pelvis is level and the patient feels comfortable. I often shift the blocks back and forth in increments of ⅛ to ¼ inch, without allowing patients to see what I am doing, to establish what correction they prefer.
- Confirm the measurements with radiographs. AP views of the hips and pelvis, knees, and ankles with a radiographic ruler in place at the maximum tube distance is usually accurate as long as the patient does not move during the examination. You may want to personally supervise these films to be certain that they are accurate. Next, place the blocks under the short side, correcting the discrepancy, and take a weight-bearing AP view of the pelvis, being certain that the cassette is level with the floor and the patient is standing perfectly erect. Comparison of all these measurements and discussion with the patient will usually lead to a decision to undertake a given correction. I rely mostly on the standing block measurements.

Angulation rarely occurs without translation. Correction of angulation alone, without addressing translational deformity, will leave the mechanical axis disturbed. In addition, there is almost always some malrotation and some degree of shortening. The radiographic appearance of these deformities, how to assess the mechanical axis, and how to measure deformity are discussed in detail in Chapter 32. Use the vector analysis technique described there to determine angulation and translation, and use the true mechanical axis technique to establish the mechanical axis.

The discussion in Chapter 32 focuses on the Ilizarov technique, but the process for characterizing the deformity is the same. The major difference in preoperative planning is that in the Ilizarov technique a simple transverse osteotomy is nearly always done, and the correction is taken through the distraction site by adjustment of the external fixator. This gives a great deal of latitude, as even if there are miscalculations, adjustments can be made in the external fixator frame as the deformity is corrected, to achieve good alignment.

PREOPERATIVE PLANNING

Careful preoperative planning is essential. After internal fixation is in place and the skin closed, adjustments are very difficult to make, especially after closing wedge osteotomies, for example. Therefore, incomplete or inaccurate correction may require reoperation.

Rotational malalignment is usually best assessed clinically, but if precise measurements are desired CT scans are useful (22). In preoperative planning, take into account how changes in angulation and rotation will affect overall length of the extremity.

The basic method of preoperative planning employs overlay drafting, a technique borrowed from architects and engineers (16, 34, 51, 58, 74, 95). Rotate and manipulate superimposed images of the major bone fragments until the desired bone configuration and limb alignment are achieved. This can be done with tracing paper, clear x-ray film, or a digitizing tablet coupled to a microcomputer (Fig. 26.15, Fig. 26.16, Fig. 26.17, Fig. 26.18 and Fig. 26.19). For the sake of accuracy, include the joints proximal and distal to the osteotomy in the drawing. In the lower extremity, do mechanical axis drawings. If the deformity is unilateral, use a contralateral tracing as a template. This allows a prediction of the outcome (Fig. 26.15C, Fig. 26.16B and Fig. 26.17B). With the overlay technique, before and after views can be compared and different proposed solutions weighed, to select the plan that will best restore the mechanical axis and equalize limb lengths.
Figure 26.15. A: Preoperative standing film shows 20° varus deformity of right tibia and 2 cm limb-length discrepancy. B: Options for surgical treatment include intraligamentous incomplete opening wedge and crescentic osteotomy. C: Overlay comparison of the two options in (B). The opening wedge (shaded areas) will gain an additional 1 cm of length while restoring the mechanical axis. D: The drawing serves as a template for sizing the tricortical iliac graft and preoperative contouring of the semitubular “hook plate.” The fibula was not cut. E: The hook plate was compressed over the tricortical graft and an interfragmentary screw was placed through the plate. By placing the screw at the apex, a wide range of angles are available. (From Stevens PM. L-Plate Fixation for Osteotomies. Orthopedics 1991;14:767.)

Figure 26.16. A: Nonunion of the tibia, presenting as a two-plane deformity with 13° of varus, translocation, and 1.2 cm of shortening. B: Overlay drafting provides direct comparison with contralateral tibia serving as a template. C: After oblique osteotomy and realignment with the femoral distractor, the tibia was fixed with an interfragmentary screw and contoured neutralization plate.

Figure 26.17. A: Radial malunion with synostosis, 6 mm shortening of the radius, wrist pain, and 0° pronation/supination. B: The difference in radial length and alignment is readily apparent on this digitized overlay comparison (left side is white; the template is shaded on the normal right side). C: The optimal plan calls for an opening wedge osteotomy through the radial malunion, excision of the synostosis with fat interposition, and stabilization with a precontoured DC plate. D: Intraoperatively, 70° each of pronation and supination were gained, while full radial length was restored with an autogenous tricortical bone graft. The transverse cut made insertion of an interfragmentary screw impractical.

Figure 26.18. A: This 13-year-old girl sustained a closed fracture of her distal femur, which led to asymmetrical closure of her distal femoral physis, resulting in 30° of varus and a 4.5 cm limb-length discrepancy. B: The digital tracing of her full-length standing film demonstrates the real versus the desired mechanical axis, and the lateral slope of her knee. C: A 32 mm medial opening wedge osteotomy would normalize the mechanical axis while restoring 3 cm of length. D: Although a medial 90° blade plate is more convenient to apply, it would be unacceptably prominent. E: Therefore, a 95° blade plate was applied through a lateral incision. The lateral femoral physis was curetted to prevent recurrent varus. F: By the fifth postoperative month, the patient had solid clinical and radiographic union, with symmetrical alignment and a 1 cm residual length discrepancy.

Figure 26.19. A: Intraoperative “plan” for correction of 10° varus malunion of the tibia. B: The transverse diaphyseal osteotomy was unstable after application of a medial buttress plate without an interfragmentary screw. An anterior plate was added, requiring excessive soft-tissue stripping. Still, no lag screw was used; note the persistent gap. C: Wound slough and an infected malunion resulted. The limb was salvaged with debridement and electrical stimulation. This unfortunate sequence of
events could have been avoided by good preoperative planning. D: (Left) In retrospect, a preplanned, incomplete opening wedge supramalleolar tibial osteotomy, secured with tension band fixation, would have safely afforded excellent correction. The length discrepancy would have been 1.2 cm. (Right) The result in this case was 12° of valgus and a limb-length discrepancy of 3 cm.

**TYPES OF DEFORMITY**

**SINGLE-PLANE DEFORMITY**

Simple deformities occurring only in the frontal plane are uncommon (and in the sagittal plane even more so), and a single drawing suffices. Plan the degree of valgus or varus correction within the context of mechanical alignment (Fig. 26.15C). If there are deformities at two locations, combined or compensatory, a double osteotomy may yield the best biomechanical solution, keeping the joints horizontal and restoring the mechanical axis (Fig. 26.16C). Simple deformities in the sagittal plane often produce an unphysiologic arc of joint motion. Examples include dorsal tilt after a Colles’ fracture, recurvatum of the knee, and ankle deformities. Wedge or displacement osteotomies can be planned on a tracing of the lateral radiograph. Maximum flexion and extension views help to delineate the desired degree of correction.

**TWO-PLANE DEFORMITY**

The term two-plane deformity derives from the angulation seen on both AP and lateral radiographs (Fig. 26.16). As already discussed, all deformities at a single level are in fact in a single plane, but they are commonly midway between the AP and the lateral planes and thus are oblique. For example, femur fractures tend to angulate in an anterolateral direction, and tibias can be in almost any plane. It is important to understand the precise plane of the deformity and the actual angulation (see Chapter 30). This can be done by vector analysis or by using geometric calculations. Although these deformities can be corrected by approaching the angulations in the different planes sequentially, as described in the discussion of the AO oblique osteotomy below, a more precise technique, although more technically challenging, is to do a single-plane osteotomy that corrects the entire deformity.

A radiographic method of determining the plane of the deformity is to examine the limb segment under fluoroscopy, rotating the limb until there is no deformity seen on the x-ray film. This marks the plane of the deformity. Taking a second radiograph at exactly 90° to this plane permits measurement of the true angulation.

**THREE-PLANE DEFORMITY**

Complex three-plane deformities include rotational malalignment. Determination of the degree of malrotation is based on the methods already described. Correction of malrotation in complex deformities can be incorporated into a single-plane osteotomy, or done in a stepwise fashion if the osteotomy is transverse or oblique as discussed in the next section. In some cases, a CT scan and a computer-generated, three-dimensional model may be beneficial for visualizing the necessary correction.

**PREOPERATIVE PREPARATION**

On the templates or computer-generated drawings, identify the location of any structural bone grafts required, and place drawings of the hardware to be used. Hardware templates available from manufacturers are quite useful. If the preoperative plan is clear-cut and changes are not anticipated, preoperative contouring of plates can save considerable time in the operating room. Plan for alternative methods of fixation and be certain that appropriate implants are available. Also have available a simple universal external fixator and a femoral distractor, which may assist in intraoperative control of fragments pending definitive internal fixation.

When performing osteotomies to correct malalignment, intraoperative fluoroscopic control is invaluable, particularly for reestablishing the mechanical axis in the lower extremities. Because fluoroscopy does not give a large field of view, however, final alignment must be confirmed with radiographs that include the joints above and below. To facilitate the fluoroscopy, use fully radiolucent operating tables that allow free passage of the C-arm from the pelvis to the foot.

**SURGICAL TECHNIQUES**

There are many options for the location and configuration of the osteotomy (Fig. 26.20). Personal preference may play a role, but place a premium on simplicity, stability, and predictability. Corrective osteotomies are best done at or near the site of deformity, which is determined by the point of intersection of the axes of the proximal and distal segments. The farther from this point an osteotomy is done, the more difficult it is to normalize the mechanical axis and the more likely it is that a zigzag compensatory deformity will result, which may be undesirable. Other factors demand consideration, however, including the condition of the soft tissues, history of infection, fixation problems, and anticipated healing time. If there are extenuating circumstances, a distant correction and compensatory deformity may be acceptable.

**TRANSVERSE OSTEOTOMY**

A transverse osteotomy (Fig. 26.20F) is ideal for correcting rotation alone. Whether in the diaphysis or the metaphysis, it is important to ascertain that the plane of cut is transverse to the long axis of the bone to avoid inadvertently producing a frontal or sagittal deformity. Although simple to perform, a transverse osteotomy is relatively unstable and is not ideally suited for interfragmentary compression. It resists an axial load but is inherently weak if subjected to torsion or bending loads. Angular corrections can be difficult to control (Fig. 26.19). In the diaphysis, locked intramedullary fixation permits load sharing and excellent stability. If an open osteotomy is performed, requiring extensive exposure and periosteal stripping, intramedullary reaming and nailing may produce unacceptable devascularization and delayed healing. In such instances, plating or external fixation is preferable. Transverse metaphyseal ostotomies may produce cortical stepoff and the risk of intra- or postoperative invagination of the smaller fragment, resulting in overcorrection. The cancellous bone may provide marginal anchorage for screws, wires, and staples (17). Consider blade-plate fixation, double plates, or supplemental external splintage.

In the femur, correction of malrotation can be done using percutaneous “closed” intramedullary osteotomy with locked nail fixation (see Chapter 30 for details). For open osteotomies, it is critical that the degree of correction be accurately controlled and determined intraoperatively. Knight (45) describes a precision guide-pin technique for wedge and rotatory osteotomy of the femur and tibia. In 85% of 47 osteotomies, his correction was within 3° of the operative goal. Pulisetti et al. (79) describe a method using CT, in which the malrotation angle value in degrees can be translated into millimeters on the circumference of the diaphysis; they feel this virtually eliminates error in correcting rotation.

- Before making the osteotomy, place a 2 mm Kirschner (K-) wire, or a stronger pin, into the proximal fragment in an area that will not interfere with the internal
fixation and where soft-tissue distortion will not bend the pin.

- Place a similar pin distally, directly in line with the proximal pin. This establishes the starting point.
- Preoperatively bend a K-wire into a V to match the angle to be corrected. This will serve as an intraoperative guide.
- Mark the bone where the ostectomy will be made. Draw a longitudinal line on the bone across the ostectomy, or mark it with a slight nick from an osteotome to provide an additional reference.
- To facilitate fixation, a plate, if one is to be used, can be molded to the bone at the site of correction; it can be temporarily fixed to the proximal fragment with a single screw and then rotated out of position for the ostectomy. Once the ostectomy is done, this plate can be rotated back into position and secured to the distal fragment with a bone-holding forceps or a single screw for a preliminary check on the correction.
- Make the transverse ostectomy. Rotate the limb to the corrected angle and secure the ostectomy as described previously.
- Always perform the sterile preparation and drape the opposite limb so that comparison of rotation can be made. Do that at this time to be certain that the correction is accurate.
- Complete the fixation using a stable construct, and close and dress the wound.
- Finally, examine the anesthetized patient after wound closure and take final radiographs to be certain that the correction is as desired. If it is not, reprep and redrap and make adjustments as needed. If the surgery has been performed precisely, following these instructions, the need to reoperate should be minimal or nonexistent.

**OPENING AND CLOSING WEDGE OSTECTOMIES**

The opening and closing wedge ostectomies are a variation of the transverse ostectomy. The most commonly used closing wedge ostectomy is a high tibial ostectomy performed to treat uncompartamental arthritis of the knee. Its advantages are simplicity, stability, and rapidity of healing. Disadvantages are that it can affect soft-tissue balance if close to joints, and it will result in some shortening. In addition, if an excessively large wedge is taken, overcorrection is possible.

The opening wedge ostectomy is easier to perform than a closing wedge, but because the degree of deformity to be corrected can be established easily before committing to an irreversible cut. Also, the correction angle can be easily adjusted intraoperatively until the correct position is obtained. It offers the advantage of some gain in length. The disadvantages result from the fact that the opening wedge must be filled by a bone graft, which slows healing, nonunions can occur, and the intercalary bone graft used must remodel before full weight bearing can begin (Fig. 26.20A, Fig. 26.20B).

The uniplanar opening wedge ostectomy is most often performed in the cancellous bone of the metaphyses; it can be done in diaphyseal bone as well but with higher risk because of its slower healing. I have used this ostectomy most commonly in the proximal and distal tibia and occasionally in the distal femur. The ideal graft is harvested as a tricortical graft from the anterior ilium, using the cortical surface of the superior rim of the ilium as the portion of the graft that supports the opposing cortices at the ostectomy site (see Chapter 9). The following technique is for an opening wedge ostectomy of the proximal tibia.

- Under fluoroscopic control, place an obtuse K-wire parallel to the tibial plateau and just slightly superior to the site planned for the ostectomy.
- Using a water-cooled oscillating saw with a long blade, and providing appropriate protection for the soft tissues, make a transverse ostectomy parallel to the K-wire and at a right angle to the long axis of the tibia in the other plane. Stop 10 mm short of the opposite cortex.
- Gently correct the deformity, and plan to create a green stick fracture of the opposite cortex. If there is significant resistance to straightening the bone, drill the opposite cortex through the ostectomy with several drill holes to weaken it.
- Try to maintain the continuity of the cortex and soft tissues on the opposite cortex, as this significantly increases the stability of the ostectomy and hastens healing.
- When the correction is achieved, prop open the ostectomy with an appropriate-size prop. I have available an assortment of plastic blocks in 5 mm increments, which are useful for temporarily holding the ostectomy open.
- Measure the mechanical axis and take AP and lateral radiographs to be certain that the correction is complete.
- Measure the width of the opening wedge thus produced and the length of bone wedge needed, and harvest as many of these as are necessary to completely fill the defect. In the tibia, usually three wedges from the iliac crest are required.
- Drive the tricortical iliac crest wedges into the ostectomy site and stabilize it with a single large plate or with two small fragment plates placed at roughly right angles to each other. The ostectomy and grafts should be in compression at the completion of the fixation.
- Take final radiographs to confirm position.

The technique for a closing wedge ostectomy until the placement of the first K-wire is identical to that for an opening wedge ostectomy. The surgical technique then continues as follows:

- Place a second K-wire parallel to the first at the angle of wedge to be removed. Be certain that the K-wires are placed so that the narrow end of the osteotomy will just meet the opposite cortex.
- With the oscillating saw, make a transverse cut parallel to and just inferior to the proximal K-wire, being certain that the plane of the saw remains parallel to the joint. Stop just short of the opposite cortex (this is just slightly farther than for the opening wedge ostectomy).
- Now make the second saw cut, watching the blade carefully under fluoroscopic control to be certain that it stays parallel to the first cut and will meet the first cut precisely at the opposite cortex. A free saw blade placed in the first ostectomy provides a useful reference.
- Remove the wedge by placing a thin osteotome into the proximal ostectomy and a second into the distal ostectomy. Use these to pry out the wedge.
- Completely close the ostectomy and temporarily fix it with a plate as for the opening wedge ostectomy, or with a wire inserted across the osteotomy site.
- Evaluate the alignment discussed previously, and complete fixation of the ostectomy with a plate and screws. An external fixator can be used as well, but I prefer internal fixation. If the ostectomy is in the mid diaphysis, perhaps an intramedullary nail can be used if the overall alignment of the canal has been established.

**OBLIQUE (SINGLE-PLANE) OSTECTOMY**

An oblique ostectomy (Fig. 26.20C) offers several advantages. It can correct all deformities with a single cut. It presents a broader surface area for healing, has superior bending and rotational stability, and can easily be compressed with an interfragmentary lag screw. By inserting the screw through a plate, the rigidity of fixation is increased by approximately 25%. (In the diaphyseal region, where both cortices must be cut, use a contoured neutralization plate.) However, the planning and execution are challenging (66, 87). The plates can be difficult to apply, but they can be effective for a rotational deformity. The oblique ostectomy is especially useful in the metaphyseal region.

- Make an incomplete cut close to the joint, leaving an intact osteoperiosteal hinge for stability; a plate can then be applied in a tension-band fashion (Fig. 26.15, Fig. 26.21A, Fig. 26.21D). The addition of an interfragmentary screw further increases stability.

- Plan the cuts to avoid a cortical stepoff.
- Add or remove bone wedges to adjust the length and the mechanical axis (Fig. 26.15).

Excessive obliquity introduces shear forces, which to some extent are neutralized by the interfragmentary screw (87). For proximal or distal tibial corrections, it is generally not necessary to cut the fibula, unless rotation is also being corrected.

The proximity of the ostectomy to a joint influences the angular change required. In the proximal tibia, an intraligamentous opening wedge ostectomy offers the additional advantage of improving knee stability. In the immature patient, a one-plane or two-plane deformity in conjunction with a partial physeal arrest is often present.
A metaphyseal opening wedge osteotomy in a patient with less than 50% physeal closure facilitates the exposure for an epiphysiolysis. Realignment also reduces the eccentric load on the recovering physis. If the percentage of physeal closure precludes an epiphysiolysis, a transphyseal closing wedge osteotomy prevents recurrence of the deformity. In the event of a malunited Salter-Harris III or IV fracture, an osteotomy through the old fracture site permits anatomic reduction using tracings of the contralateral joint as a template.

A particularly useful oblique osteotomy is that described by the AO group (85). With one cut, angular deformity in the frontal and sagittal planes, shortening, and malrotation can be corrected in a stepwise fashion (Fig. 26.22). The major disadvantage is that it requires considerable soft-tissue exposure, which can lead to devascularization of the tips of the proximal and distal fragments. I have had two AO osteotomies that were technically well done but went on to a nonunion that was difficult to recover from, so I use this osteotomy infrequently.

A much better osteotomy, although more technically challenging and difficult to plan, is the single-plane osteotomy described by Sangeorzan et al. (87), and independently by Rab (89). The technique is based on a mathematically precise calculation that characterizes the deformity. It allows the determination of an axis about which the distal fragment can be rotated to make it coincident with the proximal fragment. A plane perpendicular to this axis allows a single surgical cut to be made that will permit correction of the full deformity (Fig. 26.23). The technique requires four steps: precisely defining the location and angular measurements of the deformity in all planes; finding the angle of osteotomy required to correct the deformity; locating the starting point of the osteotomy referable to the transverse plane; and then cutting along this plane with an oscillating saw and rotating the distal segment relative to the proximal segment to bring them into the corrected position. Because the osteotomy is oblique, interfragmentary screw fixation works well, particularly when combined with a neutralization plate. The details of this technique are rather complex and beyond the scope of this chapter, but the articles by Sangeorzan et al. (87) and Rab (89) are excellent, and they provide additional references of interest.

CRESCENTIC (DOME) OSTEOTOMY

A crescentic or dome osteotomy works best in metaphyseal or epiphyseal cancellous bone, where the irregular nature of the bone and the cut provide good inherent stability, and the broad surface area and cancellous bone lead to rapid healing (Fig. 26.24). It is much more difficult to use in cortical bone, and I no longer use it in the diaphysis. It is ideal for correcting deformity near joints that are in a single plane, preferably the frontal plane. In preoperative planning, be certain that an undesirable devascularization of the tips of the proximal and distal fragments. I have had two AO osteotomies that were technically well done but went on to a nonunion that was difficult to recover from, so I use this osteotomy infrequently.

- Expose the distal tibia through an anterior approach. If correction of the fibula is needed as well, plan to incorporate it into the dome osteotomy.
- The dome osteotomy usually works best if the concave side is directed toward the joint or distally. Localize the osteotomy at the site of the major deformity in the distal tibia, leaving enough room to secure plate fixation in the distal fragment.
- After anterior exposure of the tibia and fibula just proximal to the ankle joint, draw out a gentle curve (Fig. 26.24A), the radius of which will permit correction of the deformity. (Figure 26.24 shows a moderate, 15° varus deformity, and it depicts incorporation of the fibula, which is often not necessary.)
Use appropriate-size drill points (in the figure, they are 3.5 mm in diameter, but this depends on the size of the bone). Insert the first drill point at the apex of the dome (in the figure, this is drawn on the anterior tibia), and drill it through the anterior and posterior cortices, keeping it exactly at 90° to the axis of the proximal shaft of the tibia.

Next, place two additional drill points at a point midway between the first drill point and the medial and lateral cortices, keeping them exactly parallel to the first drill point.

Add more drill points to fill in the intervals, spacing them about 5 mm apart (follow roughly the numbered sequence shown in the figure). Use the initial drill point as a guide to be certain that all the drills are parallel to each other, producing a perfect dome. In a typical adult tibia, about five or six drill points can be placed. It is very important that these all be parallel to each other along the length of the dome osteotomy.

When all drill points have been placed, remove them and connect the drill holes both anteriorly and posteriorly with a slim, ¼-inch (Hoke) osteotome (Fig. 26.24B). Do this by completing the osteotomy anteriorly first and then running the osteotome across the tibia to the posterior cortex.

Next, rotate the osteotomy to obtain correction and impact it. The combination of drill holes and osteotome cuts produces two opposed cogwheels. At the appropriate point of correction, these can be interdigitated and then impacted, producing a surprisingly stable osteotomy. Obtain initial fixation with either K-wires or a single screw. I prefer to use at least two interfractionary screws across the osteotomy for the primary fixation (see Chapter 30).

Obtain plain radiographs and determine the mechanical axis to be certain the correction is as desired. Complete the fixation by stabilizing it with a neutralization plate on the tibia.

If the tibia has been osteotomized, use a 1/2-tubular plate on the fibula.

Correction of a juxtaarticular deformity of this type is technically easier to do with a frontal plane oblique osteotomy. The advantages of the dome are that it requires less soft-tissue stripping and patients can bear weight immediately in most cases. Healing is also more rapid than with an oblique osteotomy.

### HINTS AND TRICKS

A very nice technique for the mechanical axis intraoperatively with the fluoroscope is to use a Bovie cord from the electrocautery unit, because this is radiopaque, readily available, and sterile for use in the operating field. Be certain to attach the cord to the drapes so that sufficient length is available to reach from the hip to the ankle.

- To establish the mechanical axis, center the C-arm over the femoral head and hold the Bovie cord so that it is located dead center on the femoral head. Mark this position on the skin.
- While holding the Bovie cord under tension, locate it directly over the center of the ankle mortice, visualizing the location on the fluoroscope, and mark this on the skin as well. Hold the Bovie cord on the skin so that parallax is minimized.
- Being careful not to move the Bovie cord from the center of the hip and ankle, use the fluoroscope to visualize the knee and record the image, print it, and place it on the operating room x-ray view box. On the normal side, the cord should pass directly through the center of the knee, which is usually just on the lateral side of the mediotal spine.
- Make a similar determination on the abnormal side that is to be corrected.
- Once the correction is achieved in surgery, repeat this procedure on the operated side, to ensure that the mechanical axis is comparable to the normal or unoperated extremity.
- If bilateral deformities are being done, locate the cord directly in the center of the knee.
- Bone grafts are not usually required for osteotomies unless an opening wedge osteotomy is being performed. This may require several tricortical grafts harvested from the anterior superior iliac spine (see Chapter 9). In this case, be certain to prepare and drape the iliac crest.

### DISPLACEMENT OSTEOTOMY

The displacement osteotomy described by Wagner (100) is useful to address a major juxtaarticular deformity (Fig. 26.20C). It consists of a transverse metaphyseal osteotomy in which the perarticular fragment is rotated, impacting one corner of the metaphysis into the medullary canal of the other fragment. This transforms bending loads into compressive loads while preserving length and improving joint alignment.

### STEP CUT OSTEOTOMY

In rare cases, such as one-stage diaphyseal lengthening, a stepcut osteotomy may be convenient. However, it requires significant exposure, which devascularizes the bone ends, and fixation may be tenuous. Rotational and angular corrections are limited (Fig. 26.20D, Fig. 26.20E and Fig. 26.20F).

### POSTOPERATIVE MANAGEMENT

In the majority of osteotomies, after achieving a stable mechanical construct, early motion of the extremity is safe and desirable. Base the range of motion permitted, degree of weight bearing, and level of use of the extremity on the intraoperative assessment of the stability of the reconstruction. Avoid over stressing the implants until healing occurs.

### PITFALLS AND COMPLICATIONS

An inaccurate history or cursory clinical examination cannot yield sufficient information on which to base the decision to perform an osteotomy. For instance, ankylosis of a joint may preclude the successful realignment of a limb after an osteotomy, and a flail limb or unstable joint may not fare well after an osteotomy. When performing a varus-producing osteotomy of the upper femur, you must anticipate how much the articulating surface of the hip joint to the trochanter is altered; a patient with “good containment” but restricted abduction and a marked Trendelenburg gait is not likely to be pleased with the clinical outcome. A preexisting limb-length inequality may be exacerbated by an otherwise satisfactory angular correction. The radiographic examination is critical, so adequate radiographs are a prerequisite to planning.

Inadequate preoperative planning or poor execution of an osteotomy can quickly lead to complications, as demonstrated in Figure 26.19. Although there are innumerable reasons for failure of reconstructive osteotomies, most of them are avoidable. Perceptual and technical errors can be averted if you abide by the principles described here and pay attention to details.

Surgery is not an intuitive process: Planning is essential for consistent and predictable results. The use of hardware templates prevents embarrassing and costly mistakes in the operating room. Although a preoperative plan is no guarantee of success, it narrows the range of potential intraoperative errors and allows contingency plans to be formulated. Improper positioning and draping compromises surgery at every step, as does inadequate exposure. Excessive exposure is equally reprehensible and may lead to a poor outcome (Fig. 26.19).

Undercorrection leads to postoperative “recurrence” and possible progression of the deformity because the pathomechanics continue (Fig. 26.19). Overcorrection is equally undesirable. Strive to achieve a neutral mechanical axis and to balance the forces around a joint. The key to avoiding intraoperative pitfalls is prevention, thorough planning, adequate exposure, intraoperative control with radiographic documentation, and stable fixation.

Avoid intraoperative damage to skin muscle and neurovascular structures by careful dissection, gentle retraction, and extensile approaches. Vigorous retraction and innumerable reasons for failure of reconstructive osteotomies, most of them are avoidable: Perceptual and technical errors can be averted if you abide by the principles described here and pay attention to details.

Surgery is not an intuitive process: Planning is essential for consistent and predictable results. The use of hardware templates prevents embarrassing and costly mistakes in the operating room. Although a preoperative plan is no guarantee of success, it narrows the range of potential intraoperative errors and allows contingency plans to be formulated. Improper positioning and draping compromises surgery at every step, as does inadequate exposure. Excessive exposure is equally reprehensible and may lead to a poor outcome (Fig. 26.19).

Undercorrection leads to postoperative “recurrence” and possible progression of the deformity because the pathomechanics continue (Fig. 26.19). Overcorrection is equally undesirable. Strive to achieve a neutral mechanical axis and to balance the forces around a joint. The key to avoiding intraoperative pitfalls is prevention, thorough planning, adequate exposure, intraoperative control with radiographic documentation, and stable fixation.

Avoid intraoperative damage to skin muscle and neurovascular structures by careful dissection, gentle retraction, and extensile approaches. Vigorous retraction and excessive periosteal stripping are to be avoided. Never close wounds under tension; consider delayed closure or use of appropriate flaps when the wound is excessively swollen. Perform neurolysis or fasciotomies if indicated.

The risk of infection is ameliorated by the appropriate use of perioperative antibiotics and suction drainage of the wound. Treat infection aggressively with debridement and appropriate culture-specific antibiotics. If the osteotomy remains stable and the implant is intact, the hardware should be left in place. Implant failure or loss of fixation and alignment warrant reoperation with revision of fixation. If there is infection, consider external fixation. The long-term implications of overcorrection or undercorrection should be recognized and discussed with the patient, because residual deformities have the same pathomechanical significance as the original deformity. Use bone graft in osteotomies when the risk of delayed nonunion is high.
Because the upper extremity does not normally bear weight unless crutches or a cane are used routinely, osteoarthritis resulting from malalignment does not appear to be a major problem. However, malalignment compromising precise mobility of the hand or the ability to place the hand in space may be a major disability. The decision to correct malunions or nonunions in the upper extremity depends on the patient's functional demands and the presence of pain. If function is suitable without correction and pain is not a problem, surgery is not indicated.

SCAPULA
Because the scapula is totally enclosed in an envelope of heavy muscles and lies on the posterior aspect of the thoracic cage, fractures that progress to symptomatic nonunion or malunion are exceedingly rare. Personally, I have never had to treat surgically either a nonunion or a malunion of the scapula. There are reports of nonunions of the base of the coracoid process, the scapular body and spine, and the acromion (2,21,33,52,55,105). Gupta et al. (53) reported successful treatment of a nonunion of the inferior third of the body of the scapula (the only case reported in the literature) with plate fixation and bone graft, resulting in dramatic improvement in function and relief of pain.

The epiphysis of the acromion is one of the last to unite and occasionally does not unite, remaining as an os acromiale. This should not be mistaken for a nonunion. True nonunions, if displaced inferiorly, can interfere with motion and cause impingement on the rotator cuff tendons. If symptoms justify, a small fragment can be excised. Reattachment of the deltoid must be solid and protected until healed to avoid deltoid deficiency. Excision of any substantial part of the acromion can lead to permanent deltoid weakness, and therefore, nonunions producing large fragments deserve repair. Repair can be challenging because of the thin cortical bone of the acromion, in which it is difficult to obtain secure fixation. Dounsich et al. (51) reported successful treatment of a nonunion of a fracture at the base of the acromion with plate and screw fixation combined with a tension band wire construct and autologous bone graft.

Nonunions of the coracoid process are more likely to be secondary to an osteotomy performed for reconstructive shoulder surgery as opposed to a fracture. If the nonunion is symptomatic, most can be successfully treated with freshening of the fracture site and internal fixation with a compression screw. Excision is also possible with reattachment of the muscles originating from the coracoid to surrounding soft-tissue structures.

CLAVICLE
Although the clavicle is probably the most commonly fractured bone, nonunions are rare (62). The incidence of nonunion in clavicle fractures managed nonoperatively is between 0.1% and 1.9% (10,41,68,109). In those managed operatively, the incidence is higher, particularly with intramedullary fixation (91). Functionally disabling malunions are probably even rarer. In the series of 33 patients reported by Wilkins and Johnston (106), nonunion appeared to be more common after retraction or when associated with severe trauma (108). Patients with atrophic nonunions seemed to have fewer symptoms than those with hypertrophic pseudarthroses. Atrophic nonunions seem to be much more common than hypertrophic nonunions (69).

A nonunion of the clavicle in an adult is defined as an ununited fracture at least 16 weeks after injury. The anatomic location of the fracture affects the union rates; distal clavicular fractures have a higher rate of nonunion than middle-third fractures. A displaced, interligamentous distal-third fracture (Neer type II), in which the proximal fragment is detached from the coracoclavicular ligament, is unstable and has a higher nonunion rate (68,69,72).

Malunion of a clavicle is rarely a functional or clinically significant problem. Most clavicles heal in a malunited position, because they are usually treated in a figure-eight sling, which does not provide adequate enough immobilization to ensure anatomic position (see Chapter 15). It is very uncommon to require any form of treatment for a malunion of the clavicle, except for a cosmetic deformity (69). Occasionally, brachial plexus impingement can occur when there is abundant callus. Shortening of more than 15 mm can produce shoulder discomfort.

OPERATIVE INDICATIONS
The indications for operative intervention in a nonunion or malunion of the clavicle include significant pain with use of the ipsilateral shoulder, compromising upper extremity function. Occasionally, hypertrophic nonunions cause extrinsic compression of the brachial plexus and the subclavarian artery and vein (46). This problem may

also be responsible for a thoracic outlet syndrome (16). Thorough preoperative assessment, including a bone scan, appropriate angiography, electromyographic studies, and a thoracic or vascular surgical evaluation, may be indicated. The final indication for surgical correction of clavicular nonunion or malunion is correction of unilaterally deformities. The patient must be aware that he or she is exchanging a deformity for a scar. Comparison of radiographs to the opposite, normal side are useful for planning a repair or osteotomy, particularly to estimate restoration of length. Operative techniques most commonly used today include plate fixation and bone graft (6.6,18.51,75.77.92.107), intramedullary Hagie pin and bone graft (4.12.107), and as a last resort, partial or total claviculectomy (69).

REPAIR OF NONUNION WITH PLATE FIXATION AND BONE GRAFT

- Position the patient in a modified beach-chair position on the operating table (Fig. 27.1). Because it is difficult to position an x-ray plate beneath the shoulder once the patient is positioned and draped, place a cassette in position before the prep and drape. Pad it to protect the patient.

- Prepare and drape the patient, with the involved shoulder and extremity free. Be certain to prep all the way up to the corner of the mandible and drape widely to ensure adequate access to the clavicle.

- Make an incision of sufficient length, usually 10 to 12.5 cm, using Langer lines to minimize scarring. Carry the incision directly down to the clavicle and expose the superior surface by subperiosteal dissection. There usually is no need to develop subcutaneous flaps. In malunions and in hypertrophic nonunions, the main shaft of the clavicle can be burried and quite difficult to identify. Palpathe the bone carefully as the incision down to bone is made. Simpson and Jupiter (69) mention identifying and preserving the cutaneous supraclavicular nerves crossing the anterior border of the clavicle in order to avoid hypesthesia postoperatively. I have not found it practical to preserve these nerves in the midportions of the wound. At the distal and proximal ends, they can be retracted. In spite of having transected these nerves in the midportion of the wound routinely, I have never had a patient complain of postoperative hypesthesia due to neuromas.

- Identify the nonunion. In the case of an oligotrophic or atrophic nonunion, try to identify the original fracture ends so that the fracture can be repaired as anatomically as possible. In most cases, it is worthwhile to plate the clavicle in anatomic position rather than first fix it in malposition, because patients are much happier and function is better. In most cases, this requires taking down the nonunion, freshening the bone ends, and drilling the medullary canal to help revascularization.

- If there is a reasonably stable fibrous union in nearly anatomic position, then occasionally plate fixation in situ is adequate. In my experience, this is rare.

- In hypertrophic nonunions, it is worthwhile to shave the hypertrophic callus off the clavicle, taking care to identify the original clavicle encased in the callus (Fig. 27.1A). Morcelize this bone and use it for bone graft, because this saves harvesting an iliac crest graft.

- A gap may be present owing to bone resorption, extensive comminution, or bone loss in the case of open fractures. Plan to restore the full length of the clavicle, placing an intercalary tricortical bone graft of equal size to the clavicle. Harvest it from the superior rim of the anterior iliac crest (see Chapter 9).

- Once the nonunion has been reduced, apply a 3.5 AO limited contact compression plate, Alta 3.7 reconstruction plate, or equivalent to the superior surface of the clavicle, obtaining eight cortices of solid fixation both proximally and distally, if possible. Whenever possible, try to obtain interfragmentary compression across the nonunion site either independently of the plate or through the plate (Fig. 27.1B). Plates fit best on the superior clavicle and act as a tension band, requiring less molding than plates placed anteriorly (Fig. 27.1C). Superior plates also have the advantage of protection of the underlying structures on the inferior aspect of the clavicle by the subclavus muscle.

HINTS AND TRICKS

- To ensure proper length of the clavicle, measure the length of the opposite clavicle preoperatively and use this as a guide.

- Sometimes gaining length can be difficult. Facilitate this procedure by fixing the plate to one end of the nonunion first and then using a distractor or other instrument to distract. Application of a small external fixator with a pin medial and lateral to the plate to be used as a distractor also works nicely.

- Meticulous closure of the periosteum and deep fascia with the platysma provides a smooth contour over the clavicle and may eliminate the need for plate removal later.

- Nonunions in the proximal quarter and in the distal quarter of the clavicle are difficult to fix because of the small fragments available. For these nonunions, the Alta 3.7 reconstruction plate is quite useful because of its oval holes, which give more screws per unit length than in other plates. Augmenting fixation with a tension band figure-eight wire is useful as well.

- Petal the superior and posterior surfaces of the clavicle adjacent to the plate on both sides of the nonunion, and then apply a cancellous bone graft.

- Do a meticulous layered closure of the periosteum, deep fascia, and platysma. Use a plastic skin closure to provide the best scar. See Figure 27.2 for a typical case.

OSTEOTOMY FOR MALUNION

- The technique is nearly identical to that described earlier for repair of nonunion. The only difference is that the old fracture site must be identified and an osteotomy made as much as possible through the old fracture site. I find that this usually works better than an arbitrary osteotomy, because an arbitrary osteotomy frequently results in a compensating deformity.

- Even a year or more after a malunion of a clavicle, the callus surrounding the original bone is more vascular, pink in appearance, and softer than the hard white native cortical bone of the clavicle.

- Slide an osteotome along the normal cortex of the clavicle, shaving off the callus until the malunion site is obvious.

- Use a small water-cooled oscillating saw to osteotomize through the old fracture site. Refashion the bone ends to make the clavicle as anatomic as possible, and then plate the clavicle as described earlier. Bone graft is not usually necessary, but any callus removed at the fracture site can be morcelized and packed about the osteotomy site.
The results of treatment of clavicular nonunions using the techniques described above are excellent, with success rates of 92% to 100% after the first operation.

**Results**

**Figure 27.3.** Hagie pin fixation and bone graft of a nonunion of the clavicle. A: A skin incision exposing the nonunion. B: Drilling the medullary canal of the medial fragment. C: Drilling the medullary canal of the lateral fragment. D: Petaling the ends of the clavicle. E: Drilling the Hagie pin out the hole in the lateral fragment. F: Superior view of E. G: Reducing the fracture and driving the Hagie pin retrograde into the medial fragment. H: Superior view. A nut is applied to the Hagie pin to compress the fracture. (Redrawn from Matsen FA, III, and Rockwood CA, Jr. The Shoulder. Philadelphia: W. B. Saunders, 283, with permission.)

**Hints and Tricks**

- Avoid smooth or threaded wire fixation across nonunions because of the risk of wire breakage and wire migration (see Chapter 78) (73,83,106).
- For distal clavicle nonunions, fixation in a short distal fragment can be enhanced by the use of a 3.5 mm or similar T plate, or a 3.5 mm plate with one of the screws in the plate placed into the base of the coracoid process (see Chapter 78). With this technique, take care to not excessively narrow the coracoclavicular interval. Avoid elevation of the arm above 90° until the coracoclavicular screw is removed after healing of the nonunion.
- Figure-eight tension band wires (without K-wires) are useful for augmenting plate or Hagie pin fixation (Fig. 27.4).

**Figure 27.4.** Nonunion of a distal clavicle fracture. A: A 25-year-old skier suffered a displaced fracture of the distal third of his clavicle. Nonoperative treatment was unsuccessful. He had pain and an unsightly deformity at 6 months. The atrophic nonunion was completely mobile. B: Internal fixation was performed using a third-tubular plate. There is an interfragmentary screw across the fracture site and a coracoclavicular screw. The most distal screw runs obliquely through the longest portion of the acromion. A cancellous bone graft was applied. C: At 8 weeks, the coracoclavicular screw was removed. Before this, the patient had been allowed pendulum exercises with abduction of his shoulder to only 90°. After screw removal, full range of motion was instituted. D: A radiograph 1.5 years after operative intervention shows that the plate has been removed, and there is solid union of the nonunion.

- Reduce the fracture, then drill the Hagie pin into the medial fragment. When the pin is in place, the fracture site should be in excellent apposition and compression. If there is a gap, apply the nut to the lateral end of the pin and compress the fracture (Fig. 27.3G, Fig. 27.3H).
- Finish petaling the bone ends at the nonunion site for a distance of 2.5 cm on either side of the nonunion. Bone graft the fracture on all exposed surfaces except the anterior subcutaneous border. Boehme et al. (4) use osteal/periosteal rib grafts, as described by Dineen and Greshman (19); however, cancellous graft from the iliac crest works well also.
- Closure is as described previously.

**Postoperative Care**

Assuming that good fixation has been achieved, the postoperative care for all three of the above-mentioned procedures is similar. Protect the shoulder in a sling until the patient is comfortable. Begin passive circumduction exercises (Codman’s), progressing as quickly as the patient can tolerate. Patients can use the extremity for light activities of daily living but should avoid any strenuous use of the extremity, lifting of other than very light objects, and overhead activities until 6 weeks after the surgery. Between 6 and 12 weeks, depending on the state of union, progress with gentle overhead pulley exercises but avoid raising the arm against gravity or any strenuous use until the nonunion is solidly healed, which generally takes 10 to 12 weeks.

**Bumpectomy**

In many malunions, function is normal and the patient has no pain. The major concern is the bump from the malunion. In these cases, simple removal of the bump with an osteotome and smoothing of the clavicle suffices.

**Results**

The results of treatment of clavicular nonunions using the techniques described above are excellent, with success rates of 92% to 100% after the first operation.
CLAVICULECTOMY

Removal of the clavicle is rarely indicated and usually results in only minimal morbidity (59). Patients usually complain of weakness and early fatigue when working with the extremity above the head. Some have chronic pain. Claviculectomy is usually indicated for some infected nonunions, major bone loss, or a painful nonunion that is unresponsive to surgical treatment. Sometimes, claviculectomy is necessary to relieve thoracic outlet syndrome. Claviculectomy may be combined with simultaneous resection of the first rib, which is usually done through an independent axillary exposure. To avoid an unsightly, painful, unstable clavicle, resect it only as indicated in Figure 27.5.

Figure 27.5. Partial claviculectomy. Note that the remaining segment is always stabilized by ligaments. Shaded areas indicate resected parts of bone. A: Distal claviculectomy, usually done for acromioclavicular arthritis. This can be part of a Weaver-Dunn procedure (102). B: Resection of the medial intercalary two thirds. The lateral and medial segments are stabilized by their ligamentous attachments. C: Resection of the lateral two thirds, leaving a stable medial fragment. D: Resection of the medial end for arthritis or instability of the sternoclavicular joint. Instability of the remaining clavicle at its medial end may require stabilization to the first rib (see Chapter 78).

- Expose the clavicle, as described earlier for repair of a nonunion. Expose only that portion of the clavicle planned for resection.
- When resecting the mid two thirds of the clavicle or the distal two thirds, you can facilitate resection by entering the nonunion site or making an osteotomy just lateral to the ligaments, stabilizing the medial end of the clavicle. Expose it with careful circumferential subperiosteal exposure.
- Grasp this free end of the clavicle with a bone-holding forceps and then excise the clavicle in a subperiosteal manner from its bed to the distal resection site.
- Resection of the medial end of the clavicle as illustrated in Figure 27.5D requires special consideration because of the underlying major neurovascular structures. (See Chapter 78 for a description of this exposure and resection.)
- When resecting the clavicle distal to the attachments of the coracoclavicular ligaments, it is essential that these ligaments be intact or reconstructed (see Chapter 78) (102).

HINTS AND TRICKS

- Resection of a deformed clavicle surrounded by dense scar can be challenging on occasion because of the closeness of the underlying neurovascular structures. The best technique is subperiosteal resection, keeping sharp instruments directly against the clavicle and avoiding penetration into the underlying soft tissues. The presence of the subclavius muscle and the clavipectoral fascia usually provides adequate protection for these vital structures.
- The major disadvantage of subperiosteal resection is that occasionally the clavicle partially reforms from the periosteum. This is particularly true in young adults. If reformation of a clavicular remnant is a problem, then an extra periosteal resection is indicated. This requires additional caution.
- Careful repair of the periosteum, deep fascia, and platysma usually results in the formation of a fibrous scar, which simulates the excised clavicle and gives a reasonable cosmetic result.
- Warn all patients that they will experience less strength and endurance in using the shoulder, particularly for overhead or pushing activities.

PROXIMAL HUMERUS

Fractures of the proximal humerus account for 4% to 5% of fractures and occur most frequently in the elderly (40). Failure of this fracture to unite within 6 to 8 weeks constitutes a delayed union. At 12 weeks, an unstable fracture with no evidence of callus formation is unlikely to heal. Therefore, operative treatment is usually indicated. Nonunion of the surgical neck of the humerus is rare (53). Displaced fractures that remain unreduced owing to muscle forces, interposed deltoid or biceps, or treatment producing distraction may result in nonunion. In Neer’s series (70,71), nonunions were more commonly associated with hanging casts or skeletal traction and displaced four-part fractures. The incidence of proximal humerus fractures in women is twice that in men. Osteoporosis and a short proximal fragment covered for the most part by articular cartilage makes treatment difficult (Fig. 27.6) (35). Therapeutic alternatives include symptomatic treatment only, open reduction, and internal fixation combined with a bone graft or prosthetic replacement. Because of the challenge of obtaining fixation in the proximal articular fragment, many different approaches have been used, including simple plate and screw fixation, double plate fixation, multiple stiff and malleable wires, Rush rods or Ender pins combined with malleable wires in a figure eight, and various types of blade plates or specially designed reconstruction plates for the proximal humerus (90,94,49,48,100). In elderly and in middle-aged adults with severe avascular necrosis of the humeral head, a reasonable alternative is prosthetic replacement of the proximal humerus. Because the nonunion is typically through the surgical neck, restoration of the insertion of the rotator cuff is important. If there is coexisting osteoarthrosis of the shoulder joint, consider total shoulder replacement. In young patients who require a stable pain-free shoulder for heavy labor, consider arthrodesis (see Chapter 103) (Fig. 27.7).

Figure 27.6. Bilateral painless pseudarthrosis of the proximal humerus in a 72-year-old woman. This patient had adequate motion in her shoulders for her activities of daily living.
Isolated fractures of the tuberosities leading to nonunion are usually accompanied by major ruptures in the rotator cuff. The most likely avulsion fracture to progress to nonunion is one involving the posterolateral aspect of the greater tuberosity, involving the insertions of the infraspinatus and teres minor. On an anteroposterior (AP) view, these tend to be visualized posterior to the humeral head and, therefore, are easily missed. The major focus in repair of these is reconstruction of the rotator cuff, which is described in Chapter 75. Fixation of the tuberosity is usually best accomplished by placing it back into its bed and securing it with multiple figure-eight or horizontal nonabsorbable sutures interwoven through the insertion of the rotator cuff and the proximal fragment, and tied through drill holes in the proximal shaft of the humerus. Screws and other metallic fasteners usually fail because the avulsed fragment is a thin cortical shell and is usually full of multiple cracks.

OPERATIVE INDICATIONS

Most fractures of the proximal humerus occur in elderly individuals, who, if sedentary, may function reasonably well with a painless pseudarthrosis or a malunion that does not interfere significantly with their activities of daily living. Consequently, premenopausal patient activity, age, occupation, and hand dominance play important roles in the decision whether to surgically repair a proximal humerus nonunion. Repair of a nonunion of the proximal humerus or osteotomy to correct a malunion requires careful preoperative planning because of the challenge of obtaining adequate fixation in the proximal fragment. Rigid fixation is important to allow patients to begin fairly vigorous circulation exercises immediately; otherwise, unacceptable shoulder stiffness may result. It is usually advisable to have a backup plan with the necessary implants and instrumentation available. In suitable patients, the backup to reconstruction of the fracture may be prosthetic replacement. Be certain to discuss this alternative with your patient, and have the prosthesis and instrumentation available in the event that repair of the nonunion is not technically feasible.

I have had a high rate of success treating difficult nonunions of the proximal humerus through the use of small fragment double plate fixation combined with iliac crest bone graft through a modified deltopectoral approach, which is described below.

REPAIR OF NONUNION WITH DOUBLE PLATE FIXATION AND BONE GRAFT

- Expose the proximal humerus through a Henry's deltopectoral approach (see Chapter 1). Do not take down any of the origin of the deltoit or pectoralis major muscles. If more extensive exposure is required, take down the insertion of the deltoid in a subperiosteal manner, using a sharp knife or electrocautery knife. Take this down in continuity with the brachialis muscle. Identify and coagulate the large bleeders in this area. This provides ample exposure but does not require direct reattachment of the deltoid insertion to the humerus, because simple closure of this musculofascial sleeve restores the continuity of the deltoid.
- Occasionally, exposure of the joint is necessary, in which case a partial take down of the origin of the short head of the biceps and coracobrahialis from the tip of the coracoid are useful. This step provides excellent exposure, making the spiral compression plate described by Gill and Torchia unnecessary.
- Expose the nonunion site laterally and anteriorly. Try to maintain soft-tissue attachments on the posterior and medial borders. These nonunions are nearly always pseudoarthroses or atrophic nonunions.
- Remove soft tissues from the fracture site and freshen the fracture ends, fashioning them to fit together in a manner that restores anatomic alignment and maximizes the contact of the bone surfaces. Open the medullary canal of the distal fragment and use a 2 mm drill point to drill the sclerotic surface of the nonunion in multiple places on the proximal fragment.
- Reduce the nonunion and secure the position with a bone-holding forceps. Often, these nonunions are oblique, and initial fixation can be done with an interfractionary compression screw.
- Fashion two Alta small fragment reconstruction plates (or another, similar plate) to fit along the lateral and anterior borders of the fracture, extending up to the articular surface. The bevelled ends of the plates permit fixation close to the articular surface without impingement on the acromion or rotator cuff. Locate these plates as close to 90° to each other as possible. Secure the plates to the humerus with 3.7 cortical screws, which are bicortical where there is not articular cartilage. In the proximal fragment, it is often possible to obtain bicortical fixation on the proximal fragment through the anterior plate, whereas with the lateral plate, the direction of the screws is toward the articular surface; therefore, the screws must be placed short of the subchondral bone. Cortical screws inserted without tapping tend to get a better hold than cancellous screws. If they strip out, replace them with the larger cancellous screws. To improve fixation in osteoporotic bone, try cross-threading the screws against each other in the proximal fragment or, as a last resort, inject methacrylate into each screw hole individually.
- Gently peal the nonunion site up to the articular surface on the proximal fragment for at least 2.5 cm on the distal fragment, and apply finely morcelized cancellous bone in a solid layer all along available bone surfaces. The small, narrow profile of the Alta plates usually leaves ample room for application of a bone graft. If space is insufficient, further medial exposure makes a good location for bone graft (Fig. 27.8).
- Close the deltopectoral interval and the brachialis-deltoid interval, if necessary, in a single layer with interrupted resorbable sutures. Perform a plastic closure of the subcutaneous fat and skin.
- Im mobilize the shoulder in a shoulder immobilizer.
- Alternative methods of internal fixation include blade plates fashioned out of third-tubular or semitubular plates (22). Although these plates are useful and low profile, I have found them to be weak. The construct can be reinforced by placing an oblique screw from the portion of the plate along the shaft up through the tip of the plate (see Chapter 20), but this is technically tricky. Specialized blade plates and reconstruction plates are now available as well (42,45,51).
- I no longer use large fragment T or L plates because they are difficult to bend and conform to the proximal humerus, and they can cause acromial impingement. Their broad surface area inhibits revascularization of the nonunion site.

If the construct is stable, most patients can begin gentle pendulum circumduction exercises within a few days. Allow patients to remove the shoulder immobilizer to
shower once the wound is sealed. Otherwise, have patients wear the shoulder immobilizer both night and day for the first 6 weeks to protect the repair. If at 6 weeks union seems to be progressing, then a more vigorous circumduction exercise program to maximize shoulder range of motion can begin. Avoid resistive exercises and active elevation of the arm until solid union has occurred, which usually requires 12 weeks. Thereafter, patients can engage in a full range-of-motion and strengthening program. Nonunions with nonunions have very stiff shoulders, but I have found that they reacquire good (although rarely normal) functional range of motion and strength after about a year of vigorous rehabilitation.

Correction of a malunion at the same site employs essentially the same techniques except that a closing wedge osteotomy is made through the nonunion site to correct the deformity.

HUMERAL SHAFT

Before the current functional methods of treatment, nonunion rates were as high as 30% for humeral fractures (42,72). With functional bracing, union can now be achieved in 92% to 95% of these fractures (72,88). Nonunion has been associated with inadequate immobilization, distraction of the fracture, soft-tissue interposition (particularly at the deltid tubercle), and use of inappropriate nonrigid internal fixation (21,24). A fracture that is mobile and shows no evidence of callus at 12 weeks is unlikely to heal. A gap can be seen on radiographs if nonunions may be in both treating nonoperatively until 6 months, but I tend to intervene soon after 12 weeks to prevent long-term permanent joint stiffness from prolonged immobilization. As with nonunions in the proximal humerus, nonunions in the diaphysis are frequently challenging. Esterhai et al. (28) found that, in 46 nonunions, 82% were in elderly patients who were senile and had disuse osteoporosis. Forty-two percent were synovial pseudarthroses; 20% were obese; and 5% had osteomyelitis. Of the patients they elected to treat with electrical stimulation, only 46% healed despite the fact that their group is the most expert in the world in electrical stimulation. For that reason, I do not believe that electrical stimulation is worth using in nonunions of the humerus unless it is a hypertrophic nonunion, proven by computed tomographic (CT) scan and bone scan not to be a synovial pseudarthrosis. It must be well immobilized. Internal fixation is best for most patients, but consider electrical stimulation for patients in whom surgery is contraindicated or risky.

Malunion of the humeral diaphysis is rarely a functional or cosmetic problem. The soft-tissue coverage of the arm can obscure up to 20° of anterior or posterior angulation and up to 30° of varus. Shortening of as much as 2.5 cm does not lead to disability, and rotational malalignment can easily be compensated through the shoulder (24).

OPERATIVE INDICATIONS

Treatments of nonunion and malunion are similar. Indications for surgery include:

- An unstable delayed union of the humerus at approximately 8 weeks after injury, with an obvious gap on radiographs owing to bone loss or soft-tissue interposition, which precludes healing.
- An established nonunion of the humerus at 12 weeks that is unstable and painful or, if free of pain, is so mobile that effective functional use of the extremity is not possible.
- A severe malunion of the humerus, usually in younger, active patients, that is absolutely cosmetically unacceptable to the patient (usually severe varus with loss of carrying angle) or causes a functional deficit sufficient to interfere with normal activities of daily living, vocational activities, or sports.

ASSESSMENT

Completely assess the patient’s needs and current function in order to establish appropriate goals for the surgery. The shoulder and elbow may be quite stiff, and the patient may be using the nonunion as a false joint, particularly if it is a more distal nonunion close to the elbow. Stabilization of the nonunion may result in significant loss of motion, which the patient may find more disabling than the nonunion. Concomitant soft-tissue procedures and capsular release to increase elbow and, on occasion, shoulder motion may be essential to achieve a satisfactory result. The prolonged immobilization and disuse associated with nonunions of the humerus frequently occur in osteoporosis, which diminishes the holding power of screws. Pre-existing hardware with large radiolucent areas around the fixation device can also destroy bone stock. A thorough preoperative plan with alternatives is important so that the procedure will be successful. Operative techniques include the following:

- When a preexisting intramedullary nail is in place and alignment is acceptable, closed reamed locked exchange nailing is a good technique, but the bone stock must be substantial to provide good fixation for the cross-locking screws. Union is usually slower and less dependable then plate fixation with bone grafting (67).
- Initial primary intramedullary nailing with or without bone grafting almost always requires an open reduction, particularly because the radial nerve is at risk of injury with closed techniques. Nonlocked nails and the Seidel nail do not give a high enough success rate to justify their use for nonunions (15,17,79). Intramedullary techniques do not provide as good fixation as plates and necessitate opening the humerus proximally, which can lead to rotator cuff dysfunction and chronic shoulder pain. The loss of the intramedullary blood supply may slow union. For that reason, I believe the only role for intramedullary nailing for treatment of nonunions of the humerus is exchange nailing for a preexisting nail.
- Plate fixation with bone graft is the most commonly used and most effective method for treating nonunions of the diaphysis of the humerus. It includes variations such as standard AO-type compression plating, adjunctive intramedullary screw fixation, wave plates, and intramedullary plates (13,46,79,81).
- A fibula split and then fixed on both sides of the nonunion as “plates” has been successful but, with modern internal fixation, is not indicated today. When bone stock is a major problem, however, use of a split fibula to provide a backup to the plate on the opposite cortex for screw fixation is quite useful and a good alternative to allograft (28).
- Difficult atrophic nonunions with loss of bone continuity or nonunions with major bone loss can be treated with plate fixation and a vascularized fibular graft used in a medial approach (38).
- When osteopenia precludes good screw fixation, another alternative is the use of adjunctive bone cement, which must be combined with a copious bone graft, to provide additional support for the hardware in support of a bone graft.
- External fixation is useful when osteomyelitis contraindicates the placement of implants at the fracture site but has the disadvantage of frequent loosening of pins due to poor-quality bone, pin tract infection owing to the mobile soft tissues in the upper extremity, and interference with shoulder and elbow rehabilitation owing to be down of muscles by the external fixation pins (47).

PLATE FIXATION AND BONE GRAFT

Use Henry’s extensile anterolateral approach to the humerus (see Chapter 1). The exploration of the radial nerve can be the most challenging part of this procedure, and bone quality may require a long plate; therefore, it is essential that the surgical approach be extensile to both ends of the humerus. Use a posterior approach only if suprascapular nonunions when exposure beyond the midshaft humerus is not necessary.

- The position of the radial nerve can be nonanatomic, and it commonly is involved in the soft-tissue scar or fracture callus. Identify the nerve in the interval between the brachialis and brachioradialis muscles distally and trace it past the nonunion site into the spiral groove. If the nerve is embedded in scar, it is usually necessary to place it in a vascular loop and protect it during the repair of the nonunion.
- It is rare to be able to fix the nonunion in situ; therefore, take the nonunion down, remove all fibrous tissue from between the bone ends, send a specimen for culture, freshen the bone ends, and open the medullary canals. Sculpt the ends of the bone fragments as necessary to maximize cortical contact and to ensure good alignment.
- Shortening up to 2.5 cm in most patients is acceptable if it is necessary to obtain apposition over the full width of the cortex. In elderly patients, in whom functional demands are lower, even more shortening is acceptable.
- Apply a broad plate with 4.5 to 5.0 mm cortical screws, obtaining at least eight cortices of solid fixation both proximally and distally. Many of the tricks for obtaining solid screw fixation are described earlier. Plates usually fit best along the anterolateral aspect of the humerus. In this location, they are free of the radial nerve and function as a tension band. Always try to obtain interfragmentary compression, either through the plate or, better, independent of the plate.
- After the initial plate and interfragmentary screw are in place, gently stress the construct, looking for micromotion in the fracture site. If it is present, or the hold of the screws is tenuous, I always put a second plate at right angles to the first plate along the anteromedial cortex. This plate should be a small fragment plate shorter than the original plate, with at least six cortices of fixation above and below. The shorter, lighter plate leaves more humerus exposed for revascularization and bone graft, and minimizes the risk of a stress riser at the end of the double plates.
- Place the available bone surface with a quarter-inch osteotome for at least 2.5 cm proximal and distal to the fracture, and lay a morcelized cancellous bone graft along the humerus. If there is cortical deficiency, cortical cancellous grafts are useful.
- Place a suction drain and meticulously close the soft tissue. Close the intermuscular interval in which the radial nerve lies with a layer of sutures deep to the radial nerve, and skin in a routine fashion. A drain is usually advisable.
- Place the arm in a sterile dressing and shoulder immobilizer.

Postoperative Care

Fixation is solid enough that most patients do not require protection, although I have them wear a shoulder immobilizer for the first 6 weeks to remind them not to use...
the arm for anything but the lightest of activities of daily living. A Sarmiento-type fracture brace is also useful. Begin gentle, active range-of-motion exercises for the elbow and shoulder immediately, using circumduction exercises for the shoulder to avoid bending stresses on the plate. At 6 weeks, if healing is progressing well, overhead pulley exercises for the shoulder can begin. Avoid resistive exercises or any use of the extremity for other than light activities of daily living until solid union is documented, which is usually 12 or more weeks after surgery. Once solid union occurs, continue a vigorous range-of-motion and strengthening rehabilitation program to restore shoulder and elbow function (Fig. 27.9).

Figure 27.9. A 25-year-old man who had previous plate fixation of a fractured humerus, which resulted in a painful nonunion. A: Notice the inadequate plate and the radiofluencies around the screws, demonstrating looseness of internal fixation. B: The contoured “wave” plate was placed on the tension side of the nonunion. C, D: The nonunion has consolidated. The most distal screw is unicortical, not blocking the olecranon fossa.

Results

Plate fixation with bone grafting for nonunions of the humerus is very successful, with union rates in various series reported from 91% in a difficult group of nonunions in elderly patients to 100% (29, 38, 42, 57, 66, 81, 88, 103). The results with intramedullary fixation are much less predictable, with union rates reported from 54% to 87% (15, 32, 78).

OSTEOTOMY FOR MALUNION

Osteotomies for malunions of the diaphysis of the humerus are exceedingly rare. Most are performed for supracondylar nonunions with varus deformity and loss of the carrying angle. (See the next section.) The surgical technique is nearly identical to that described earlier for the nonunion. In most cases, a single-plane osteotomy permits correction of the deformity, and some length can be regained if the osteotomy is long enough. Stabilize it with an interfragmentary screw and a broad plate, as described earlier.

DISTAL HUMERUS SUPRACONDYLAR AND INTRAARTICULAR NONUNIONS AND MALUNIONS

Nonunions of the distal humerus can be classified as nonarticular (that is, supracondylar) or intraarticular (usually involving the lateral condyle, but involvement of the medial condyle is possible as well) (59). Nonunions in this region are exceedingly rare, because acute fractures about the elbow make up only 2% of all fractures and the cancellous bone in this region usually leads to union. Malunion is more common. Ackerman and Jupiter (1) treated only 20 patients with nonunions of the distal humerus during a 16-year period at a major referral center. A general orthopaedic surgeon may encounter only one of these nonunions in his or her career. Patients treated nonoperatively and those with neglected fractures frequently have considerable stiffness in the elbow joint and use the nonunion as a false joint to gain additional motion at the elbow. Knowledge of the available range of motion in the elbow is essential for preoperative planning. Lateral radiographs of the elbow joint in flexion and extension and the distal humerus usually demonstrate the true range of motion in the elbow and the instability in the fracture. In supracondylar nonunions, the cartilage of the joint is usually well preserved; therefore, a comprehensive soft-tissue release to regain elbow motion not only greatly enhances function but makes it more likely that the nonunion will heal by relieving stress on the nonunion site through the increased motion of the elbow joint. Previously open supracondylar fractures with nonunion, such as in side-swipe injuries, may have occurred because of bone loss. In a neglected nonunion that is functioning as the elbow joint, mechanical erosion of the bone ends frequently leads to shortening and loss of bone substance (Figs. 27.10 and 27.11). Reconstruction of these injuries can be difficult owing to the short articular fragment and the differential in size between the articular fragment and the shaft. Although the risk of failure is somewhat higher, use of a structural intercalary bone graft is sometimes necessary to reconstruct these difficult nonunions, as illustrated in Figure 27.11.

Figure 27.10. AP and lateral radiographs of a 42-year-old man with a supracondylar nonunion of the humerus. He had only a 40° arc of motion in the elbow joint and had been using this pseudarthrosis for motion. Note the resorption of the proximal fragment and the size mismatch at the fracture site. See Figure 27.11 for management of this problem.

Figure 27.11. A: Nonunion of a supracondylar fracture of the humerus in a 50-year-old woman. AP view shows 2.5 inches (7.5 cm) of bone loss. This fracture was open and was initially fixed with K-wires. No infection occurred, but it did not heal. A second operation at another institution, using bone graft and the K-wire fixation seen in this radiograph, was unsuccessful. B: Lateral view. C: The nonunion was treated with bone grafting and internal fixation in the following manner:

- Through a posterior approach, the hardware was removed, fracture ends curedtted, and length restored.
- A bicortical graft from the ilium was harvested.
- The graft was shaped and fitted into the defect with some tension in the surrounding soft tissues to produce compression across the graft.
- Internal fixation with two AO 4.5 mm reconstruction plates, one on each pillar of the distal humerus was achieved.

D: Anteroposterior view 12 weeks after surgery, at which time union appears to have occurred. The plates stop at different levels proximally to reduce the stress-riser
Indications for surgery include necessary to improve or maintain motion.

OPERATIVE INDICATIONS AND ALTERNATIVES

Indications for surgery include:

- Intolerable pain from the nonunion.
- Deformity that is not compatible with the level of function the patient expects or is cosmetically unacceptable.
- Enough instability in the nonunion that the patient can no longer function at the level needed.
- Prior attempts at nonoperative treatment have been unsuccessful.
- Progressive ulnar nerve palsy. Treatment alternatives include Nonoperative treatment with supportive bracing.

REPAIR OF SUPRACRYPHAL HUMERUS NONUNION WITH DOUBLE PLATE FIXATION AND BONE GRAFT

Position the patient in a lateral decubitus position on a regular operating table, with the operated extremity uppermost. Support the arm on a well-padded obstetrics and gynecology leg holder or similar device, permitting gravity to allow the forearm to dangle at an angle of 90°. Prepare and drape the extremity free to the shoulder, and prepare the iliac crest for bone graft harvest as well.

Approach the nonunion through double plate fixation and bone graft.

For cubitus valgus with a healed malunion of the lateral condyle or a stable fibrous union, a closing-wedge or opening-wedge osteotomy with plate fixation and a structural bone graft, if an opening wedge is performed. Anterior transfer of the ulnar nerve for tardy ulnar nerve palsy is usually necessary.

In some cases, direct repair of a nonunion of the lateral condyle is possible, but usually there is sufficient remodeling that a satisfactory intraarticular contour is exceedingly difficult to obtain.

Now take down the nonunion, freshen the bone ends, and reshape them to obtain maximum cortical apposition and to correct deformity. Open the medullary canal proximally, and multiply drill the facet of the distal fragment distally with a 2 mm drill point.

Now internally fix with double plates, one on the posterior aspect of the lateral condyle and another along the medullary supracondylar ridge at right angles to the posterior lateral plate. Molding the plates to the bone is challenging; therefore, use 3.5 mm reconstruction plates or their equivalent.

On the lateral side, fashion the plate to fit down to the articular surface of the lateral condyle, taking care to be certain that there is no impingement with the radial head when the elbow is in full extension. Try to obtain at least three cortical screws of fixation in the distal fragment. The most distal screws running from posterior to anterior must not pass through the articular surface, and therefore cannot be bicortical. I prefer to use non-tapped cortical screws, because this seems to provide better purchase than cancellous screws. Approximately four bicortical screws of solid fixation in the proximal fragment are usually adequate. On the medial side, usually the plate does not need to extend around the medial curvature of the medial epicondyle unless the distal fragment is quite small. This plate normally provides excellent fixation, because the distal screws can extend transversely across the condyles in a bicortical fashion. Try to place a similar number of screws in both fragments mediaevally as well.

If an intercalary defect is present that cannot be handled by direct apposition of the two fragments, use a technique similar to that described in Figure 27.11.

Examine the elbow to determine the range of motion. A range of –20° of extension to 120° of flexion provides reasonably good function. If it is not present, consider a soft-tissue release (60,63).

Excise all intraarticular adhesions.

Inspect the olecranon and remove any osteophytes that are preventing full extension.

Excise the olecranon fossa and remove any osteophytes that are blocking full extension. If there is a block to flexion, make a window in the olecranon fossa to provide access to the coronoid fossa and permit removal of anterior osteophytes that may be blocking motion. This should provide extension to within 10° of neutral.

If extension appears to be limited owing to a tight anterior capsule, then dissect carefully along the anterior aspect of the capsule from lateral to medial, isolating the capsule from the anterior soft-tissue structures. Then carefully excise the anterior capsule, taking care to avoid injury to the anterior neurovascular structures. This also will provide excellent exposure for removal of any anterior osteophytes that might be impeding full extension.

When carrying the elbow through range of motion, be certain that the articular surface of the olecranon remains completely congruent with the distal end of the humerus rather than hinging open, which gives a false measurement of the available motion in flexion.

Appraise the bony nonunion, taking care to inspect the bone graft against the joint.

If a tourniquet is used, deflate it now and ensure good hemostasis. Drain the elbow. Meticulously close the posterior longitudinal wound. In the case of a triceps-splitting approach, close the deep capsule and deep triceps in a separate layer and then close the triceps aponeurosis and approximate the fascia of the extensor and flexor compartments of the forearm in a single layer with interrupted #0 resorbable sutures. Close the subcutaneous fat and skin in the usual manner. Take care to be certain that the ulnar nerve remains in good position.

Most patients tolerate immobilization better in a position of about 20° of flexion than in one of 90°. Apply a bulky dressing and medial and lateral splints to support the elbow just short of full extension. Elevate the arm 10 cm above the heart.

Postoperative Care

Considerable swelling and occasionally even skin blistering or compartment syndrome can occur after extensive reconstructive procedures about the elbow. Monitor the patient carefully during the first 48 hours postoperatively. If the patient has pain beyond that expected, be certain to release the dressing fully and inspect the wound carefully. If swelling is excessive or compartment syndrome threatens, early release of the surgical incision down to the deep fascia, and occasionally even deeper, may be necessary. After swelling subsides, the wound is usually easily reapprroximated.

As soon as swelling subsides and the patient becomes comfortable, remove the bulky dressing and splint, apply a lightweight Bledsoe-type brace, and immediately begin active range-of-motion exercises. With this procedure, it is absolutely essential that the patient begin early aggressive, active motion under the supervision of a therapist. The goal is to achieve the full motion expected by 6 weeks after surgery. On the operative table, before awakening the patient, it is possible to examine the elbow under anesthesia to establish what the safe range of motion is before excessive stress is placed on the reconstruction of the nonunion. A brace can be set for this range of motion to protect the nonunion during this rehabilitation. When bone-to-bone apposition has been achieved, reasonably good stability is present at 6 weeks, but full union usually requires 12 to 16 weeks. Do not allow resistive exercises or use of the extremity for other than light activities of daily living until full union has occurred. I have not found continuous passive motion for the elbow to be of value.

OSTEOTOMY FOR CUBITUS VALGUS

Position the patient in the supine position on an operating table, and prepare and drape the operated extremity free as well as the iliac crest for bone graft harvest. Make a longitudinal incision, beginning over the radial head and extending proximally along the midlateral aspect of the humerus. Dissect directly down to the capsule from the anterior soft-tissue structures. Then carefully excise the anterior capsule, taking care to avoid injury to the anterior neurovascular structures. Then perform a bicortical osteotomy through the lateral condyle, extending into the proximal humerus. This also provides excellent exposure for removal of any anterior osteophytes that might be impeding full flexion.

Inspect the olecranon and remove any osteophytes that are preventing full extension.

Inspect the olecranon and remove any osteophytes that are preventing full extension. If extension appears to be limited owing to a tight anterior capsule, then dissect carefully along the anterior aspect of the capsule from lateral to medial, isolating the capsule from the anterior soft-tissue structures. Then carefully excise the anterior capsule, taking care to avoid injury to the anterior neurovascular structures. This also will provide excellent exposure for removal of any anterior osteophytes that might be impeding full extension.

When carrying the elbow through range of motion, be certain that the articular surface of the olecranon remains completely congruent with the distal end of the humerus rather than hinging open, which gives a false measurement of the available motion in flexion.

Appraise the bone graft along the edge of the nonunion, taking care to inspect the bone graft against the joint.

If a tourniquet is used, deflate it now and ensure good hemostasis. Drain the elbow. Meticulously close the posterior longitudinal wound. In the case of a triceps-splitting approach, close the deep capsule and deep triceps in a separate layer and then close the triceps aponeurosis and approximate the fascia of the extensor and flexor compartments of the forearm in a single layer with interrupted #0 resorbable sutures. Close the subcutaneous fat and skin in the usual manner. Take care to be certain that the ulnar nerve remains in good position.

Most patients tolerate immobilization better in a position of about 20° of flexion than in one of 90°. Apply a bulky dressing and medial and lateral splints to support the elbow just short of full extension. Elevate the arm 10 cm above the heart.

Postoperative Care

Considerable swelling and occasionally even skin blistering or compartment syndrome can occur after extensive reconstructive procedures about the elbow. Monitor the patient carefully during the first 48 hours postoperatively. If the patient has pain beyond that expected, be certain to release the dressing fully and inspect the wound carefully. If swelling is excessive or compartment syndrome threatens, early release of the surgical incision down to the deep fascia, and occasionally even deeper, may be necessary. After swelling subsides, the wound is usually easily reapprroximated.

As soon as swelling subsides and the patient becomes comfortable, remove the bulky dressing and splint, apply a lightweight Bledsoe-type brace, and immediately begin active range-of-motion exercises. With this procedure, it is absolutely essential that the patient begin early aggressive, active motion under the supervision of a therapist. The goal is to achieve the full motion expected by 6 weeks after surgery. On the operative table, before awakening the patient, it is possible to examine the elbow under anesthesia to establish what the safe range of motion is before excessive stress is placed on the reconstruction of the nonunion. A brace can be set for this range of motion to protect the nonunion during this rehabilitation. When bone-to-bone apposition has been achieved, reasonably good stability is present at 6 weeks, but full union usually requires 12 to 16 weeks. Do not allow resistive exercises or use of the extremity for other than light activities of daily living until full union has occurred. I have not found continuous passive motion for the elbow to be of value.
This is an exceedingly rare nonunion; I was able to identify only one reported case of bilateral radial neck nonunion. The definitive treatment involves open reduction and internal fixation with a compression plate and interfragmentary lag screws.fixation with a compression plate and interfragmentary lag screws. The healing period is approximately 6 to 8 weeks, during which the patient should avoid any strenuous activity. Failure may occur if the nonunion is not treated promptly or if there is inadequate bone stock.

**Results**

From the standpoint of achieving union in nonunions, the results are quite good. Ackerman and Jupiter achieved union in 17 of 18 patients, Sanders and Sackett achieved union in five of five patients, and in my personal series of 12 patients, I achieved union in 100%. Those who required a soft-tissue release to achieve union, or who have intraarticular fractures, have difficulty achieving union, and we generally have joint resection arthroplasty. However, in some patients, we have had astounding results, with gains in total motion of over 100°, and in others, we have seen no improvement from the preoperative range of motion. The determining factors appear to be the degree of intraarticular adhesion and arthritis, and the ability of the patient to exercise in the face of discomfort during the postoperative recovery.

**TOTAL ELBOW ARTHROPLASTY FOR SALVAGE OF DISTAL HUMERAL NONUNION**

Failed salvage of supracondylar nonunions can leave patients with a painful, flail extremity with which they are unable to perform even the minimal activities of daily living. In these patients, particularly if they are elderly, total elbow arthroplasty provides a method for salvage. Morrey and Adams reported on 36 consecutive patients with an average age of 62 years who underwent semiconstrained elbow replacement for distal humeral nonunion, with an average follow-up of somewhat more than 4 years. Of these patients, 86% had a satisfactory result and only two had a poor result. Patients showed a marked decrease in pain and an improvement in the overall mean arc of motion from 74° to 111°. This is a challenging procedure, however, as evidenced by the fact that seven patients had complications and five of these required reoperation.

**OLECRANON**

Nonunion of the olecranon is usually due to neglect of the original fracture (such as in alcoholics who fail to seek treatment) or failed internal fixation (usually a tension band wire), or is secondary to major bone loss such as in side-swipe injuries. Nonunions due to bone loss are much more challenging because they often involve a segment of the articular surface. Indications for surgery include pain and functional loss. Alternative methods of treatment in addition to bone graft include compression-plate fixation with a 3.5 reconstruction plate placed on either the medial or lateral surfaces of the olecranon and ulnar shaft; tension band plating with a hook plate, as illustrated in Figure 27.12; or repeat tension band wiring, using a combination of screws and 18-gauge wire for the tension band.

**Figure 27.12.** Nonunion of the olecranon. A: Inadequate tension band fixation of an olecranon fracture resulted in a nonunion. B: Fixation has been removed, and a one third tubular plate has been fashioned as a hook plate, using the end hole as two sharp prongs. The tensioning device was applied after fixation of the plate to the olecranon and ulnar shaft; tension band plating with a hook plate, as illustrated in Figure 27.12; or repeat tension band wiring, using a combination of screws and 18-gauge wire for the tension band.

**REPAIR OF NONUNION**

- Expose the olecranon by subperiosteal dissection. If there is a stable fibrous nonunion in good position, internal fixation in situ is indicated.
- Otherwise, excise the fibrous tissue from the nonunion site, freshen the bone ends and open the medullary canal of the distal fragment, and reduce the fracture.
- Take care to not reduce the diameter of the olecranon fossa because this will produce incongruence in the elbow joint, which can lead to loss of motion, pain, instability, and precocious arthritis.
- If a gap is present, harvest a tricortical bone graft from the anterior iliac crest to interpose in the nonunion site. Place this so that it does not impinge on the articular cartilage. This will leave a gap in the articular surface, which is usually acceptable.
- Place a reconstruction plate along the medial or lateral border of the olecranon, and mold it carefully to maintain anatomic position.
- Apply a cancellous bone graft.
- After completion of the fixation, examine the elbow under anesthesia to determine the safe range of motion that can be used postoperatively without excessively stressing the construct.
- Close the wounds and apply a bulky soft dressing, splinting the elbow just short of full extension.
- After swelling has subsided, apply a Bledsoe-type brace with the locks set to permit a safe range of motion, and immediately begin active gentle motion. Avoid use of the extremity for anything but light activities of daily living until union occurs, which is generally no earlier than 8 weeks. Most heal by 12 weeks, but some take as long as 16 weeks if an intercalary bone graft has been used (Fig. 27.13).

**Figure 27.13.** Nonunion of the olecranon. A: AP and lateral radiographs showing failure of a third tubular plate, resulting in nonunion. B: AP and lateral radiographs. This fibrous nonunion was in an acceptable position and, therefore, was treated with compression plate fixation and an interfragmentary compression screw in situ, resulting in rapid healing.

**NONUNION OF THE NECK OF THE RADIUS**

This is an exceedingly rare nonunion; I was able to identify only one reported case of bilateral radial neck nonunion. This was treated with an intramedullary iliac...
The precise definition of what constitutes a malunion in the forearm has been elusive, but recent work provides reasonably good guidelines. Operative intervention for malunion is not always indicated. As long as the hand can be used appropriately and can be placed in the appropriate positions to perform day-to-day activities, no additional treatment is required. This usually is in the neutral or somewhat pronated position, allowing shoulder and elbow motion to compensate.

Current union rates for internally fixed forearm fractures are 98% or better, with good to excellent functional results and less than 30% loss of total pronation and supination. Nonunions of the fractures of the shafts of the radius and ulna are now most commonly due to segmental bone loss, infection, or inadequate internal fixation with mechanical failure. Poor surgical technique with excessive soft-tissue stripping can also lead to nonunion because of the devascularization of the bone ends.

REPAIR OF NONUNION WITH PLATES AND BONE GRAFT

- Treatment of nonunions of the diaphysis of the radius and ulna does not differ significantly from primary internal fixation. Approach the ulna through a longitudinal incision along the subcutaneous border and the radius through a modified Thompson’s dorsal radial approach. Making the skin incision on a line drawn from the tip of the radial styloid to the lateral epicondyle of the humerus, using the appropriate intermuscular interval, allows exposure of the radius from radial head to radial styloid (see Chapter 1).
- In most cases, loose screws or broken plates, or both, are present. Remove these and identify the nonunion site. If the overall alignment is acceptable and there is a stable fibrous nonunion, then simple plate fixation and compression usually suffice.
- In most cases, however, deformity is present. Most likely you will have to deal with shortening and angulation, and possibly intercalary bone loss. Restoring alignment in the ulna is not too difficult because, other than in the area of the olecranon, the bone for the most part is straight. Restoring the radial bow of the radius, however, can be difficult, and intraoperative radiographic guidance with either a fluoroscope or plain radiographs is very important. Occasionally, nonunions or malunions are complicated by synostosis or collapse of the interosseous membrane. This requires take down of the synostosis and shaving of the bone to restore the normal contour, as well as soft-tissue release in the area of the interosseous membrane. This can be quite challenging because of the presence of the neurovascular bundles in this area.
- Restore normal alignment and length. A temporary distractor or an external fixator may be necessary to hold the radius out to length. Place cancellous bone or a structural cortical iliac crest bone graft into any bone deficiency, and apply a 3.5 mm or equivalent plate, using interfractional compression and longitudinal compression where possible. Try to obtain at least eight cortices of fixation proximal and distal to the fracture. In some cases in which there is no bone loss, the internal fixation can be carried out first and the bone graft applied second.
- Apply plates to the dorsal lateral aspect of the radius, where they act as a tension band, and on the ulna they can be placed on the subcutaneous border or slipped off to the side so that they are less prominent beneath the skin. When applying bone graft, do not impinge on the interosseous membrane because this may lead to synostosis or restriction in motion.
- After internal fixation, determine the safe range of motion in flexion and extension of the wrist and elbow, and in pronation and supination. This will be useful in instructing the patient about postoperative exercises.
- Close the muscle envelope over the fracture sites but leave the deep fascia open because of the predilection for swelling after these extensive procedures. Close the skin in a routine manner and place the arm in a bulky long arm splint with the elbow at 90° or so of flexion and the forearm in neutral supination and pronation. After swelling has abated, a lightweight brace or molded orthotic cuff is useful to remind the patient to be careful with the forearm. Have the patient begin active motion immediately, using the extremity only for light activities of daily living until union occurs. In the forearm, nonunions usually require at least 16 weeks and may require up to 6 months to heal solidly (Figs. 27.14 and 27.15).

**Figure 27.14.** Delayed union of a Galeazzi fracture. A: An oblique fracture has been internally fixed using a semitubular plate with inadequate cortical purchase. There is no interfragmentary screw across the fracture. B: Union after fixation with a 3.5 mm dynamic compression plate placed on the dorsal radial surface with an interfragmentary screw, along with a cancellous bone graft.

**Figure 27.15.** Atrophic nonunion of the ulna in a Monteggia fracture dislocation. A, B: Atrophic nonunion of the fracture of the ulna treated previously by cerclage wire and intramedullary fixation. C: A 3.5 mm dynamic compression plate and cortical cancellous bone grafting were used to stabilize the ulnar fracture. D: After 1 year, union had occurred. Restoration of the alignment and length of the ulna resulted in satisfactory position of the radius and functional forearm rotation.

MALUNIONS OF THE RADIUS AND ULNA

Malunions in the forearm resulting in loss of forearm motion or rotation can be related to fixation of the radius in malposition; loss of the normal arc and spacing between the radius and ulna due to collapse of the bones toward the interosseous membrane; or to subluxation or internal derangements in the proximal radioulnar joint or the distal radioulnar joint. The latter problems in the joints are addressed in Chapter 43. It can be corrected by osteotomy to place forearm motion in a more functional range. It is difficult to increase the total range of motion because of intraosseous membrane contraction and soft-tissue scarring.

With increased dissection through the soft tissue, cross-unions may occur. Rotational problems are best managed at the time of acute fracture care. Radioulnar synostosis (3.5, 55) may follow closed or open treatment. It appears to be related directly to the extent of injury to the interosseous membrane, because it is more common in fractures that are at the same level, in open fractures, and after internal fixation. Early motion can significantly reduce the incidence of this problem in internally fixed fractures.

Operative intervention for malunion is not always indicated. As long as the hand can be used appropriately and can be placed in the appropriate positions to perform day-to-day activities, no additional treatment is required. This usually is in the neutral or somewhat pronated position, allowing shoulder and elbow motion to compensate.

The precise definition of what constitutes a malunion in the forearm has been elusive, but recent work provides reasonably good guidelines (54, 90, 96). This is
was present with autologous fat helps prevent reformation (Fig. 27.16). If large raw areas of bone are left after excision of the synostosis, I find that coating these with a thin layer of bone wax and then filling the gap where the synostosis was excised with bone graft helps restore forearm motion. Scarring frequently compromises forearm motion, and avoiding injury to the anterior and posterior interosseous neurovascular bundles can be challenging. Another technique is to use suture liga-ment replacement during surgery. In my experience, synostosis between the radius and ulna is most common after severe proximal forearm fractures. It can be managed by radial head resection with 25°). The patient operated on for cosmetic problems was pleased with the appearance of the forearm but lost 10° of rotation. Their outcomes point out that it is possible to achieve significant improvement in patients with forearm malunions, but the surgery is better done earlier than later and does not have consistent results, and the fact that Trousdale and Linscheid had complications in 11 of their 27 patients demonstrates that the surgery is challenging.

OSTEOTOMY

- Interoperative radiographic evaluation of the correction achieved is important; therefore, use a radiolucent hand table and fluoroscopy or plain radiographs, or both.

- Depending on whether osteotomies are planned for an isolated forearm bone or both bones, use the surgical approaches described earlier. Expose the site for osteotomy in a subperiosteal fashion. This should be at the maximum point of deformity. Use gentle technique to minimize soft-tissue injury and to avoid invading the interosseous space. When performing osteotomies of both the radius and ulna at the same level, it is important to try to prevent communication of the hema-tomas from the two operative sites because this could lead to synostosis.

- Perform an appropriate osteotomy, depending on the deformity to be corrected. In many cases, it is possible to identify the old fracture site and reassemble the fracture in anatomic position after removing excess callus and refashioning the bone ends. In more mature malunions, it is necessary to perform a formal osteotomy. Often this must be in an oblique plane to allow correction of angulation and rotary deformity, which are frequently combined. This can be challenging because the rotational component of the deformity is difficult to assess by radiography preoperatively. Some repeat shaping of the osteotomy site after intraoperative radiographs and examination for range of motion is usually necessary.

- Internally fix the osteotomy, taking care to place an appropriate bone plate in the plate on the radius to restore full radial bow. Obtain eight cortices of fixation proximal and distal to the osteotomy site with an interfragmentary screw across the osteotomy, if possible. The plates are best located just off the subcutaneous border of the ulna and on the dorsal radial aspect of the radius. You may make an exception for a very distal radius osteotomy, where the plate might be better placed palmarly.

- If the patient has pathology in the interosseous membrane or at the distal radialulnar joint (DRUJ), additional procedures to release contractures of the interosseous membrane or to address problems in the DRUJ may be necessary. See the discussion of treatment of synostosis below; see Chapter 43 for DRUJ problems.

- Perform a meticulous soft-tissue closure, leaving the deep fascia open. Initially immobilize the extremity in a well-padded long-arm splint, with the elbow at 90° and the forearm in neutral pronation and supination. As soon as pain subsides and the swelling is controlled, begin a supervised range-of-motion exercise program under the supervision of a hand therapist. Solid stability of the internal fixation is obviously necessary to obtain an optimal result, the latter requiring fairly vigorous early active range of motion without resistance.

Malunions of the radial head and neck can be reconstructed with an osteotomy, but in most cases, assuming that the radius and ulna are longitudinally stable and there are no major DRUJ problems, the easiest procedure producing the best results is radial head excision.

RESECTION OF THE RADIAL HEAD

- Approach the radial head through a Kocher incision (see Chapter 1). Expose the radial head and proximal neck as far as the annular ligament. Take care to avoid injury to the posterior interosseous nerve.

- With a water-cooled mini-oscillating saw or high-speed burr, transect the radial neck just proximal to the radial head and smooth the edges to remove any osteophytes or malunited fragments.

- Leave the annular ligament intact. If it is disrupted and the proximal radius is unstable, reconstruct it.

- Close the wound in a routine fashion, apply a bulky sterile dressing and splint, and begin elbow and forearm exercises as soon as the patient will tolerate them.

PITFALLS AND COMPLICATIONS

The complications of treating malunions and nonunions of the upper extremity are similar to those of all major surgery in the upper extremity, including infection, neurovascular injury, failure of the fixation, loss of joint motion, and others. The risk of these problems can be minimized by careful attention to patient selection and details of the surgery. The outcome depends strongly on a fully cooperative patient who is capable of performing exercises in the face of discomfort and who is completely compliant with postoperative instructions.

SYNOSTOSIS

In my experience, synostosis between the radius and ulna is most common after severe proximal forearm fractures. It can be managed by radial head resection with excision of the synostosis, as described earlier. Restoration of forearm motion through excision of a synostosis is challenging because soft-tissue contracture and scarring frequently compromise the motion that can be gained, and avoiding injury to the anterior and posterior interosseous neurovascular bundles can be challenging. To prevent reformation of the synostosis, fat, muscle, and Sliats membranes have been used to fill the space between the radius and the ulna (50,74,101,108,109). If large raw areas of bone are left after excision of the synostosis, I find that coating these with a thin layer of bone wax and then filling the gap where the synostosis was present with autologous fat helps prevent reformation (Fig. 27.16).
Figure 27.16. Synostosis of both bones of the forearm. A: A 25-year-old man sustained an open fracture of both bones of the forearm, which was treated with plate fixation. He developed a synostosis of his forearm in a nonfunctional position. B: This postoperative radiograph shows excision of the synostosis with a free fat graft packed in the area of the synostosis. At 9 months, he had functional forearm rotation, lacking the last 20° of supination and pronation.

POSTTRAUMATIC CONTRACTURE OF THE ELBOW

Posttraumatic contracture of the elbow is a complex and challenging problem. Refer to the excellent review articles by Morrey (63) and Modabber and Jupiter (60) for a detailed discussion. For most activities of daily living, an elbow flexion and extension arc of motion from 30° to 130° is necessary. A marked impairment of the ability to position the hand in space occurs when a flexion contracture exceeds 45° and flexion is less than 110°. These are indications for operative treatment of contracture of the elbow. Lesser degrees of loss of motion may be an indication, depending on the patient's functional needs. Loss of motion can be caused by extrinsic contractures involving the joint capsule, ligaments, and osseous structures, and intrinsic contractures can be caused by intra-articular incongruity or malunions and adhesions. If there is significant loss of articular cartilage or if posttraumatic degenerative arthritis is present, fascial interposition arthroplasty may be necessary to gain a satisfactory outcome. This usually requires use of distraction with a specialized external fixator.

Release with Fascial Arthroplasty

Methods for addressing both intrinsic and extrinsic contracture, with and without distraction, are available. Morrey's technique (63) is utilitarian and is commonly used for treatment of contractures (Fig. 27.17).

| --- |

- Place the patient supine on an operating table with a sandbag under the operated side. Drape the upper extremity free.
- Prep and drape the ipsilateral lateral thigh for possible harvest of a fascial graft.
- Make an extensile posterolateral approach, using the interval between the anconeus and extensor carpi ulnaris (see Chapter 1). Expose as much of the elbow joint as necessary to achieve an adequate release by elevating the triceps from the posterior aspect of the humerus in continuity with the lateral forearm musculature and triceps aponoeurosis. Dissect medially along the anterior aspect of the humerus joint capsule to expose the anterior structures (Fig. 27.17A).
- Excise the posterior tip of the olecranon process and any osteophytes, and remove the posterior capsule. Excise or release anterior capsular adhesions and structures as necessary. Lyse all intracapsular adhesions.
- If possible, preserve the lateral collateral ligament. If release is necessary, reflect it distally, releasing its humeral origin. Resect the anterior capsule (Fig. 27.17B).
- If anterior impingement is found, excise any bony osteophytes.
- If 50% or more of the articular surface of the elbow is not covered by hyalin cartilage, or if a significant malunion is present, recontour the joint and perform an interpositional fascial arthroplasty. Smooth the joint surfaces of the humerus and ulna with a burr (Fig. 27.17C).
- Make an 18 cm long incision over the lateral aspect of the thigh, and harvest a sheet of fascia 4 to 5 cm wide and 12 to 15 cm long.
- Trim the fascial graft to the appropriate size and shape, and attach it to the articular surface of the distal humerus through sutures along the edges of the humeral joint surface. This can be aided by front-to-back drill holes. Then double the fascial membrane back on itself to form a continuous double layer covering the olecranon. Secure the graft to the olecranon in a similar manner (Fig. 27.17D).
- Try to preserve the radial head, but excise it if it presents problems.
- If an external fixator will be applied or there is a need to complete the soft-tissue release, make a medial approach over the medial epicondyle. Split the flexor-pronator muscles in line with their fibers and complete the medial part of the capsulectomy. If necessary, perform an anterior transfer of the ulnar nerve (Fig. 27.17D).
- Apply a distraction or dial-compass external fixator.
- Under fluoroscopic control, insert a guide pin through the center of the capitellum, transversely across the condyles of the humerus, to exit the trochleae head center. It is important that this be done directly in line with the instant center of rotation of the elbow (Figs. 27.17E, 27.17F).
- Mount the external fixator on this pin, and then place two or more half pins into the distal humerus and two in the proximal ulna according to the directions of the manufacturer. Adjust the frame to ensure appropriate motion and to separate the joint surfaces 4 to 5 mm in all positions of the elbow. Remove the guide pin (Fig. 27.17G).
- Repair the lateral collateral ligament, using a Bunnell stitch placed through the drill holes in the humerus (Fig. 27.17H).
- Place a small suction drain and close the wounds in layers.
- Apply a sterile dressing and a bulky compression dressing.
- Begin motion as soon as possible. Morrey uses continuous passive motion.

Postoperative Management After 3 to 4 weeks, Morrey (63) removes the external fixator under anesthesia, gently examines the elbow (avoiding manipulation) to assess the end points of motion, and then uses turnbuckle splints, one for extension and one for flexion, to help the patient gain range of motion while continuing on an active daily exercise program. He uses the turnbuckle splints regularly for as long as 6 months following the routine outlined in Table 27.1.

Results In six patients who Morrey (63) treated by release without distraction external fixation, the preoperative arc of total motion was 32°. Postoperatively, it increased to 74°. In those treated with distraction arthroplasty without interposition, total motion before operation was 32° and increased to a total average arc of motion of 99°. In the six treated with interpositional arthroplasty and distraction, motion increased from a total of 27° to 107°. The increases in pronation and supination were modest and were best in the interposition-distraction group.

AUTHOR'S PERSPECTIVE

It is somewhat hazardous to generalize about the treatment of nonunions and malunions in the upper extremity, because these are uncommon problems that may appear only one or two times in the lifetime of an average surgeon. Large series are rare even in the hands of surgeons working in major referral centers. In addition, each patient’s problem is unique and requires an individualized approach. Recognizing these limitations, my recommendations for the treatment of nonunions and malunions in the upper extremity are as follows:

- Use a careful soft-tissue technique with as limited exposure of bone as possible (usually two of the four quadrants of circumference available) in an effort to maintain the blood supply to the bone.
- Take down the nonunion site in most cases by fashioning of the bone ends to correct deformity and maximize surface area, opening the medullary canal and placing multiple shallow drill holes on metaphyseal fragments to encourage revascularization.
- Use solid internal fixation, eliminating any micromotion; try to obtain fixation in two planes, usually with a plate in one plane and an interfragmentary screw in the other, followed by autologous bone graft laid on a petalled cortical surface.
- During surgery under anesthesia, establish the safe range of motion possible for early rehabilitation. Institute early motion and then progress the rehabilitation program as the fracture consolidates.
- For nonunions of the surgical neck of the humerus, use 3.5 mm reconstruction double plate fixation combined with iliac crest bone graft.
- For mid-diaphyseal nonunions of the humerus, use broad plate fixation with interfragmentary screws combined with autologous bone graft.
- For supracondylar humerus nonunions, use double plate fixation with 3.5 mm or equivalent reconstruction plates, placing one plate on the posterior aspect of the lateral column and one on the medial aspect of the medial column combined with iliac crest bone graft.
- For elbow arthroplasty, I follow the tenets advocated by Morrey (63,64) as outlined earlier; using a straight posterior approach when accompanying bony reconstruction makes this a more convenient approach.
- For olecranon nonunion, use single and occasionally double plate fixation with small reconstruction plates combined with iliac crest bone graft (tricortical graft for bone deficiency).
- For nonunions of the radius and ulna, use small reconstruction plates or AO 3.5 LCDC plates with interfragmentary screws combined with cancellous bone graft or structural tricortical iliac crest graft for bone deficiencies.
- For malunions, I try to use oblique single plane oblique osteotomies with interfragmentary screw fixation and neutralization plates.

Using these techniques, between 1980 and 1995 I was able to achieve union in 36 of 37 nonunions of the humerus and 100% healing of five nonunions in the radius and ulna.

CHAPTER 28

NONUNIONS AND MALUNIONS OF THE PELVIS

Ross K. Leighton

It has been commonly taught, and correctly so, that because of the cancellous nature of the pelvis, nonunion is rare. Nonetheless, nonunions can occur in the pelvis and have occasionally been described in the literature (1). Factors that may contribute to a pelvic nonunion include a delay in treatment, inadequate immobilization of the fracture, an unstable fracture pattern, high-energy trauma, and a large initial displacement of the fracture.

The most common symptom is sacroiliac pain secondary to instability of the posterior sacroiliac complex. This symptom, along with others (Table 28.1), is most likely to occur following a very unstable, severely displaced, vertical shear fracture (Fig. 28.1). Fractures caused by lateral compression can also lead to posterior complex pain, however.

Figure 28.1. Very unstable vertical shear fracture of the pelvis.

Nonunion of the anterior pelvis is rare but can occur with any fracture mechanism. The anteroposterior and lateral compression types of injuries are the most commonly implicated in this type of nonunion. The nonunion is usually in the symphysis or pubic rami and may result in rotational instability of the pelvis with anterior or posterior pain. Anterior pelvic nonunions are rarely symptomatic and only occasionally require treatment.

Perform a good history and physical with adequate documentation of the problem. Once you are convinced that a nonunion exists, obtain plain radiographs with inlet and outlet views of the pelvis. Judet views may be indicated, depending on the fracture pattern (i.e., if there is an associated acetabular fracture). If further diagnostic information is needed, a CT scan and possibly a technetium bone scan may be helpful to confirm your suspicions. The technetium scan will help distinguish an atrophic from a hypertrophic nonunion. If your differential diagnosis does not exclude infection, do a CBC, a differential, and an erythrocyte sedimentation rate along with a comparison of technetium and gallium scans (Table 28.2).
The only absolute indication for surgery is pain unrelieved by nonoperative treatment. Everything else is relative: leg-length discrepancy, gait abnormality, permanent nerve-root damage, or urinary disturbance. The area of pain must be accurately identified. Posterior versus anterior and joint-related pain versus bony nonunion must be clearly elucidated so that an appropriate treatment plan can be developed.

In general, the basis for promoting healing of any nonunion is copious cancellous or corticocancellous bone grafting, with or without rigid internal fixation. This is true with nonunions of the pelvis, and these principles must be followed to obtain a successful result. I feel that except for the rare occurrence of a painful nonunion of a pubic ramus, bone grafting should be combined with rigid internal fixation to provide stability and maintain anatomic reduction.

**ARTHRODESIS OF THE SACROILIAC JOINT OR REPAIR OF NONUNION**

**POSTERIOR NONUNIONS**

In surgery for posterior nonunions of the pelvis, I generally prefer the anterolateral approach described by Simpson et al. (29). This approach allows direct access to the sacroiliac joint, permitting bone grafting and fixation. In addition, because it is done in the supine position, it allows better orientation and ease of access to the pubis, if necessary. I consider the anterolateral incision to be the utility approach to the pelvis because it permits access to the sacroiliac joint, the iliac wing, and, by extension to the ilioinguinal incision, the anterior column of the acetabula, pubic rami, and symphysis. Thus, with the patient in the supine position, all areas of the pelvis can be approached; this allows easier mobilization and better orientation for final reduction.

**Anterior Sacroiliac Joint Plate—Operative Technique**

My colleagues and I have designed an anterior sacroiliac joint plate that we use to hold the reduced sacroiliac joint after fresh pelvic fractures (Fig. 28.2) (14). We also use this plate to stabilize sacroiliac nonunions (Fig. 28.3, Fig. 28.4, Fig. 28.5, Fig. 28.6 and Fig. 28.7). In laboratory tests using cadaver pelves, this plate provided equal or greater fixation than other available devices, external or internal, now used on the sacroiliac joint. When deformation to vertical and rotational loads was measured, the external fixator proved to be the weakest of all devices tested. Simpson et al. (29) have successfully used two two-hole, 4.5-mm narrow dynamic compression plates for the same purpose, but no biomechanical tests of this system have been reported to date.

**Figure 28.2.** Anterior sacroiliac joint plate used to stabilize the sacroiliac joint.

**Figure 28.3.** Anterior sacroiliac joint plate used to fuse the sacroiliac joint. The plate is available in a small size as well (20% smaller than the one shown).

**Figure 28.4.** A 45-year-old woman with a very painful nonunion of the sacroiliac joint on the left plus symphyseal diastasis. Her initial fixation, months ago, was with an external fixator. Of note, she also had a nonunion of the tibia on the left and an L-5 nerve root deficit.

**Figure 28.5.** Three-dimensional reconstructions from CT scans demonstrating the pathology present in Figure 28.4.
Prepare and drape the area of the pelvis and ipsilateral leg. Drape the leg free as if doing a hip procedure. Make a 15-cm incision along the iliac crest (Fig. 28.8). Divide the subcutaneous tissue and, with cutting cautery, divide the fascial attachment to the iliac crest. Locate the lateral cutaneous nerve of the thigh and retract it medially.

Using a Cobb periosteal elevator, perform a subperiosteal dissection along the iliac crest back to the sacroiliac joint (Fig. 28.9). Once the joint is reached, keep the hip and knee flexed to allow relaxation of the femoral nerve and carry out a subperiosteal dissection over the sacral promontory.

Retract the L-5 nerve root anteromedially using a narrow, pointed Hohmann retractor placed over the anteroposterior aspects of the sacral promontory. Make a trough over the sacroiliac joint in its central portion. Obtain a graft from the anterior portion of the ipsilateral iliac wing and use it to fill the trough across the sacroiliac joint. Place the sacroiliac joint plate over the trough and secure it with 6.5-mm cancellous screws in the sacrum and cortical screws in the iliac wing (Fig. 28.10). Use a flexible drill to make the holes.

Direct the screws in the sacrum posteromedially and those in the iliac wing into the posterosuperior iliac spine. The plate is designed so that the two screws in the iliac wing produce compression across the sacroiliac joint. Thus, instant stability is achieved, usually with prompt reduction in the patient’s pain.

Irrigate the entire area copiously with bacitracin and normal saline. Place a suction drain in the wound and close it using #1 sutures in the deep fascia overlying.
the iliac crest, 2-0 in the subcutaneous tissue, and 3-0 or skin staples for skin closure.

This approach has become my preferred method of treating sacroiliac joint disruptions with associated iliac wing fractures or those that cannot be reduced anatomically via a closed reduction.

**Fixation with Iliosacral Screws—Operative Technique**

Once the SI joint has been exposed, an alternative to the sacroiliac plate is fixation with iliosacral screws. These can be inserted with the patient in the supine position through small stab incisions laterally. Accurate placement of the screws is essential.

---

**HINTS AND TRICKS**

- Do not place a sandbag under the iliac crest because this rotates the pelvis away from you.
- Drape the ipsilateral leg free.
- Use of the flexible drill and tap from the AO/ASIF acetabular reconstruction set is very helpful.
- For plate fixation, use either the sacroiliac joint dynamic compression plate (Fig. 28.3) or two two- or three-hole, 4.5-mm narrow dynamic compression plates.
- Check the patient pre- and postoperatively for L-5, S-1, or sacral plexus nerve-root deficit.

---

- Place patient in the supine position on a radiolucent operating table.
- Use fluoroscopy as a guide. The procedure is based on the surface anatomic landmarks and good inlet and outlet views to determine an accurate starting point on the iliac wing. Position the imager to obtain a clear view of the sacral bodies. The view from above the transverse plane is termed the “inlet” view, and the anterior–posterior (AP) view is termed the “outlet” view. The lateral view of the sacral bodies is important. Record the angle of the inlet and outlet views on the imager for ease of repositioning.
- Identify landmarks on the pelvis to help find the insertion point of the guide wire. This is done by drawing a vertical line on the skin of the patient beginning at the anterior superior iliac spine (ASIS) and extending posteriorly toward the operating table. Draw a second horizontal line beginning at the posterior edge of the trochanter. These lines intersect to create a cross. The center of this cross represents the entry point of the guide wire seen in Figure 28.11. A line should also be drawn to indicate the projections of the inlet and outlet image. These may also intersect to create a small triangle to again help determine the entry point of the guide wire, as seen in Figure 28.11. The main importance of these two lines, however, is to indicate the planes of adjustment of the pin on the inlet and outlet view so that its track can be adjusted easily to avoid a malposition of the screw.

---

**Figure 28.11.** Anatomic landmarks on the pelvis of a patient to help find the insertion point of the guide wire. (Note: The head of the patient is on the left, and the foot of the patient is on the right.)

---

- Incise the skin with a #15 blade.
- Insert and aim the guide wire for a cannulated screw to position the tip on the external aspect of the iliac wing just lateral to the posterior superior iliac spine, approximately 1 to 1.5 cm lateral to the SI joint. Take an image in both planes to confirm the guide wire’s orientation.
- Position the guide wire relative to the spinal canal and the sacral promontory as seen on the inlet view (Fig. 28.12). The outlet view shows the pin’s position relative to the S-1 and S-2 foramina (Fig. 28.13). Aim the guide wire to approach the sacral body in a posterior-to-anterior direction from caudad to cephalad. As the guide wire is advanced, check it frequently in both the inlet and outlet views. The pin should cross the midline.

---

**Figure 28.12.** Inlet view of the pelvis, showing the guide wire central to the spinal canal and sacral promontory.

---

**Figure 28.13.** Outlet view of the pelvis, showing the guide wire’s relative position to the S-1 foramina with the pin in the midbody of S-1.

---

- Once the pins are in place, measure for screw depth and drill the iliac cortex and SI joint. Do not overdrill the full length of the guide wire to avoid pin pullout.
- Then insert self-tapping screws over the guide wire. See Chapter 17 for a somewhat different approach to this same fixation.

**Posterior Approach and Fixation with Iliosacral Screws—Operative Technique**

The absolute indication for this particular approach is for sacral nonunions, as these cannot be approached safely through the anterior approach, and it is useful for malunions as well (Fig. 28.15). Sacral malunions or nonunions are an absolute contraindication for the anterior SI joint plate.
Figure 28.15. Computed tomographic scan illustrating nonunion of the right sacral alae.

- It may be used to treat fresh sacroiliac joint disruptions as well as nonunions and is preferred by some authors (5,6,12).
- Place the patient in the prone position (Fig. 28.16).

Figure 28.16. Incision used for posterior approach to the sacroiliac joint.

**HINTS AND TRICKS**

- Use a full radiolucent table such as an OSI table.
- Start the guide pins low in the iliac wing area and aim caudad to cephalad and posterior to anterior to avoid a wire that partially exits the anterior cortex and can injure the L-5 nerve root.
- Do not tip the patient but raise the patient off the bed using a pad under the sacrum.
- Do not accept a screw position close to the foramina or sacral canal. The screws must be in “ideal” position. They must be dead center on the inlet and outlet view. If they are “close” to the canal or foramina, there is a 30% chance that they are malpositioned (12). The S-1 pedicle has adequate cross-sectional area for two to three 7.0-mm screws (Fig. 28.14).

Figure 28.14. Iliosacral screws in the midbody of S-1.

- Use an image intensifier to establish the orientation of the anterior sacral foramina on the outlet view and the spinal canal and sacral promontory on the inlet view.

The primary problem with this approach is poor visibility of the sacroiliac joint. It is difficult to obtain an accurate reduction, and extraarticular fusion is usually necessary, as opposed to an intraarticular fusion. Nerve root damage can occur from inaccurate placement of screws and is always of concern. However, careful technique and placement of screws in the “ideal” position, not close to the foramina or to the spinal canal, makes the chance of nerve injury slight (12).

- Identify the nonunion and curet the lesion out to allow for bone grafting.
- Insert a cancellous iliac bone graft after achieving adequate reduction (Fig. 28.17). Obtain the bone graft from the ipsilateral iliac crest, slightly anterior to the operative site, and through a separate incision. Perform an extra-articular fusion between the posterior spine of the ilium and the posterior sacrum by creating a trough and laying in a cancellous and cortical-cancellous graft. No fixation is used over the graft.

Figure 28.17. The initial postoperative film after bone grafting and fixation of the sacral nonunion with iliosacral screws via the posterior approach.

- Position the screws as for the anterior approach with iliosacral screw fixation. The inlet and outlet views are, of course, reversed, as the patient is in the prone position. Again, caudad-to-cephalad and posterior-to-anterior positioning of the screws is essential to prevent injury to the L-5 nerve root. The case in Fig. 28.17 and Fig. 28.18 shows good fixation and healing of the sacral nonunion, and the patient was without pain 6 months after the repair.
Pubic Symphysis Fusion through a Pfannenstiel Approach—Operative Technique

When the nonunion is in the pubic rami, we prefer to use an onlay autologous bone graft. A nonunion in the pubic rami usually is atrophic, so a bone graft and internal fixation is required.

Fixation

Figure 28.18. Six-month follow-up of the patient with a united sacral nonunion (pain-free with excellent mobility).

HINTS AND TRICKS

- Use a radiolucent back frame and a full radiolucent table, such as an OSI fracture table.
- Insert the screws to the midbody of 5-1 or beyond in order to achieve adequate fixation.
- Make the skin incision laterally. Reflect the gluteus maximus off the spinous process so that its blood supply is not disturbed; this is needed for good healing.
- Use short-threaded screws if sacral malunions or nonunions are being treated.
- Insert the screws through a percutaneous stab incision laterally rather than through the surgical wound, as this requires more reflection of the soft tissues than desirable.
- Use guide wires for the cannulated screws, which should be at least 3.0 to 3.2 mm in diameter to avoid bending, which affects accuracy of placement.
- Use self-tapping screws.

Postoperative Regimen

According to our biomechanical testing (14), both the anterolateral and posterior methods give fixation that will approach about 50% of the normal strength of the pelvis. Therefore, it is possible to allow the patient to ambulate with crutches after the drain is removed at 48 h. Permit touch-down weightbearing for 6 weeks and partial weightbearing for a further 6 weeks. Full weightbearing is allowed once radiologic union is achieved at 10 to 12 weeks.

ANTERIOR NONUNIONS

Symphyseal widening, although fairly common following gross disruption of the pelvis, is rarely symptomatic. If the pelvis is rotationally unstable because of symphyseal nonunion, however, it may require treatment to relieve pain or bladder irritability. The only absolute indication for operative intervention is pain unrelieved by nonoperative measures. Anterior nonunions are not as common as those in the posterior portion of the pelvic ring but can be just as debilitating. The patient may complain of pain, clicking of the symphysis on ambulation, urinary problems, or citalal irritation.

A preoperative workup must include an intravenous pyelogram, cystogram, and urothrogram to identify bladder or urethral impingement. A cystometrogram may be indicated if urinary complaints are the main symptoms. The approach to the problem, once identified, must be individualized to the patient and the site of nonunion.

Nonunion or Instability of the Symphysis

We prefer a special symphyseal plate (available from Terray Manufacture, Arenprior, Ontario; in conjunction with Zimmer USA) or a six-hole 3.5-mm pelvic reconstruction plate for fusion of the public symphysis (Fig. 28.19). In biomechanical studies done by Tile et al. (32; personal communication, 1984) and Leighton et al. (14), the symphyseal plate provided greater stability of the anterior pelvic ring, followed closely by the application of two plates. The single plate, although clinically successful, provided the least stability in biomechanical studies.

Figure 28.19. Pelvis with symphyseal plate and bone graft to treat symphyseal nonunion.

When the nonunion is in the pubic rami, we prefer to use an onlay autologous bone graft. A nonunion in the pubic rami usually is atrophic, so a bone graft and internal fixation is required.

Pubic Symphysis Fusion through a Pfannenstiel Approach—Operative Technique

- Insert an indwelling Foley catheter before surgery to help identify the urethra and bladder.
- About 3 to 4 cm above the pubis, make a transverse skin incision 6 to 10 cm long.
- Divide subcutaneous tissue and identify the rectus abdominis muscle. Make a vertical midline incision through the rectus abdominis fascia; identify the two heads. Separate them in the midline and reflect laterally, taking care to protect the spermatic cord or round ligament.
- Once the rectus is reflected as much as needed, the symphysis is readily seen. Expose the symphysis and pubic rami with subperiosteal dissection to either side for a total of 10 to 12 cm. Make the exposure both superiorly and anteriorly along the superior pubic ramus.
- Once the body of each pubic ramus can be identified, dissect the bladder free of the symphysis.
- Place a retractor posterior to the symphysis to protect the bladder and urethra and remove the fibrous mass from the symphysis.
- Place a pointed reduction forceps in each obturator foramen and reduce the symphysis.
- An alternative to this technique is to use the pubic tubercles as a purchase point for the pointed clamps. This works best when a six-hole reconstruction plate is used.
- Once reduction is achieved, place the special symphyseal six-hole plate for a trial fit. It may be necessary to rongeur the pubic tubercles down slightly to obtain a flat surface. Bend the four tabs of the plate as necessary to achieve a close fit. Be certain that the lateral holes are sitting on the bone. There is a tendency for plates on the symphysis to shift anteriorly off the pubic rami.
- To place screws, drill through the two holes in the plate closest to the symphysis first. Palpate the posterior aspect of the symphysis to be certain that the drill points remain in the bone until they exit the lower border of the inferior pubic rami.
- If fully threaded cancellous screws, which are usually 40 to 60 mm in length.
- Then drill the lateral holes to accept 4.5-mm cortical screws. Use cancellous screws if the bone quality is poor.
- Now place screws in the anterior holes of the plate while protecting the bladder with a retractor. Use cortical screws (3.5 mm with 4.5-mm washers or 4.5-mm screws; 4.5-mm washers are available from Zimmer USA) the average length of which is approximately 20 to 24 mm. If the quality of the bone is poor, use cancellous screws.
The vertical shear fracture is the most common cause of pelvic malunion because it is the most unstable fracture and, therefore, the most difficult to maintain in a malrotated or shortened position, but these malunions are not symptomatic. However, other types of pelvic fractures can also result in malunion. A lateral compression injury usually results in an internal rotational deformity, which can lead to a major leg-length discrepancy and impingement of the rami on the bladder or perineum. In one variant of the lateral compression fracture, the pubic rami and the pubic body distort to the fracture are spun into a vertical position, which can cause impingement on the perineum and cause dyspareunia. Bucholz has described the displacement of vertical shear fractures as being posterior, cephalad, and externally rotated, leading to a very prominent posterior superior iliac spine. Other types of pelvic fractures can also result in malunion. A lateral compression injury usually results in an internal rotational deformity, which can lead to a major leg-length discrepancy and impingement of the rami on the bladder or perineum. In one variant of the lateral compression fracture, the pubic rami and the pubic body distort to the fracture are spun into a vertical position, which can cause impingement on the perineum and cause dyspareunia. Bucholz has described the displacement of vertical shear fractures as being posterior, cephalad, and externally rotated, leading to a very prominent posterior superior iliac spine.

Nonunion of the Pubic Rami—Operative Technique

Nonunion of the pubic rami is very rare, and only a small percentage of these nonunions require surgical treatment. Consequently, no one has a great deal of experience in dealing with this problem. Be certain that this is the cause of the patient's pain before undertaking surgery. The treatment requires autologous bone graft, with or without internal fixation, depending on the type of nonunion (i.e., atrophic versus hypertrophic) and bone quality.

- To expose the superior pubic ramus, use the ilioinguinal approach described in Chapter 2. Protect the contents of the inguinal canal.
- Debride both ends of the nonunion and clear them of any fibrous tissue. Open the intramedullary canal on each side. Petal the cortical bone for 2 to 3 cm on each side of the nonunion using a small osteotome and a powered burr.
- Place cancellous bone graft around the site of nonunion in a barrel-stave fashion. Plate the ramus if additional stability is needed.
- Close the wound over a suction drain in the usual manner.

Rarely, the inferior pubic ramus may be the site of nonunion. This is usually an atrophic nonunion at the junction of the ramus with the ischial tuberosity. The patient has pain on sitting.

- Place the patient in the lithotomy position. In this position, the ischium is very easy to palpate.
- Incise directly down to the ischion and inferior pubic ramus. Take care to avoid the pudendal vessels, which exit anteromedially. Occasionally, the nonunion site may be more proximal, near the posterior column of the acetabulum. If this is the case, then use the standard Kocher-Langenbeck approach, as described in Chapter 3.

Nonunion of the Iliac Wing—Operative Technique

Nonunion of the iliac wing is rare but is usually easy to correct.

- Use the anterolateral approach to the sacroiliac joint: it allows good visualization of the entire iliac wing.
- Identify the site of the nonunion. If the ununited fragment is small, then excise it. If it is a large fragment or involves the whole ilium, then use the methods described above for treating the nonunion.
- Expose the bone ends, freshen them, and achieve an anatomic reduction.
- Then place a lag screw from the anterior iliac crest across the fracture site and into the body of the ilium. Augment this with a wide 4.5-mm dynamic compression plate, fixing at least four cortices on either side of the fracture site. I also add an anterior external frame to increase stability.
- Place cancellous bone graft around the site of nonunion in a barrel-stave fashion. Plate the ramus if additional stability is needed.
- Close the wound over a suction drain in the usual manner.

Malunions of the Pelvis

Malunions of the pelvis are much more common than nonunions; however, little is available in the literature regarding these challenging problems. Slatis and Huittinen, in their review of 65 vertical shear fractures treated closed without internal or external fixation, noted a 46% incidence of late sequelae. These included pain from a malreduced posterior sacroiliac complex, limb-length discrepancy and gait abnormalities, urinary symptoms, and permanent nerve damage. Other types of pelvic fractures can also result in malunion. A lateral compression injury usually results in an internal rotational deformity, which can lead to a major leg-length discrepancy and impingement of the rami on the bladder or perineum. In one variant of the lateral compression fracture, the pubic rami and the pubic body distort to the fracture are spun into a vertical position, which can cause impingement on the perineum and cause dyspareunia. Bucholz has described the displacement of vertical shear fractures as being posterior, cephalad, and externally rotated, leading to a very prominent posterior superior iliac spine.

The vertical shear fracture is the most common cause of pelvic malunion because it is the most unstable fracture and, therefore, the most difficult to maintain in a malrotated or shortened position, but these malunions are not symptomatic.
reduced position. For that reason solid fixation of the pelvic ring both posteriorly and anteriorly is recommended. Permanent nerve damage is present in a surprising number of pelvic fractures (5%) (13). L-5 and S-1 are the roots most commonly involved, but the sacral plexus can also be injured. It is important to document any problems and discuss them with the patient, because surgery generally will not improve a nerve palsy or causalgia.

The primary indication for surgery is pain unrelied by nonoperative treatment. Many of these patients are involved in workers compensation or legal conflicts. It may be wise, therefore, to wait until these conflicts are resolved before undertaking surgery, as the indications are usually based on subjective symptoms and the outcomes are not very predictable. In my experience, most of these patients, if given time, can return to their normal daily activities without surgical intervention. A strong relative indication for surgery is a leg-length discrepancy of 2 cm or more.

The posterior pelvic ring is the area most likely to cause problems and is the most difficult to correct. Direct fusion of the area (see the discussion in Nonunions, above) is the mainstay of treatment, although reduction of any coexisting malunion or malposition is indicated also. Late reduction of a malpositioned sacroiliac joint is very difficult, however.

POSTERIOR SACROILIAC COMPLEX MALUNION

The surgical technique for reduction requires mobilization of the anterior pelvic complex to realign the position of the entire hemipelvis, which is why this type of surgery is so difficult and rarely indicated. This surgery is fraught with complications, and the results cannot be predicted reliably. If surgery is indicated, however, I recommend an anterior–lateral approach that must be individualized to the original fracture pattern. Most other authors have recommended a posterior approach, and certainly this can be used (5,6,12,13). A combined anterior and posterior approach is often required. Recently, the anterolateral approach has become popular (3,7,10).

Operative Technique

- If the original disruption occurred at the symphysis, use a Pfannenstiel incision to mobilize this area.
- When the deformity is in the pubic rami, individual ostotomies must be done through separate incisions. Approach the superior pubic ramus through an inguinal incision in the lithotomy position, as described above.
- Once the anterior pelvis has been mobilized, make an anterolateral utility incision to mobilize the posterior sacroiliac complex. Expose the ilium and the sacroiliac joint.
- Place small Kirschner wires parallel to each other in the sacrum and ilium in such a way that they will end up in the same plane once reduction has been achieved. These pins also serve as a guide to internal and external rotation of the pelvis.
- Use an osteotome and sharp dissection to mobilize the sacroiliac joint if required. It is extremely difficult to mobilize the hemipelvis. Much soft-tissue release is required along the inside and outside of the iliac wing.
- Once the hemipelvis is mobilized, place a clamp on the iliac wing to aid in its manipulation. Externally rotate the leg and apply traction. Reduce the pelvis internally rotate the leg, and drive a wide staple across the sacroiliac joint along its posterosuperior edge.
- Place a bone graft across the joint as discussed above for nonunion.
- Apply the sacroiliac plate, using dynamic compression plating. I have found this method of fusing the sacroiliac joint to be successful, as have Rand (22), Tile (32), and Simpson et al. (29), but the total number of cases is small.
- Once reduction is achieved, apply the symphyseal plate along with bone graft.
- If independent ostotomies were used on the pubic rami, then use an anterior external fixator or internal fixation to stabilize the anterior pelvis.
- Close all wounds over suction drains in the usual fashion.
- As stated earlier, a combination of a posterior approach to the sacroiliac joint plus a Pfannenstiel incision can be used to accomplish the same result.

Postoperative Regimen

Keep the patient on bed rest for 3 to 5 days and allow movement only from bed to chair for 2 to 3 weeks. Allow crutch walking at 3 weeks with touch-down weightbearing on the unstable side, continuing until union is achieved at about 12 to 16 weeks.

ANTERIOR MALUNIONS

The symphysis can heal in a widely displaced position. This usually is secondary to an anteroposterior (open book) fracture, which is rarely symptomatic. If it is believed to be the cause of the patient's discomfort, treatment is the same as for a nonunion of the symphysis.

A lateral compression injury can result in malunion of the pelvis with the hemipelvis internally rotated and the symphysis healed in an overlapped position. If union has occurred, the anterior complex is rarely the cause of the problems. However, the real problem anteriorly is the variant of a lateral compression injury mentioned earlier in which the pubic rami fragments are rotated in the frontal plane (Fig. 28.20). If these structures impinge on the perineum and cause dyspareunia, treat the malunion either by excision, if the fragment is small, or by reduction and internal fixation.

Operative Technique

- Use an ilioinguinal approach plus a separate incision to osteotomize the inferior pubic ramus.
- Place patient in the lithotomy position. Expose and osteotomize the inferior pubic ramus first.
- Then make an ilioinguinal incision and expose the superior pubic ramus and the symphysis.
- Mobilize the fragment. If it is small, excise it; otherwise, fix it with a symphyseal plate.
- Mobilize the patient with crutches, touch-down weightbearing on the affected side, for 4 to 6 weeks.

LEG-LENGTH DISCREPANCY

A strong relative indication for surgical intervention is leg-length inequality. I feel that if the discrepancy is 2 cm or more, then surgical intervention is justified. If the pelvis is not too deformed, and the patient is relatively young, I do a modified Salter osteotomy. With an older patient, or one who has a deformed pelvis but no real pain, a leg-lengthening or leg-shortening procedure is the treatment of choice. Thicker more mature the patient, the more I would favor a lengthening procedure. Leg-length films are needed to document the true leg-length discrepancy. The leg length must be measured on the pelvis from the anterosuperior iliac spine to the ankle, not from the acetabulum to the ankle as in standard leg-length films. Remember, the loss of height is within the pelvis and not in the femur or tibia.

MODIFIED INNOMINATE OSTOTOMY

The innominate osteotomy, as described by Salter, is modified in that a block of bone is used instead of a wedge of bone (Fig. 28.21) (9). In this way, the posterior aspect of the pelvic brim is opened, thus gaining length in the shortened extremity. This usually will allow an increase of 2 to 2.5 cm in leg length. By externally rotating the distal fragment, the osteotomy will allow correction of an internal rotation of the pelvis and permit the leg to assume its normal position.

---

Figure 28.21. Modified Salter innominate osteotomy. Note that the block of bone actually opens the posterior cortex.
LEG LENGTHENING OR SHORTENING
The method for shortening the femur on the long side is detailed in Chapter 30. Leg lengthening using Ilizarov’s method is discussed in Chapter 32.

URINARY SYMPTOMS
The patient who complains of urinary symptoms must be carefully evaluated by the orthopaedist and a urologist. If the symptoms are attributed to pressure on the bladder secondary to pelvic deformity, then surgery may be helpful. An adequate preparative workup must be done, including radiographic contrast studies and possibly a cystometrogram. If surgery is to be performed, make sure a catheter is inserted before the operative procedure. With a urologist’s help, use a direct approach to the pubis through a Pfannenstiel incision and remove the excess bone to take the pressure off the bladder. An osteotomy of the pelvis to correct the deformity is rarely indicated for urinary symptoms alone. Nonunion at the symphysis can cause urinary symptoms with or without discomfort. The treatment in this case is symphysis-plate fixation with bone grafting of the symphysis, as described above in the section on nonunions.

AUTHOR’S PERSPECTIVE
Reconstructive surgery for nonunions or malunions of the pelvis is rare, and, therefore, there are few large series documenting results of treatment. Pennal and Massiah (20) have the largest series and report good results using the posterior approach to the sacroiliac joint. Their series consisted of 42 patients with nonunion and delayed union, 39 men and 3 women, with an average age of 35 years. Of the patients, 24 were treated nonoperatively and 18 by surgery. The surgery was aimed at stabilizing the nonunion and supplemental bone grafting. The operative group did better than the nonoperative group as far as returning to preinjury jobs and activities, and a solid union was achieved in 15 of the 18 treated with surgery.

Tile previously used the posterior approach but has advocated the anterolateral approach to avoid posterior skin sloughs (32). Rubash et al. (25) reported good results in all seven patients who underwent a direct approach to the malunion site. However, despite their expertise in surgery, the average operating time in these patients was 6 h, and the average blood loss was 1,200 mL.

The best results with pelvic fractures are obtained by anatomic reduction as early as practical. Late reduction and fusion are definitely much more difficult and hazardous. Fortuitously, since the mid-1990s, many companies have developed superior plate reduction clamps and pushers in order to allow for better and easier anatomic alignment of acute fractures. With the use of these advanced tools, and more rigid internal fixation, such as the iliosacral screws and symphysis plates, anatomic reduction can be achieved and maintained while the pelvic ring heals. Although these techniques do not allow for perfect reduction in every case, they do allow for a very acceptable reduction in most patients. As stated earlier, it is very important that the source of the pain be identified as accurately as possible before any type of posttraumatic reconstruction is undertaken, as pain, particularly posterior pelvic and back pain, can have many origins other than from the bony pelvic ring.

NONUNIONS AND MALUNIONS OF THE HIP

Michael W. Chapman

NONUNION OF THE FEMORAL NECK

Despite modern techniques and a better appreciation of what is necessary to achieve union in the femoral neck, most recent series continue to report an incidence of avascular necrosis that ranges from 20% to 25% and about a 10% rate of nonunion (4,7,8,14,16,17,18,19 and 20,28). These statistics show that union is possible in the presence of avascular necrosis. The live bone from the femoral neck can grow into the avascular bone of the femoral head or, in some cases, partial union may occur between viable sections of the femoral head and the neck. When union to an avascular femoral head occurs, complications generally do not develop until resorption of the avascular bone in the head occurs, resulting in segmental collapse (11).

CAUSES

The most common cause today in developed countries of nonunion of the femoral neck is loss of blood supply to the femoral head. In developing countries, neglect of these fractures is common and leads to nonunion in most cases. Disruption of the blood supply is most likely to occur when the fracture displaces, resulting in tearing of the vessels. Consequently, there is an increased incidence of avascular necrosis in displaced fractures (5). The incidence of avascular necrosis and nonunion is increased in young adults, probably because a greater force is required to break the femoral neck in this population. The greater force leads to increased displacement, which correlates with avascularity. Avascular necrosis is common, occurring in 20% to 25% of all femoral neck fractures; its incidence is greater with poor reduction (52%) and in young patients (90%) (13,19,26). A high index of suspicion for an avascular head should be accorded patients with marked shortening of the femoral neck after surgery. High-risk patients include those who have undergone pelvic irradiation therapy, those with alcoholism, and those receiving large-dose steroidal therapy. Patients with a great deal of initial displacement may do well, and displacement at injury should not be used as the sole reason for prosthetic replacement. Delay in treatment is associated with avascular necrosis; the incidence is nearly 100% after a delay of 7 days.

It has also been suggested that a rise in intracapsular pressure secondary to a hematoma may occlude the blood supply, leading to avascular necrosis (35,31). Currently, only two steps can be taken to improve the blood supply to the fracture site and head immediately after injury. First, obtain a reasonably good reduction by closed means as soon as possible to minimize distortion of the vessels. Second, decompress the intracapsular hematoma, either by aspirating the hip joint or by incising the capsule at the time of internal fixation.

Since little can be done to restore blood supply once it has been disrupted by a fracture, recent efforts have been aimed at diagnosing avascularity early so as to permit either revascularization of the head or, in older patients, immediate hemiarthroplasty (30). Other than loss of blood supply, the most common causes of nonunion are inaccurate reduction and loss of fixation secondary to inadequate technique or poor bone quality. In most displaced femoral neck fractures, the fracture angulates into a varus position and the head collapses posteriorly (5). This results in posterior comminution of the femoral neck with loss of bone substance. Medial comminution of the calcic femorale does not occur often; however, the calcar may impact into the femoral head, crushing cancellous bone there. When major displacement disrupts soft tissues, reduction and maintenance of position can be extremely difficult. With the posterior bone deficit, malposition is common. When this is combined with severe osteoporosis, internal fixation is difficult. For this reason, the standard of practice for displaced fractures of the femoral neck (Garden type III or IV) in the elderly is immediate hemiarthroplasty (4,8,22,32).

DIAGNOSIS

The patient with pain in the hip 2–6 months after fixation usually has delayed union with motion at the fracture site and loosening of the fixation. Pain from the fixation device itself is highly unusual, unless it is prominent at the hip, producing a trochanteric bursitis. Removal of the internal fixation device at this time causes instability, loss of position, and nonunion. With displacement, nonunion is fairly easy to diagnose by routine radiographs. In undisplaced fractures, nonunion can be very difficult to diagnose, particularly when a great deal of fixation hardware is present. In obese and elderly patients, soft-tissue density and bone porosity may make roentgenograms difficult to interpret. In addition, overlap of bone secondary to settling at the fracture site can suggest union when, in fact, a nonunion is present. The preoperative workup must establish whether union is present and whether the head is avascular.

Nonunion is best diagnosed by computed tomography (CT) with reconstruction or anteroposterior (AP) tomograms of the femoral neck. The cuts must be spaced closely, must extend through the entire femoral neck region, and must be taken with the hip in internal rotation to place the femoral neck into maximum profile. Fluoroscopic examination of the fracture site while oscillating it through 5° to 10° of rotation or varus–valgus positioning may also reveal instability at the fracture site. We have not found arthrography to be helpful in diagnosing nonunion. Magnetic resonance imaging (MRI) is very sensitive for detecting avascular necrosis and is very helpful in the diagnosis of nonunions, particularly in cancellous bone.

Displacement that is manifested as widening of the fracture line on radiography, increasing displacement of the fracture, any varus position, or any angulation of the femoral head of greater than 20° in relationship to the neck indicates impending failure. Each of these suggests a fracture that is not likely to heal and is an indication for operative intervention. Because their prognosis is otherwise good, this applies particularly to fractures that are initially minimally displaced (Garden type I or II) and that have been reduced incompletely or fixed insecurely.

It must be established that there is good blood supply to the femoral head before undertaking reconstruction. The viability of the femoral head is best determined by technetium-99m sulfur colloid bone scans (21). However, false-positive uptake of contrast material may be seen after 1 month, as blood from the creeping substitution process may be present, but on a scaffold of necrotic bone so extensive as to be doomed to collapse. Although an MRI scan is more reliable than a bone scan in determining whether the head is viable and suitable for reconstruction, it cannot be used if there is metallic fixation in the head unless the software can subtract the artifacts from the fixation devices.

All patients for whom hip reconstruction is being contemplated should undergo a sedimentation rate study, a joint aspiration culture, and, if the latter is suspicious, a gallium radionuclide study to rule out a septic process. In questionable cases involving an elevated sedimentation rate, leukocytosis on joint aspiration, or a positive gallium scan, an open biopsy and culture may be necessary.

TIMING OF SURGICAL INTERVENTION

If there is evidence of instability—particularly if there is a halo about the fixation device—operative intervention is indicated, as further nonoperative care is unlikely to lead to fracture union. Not only does delay prolong the healing period, but nail penetration may destroy bone stock, blood supply, or acetabular cartilage, preventing...
reconstruction. On the other hand, if the radiographs are suggestive of delayed union or nonunion but the fracture appears to be stable, well aligned, and well fixed, continued treatment with touch-down weight bearing on crutches may lead to eventual union. If union does not occur within 6 months, a nonunion is likely. In young adults, avascularity of the head with an impending nonunion may precipitate a decision for early surgery. A muscle-pedicled bone graft may be considered in an effort to revascularize the head if there is no segmental collapse of the femoral head and no bone stock loss that would make stable fixation unlikely (16,17,18,19,20 and 21). In the elderly, however, if the fracture is stable, it is best to wait, as a satisfactory clinical outcome may be achieved.

Other considerations in the decision-making process are the patient’s physical condition, the status of the femoral neck, degenerative changes in the hip joint, and the duration of the nonunion. In sedentary patients who are elderly or disabled and who are high-risk surgical candidates, it may be best to continue nonoperative care, using assistive devices for walking and appropriate analgesics. Disabling pain or deformity usually warrants surgery. Avascular necrosis in the femoral head substantially lowers the likelihood of success with internal fixation and bone grafting. In young, active patients, it is worthwhile to try to salvage the femoral head. Elderly patients or those who cannot protect the injured hip because of Parkinson’s disease, neurotrophic arthropathy, or other disabilities, should be considered for a prosthetic. Prosthetic replacement is indicated in patients who have less than a 15-year life expectancy and who are not progressing normally after conventional techniques of reduction and fixation. The operative timing of the hip replacement is not as urgent as that of the reconstructive procedures, but if the gait is unsatisfactory or if penetration of the metallic devices is likely, which would cause additional destruction of the acetabulum, try to save the acetabular surface.

With longstanding nonunion, or when the patient has been walking with an unstable nonunion, crushing and resorption of the femoral neck may occur. Loss of the femoral neck normally makes internal fixation and bone grafting impossible. Once a nonunion is diagnosed, it is important to move ahead with surgery to avoid resorption of the femoral neck.

The duration of nonunion per se has no role in the decision-making process. Longstanding nonunions are likely to be associated with resorption of the femoral neck or associated degenerative changes in the hip, and this must be taken into account.

**SURGICAL RECONSTRUCTION**

Nonunion of fractures of the femoral neck can be treated by valgus osteotomy, internal fixation and bone graft, prosthetic replacement, Girdlestone resection, or hip arthroplasty. Preserving the femoral head is the primary consideration for younger patients (under 60 years old), very active patients, and obese patients (weighing more than 200 pounds), all of whom have poorer long-term results with total hip arthroplasty.

**Valgus Osteotomy**

The principle of valgus osteotomy is to shift the weight-bearing line medially and, most importantly, to place the fracture plane more horizontally to reduce the shear stress on the fracture (1,2). The procedure is most successful when the fracture is undisplaced, when there is no femoral neck resorption, and when the femoral head is viable. An osteotomy can also be useful when the fracture line is vertical and resistant to valgus reduction, as may occur in high-velocity trauma. If healing has progressed but loss of leg length and hip mechanics secondary to varus positioning is a problem, osteotomy is indicated.

If there is greater than 20° of varus angulation in the fracture, the asymmetric forces exerted on the femoral head and neck lead to increasing displacement. Such a reduction is unacceptable. The angulated fracture may be remanipulated and repositioned if it is detected within a few weeks of injury and the deformity is mild. If it is detected later, at the time of initial healing, or if it is accompanied by a severe deformity, a change in position will require force, or dissection that is likely to interrupt the blood supply. These delayed cases are more safely treated with an osteotomy. Since the procedure is performed in the intertrochanteric region, the risk of avascular necrosis is minimal.

The disadvantage of valgus osteotomy, particularly if the head and neck are placed in extreme valgus (greater than 150°), is that the trochanteric lever arm is shortened. A greater abductor pull is then required to counterbalance the body weight during the single-leg stance phase. If the abductors are weak, a Trendelenburg gait will result. If they are strong enough to avoid a Trendelenburg gait, pressure on the femoral head will be increased, possibly leading to early degeneration of the cartilage. For these reasons, the patient may need to use a cane permanently. There is usually enough neck resorption and shortening accompanying nonunion of the femoral neck for the valgus osteotomy to compensate and for leg length to remain relatively normal. Warn the patient, however, that a discrepancy in leg length—either too long or too short—may be a permanent outcome.

Because of the prolonged time required for union to occur after osteotomy, external immobilization is impractical. Therefore, rigid internal fixation is essential so that the patient can start touch-down weight bearing using crutches immediately after surgery.

**Surgical Options**

The basic principles of valgus osteotomies were established by Pauwels in 1935 (27,28) and refined by Müller (23,24 and 25). As described by Weber and Cech (33), there are four types of valgus-transposition osteotomies: valgus intertrochanteric wedge osteotomy, valgus wedge prop osteotomy, valgus Y-shaped prop osteotomy, and a variation described by Müller (Fig. 29.1, Fig. 29.2, Fig. 29.3 and Fig. 29.4). Weber and Cech (33) provide an exhaustive discussion of the treatment of femoral nonunion by osteotomy in their excellent text. The most common osteotomy used is the valgus intertrochanteric wedge osteotomy, the procedure for which is described in the following section.

**Figure 29.1.** A valgus intertrochanteric wedge osteotomy is performed to treat a nonunion of the femoral neck with a shear angle of 50°. A 35°, laterally based wedge is removed to place the nonunion 20° off horizontal. (From Weber BG, Cech O. Pseudoarthrosis. Bern: Hans Huber, 1976, with permission.)

**Figure 29.2.** A valgus wedge prop osteotomy is indicated when the fracture is nearly vertical, when there is minimal varus deformity, and when the femoral neck is fairly long. A 30° wedge is removed, reducing the fracture angle of 75° to 45°. This restores the normal anatomy of the neck–shaft angle. A 130° plate is then used to offset the shaft medially. This slides the distal femur beneath the femoral neck to support the nonunion site. (From Weber BG, Cech O. Pseudoarthrosis. Bern: Hans Huber, 1976, with permission.)
Perform the osteotomy as follows:

- Blade plate with an angle of 120° between the blade and the shaft portions and an angle of 30° between the shaft portion and the trochanteric bend in the plate.

- Femoral neck is at an angle of 60° in relation to horizontal; therefore, a 30° valgus osteotomy is performed to place the neck at a 30° angle to horizontal. Use an AO superiorly or posteriorly, to avoid injuring the blood supply to the femoral head.

- In this after inserting the 6.5 mm lag screw. The illustration shows the location of the transverse osteotomy and the 30° wedge to be removed.

- Fracture site, as well as to compress it. Note the 4.5 mm cortical screw inserted through the impaction hole in the blade plate to secure the position of the blade. Place for the chisel.

- With no evidence of avascular necrosis or arthritis so far.

- This 42-year-old man sustained a femoral neck fracture in a bicycle accident. Note the high shear angle. Initial treatment was closed reduction and percutaneous multiple screw fixation in excellent position. This AP radiograph shows the hip at 2 months after surgery. B: Lateral view 2 months after surgery. C: AP radiograph at 8 months after fracture showing a nonunion with shortening and varus position. D: Preoperative planning drawing showing a reduction in the fracture angle from 60° to 30° off horizontal and a projected gain in length of 13 mm. E: Guide pin in place with 4.5 mm drill inserted through a triple drill sleeve to create a track for the chisel. F: Seating chisel in place. G: This 120° angled blade plate is in place with an independent 6.5 mm cancellous lag screw to gain further stability at the fracture site, as well as to compress it. Note the 4.5 mm cortical screw inserted through the impaction hole in the blade plate to secure the position of the blade. Place this after inserting the 6.5 mm lag screw. The illustration shows the location of the transverse osteotomy and the 30° wedge to be removed. H: Immediate postoperative AP radiograph. I: Immediate postoperative lateral radiograph. J: AP radiograph at 18-month follow-up showing union of the osteotomy and the fracture with no evidence of avascular necrosis or arthritis so far. K: Lateral radiograph at 18 months after osteotomy.

Preoperative Planning

Obtain maximum abduction and adduction radiographs to ensure that the head of the femur moves freely within the acetabulum. If it does not, arthrolysis and lysis of adhesions may be necessary before acceptable motion is achieved. A fibrous ankylosis of the hip is usually accompanied by degradation of the articular cartilage, and it may be a contraindication for osteotomy. The goal of the osteotomy is to place the femoral neck fracture at an angle 20° to 30° off horizontal (Fig. 29.1). Preoperative planning must include a determination of the size of the bone wedge to be removed, the position of the seating chisel (which will determine the position of the blade plate in the proximal fragment), and the size and angle of the blade plate to be used (Fig. 29.5A, Fig. 29.5B, Fig. 29.5C, Fig. 29.5D, Fig. 29.5E and Fig. 29.5F).

Positioning and Surgical Approach

An osteotomy on a fracture table affords the best radiologic control but is technically difficult. I prefer to place the patient in a semisupine position on a regular operating table (with bolsters to raise the operative site about 25° to 30°), or in the full lateral decubitus position. Use a Watson-Jones anterolateral approach. Obtain good exposure of the femoral head, neck, and shaft. Do not disturb the soft-tissue attachments to the femoral neck superiorly or posteriorly, to avoid injuring the blood supply to the femoral head. In Figure 29.5A, Figure 29.5B, Figure 29.5C, Figure 29.5D, Figure 29.5E and Figure 29.5F, the femoral neck is at an angle of 60° in relation to horizontal; therefore, a 30° valgus osteotomy is performed to place the neck at a 30° angle to horizontal. Use an AO blade plate with an angle of 120° between the blade and the shaft portions and an angle of 30° between the shaft portion and the trochanteric bend in the plate.

Perform the osteotomy as follows:

- Insert a guide pin through the lateral aspect of the greater trochanter, across the femoral neck, and into the femoral head just proximal to where the blade plate will be inserted. This must be parallel to the superior cut of the osteotomy and on the lateral view must be in the center of the femoral head. Obtain a full lateral view of the hip by rotating it into the frog position, with the hip flexed to 90° and with the C-arm fluoroscope in the cross-table position (Fig. 29.5E).
- Use the triple guide and 4.5 mm drill points to predrill the path for the seating chisel. This avoids deflection of the chisel by intramedullary callus and/or the dense bone around the nonunion. Drive the seating chisel parallel to and in line with the guide pin in the position determined by preoperative planning using fluoroscopic guidance. Most likely, it will enter somewhat proximal to the ridge of origin of the vastus lateralis, Place it in the inferior half of the femoral head. Determine the proper blade length for the blade plate by measuring off the chisel (Fig. 29.5F). Withdraw the chisel and insert the blade plate (Fig. 29.5G).
- With a water-cooled oscillating saw, make the proximal osteotomy cut parallel to the blade and just proximal to the lesser trochanter, as determined by preoperative drawings (Fig. 29.5G).
- With a template or goniometer, mark a 30° angle for the distal osteotomy and cut it with the oscillating saw, removing the appropriate-size wedge of bone from the distal fragment. Note that in this patient the wedge stops at the mid femur, so that as the osteotomy is closed more length will be gained to compensate for the shortening.
- Reduce the osteotomy into position, apply longitudinal compression, and secure the side plate to the femur with screws of an appropriate size. Morphine or place the removed wedge as a structural graft medially in the osteotomy site. If desired, perform supplementary fixation of either the fracture or the osteotomy using cancellous screws with washers to achieve interfragmentary compression (Fig. 29.5H, Fig. 29.5I, Fig. 29.5J and Fig. 29.5K).

**Figure 29.3.** A valgus Y-shaped prop osteotomy is indicated when there is significant varus deformity. This osteotomy can correct severe deformities with a valgus inclination of up to 70°. In this case, the nonunion is at a 70° angle, so a 50° wedge with its medial apex located at the fracture site is removed. A 50° blade plate is used. The lower cut of the osteotomy is placed to preserve the remnants of the calcar femorale. After correction and fixation, the nonunion is at 20°, the shaft is medially displaced, and the fracture site is supported by the medial shaft. Additional screws can be added to improve fixation. (From Weber BG, Cech O. *Pseudoarthrosis.* Bern: Hans Huber, 1976, with permission.)

**Figure 29.4.** Transposition osteotomy, as described by Müller, permits correction of severe varus deformity with inferior subluxation of the femoral head. The femoral neck and head in this example are 30° below horizontal, and therefore in 65° to 70° of varus. To correct this, a 70°, laterally based wedge is removed. Note that the proximal cut preserves the remaining calcare femorale on the distal fragment, as does the inferior cut. Careful preoperative planning is necessary to make this osteotomy match up as well as the one depicted here. After repositioning, the fracture line is within 20° of horizontal, and the shaft supports the fracture site and is medially displaced. (From Weber BG, Cech O. *Pseudoarthrosis.* Bern: Hans Huber, 1976, with permission.)

**Figure 29.5.** A: This 42-year-old man sustained a femoral neck fracture in a bicycle accident. Note the high shear angle. Initial treatment was closed reduction and percutaneous multiple screw fixation in excellent position. This AP radiograph shows the hip at 2 months after surgery. B: Lateral view 2 months after surgery. C: AP radiograph at 8 months after fracture showing a nonunion with shortening and varus position. D: Preoperative planning drawing showing a reduction in the fracture angle from 60° to 30° off horizontal and a projected gain in length of 13 mm. E: Guide pin in place with 4.5 mm drill inserted through a triple drill sleeve to create a track for the chisel. F: Seating chisel in place. G: This 120° angled blade plate is in place with an independent 6.5 mm cancellous lag screw to gain further stability at the fracture site, as well as to compress it. Note the 4.5 mm cortical screw inserted through the impaction hole in the blade plate to secure the position of the blade. Place this after inserting the 6.5 mm lag screw. The illustration shows the location of the transverse osteotomy and the 30° wedge to be removed. H: Immediate postoperative AP radiograph. I: Immediate postoperative lateral radiograph. J: AP radiograph at 18-month follow-up showing union of the osteotomy and the fracture with no evidence of avascular necrosis or arthritis so far. K: Lateral radiograph at 18 months after osteotomy.
Postoperative Care

Mobilize the patient as soon as symptoms permit. Maintain touch-down weight bearing until union occurs, usually in 3–6 months. Teach the patient to support the leg when making transfers, and to avoid straight-leg-raising exercises. Active and active-assisted range-of-motion exercises for the hip and knee, as well as light resistive exercises with the thigh and hip supported on a table surface, are permitted. Once union occurs, unrestricted rehabilitation is possible.

Results

Weber and Cech (33) reported the results of osteotomy in the management of 85 patients with femoral neck pseudarthroses, 41 of whom were treated with transpositional osteotomy. Of 23 osteotomies performed in patients with pseudarthroses but without femoral head necrosis, 21 healed, 1 failed as a result of infection, and 1 failed because of faulty technique. Fourteen of the patients so treated achieved normal function; 7 had good results but some shortening or diminished range of motion, and in 3 patients, partial avascular necrosis of the head occurred, leading to a poor outcome. In 7 of 13 patients with associated avascular necrosis, healing and revascularization of the femoral head occurred, producing a good result; the other 6 patients had poor results. The other 5 osteotomies were done in adolescents younger than 20 years of age. Of these patients, 1 achieved a normal hip, 3 had a good result, and 1 had a failure.

Meyers’s Pedicle Bone Graft

The muscle-pedicled bone graft, originally described by Judet (12), has been modified by Meyers (15,17,18,19,20 and 21) and others (28) and popularized for the treatment of fresh fractures when there is extensive posterior neck comminution and a high risk of avascular necrosis. It is also useful in cases of nonunion. Although the technique is best suited for nonunion without significant displacement, we have successfully used it for displaced nonunion by repositioning the fracture through the old fracture site. Open reduction with a pedicle graft or other graft (26) may be necessary when a true synovial pseudarthrosis is present, or when there is severe loss of bone substance posteriorly with substantial retroversion of the head.

Meyers advocates performing a pedicle bone graft in the supine position on a fracture table with the limb in traction. Although this works well, I have found it to be much more convenient if the patient is placed in the lateral decubitus position with the leg draped free.

HINTS AND TRICKS

- The location of the apex of the wedge osteotomy on the AP view determines how much length will be regained with the osteotomy. This can be predicted from the preoperative drawings (e.g., the case in Fig. 29.3).
- Obtain hemostasis, place suction drainage, and close the wound in the usual fashion.
- Fig. 29.2. Absorption of the femoral neck with shortening, or drift of the femoral neck into a severe varus or inferior position, requires modifications (Fig. 29.2, Fig. 29.3 and Fig. 29.4).
- The location of the apex of the wedge osteotomy on the AP view determines how much length will be regained with the osteotomy. This can be predicted from the preoperative drawings (e.g., the case in Fig. 29.3).
- Fig. 29.3. Distortion of anatomy as a result of shortening may displace the sciatic nerve into an unexpected position. Identify the nerve and protect it throughout the procedure. If the nerve must be retracted for exposure, keep the hip extended and the knee flexed to avoid putting tension on the nerve. Consider using somatosensory evoked potentials to monitor sciatic nerve function.
- Fig. 29.4. Reconstruct the bone graft and attached quadratus femoris, freeing the underside of the muscle. Once mobilized, it should easily swing superially to lie against the posterior aspect of the femoral head and neck, without tension on the quadratus muscle.
- Fig. 29.5. Incise the joint capsule using an H or T pattern to expose the femoral neck, the site of nonunion, and the posterior aspect of the femoral head. Identify the nonunion site and remove all fibrous tissue. In longstanding nonunion, the bone surfaces in the nonunion site may be quite sclerotic. If so, remove the sclerotic bone with a curet. Drilling may be necessary as well.
- Fig. 29.6. Retract the bone graft and attached quadratus femoris, freeing the underside of the muscle. Once mobilized, it should easily swing superiory to lie against the posterior aspect of the femoral head and neck, without tension on the quadratus muscle.
- Fig. 29.7. At this point, access to the fracture site may be compromised by shortening and varus position. Achieve reduction and anatomic position either by manual traction and manipulation or by use of an AO femoral distractor with one Schanz pin in the supra-acetabular area and the other in the greater trochanter. The latter method is preferred.
- Fig. 29.8. At this point, access to the fracture site may be compromised by shortening and varus position. Achieve reduction and anatomic position either by manual traction and manipulation or by use of an AO femoral distractor with one Schanz pin in the supra-acetabular area and the other in the greater trochanter. The latter method is preferred.
- Fig. 29.9. Determine the necessary posterior cortex beneath the quadratus femoris that needs to be cut. Cut this with the osteotome extending from the posterior ridge to the posterior aspect of the femoral head and neck. The bone block should be at least 5.0–7.5 cm long, and 1.5–2.0 cm wide and deep. The superior part of the bone should extend beyond the upper margin of the quadratus femoris by about 2 cm.

Figure 29.6. Meyers’s quadratus muscle pedicle bone graft. Remove the external rotator tendons from the greater trochanter, taking care to avoid injury to the medial femoral circumflex artery. Then harvest the bone graft as is outlined with the attached quadratus muscle.

- Fig. 29.10. Obtain hemostasis, place suction drainage, and close the wound in the usual fashion.
- Fig. 29.11. Postoperative Care
- Fig. 29.12. In most cases, this step is followed by fixation of the femoral head and neck with three or four lag screws.
Finally, screw the pedicle graft into place (Fig. 29.7). The order of placement of the screws depends on the stability of the fracture. Verify the accuracy of the reduction and placement of the fixation devices with the C-arm monitor.

Figure 29.7. A completed Meyers’s quadratus pedicle bone graft. Note that the graft is inserted into the posterior femoral head through a hole in the posterior nonarticular aspect of the head. Secure the graft to the distal femoral neck with a single bicortical screw. Overdrill the graft to produce a lag effect. Use a washer on all screws. Pack cancellous bone graft into remaining areas of bone defect. Then fix the fracture with multiple cancellous screws.

Close the hip joint capsule and reattach the external rotators to the greater trochanter by suturing them to the insertion of the gluteus medius. Place a suction drain and proceed with routine closure.

Postoperative Care The postoperative regimen is the same as described for intertrochanteric osteotomy. Full weight bearing must be delayed until complete consolidation of the fracture occurs. In most cases, the immediate postoperative radiographs appear to show union because of the density of bone created by the bone-grafting procedure. An AP tomogram or CT scan is often necessary to confirm that union has occurred. Figure 29.8 illustrates a typical case.

Figure 29.8. A: Three months after intramedullary nailing of a femoral shaft fracture, a 39-year-old woman continued to have hip pain. This AP radiograph shows early healing of the shaft fracture but a nonunion with displacement of a femoral neck fracture. B: The lateral radiograph shows 90° of angulation in the fractured femoral neck. C: The intramedullary nail was removed and a Meyers’s pedicle bone graft combined with multiple screw fixation was performed. This AP radiograph 5 months after the graft shows union of the fracture. D: Lateral radiograph shows excellent restoration of alignment with union of the fracture.

Open Reduction, Internal Fixation, and Fibular Autograft

In developed countries, most nonunions of the femoral neck occur after internal fixation. In underdeveloped countries, however, lack of access to medical care frequently results in neglected fractures of the femoral neck in young adults going on to nonunion in poor position. Nagi et al. (29) in India treated 52 cases by open reduction, fixation by compression hip screw, and a free fibular graft, at a mean of 5 months after the initial fracture. Of 40 fractures available for evaluation at 59 months mean follow-up, 38 were healed. Seven of 8 hips that showed avascular necrosis before surgery revascularized without collapse, while 7 others developed postoperative avascular necrosis. There were a considerable number of later failures, including collapse of the femoral head in 5, coxa vara in 11, fracture of the graft in 4, and penetration of the hip by the screw or graft in 9. Of the 40 fractures, satisfactory functional results were achieved in 35 and poor results in 5. I suspect that a microvascularized graft will provide superior results to a fibular graft, therefore in these cases, a Meyers’s pedicle graft or free microvascularized fibular graft is worth consideration.

Prosthetic Replacement

Treatment by prosthetic replacement—either hemiarthroplasty or total hip arthroplasty—is limited to cases of nonunion of the femoral neck that are not salvageable by osteotomy or internal fixation and bone grafting (3). Avascular necrosis with segmental collapse is the most common reason for prosthetic replacement. Extensive resorption of the femoral neck, making reconstruction impossible, is also an indication. In some cases, even after successful union has been achieved, degenerative arthritis may intervene, in which case arthroplasty would be indicated. Hemiarthroplasty is adequate for hips without degenerative changes in the acetabulum. Total hip arthroplasty is indicated when degenerative changes are present in the acetabulum. The patient's age and activity level must be considered when determining whether to proceed with arthroplasty or to perform a hip fusion. Arthroplasty is reserved for patients who are physiologically older than 70 years of age, or in younger patients whose lifestyle is sedentary. Young adults (those physiologically younger than 50 years of age) who can continue to participate in sports are better candidates for arthrodesis because of the risk of prosthetic loosening. The techniques for hemiarthroplasty and total hip arthroplasty are described in Chapter 105.

Hip Arthrodesis

Hip arthrodesis is indicated in young adults with active lifestyles (9,10). Because of the absence of the femoral head and neck, fusion is difficult. The technique for fusion after removal of a total hip prosthesis is applicable to this group as well. To maintain length, ischiotrochanteric fusion may be necessary. Internal fixation of the proximal femur into the old acetabulum, combined with subtrochanteric osteotomy, is an alternative technique but usually results in unacceptable shortening (see Chapter 109).

Infected Nonunion

Infected nonunion of the femoral neck is very difficult to treat, often because of multiple resistant organisms. The femoral head is often totally avascular, and severe bone stock loss precludes arthrodesis or arthroplasty. Salvage by osteotomy or bone grafting and internal fixation is rarely, if ever, possible. If the fracture is superficially infected, debride all necrotic tissue and place at the fracture site polymethylmethacrylate beads (not yet approved by the U.S. Food and Drug Administration) containing an appropriate antibiotic—usually 1.2 g of tobramycin and 1 g of vancomycin in 10 g of bone cement. Close the wound, eliminating all the dead space. Plan to internally fix when the patient’s wound heals, usually within 3–4 weeks. Infection cannot be cleared if the nail penetrates the hip, causing infection within the hip joint. The presence of septic arthritis requires resection of the head and neck fragment, insertion of antibiotic beads, and subsequent total hip reconstruction. Final treatment involves removal of all internal fixation hardware and necrotic bone, which usually leads to Girdlestone resection of the hip. After debridement, leave the wound open and treat with appropriate antibiotics. Secondary closure of the wound may be possible, but often healing by secondary intention becomes necessary, particularly when there is significant pelvic or acetabular involvement.

The functional outcome is rarely good. Shortening requires the use of a lift, and persistent instability nearly always warrants the use of a cane or single crutch for ambulation. Subsequent conversion to an arthrodesis is a consideration, but this is technically difficult, and infection may recur.

INTERTROCHANTERIC AND SUBTROCHANTERIC NONUNION

Nonunion in the intertrochanteric area is very uncommon. Nonunion after nonoperative treatment is also rare. Nonunion can be manifested by a loss of fracture reduction, fracture of the fixation device, varus collapse of the fracture, or pulling of the screws from the shaft. Nails currently in use are strong at the nail–plate junction;
Nonunion after operative treatment is usually preceded by failure of fixation, with drifting of the fracture into a varus position and external rotation. Normally, this leads to good apposition of the bone fragments and union in malposition. The likelihood of nonunion is increased when hardware interposition, major bone loss, or excessive prolonged traction results in lack of good bone contact across the fracture site.

Infection after internal fixation may predispose a patient to nonunion. Since infection can also cause the fixation device to loosen, in any patient with an apparent nonunion, rule out infection with a sedimentation rate, aspiration of the hip, wound culture, and if necessary a biopsy of the fracture site.

Subtrochanteric nonunion is far more common than intertrochanteric nonunion, as the former is the highest stress area of the femur. Nonunion occurs after both operative and nonoperative treatment. The overall incidence of nonunion in the trochanteric and subtrochanteric region is about 1.5%. The most common cause of nonunion after internal fixation of subtrochanteric fractures is the use of a compression hip screw or blade plate device when the medial buttress is not established and bone graft has not been used. Early activity causes excessive bending motion of the unsupported plate, resulting in mechanical failure and subsequent nonunion.

Treatment of intertrochanteric and subtrochanteric nonunion requires operative intervention. Externally applied or semi-invasive methods of electrical stimulation are not indicated, as the incidence of true synovial pseudarthrosis in subtrochanteric and trochanteric nonunion is high, and the prolonged immobilization in a spica cast that is required for electrical stimulation is unacceptable if operative intervention is feasible.

The indications for operative intervention include unacceptable pain, unacceptable instability, or malposition that interferes enough with function to justify operative intervention. In sedentary or elderly patients in whom a stable, fibrous union has been achieved without pain, surgery may not be necessary as long as the malposition is acceptable. The treatment of intertrochanteric nonunion and high (within 1 inch of the lesser trochanter) subtrochanteric nonunion is nearly identical. Alternatives include AO condylar blade-plate fixation, compression hip screw with or without anterior plating, and intramedullary nails of the third-generation or reconstruction type. Subtrochanteric nonunions are best treated with intramedullary nails of the reconstruction type. The technique does not differ much from that used for fresh fractures (see Chapter 19 and Chapter 20). A sample case is illustrated in Figure 29.9. Contraindications to this approach include coexisting infection and osteopenic bone that is incapable of providing good fixation.

**COMPRESSION HIP SCREW FIXATION WITH BONE GRAFT**

Although the surgical procedure for treatment of intertrochanteric or subtrochanteric nonunion can be performed on a fracture table, I prefer to use a radiolucent operating table with the patient in the lateral decubitus position. The purpose of the fracture table is to use traction to correct the deformity; it also improves radiographic control. However, the same goals can be met by using an AO femoral distractor to correct malposition. A C-arm fluoroscope placed over the top of the patient, using a frog-leg position for the lateral view, is sufficient for radiologic control.

- Prepare the skin and drape the hip and affected lower extremity free.
- Use a Watson-Jones exposure (see Chapter 3). Adequate anterolateral exposure of the femoral neck and the adjacent proximal shaft is essential.
- If a fibrous nonunion is in good position, internal fixation in situ is possible; otherwise, the nonunion must be taken down, the medullary canal opened, and the fracture ends freshened. Correct shortening, malrotation, and varus malformation using an AO femoral distractor if necessary. A useful supplemental technique involves placing a hip screw and side plate into correct position in the proximal fragment and then reducing the proximal fragment, along with the side plate, to the shaft of the femur. The AO outrigger compression device can be placed in distraction to help gain length.
- If length of more than 15 mm is gained, maintain the hip in extension and the knee in flexion to avoid excessive traction on the sciatic nerve. Gaining more than 2.5 cm is technically challenging, and in some cases preoperative traction may be useful. In repositioning the fracture, try to reestablish medial contact between the femoral head/neck and shaft fragments. If good apposition is attained and interfractional screw fixation is possible, an anterior plate may not be necessary. If the medial buttress is not reestablished, place a medial bone graft and use an anterior plate.
- Once satisfactory position is achieved, fix the fracture internally with an appropriate-size compression hip screw with a side plate or other heavy-duty appliance. Screw fixation in at least eight cortices of the distal fragment is necessary. Attain interfractional screw fixation across the fragments if possible (Fig. 29.10). In both intertrochanteric and subtrochanteric nonunions treated with a hip screw, an anterior plate is useful. Use a 3.5 or 4.5 mm reconstruction plate. With an intertrochanteric nonunion, the plate must extend onto the base of the femoral neck, and proximal fixation may have to be achieved with only two screws. In subtrochanteric fractures, it is usually possible to place a six-hole plate with three screws in each major fragment. Distally, the anterior plate should be at least 2.5 cm short of the end of the side plate to avoid a stress riser at the end of the plate.

**Figure 29.10. A:** A 55-year-old woman 3 years after an intertrochanteric fracture of the left hip. She was originally treated with a Smith-Peterson nail and Thornton side plate. This was complicated by infection with a penicillin-sensitive Staphylococcus aureus. Now she has painful nonunion with 1½-inch (3.75 cm) shortening. B: This was treated with reduction, autologous bone graft, and double plate fixation with a hip screw and semitubular plate. She healed and regained her lost leg length and function.

- Harvest a copious bone graft from the posterior ilium and apply it to the nonunion site.
- Place two deep suction drains and close the wound in the usual fashion. Balanced suspension will make the patient more comfortable in the immediate postoperative period.

**Postoperative Care**

As soon as symptoms allow, permit weight bearing to the weight of the leg with crutches or a walker. If good internal fixation has been achieved, active-assisted joint range-of-motion exercises can normally be started immediately. With the thigh supported, resistive exercise to muscles is also possible. Delay straight-leg-raising and
resistive exercises across the hip joint until healing occurs.

With good internal fixation and bone grafting, the immediate postoperative radiographs may show obliteration of the fracture. The time of postoperative bone union can, therefore, be difficult to judge. AP and lateral tomograms can be necessary to confirm union. In any case, the minimal amount of time required for union is 12 weeks; often 6 months is needed.

If the patient is elderly and sedentary or has a large bone defect, a proximal femoral replacement total hip or hemiarthroplasty may be indicated. However, a prosthesis that preserves the trochanter is preferred. Prosthetic replacement of trochanteric bone usually results in poor muscle reattachment and consequent dislocation. The type of prosthetic reconstruction to use is quite variable and depends on many factors (see Chapter 105 and Chapter 106).

**HINTS AND TRICKS**

- If there is marked osteoporosis in the femoral head, supplemental fixation with methylmethacrylate may be necessary. Make a nail track that does not enter the hip joint. Inject cement into the nail track before replacing the device in the neck. This procedure is, however, rarely necessary in fresh fractures treated with a sliding nail that reaches the center of the head, near the articular surface. If the purchase of screws in the femoral shaft is inadequate, remove some of them, pack methylmethacrylate into the medullary canal, let it set, and then drill and reinsert the screws. Do not allow methylmethacrylate to enter the fracture site. Always use a copious circumferential bone graft when methylmethacrylate is used.

**MALUNION**

Malunion of fractures in the femoral neck and trochanteric region is associated with varying degrees of varus and shortening. External rotation is usually present as well, but occasionally internal rotation occurs. It is important to correct these deformities in children, as further shortening secondary to disuse may occur if the deformity is not corrected and normal function restored. Altered mechanics about the hip, which influence bone remodeling, may contribute to further shortening. Most cases of malunion in this region are treated with intertrochanteric or subtrochanteric osteotomies, using techniques similar to those described in the section on nonunion. With simple valgus osteotomy, it is easy to correct malrotation through the osteotomy site. Correction of the varus position and malrotation will also resolve a substantial amount of the shortening in most cases. Further length can be gained by sliding an intertrochanteric or subtrochanteric osteotomy, using the femoral distractor for distraction.

It is difficult, and somewhat hazardous for the sciatic nerve, to attempt to gain more than 2.5 cm in leg length at the time of surgery. Patients with leg-length discrepancies of more than 2.5 cm may have residual shortening. A secondary procedure, to lengthen the affected extremity or shorten the contralateral extremity, may subsequently be necessary to equalize leg lengths.

In the case of nonunion with extreme shortening and disjunction between the femoral head/neck fragment and the shaft, it may be necessary to take down the malunion, placing the patient either in traction or in an external fixator to regain length before fixation. Skeletal traction is preferred in most cases, as it is least invasive and does involve placement of pin tracks in the hip region, which might otherwise be a source of contamination with subsequent surgery.

The strongest fixation device with the best mechanical axis for a subtrochanteric nonunion is an intramedullary nail. The first choice is an interlocking or reconstruction nail (Fig. 29.9). An advantage of nails is the closed reaming process that provides bone graft to the fracture site and stimulates callus formation. Additionally, the nail provides lasting protection at a time when the partially avascular comminuted fragments are brittle and subject to refracture.

Nail plate fixation is desirable only in two-part subtrochanteric nonunion associated with a long, oblique fracture surface that is suitable for lag-screw fixation. The bone must be in good contact to carry compression forces. This oblique configuration may be relatively unstable with intramedullary nailing and tends to gap. Nail plates are also an alternative treatment for two-part nonunion with a transverse component. Accurate reduction, restoration of the medial buttress, and medial bone grafting are necessary. Limited weight-bearing until union occurs is essential.

Ilizarov methods have not been used commonly in North America for nonunions and malunions of the hip (see Chapter 32).

**ACKNOWLEDGMENT**

This chapter is dedicated to the memory of Dr. Thomas H. Comfort, who, prior to his untimely death, was a coauthor of this chapter and a highly respected orthopaedic traumatologist.

28. Pauwels F. Spatfolgen der Schenkelhalsfraktur (Late Results of Fractures of the Neck of the Femur). Hefte Unfallheilkd 1953;45:22.

Nonunions of the femur are rare, except in the femoral neck. Both nonoperative and operative treatment methods have high rates of union because of the excellent blood supply to the femur. The most common cause of nonunion (other than in the femoral neck) is an open fracture complicated by infection (15). The etiology of nonunion and the preferred methods of treatment for each section of the femur are quite variable.

MIDSHAFT

This discussion focuses on nonunions of the midshaft from more than 2.5 cm distal to the lesser trochanter, to within 10 cm of the knee joint. Supracondylar nonunions are discussed in the next section of this chapter. See Chapter 29 for nonunions about the hip.

Because of the development and subsequent popularity of locked intramedullary nailing using closed techniques, nonunions of the femoral shaft are unusual (65). The literature up to 1978 reported an incidence of nonunion of 2.1% in open nailing of the femur and 0.2% in closed nailing of the femur (11). Today, the incidence in closed fractures remains less than 1%. Nonunion is more likely to occur when an open fracture is complicated by infection or when there is loss of bone substance. External fixation is usually indicated for infected nonunions (3). Infected nonunions are discussed in detail in Chapter 133 and Chapter 135. The incidence of nonunion is higher in nonoperative treatment of shaft fractures than with intramedullary nailing. Nonunion is most likely to be a complication of failure of plate fixation of the femur. Nonunions of fractures treated nonoperatively are usually accompanied by shortening, malrotation, and significant angulation. Nonunions accompanying intramedullary fixation are usually in good alignment, but a broken nail may be present. Nonunions with plate fixation are usually accompanied by failure of fixation. Good cortical contact is usually present, but angulation may be a problem.

Delayed union or nonunion after intramedullary nailing can be treated, if the medullary canal is in reasonable alignment, by removal of the original nail and closed reamed intramedullary nailing (27). An open procedure is necessary when alignment of the medullary canal is poor or there is hardware in place that requires removal. With closed intramedullary nailing, bone grafting is usually unnecessary (30). In open procedures, however, onlay cancellous bone grafting should be done routinely (21,36,37). Intramedullary nailing is the preferred method of fixation, except where distortion of the intramedullary canal makes nailing impossible (13). In such cases, plate fixation is indicated, and the principles described for plate fixation of supracondylar nonunions apply (35). Nonunions with defects or severe shortening may need specialized techniques such as allograft replacement, free microvascularized bone grafts (45), newer bone inductive methods (23,24), or ilizarov techniques (see Chapter 32).

Closed Intramedullary Nailing without Bone Grafting

For closed intramedullary nailing of a nonunion of the shaft of the femur without bone grafting, follow the basic principles of closed intramedullary nailing described in Chapter 11, Chapter 19, and Chapter 20.

Place the patient in a lateral decubitus position on a fracture table or on a radiolucent regular table, with the femur to be operated on uppermost. The supine position on a fracture table can be used as well.

Expose the trochanteric region through a gluteus maximus-splitting incision.

If an intramedullary nail is present, remove it. If it is a cannulated design, first place a 3.5 mm reaming guide pin. If the nail is broken, it is usually possible to remove it by closed technique. First, remove the broken proximal piece of the nail. Ream the proximal fragment until it is larger than the diameter of the remaining distal portion of the nail. In most nonunions in average-size patients, I use a 15 mm or larger nail. In large patients, I advise a 16 or 17 mm nail. Thus, it is possible to ream up to 15 to 17 mm.

The distal fragment of the nail can then be removed by one of several techniques. It may be possible, under fluoroscopic control, to grasp its proximal end with a strong bronchoscopy forceps and pull it out. A set of specialized instruments for removal of nails and nail fragments designed by Dr. Robert Winquist is now available from Snap-On MPD (Kenosha, WI). In this set, one of the most useful devices I have found for removal of nails is a series of guidepins in various sizes with bulb tips, together with associated guidepins with no bulb. To remove a cannulated broken nail, insert (under fluoroscopy) the largest ball tip that will fit through the end of the nail and locate the ball just outside the tip of the nail. Then jam this guidepin by driving a non-ball-tip guidepin beside it. Attach the Jacobs chuck T-wrench with flanges to the ball tip guidepin and using a mallet, extract the broken segment. "Easy outs" and other special tools for broken nail removal are also available. If it is impossible to remove the distal section of the nail by one of these techniques, or if the nail is solid, make a small window in the bone distally and tap it out, or open the nonunion site to extract the remaining portion of the nail.

Once the canal is clear, carry out closed nailing by the usual technique (see Chapter 11, Chapter 19, and Chapter 20). Use a nail at least 2 mm wider than the previous nail, if possible. Ream sufficiently to obtain good cortical contact on both sides of the nonunion, and use a nail that extends distally to within 1 cm of the subchondral bone of the knee. I always use statically locked interlocking nails. I prefer the Alta nail (Howmedica, Rutherford, NJ) because its slap-hammer driver facilitates compression of the fracture. In the vast majority of cases, I lock the nail distally first, impact the fracture by reversing the slap-hammer or by applying an AO distractor in compression, and then lock proximally (Fig. 30.1, Fig. 30.2, Fig. 30.3).

Figure 30.1. A: Radiograph of a nonunion of the midshaft of the femur in a 47-year-old man who sustained the fracture 29 years earlier. Treatment was complicated by infection. Thirty previous operations had been performed. At this point, the limb was 1 inch short, the patient had had no recurrence of infection for 5 years, and he had a painful deformity of the femur. B: Closed intramedullary nailing using a 17-mm-diameter nail was performed. This AP radiograph shows early union 12 weeks after the procedure. The patient was treated before locking nails were available. Today, the fracture site would have been fixed in...
compression with a statically locked nail.

Figure 30.2. A: AP radiograph of a subtrochanteric nonunion after blade plate fixation of a comminuted subtrochanteric fracture with failure of the plate. B: AP radiograph showing treatment with an Alta rod connector combined with a hip screw and an autologous bone graft.

Figure 30.3. A: AP radiograph of a 45-year-old man 1 year after ipsilateral concomitant fracture of the femoral neck and shaft treated with an Alta rod connector. There was union of the femoral neck and nonunion of the shaft fracture. B: The nonunion was treated by removal of the rod connector and repeat closed nailing with a larger nail with static locking in compression. This AP radiograph shows union 9 months after repeat nailing.

Unless pathologic bone or infection is present, the union rate after repeat reamed closed nailing of femoral nonunions is reported to be 53% to 78% after a single procedure and 87% to 95% after a second procedure (15, 16, 43). In my personal experience of 41 nonunions of the femoral shaft treated by this technique between 1983 and 1999, the union rate was 78% after one procedure and 95% after two procedures (16).

For proximal shaft and subtrochanteric nonunions, reconstruction nails that provide fixation into the femoral head are usually necessary (2, 47) (Fig. 30.2).

Open Intramedullary Nailing and Bone Grafting

- If an open technique is indicated, place the patient in the lateral decubitus position on either a regular operating table or on a fracture table, depending on your preference and the technique to be used. Use a direct lateral approach to dissect posteriorly to the vastus lateralis and expose the femur by subperiosteal dissection (see Chapter 3). Preserve the medial and posterior soft-tissue attachments.
- If plates and screws are present, remove them. If an intramedullary nail is present, remove it as described previously. If the nail is broken, it is possible to remove it directly through the nonunion site rather than through the buttck incision. Special techniques are not usually required.

In most cases, it is necessary to take down the nonunion, open the medullary canal, and freshen the ends of the fracture. Reduce the fracture and carry out locked intramedullary nailing. With an osteolome, petal the femur for 5 cm proximal and distal to the nonunion site and place copious cancellous bone graft around the nonunion site. Close in the usual fashion over a drain.

In most cases of exchanged reamed nailing for nonunions, the nonunion site is in compression and the femur is statically locked postoperatively. This provides solid fixation, which permits early weight bearing and a full rehabilitation program to work on joint range of motion and muscle strengthening. For the first 6 weeks after repair, it is advisable to ask the patient to use assistive devices, but I usually allow them to progress to full weight bearing as tolerated. Thereafter, patients can usually progress to full weight bearing but must avoid activities other than ordinary walking and nonimpact activities such as swimming and stationary bicycling until healing of the nonunion occurs, as heralded by bridging callus or disappearance of the nonunion site seen on two views.

Dynamization for Delayed Unions or Nonunions

Prior to the advent of interlocking nails, we treated nonunions with exchanged reamed nailing using first-generation nonlocking nails such as the Kuntscher nail (7). This resulted in union rates of 90% or better. The principle with this technique was to allow full weight bearing on a nail, which would allow compression of the fracture site. The same philosophy applies to removing the cross screws from a locked screw to “dynamize” the fracture, allowing weight bearing to cause compression and pulsatile stimulus at the fracture site to promote union. This technique does work and is most effective when the fracture pattern is such that with impaction it becomes rotationally stable, such as in oblique nonunions. In many nonunions, however, the configuration is such that either excessive shortening will occur or rotational stability may ensure. I have also found that the dynamization worsens some patients’ pain and is not well tolerated. Currently, I dynamize only when there is no comminution in the fracture site and an oblique pattern is present that will stabilize with weight bearing. It is necessary to remove the cross screws from only one end of the rod, and these should be at the end farthest from the fracture site. This applies only to delayed union or nonunions in the mid diaphysis. In all other fractures with delayed union or nonunion, a much higher success rate will be achieved with exchanged reamed locked nailing with compression across the fracture site.

SUPRACONDYLAR AREA

Supracondylar nonunions may be entirely extra-articular or may have an intra-articular component. With interlocking nails, it is possible to treat any nonunion that is sufficiently proximal to the knee joint (a distal segment of 10 cm is required) by placing two distal cross-locking screws. Modification of the nail by cutting off part of its tip to allow it to be placed more distally may permit the treatment of more distal nonunions, but this is a specialized technique. Custom nails can be ordered as well.

Recently, retrograde intramedullary nails inserted through the intracondylar notch of the femur—these nails are specially designed for this purpose—have been advocated for the treatment of supracondylar nonunions. Experience with these nails, however, has not proven successful (P. Tornetta III, personal communication 1999). The nails apparently do not provide sufficient purchase in the distal fragment because of disuse osteoporosis secondary to the nonunion. At present, I do not advise the use of retrograde supracondylar nails for supracondylar nonunions.

Most supracondylar nonunions require bone grafting and internal fixation using a variety of plates. Double-plate fixation comparable to that described for the trochanteric region may be indicated (see Chapter 29). Osteoporosis may make solid screw fixation difficult to achieve. In elderly patients, in cancellous bone, methacrylate can be inserted into the screw holes to improve screw fixation. Cement is not advisable in younger patients because if the appliance must be removed, considerable bone destruction may be necessary to remove it. Consequently, methacrylate is used only as a last resort. Back-up washers and nuts on the screws on the opposite cortex are often helpful. Another useful technique is to take a cortical or corticocancellous bone graft from the tibia or ilium, or a femoral allograft, place it opposite the plate, and fix the screws into this stronger bone. I believe this is more useful than dual-onlay grafts. See the section on periprosthetic fractures in Chapter
Plate Fixation and Bone Grafting

- If plate fixation and bone grafting are necessary, use the basic techniques for fixation of the shaft or supracondylar fractures of the femur (see Chapter 20 and Chapter 21). Place the patient in a supine position on a radiolucent operating table with a C-arm fluoroscope available.
- Use an anterolateral exposure (15) because visualization of the condyles of the femur and knee joint is often necessary. Try not to strip the medial and posterior soft tissues. I have never found release of the patellar tendon to be necessary.
- Remove any hardware and correct any secondary deformity. A fibrous union in good position can be internally fixed in position; otherwise, take down the hardware, freshen the bone ends, open the medullary canal, and refashion the bone ends to correct any deformity and maximize bone contact. Fixation choices include the AO 95° condylar blade plate, a dynamic compression screw and side plate, or the Allo Distal Condylar Plate or 95° screw or bolt and side plate. I no longer use the AO condylar plate because it is difficult to use and not as versatile as the newer devices. (See Fig. 30.4, Fig. 30.5, Chapter 21 describes the full operative technique.

**Figure 30.4.** AP radiograph of a 24-year-old woman 18 months after a T-type supracondylar fracture of the femur treated with an AO T plate. She has a painful nonunion with shortening and a varus deformity. B: AP radiograph of treatment with an Allo Distal Condylar Plate and Screw combined with autologous bone graft.

**Figure 30.5.** Supracondylar femoral nonunion. A: AP radiograph of the femur in a 35-year-old man who sustained a grade 3A open comminuted supracondylar fracture. B: After irrigation, debridement, and plate fixation, the fracture became infected and went on to a nonunion. This AP radiograph shows the original internal fixation with antibiotic beads in place. C,D: The plate and screws were removed and after resolution of the infection, the original treating physician internally fixed the fracture with a retrograde suprapatellar nail. Unfortunately, this failed as well, resulting in a persistent nonunion. E,F: I first encountered the patient 18 months after the original fracture. There had been no evidence of infection for 15 months. I removed the nail and screws, and through an anterolateral approach applied an Allo lateral plate assembly. I augmented this with a smaller anterior plate and applied an iliac crest bone graft. The nonunion healed in 16 weeks with no recurrence of infection. Knee motion was from full extension to 110° of flexion.

- If necessary, add a second anterior 3.5 or 4.5 mm narrow or reconstruction plate with six holes to place three bicortical screws in each fragment. Make this plate shorter than the side plate proximally. Obtain interfragmentary lag screw compression if possible.
- Petal the bone about the fracture site, apply an onlay cancellous bone graft, and close over suction drainage.

Other specialized plating techniques include the “wave” plate (14,38) and an intramedullary plate (31). Cove et al. (14) advise wave plating when treating nonunions where there is a segmental defect more than 5 cm in length, where there has been a history of sepsis, or where the medullary canal is unsuitable for intramedullary nailing. Wave plating involves molding the plate into a wave configuration so that it stands out from the femur throughout the zone of bone deficiency and nonunion. This permits the placement of a large volume of bone graft, which promotes healing, makes for a structurally stronger union when it occurs, and permits the use of a free microvascularized fibular transfer. Using the wave plate method, Ring et al. (38) achieved union in 41 of 42 consecutive complex ununited fractures of the femoral shaft at an average of 6 months after fracture. Three required a second bone graft, and two had recurrence of infection; in one of these there was a persistent nonunion. Matejcic et al. (31) have promoted the use of an AO dynamic compression plate placed in an intramedullary location to serve as a medial buttress in fresh fractures and nonunions where there is medial bone deficiency. The advantages of the intramedullary location are that less soft-tissue stripping (and thus devascularization) of the bone is necessary; more surface area at the fracture site is available for bone grafting; and the screw fixation from the accompanying lateral plate can be inserted through the intramedullary plate, increasing the strength of fixation and buttressing the medial cortex. The primary disadvantage of endoosteal plating is that it is technically demanding, resulting in longer surgery times and increased blood loss. In seven patients with complex nonunions of the distal femur, Cove et al. (14) achieved union in all with an average time to union of 19 weeks (Fig. 30.6).
Unstable and/or open fractures with small intramedullary nails. Almost all malunions of the shaft show combined deformities of malrotation, angulation, and shortening.

Malunions of the femoral shaft are not uncommon. In my experience, they occur most often after treatment with cast-braces, which is rare today, or after treatment of unstable and/or open fractures with small intramedullary nails. Almost all malunions of the shaft show combined deformities of malrotation, angulation, and shortening.

In my own series of 21 supracondylar femoral shaft nonunions treated between 1983 and 1997, using plating and bone graft, I was able to achieve union in 95% (Fig. 30.6) (31). Generally, this requires a radical debridement of the nonunion site, removing all scarred soft tissues that are impairing revascularization and all necrotic bone. Take cultures to identify the infecting organisms. In the femur, stabilization to maintain alignment and length is essential. Although traction can be used, in most cases the period of time that stabilization in the absence of internal fixation will be necessary is such that external fixation is best. If the infection can be resolved and there are particular advantages in converting from external to internal fixation, such conversion may occur, but definitive treatment to union in external fixation may be necessary. Usually, several debridements are necessary and treatment with intravenous antibiotics for up to 6 weeks, with suppressive oral antibiotics for longer, may be necessary.

The success of treatment of nonunion is greatly enhanced by having a well-vascularized muscular envelope completely around the fracture. This is usually not a great problem in the femur because of the large muscle envelope of the thigh, but skin grafts, rotation flaps, and free tissue transfer may be necessary to provide an appropriate environment for definitive treatment of the nonunion (46). Ilizarov techniques may be appropriate for the particular fracture (see Chapter 32 for details).

Once the infection is eradicated or well controlled, then iliac crest bone graft in external fixation usually suffices for those nonunions without a major gap. Usually, conversion from external fixation to intramedullary nailing is not appropriate because of the high risk of infection, but conversion from the external fixator to plates may be appropriate. In such cases, removal of the external fixator to allow the pin tracks to heal prior to open plate fixation is usually advisable. In the interim, stability and length can be maintained with a cast-brace with intermittent traction if necessary. For larger defects, iliac crest bone graft combined with a vascularized fibula may be necessary (46). Slätis and Paavolainen (41) advocate one-stage treatment of infected nonunions of the femoral shaft by excision of dead and infected tissue, resection of bone ends, cancellous bone grafting, and external fixation. They were successful in four of five cases. This small series, however, does not prove the efficacy of this method, and I prefer the staged approach advocated by Cove et al. (14) (Fig. 30.6).

In my own series of 21 supracondylar femoral shaft nonunions treated between 1983 and 1997, using plating and bone graft, I was able to achieve union in 95% (19). In most series, overall success rates for treatment of aseptic and septic nonunions of the femur are 70% to 97% (4, 5, 12, 13, 14, 25, 27, 31, 38, 39, 40) and 41).

MALUNIONS OF THE FEMUR

SHAFT

Malunions of the femoral shaft are not uncommon. In my experience, they occur most often after treatment with cast-braces, which is rare today, or after treatment of unstable and/or open fractures with small intramedullary nails. Almost all malunions of the shaft show combined deformities of malrotation, angulation, and shortening.
Shortening of more than 2.5 cm necessitates a cumbersome shoe lift and causes considerable inconvenience to active patients. It generally requires correction either by lengthening the shortened femur or by shortening the contralateral femur. Malrotation is better tolerated in external rotation than in internal rotation. As long as there is at least 10° to 15° of rotation beyond neutral in either external or internal rotation, patients rarely have functional problems. When they cannot rotate to neutral, significant functional problems usually require correction of the malrotation. Inability to rotate to the extremity at least to a neutral position places the knee and ankle joints out of the plane of progression for walking. This produces an inefficient and unsightly gait and interferes with sports activities.

Minimal to moderate anqulation is better tolerated than significant malrotation or shortening. There are three indications for correction of anqulation: poor function, often accompanied by pain, poor cosmesis; and the potential for late degenerative arthritis due to abnormal stresses across the knee joint (20). Decisions to undertake surgical correction for the first two complaints depend not so much on the degree of angulation present as on the patient's complaints. Generally speaking, angulation of less than 10° rarely produces significant functional or cosmetic impairment. Angulation of more than 20° almost always creates problems for the patient. The effect of angulation on joint function and possible late degenerative arthritis is more difficult to judge. In most patients, angulation of less than 10°, particularly in the middle third of the shaft, rarely creates problems. The preexisting alignment of the patient's legs, however, has a major effect; for example, a patient with preexisting genu varum may not tolerate an additional 10° of varus angulation and may require surgical correction. Generally, angulation of more than 15° requires correction in active patients. These are multifactorial decisions that require close consultation with the patient. The goal of restoration of the mechanical axis of the extremity is discussed in Chapter 26 and Chapter 32.

The type of surgical procedure indicated for correction of malunion of the femur depends on the degree of deformity, the alignment of the medullary canal, and the location of the deformity. From a technical viewpoint, open procedures are the easiest to perform, but many deformities of the femur are correctable by closed intramedullary osteotomy and nailing techniques. Ilizarov techniques have added a whole new dimension to the treatment of malunions (see Chapter 32).

Malunions in recently united fractures have soft callus. In most cases, it is best to expose the fracture site, take down the malunion, and restore the normal anatomy of the femur. Late malunions with significant remodeling are difficult to take down through the original fracture site, and various osteotomies are applicable.

Closed Intramedullary Osteotomy
Closed intramedullary osteotomy is a specialized technique that requires significant experience with closed intramedullary nailing (6,17,44). For this technique, the offset in the diameter of the medullary canal must be less than 25%. Alignment must be good enough to allow the passage of intramedullary instruments and a nail down the medullary canal of the femur past the deformity. The technique is best suited for correction of shortening of less than 5.0 cm and for correction of malrotation. In some cases, angulation is correctable as well, but an open osteotomy to realign the femoral canal is necessary. In malunions of the middle third of the shaft, internal fixation with medullary nails rather than plates and screws is preferred because failure is less likely and immediate weight bearing is possible in most cases.

- Place the patient in the lateral decubitus position on a fracture table with the extremity to be operated on uppermost (see Chapter 11 and Chapter 20). Prepare and drape from buttocks to the tubial traction pin. Through a gluteus-splitting incision, expose the piriformis fossa of the femur.
- If an intramedullary nail is already in place, the procedure is greatly simplified; remove the nail and insert a reaming guide pin. If a nail is not present, it is necessary to reestablish the patency of the medullary canal. In some cases, a 3.5 mm guide pin can be passed directly down the canal, and reaming can proceed. In other cases, the medullary canal at the fracture site is blocked by callus and must be reamed before correction. To achieve this, a set of recently sharpened, heavy, flagged Küntscher guide pins or hand reamers must be available. If angular deformity is present, one of the guidepins will need a bent tip.
- First, place a reaming guide pin down to the blockage and progressively ream the canal to the size required for the nail to be inserted. For these osteotomies, larger-than-normal nails are used; in the average-size man, I use at least a 16 mm nail. Enlarging the proximal canal allows better working room for the guides necessary to perforate the blockage.
- Insert a sharp-tipped guide pin of the appropriate curvature and drive it with a mallet into the bone block or the canal. Take care to remain in the central axis of the canal. If a straight-tipped pin is used, this can be attached to a power source and the blockage drilled. If the bone is soft, direct penetration may be possible. Otherwise, it will be necessary to withdraw the sharp-tipped guide pin after penetrating 1 cm or so. Reinsert the reaming guide pin, and with the end-cutting reamer open the canal in the perforated portions. Alternately these two methods until the blockage is opened. If the blockage is in the proximal half of the femur, the hand reamers from the AO instrumentation are useful as well. This technique can be difficult and time consuming.

- Rather than spending inordinate amounts of time trying to open the canal by closed technique, I often open the malunion site and perform an open osteotomy. Once the canal is open, insert the reaming guide pin distally to the subchondral bone at the knee, and progressively ream the canal to the desired diameter.
- With this technique, insert the Pearson intramedullary saw (Fig. 30.9) (a) and transect the femur at the appropriate level. In preparative planning, it is important to select an osteotomy site slightly proximal or distal to the fracture site in normal bone. Closed osteotomies at the old fracture site give the most precise correction, but an incomplete cut due to asymmetry of the canal will require osteoclasis, or percutaneous insertion of a 0.25-inch osteotome from the lateral side of the thigh, to complete the osteotomy.

Intramedullary saw for osteotomy of the femur using the closed intramedullary technique. The cutting blade at the distal end works on the principle of a cam and is available in diameters of 12 to 17 mm. (Courtesy of Biomet, Bourbon, IL.) B: Saw with parts labeled. (From Winquist RA, Hansen ST Jr, Pearson RE. Closed Intramedullary Shortening of the Femur. Clin Orthop 1978;136:54, with permission.)

- When straightening an angular deformity, drive the nail into the central portion of the distal femoral condyles. This will correct any angular deformity.

- If malrotation is present, place two Steinmann pins or Schanz screws, one above and one below the osteotomy, for rotational control before performing the osteotomy. Place these pins directly lateral, with one in the proximal fragment and one in the distal fragment, through only the lateral cortex of the femur. Do not penetrate the medullary canal proximally or the pin will interfere with the saw. Place the pins in alignment with each other initially, and then measure the angulation between the pins after correction of the deformity. Before surgery, make a template by bending a K-wire or cutting a piece of sheet aluminum to measure the rotational angle. A commercially available goniometer can be used instead, but this is more difficult to read.

- Maintaining rotational correction during the drive of the medullary nail can be difficult. For this reason, I prefer to use the Chick-Langreen table (Kirsheh Medical, Greenwood, SC), where the extremity is controlled by a large, threaded Steinmann pin through the proximal tibia or distal femur attached to the traction apparatus of the table. This gives nearly absolute control during the nailing.

- Then drive an interlocking nail, which can be stably locked. If the limb is less than 2.5 cm short, this discrepancy can usually be corrected at the same time by distraction and closed intramedullary bone grafting (Fig. 30.10) (b). Although length can be gained through the traction apparatus of the fracture table, it is more effective, and safer, to use an AO femoral distractor. Attach the two Schanz pins inserted as guides for correction of rotation to the femoral distractor. Distact slowly over 15–20 minutes. To avoid excessive traction on the sciatic nerve, do not soft-tissue releases and keep the knee flexed to 90° during the lengthening. Although I have had no difficulty with the sciatic nerve with acute lengthenings of less than 2.5 cm, it is advisable to use sensory-evoked potentials to monitor function in the sciatic nerve during lengthening. Johnson has performed acute lengthenings of 0.4–3.3 cm using an open technique with various bone grafting materials and has achieved healing in 18 of 19 patients (62,63).

- First, place a reaming guide pin down to the blockage and progressively ream the canal to the size required for the nail to be inserted. For these osteotomies, larger-than-normal nails are used; in the average-size man, I use at least a 16 mm nail. Enlarging the proximal canal allows better working room for the guides necessary to perforate the blockage.

- Insert a sharp-tipped guide pin of the appropriate curvature and drive it with a mallet into the bone block or the canal. Take care to remain in the central axis of the canal. If a straight-tipped pin is used, this can be attached to a power source and the blockage drilled. If the bone is soft, direct penetration may be possible. Otherwise, it will be necessary to withdraw the sharp-tipped guide pin after penetrating 1 cm or so. Reinsert the reaming guide pin, and with the end-cutting reamer open the canal in the perforated portions. Alternately these two methods until the blockage is opened. If the blockage is in the proximal half of the femur, the hand reamers from the AO instrumentation are useful as well. This technique can be difficult and time consuming.

- Rather than spending inordinate amounts of time trying to open the canal by closed technique, I often open the malunion site and perform an open osteotomy. Once the canal is open, insert the reaming guide pin distally to the subchondral bone at the knee, and progressively ream the canal to the desired diameter.

- With this technique, insert the Pearson intramedullary saw (Fig. 30.9) (a) and transect the femur at the appropriate level. In preparative planning, it is important to select an osteotomy site slightly proximal or distal to the fracture site in normal bone. Closed osteotomies at the old fracture site give the most precise correction, but an incomplete cut due to asymmetry of the canal will require osteoclasis, or percutaneous insertion of a 0.25-inch osteotome from the lateral side of the thigh, to complete the osteotomy.

Figure 30.9. Intramedullary saw for osteotomy of the femur using the closed intramedullary technique. The cutting blade at the distal end works on the principle of a cam and is available in diameters of 12 to 17 mm. (Courtesy of Biomet, Bourbon, IL.) B: Saw with parts labeled. (From Winquist RA, Hansen ST Jr, Pearson RE. Closed Intramedullary Shortening of the Femur. Clin Orthop 1978;136:54, with permission.)

- When straightening an angular deformity, drive the nail into the central portion of the distal femoral condyles. This will correct any angular deformity.
Intraoperative blood loss is usually less than 500 cc; however, postoperative bleeding into the thigh can result in up to a 40% drop in the hemoglobin level. In young trochanter, taking into account x-ray magnification.

If bilateral femoral trauma has occurred and shortening is to be performed on a previously fractured femur, the osteotomy must be performed in an area of normal establish a level plane of reference. Take full-length AP and lateral radiographs of the femur to be shortened to ensure that there is no abnormality that would an AP radiograph of the pelvis with the patient again standing on enough blocks to correct the leg-length discrepancy. Use either the film or a horizontal marker to to be consistently reliable, so I use them only for confirmation of other measurements. The best technique is to place blocks under the short leg of the standing patient

Preoperative Planning
Preoperative planning is extremely important. Determination of the actual leg-length discrepancy can be difficult. I have not found scanograms to be consistently reliable, so I use them only for confirmation of other measurements. The best technique is to place blocks under the short leg of the standing patient to level the pelvis. Rely on your judgment of the correction of the discrepancy and the patient's feelings about the correction. Try to obtain a level pelvis and take into account any distortion of the pelvis that may be present from old trauma or developmental or congenital abnormalities. Then confirm the clinical measurement by taking an AP radiograph of the pelvis with the patient again standing on enough blocks to correct the leg-length discrepancy. Use either the film or a horizontal marker to establish a level plane of reference. Take full-length AP and lateral radiographs of the femur to be shortened to ensure that there is no abnormality that would contraindicate shortening.

If bilateral femoral trauma has occurred and shortening is to be performed on a previously fractured femur, the osteotomy must be performed in an area of normal bone, preferably proximal to the fracture site. Using the preoperative radiographs, plan the site of the osteotomies and measure their distance from the tip of the trochanter, taking into account x-ray magnification.

Intraoperative blood loss is usually less than 500 cc; however, postoperative bleeding into the thigh can result in up to a 40% drop in the hemoglobin level. In young healthy patients, transfusion is rarely required.

Technique

- Place the patient in the lateral decubitus position on a fracture table with the extremity to be operated on uppermost, and expose the entry to the medullary canal in the usual fashion (see Chapter 11 and Chapter 20).
- Insert a 3.5 mm reaming guide pin. Progressively ream the medullary canal to the desired size. In closed shortening, the saw is more likely to transect the femur if a larger saw is used and the canal is reamed widely. With a reamer of known diameter in the site of the proposed saw cut, visualize the femur on a lateral view.
- The size of the reamer provides a guide to the size of the saw needed to cut through the linea aspera. Take care in smaller patients not to overream the femur.
- Overreaming of the anterior cortex will result in comminution and inability to complete the osteotomy. Intraoperative monitoring of the reaming process by fluoroscopy avoids this problem. When reaming a closed intramedullary canal, make a 5 mm or larger drill hole in the distal metaphysis of the canal to decompress the canal to reduce the embolization of marrow contents. Proceed slowly with reaming and progress by 0.5 mm increments. Although it has been
reported, I have never encountered fat embolism syndrome or adult respiratory distress syndrome after closed intramedullary osteotomy (Fig. 30.14D).

- Set the medullary saw for the most distal cut first. Insert the saw and verify by fluoroscopy that it is in the appropriate position. Make the saw cut. Because of the beardrop cross-sectional shape of the femur, if the saw used is too small, the cut may be incomplete posteriorly. Either place a larger saw or complete the osteotomy, either by osteolysis or by placing a 5 mm osteotome percutaneously from a lateral approach to cut the remaining bridge. In most cases, sufficient reaming can be done to allow a large-enough saw to make a complete cut (Fig. 30.11B).

- Carefully set the measuring device on the saw for the second osteotomy, insert and verify correct position by fluoroscopy. The cam of the cutter is 15 mm in length. If this is a useful reference to tie the required length between the osteotome and the nail. A short cut is made at one end of the intercalary fragments. If only a small bridge of bone remains, insert a 12 mm Kuntscher nail down to the proximal osteotomy and abduct the proximal fragment. A firm blow to the tip of the fragment will often break it free. If this does not occur easily, then percutaneously insert a 5 mm osteolysis from a lateral approach and transpose the osteotomy. Occasionally, half-spikes are left on the main shaft fragments, which will prevent complete shortening; these can be removed by a percutaneous osteolysis if necessary (Fig. 30.11C).

- Next, split the intercalary fragment using the back-cutting osteotomy supplied with the medullary saw. Under fluoroscopic control, insert the back-cutting osteotomy against the diaphysis of the intercalary fragment and gently tap the handle of the saw with the slotted mallet to cut the intercalary fragment. A single cut usually splits the fragment into two halves (Figs. 30.11D).

- Displace the intercalary fragments out of the osteotomy site. This can be done by pulling them to the side with the back-cutting osteolysis, or they can be pushed out using an intercalary tool with small handles. As long as one end of the intercalary fragments lies outside the femoral shaft, they will come to lie outside the osteotomy site and adjacent to the femoral shaft when shortening is performed. The preferred location for the intercalary fragments is medial, although generally one fragment ends up medial and the other lateral.

- Insert and drive an intramedullary pin into the intercalary medullary nail interlock site. The nail should be 1 mm in diameter smaller than the canal was reamed. To accomplish shortening, it is easiest to drive the nail until it just exits the proximal fragment. Loosen the traction and manually shorten the femur to close the osteotomy and bring the tip of the nail just into the distal fragment. While manually holding the osteotomy closed and maintaining proper rotation, drive the nail into the distal fragment. If the osteotomy occurs during the nail insertion, insert the nail until the osteotomy closes and then release the osteotomy while holding the osteotomy closed. I always interlock both distally and proximally. Lock distally first, impact the osteotomy to close it and achieve compression, and then lock proximally (Fig. 30.11E).

- Wash and debride the wound thoroughly to help prevent heterotopic bone formation. Close the wounds in layers. Do not use a drain.

Postoperative Care

After shortening, considerable hemorrhage into the thigh can occur. Without blood replacement, I have seen a drop in the hematocrit in some patients into the low 20s. Monitor the hematocrit or hemoglobin on a daily basis until it stabilizes. Immediately apply a knee immobilizer in the operating room, with good thigh coverage to compress the thigh; this may help control hemorrhage. Because of the shortening, patients lose some control of the quadriceps and hamstring muscles and will have an unstable knee immediately after surgery. The knee immobilizer controls the knee and allows immediate weight bearing. Start the patient immediately on range-of-motion and thigh muscle progressive resistance exercises. Patients can bear weight as tolerated wearing the knee immobilizer and using crutches for about 4 weeks. When weight-bearing is free, the 2 pain gain can ambulate independently. The 2 pain gain can ambulate independently after 6 weeks. Most patients will switch from crutches to a cane at that time, and within a few additional weeks will be fully weight bearing without assistive devices (Fig. 30.12).

HINTS AND TRICKS

- Perform closed intramedullary shortening of the femur only in the lateral decubitus position on a suitable fracture table. Full access for the instrumentation is critical and is not really possible in many patients in the supine position. It may be feasible to do this procedure in the lateral decubitus position on a regular radiolucent operating table, but I have never attempted it.

- During planning, note how much anterior or posterior the femur has on the lateral view, and the thickness of the linea aspera. The saw is straight, so the cut needs to be located where the saw will fit. A very bowed femur will make passage of the saw very difficult distally. In addition, try to select an area for the osteotomy where the linea aspera can be cut completely by an appropriate-size saw.

- Attention should be given to the anterior cortex, be careful not to advance it too much between cuts, as it may catch and again break. Never force the saw.

- The linea aspera is always the last section to be cut through. This can be enhanced by angulating the saw gently within the canal to press it against the posterior aspect. Try to avoid incomplete cuts, because subsequent completion of the cut is complicated, as is closure of the osteotomy.

- When driving the nail, if difficulties are encountered in keeping the osteotomy closed, use a nail that is smaller in diameter and/or shorter, because this will facilitate sliding of the bone on the nail. Recognize that this decreases the stability of the nailing.

- Shortening becomes increasingly difficult as the length of the intercalary segment removed increases. Little difficulty is encountered in shortening up to 3 cm in length with good exposure of the posterior aspect of the greater trochanter, because the need to repeatedly enter the canal with instrumentation requires good exposure. In addition, the length of the cut is determined by the placement of the measuring device of the intramedullary saw against the tip of the greater trochanter. It is necessary to reproduce this position when the saw is inserted for the second cut. This necessitates having no soft tissues in the way.

- Protect and be gentle with the gluteus musculature. One of the primary problems in rehabilitation is regaining abductor muscle strength.

- The entry for the nail must be directly above the medullary saw and nail. An eccentric entry will complicate entry of the medullary saw and nail.

- Entering the saw into the medullary canal can be difficult. Reaming the entry hole several millimeters larger than the saw is helpful. When placing the saw, enter from slightly posterior to the long axis of the femur and screw the saw into place. The saw is easily bent, so be gentle with it.

- When seating the saw for the first cut, be certain that the measuring device is firmly implanted on the tip of the greater trochanter and that all components of the saw are fully closed. During the cut, be certain that this position is maintained. Reproduce it for the second cut. Lack of attention to these details can lead to incorrect shortening.

- When selecting the place for the saw cuts, pick a place where there is no pathology in the femur, where there will be good purchase of the intramedullary rod with the inner wall of the cortex in both the proximal and distal fragments, and where the linea aspera is as narrow as possible. Be certain that you are within the operating length of the saw.

- When cutting with the saw, always advance it in a clockwise direction. Do not reverse it, as this may catch and break off the blade. Once the saw breaks through the anterior cortex, be careful not to advance it too much between cuts, as it may catch and again break. Never force the saw.

- When the osteotomy is fully closed. During the cut, be certain that this position is maintained. Reproduce it for the second cut. Lack of attention to these details can lead to incorrect shortening.

- Finally, it is very important to carefully examine the extremity on the operating table under anesthesia after completion of the shortening, to be certain that leg length equalization is appropriate. For shortening of 2.5 cm or more, plus or minus 5 mm will leave most patients satisfied, although I try to get them exact. Verify that rotation has not changed because occasionally the proximal fragment will rotate externally because of muscle pull, which will result in nailing in too much internal (over 10 or more than 75 degrees). I have had this only a couple of times. We corrected it by repping the knee, pulling the distal cross-locking screws, rotating the femur to the correct position, and then reinserting the screws.

Complications

Most problems and complications from closed intramedullary osteotomy of the femur can be avoided by following the technical guidelines just discussed. Avoid inadequate correction of deformity and inadequate fixation by good preoperative planning. Closed intramedullary osteotomies are technically challenging and require considerable experience with intramedullary nailing techniques. I advise that the surgeon gain considerable experience with routine fracture fixation techniques before attempting closed intramedullary nailing before attempting these osteotomy techniques. Avoid commination by not overreaming. I have not had an infection or nonunion from closed shortening.

With shortening of less than 2.5 cm, muscle function returns rather quickly. By Biodex measurement (Biodex Medical Systems, Inc., Shirley, NY), most return to within a few percentage points of normal (9). With shortening of more than 2.5 cm, at least 1 year is required to achieve 90% of normal muscle function, and most patients are left permanently with about 5% of residual weakness. In my patients, this has never been of functional significance. Because union of the osteotomy is almost always present by 6 weeks and quite mature at 12 weeks, the reestablishment of muscle function and joint range of motion is the major determinant of return to sports and vocational activities.

Because equalization of leg lengths is generally performed in active patients, most will want the nails removed. Although I have removed them as early as 9 months after surgery, I advise most patients that removal is best delayed to 1 year.

Occasionally, a patient will develop some heterotopic bone about the tip of the medullary nail that is symptomatic. Because these patients are quite active, a nail that is left protruding will also be symptomatic. In most cases, you can emphasize to patients that you are operating on a normal extremity and that they will be left with some residual disability, including a scar in the buttock, and that some patients will have minor, long-term discomfort in the operative site. This has discouraged none of my
patients from having the surgery, because the benefits of equal leg lengths far outweigh these minor residuals.

Open Osteotomy with Intramedullary Nailing

Open osteotomy is technically much simpler than closed osteotomy, but it has the disadvantage of slightly higher rates of infection and nonunion. Before interlocking nails were available, step-cut osteotomies were used to gain rotational control and better stability. With locked nails, a step-cut osteotomy is not necessary. In most instances, a straight transverse osteotomy can be used. When angular deformity is present, a transverse osteotomy will result in an open wedge-type osteotomy when the nail is driven. Graft all osteotomies with the reamings and autogenous cancellous bone if necessary.

- Place the patient on a fracture table as you would for the closed intramedullary nailing technique. Prepare and drape the entire thigh and buttocks area. Use a direct lateral approach (see Chapter 3) and expose the fracture site by subperiosteal dissection.
- If length needs to be regained, take down the fracture site in a step-cut fashion (Fig. 30.13). Apply a femoral distractor or use traction on the fracture table to gain length.

**Figure 30.13.** A: Malunion of a midshaft fracture of the femur with angulation and overriding. Even a year after the original fracture, the original cortex can be differentiated from the surrounding callus. To restore length, shave off the callus and identify the original cortex. Take down the malunion through the old fracture site. B: Apply an AO femoral distractor and restore alignment and length. Avoid excessive tension on the sciatic nerve. C: Fix the osteotomy with a 10- to 12-hole broad dynamic compression plate. Interfragmentary screw fixation is recommended. Apply the callus removed earlier as a bone graft. Add additional graft if necessary. (From Müller ME; Allgöwer M, Schneider R, Willenegger H. Manual of Internal Fixation. New York: Springer-Verlag, 1979, with permission.)

- Align the femur and internally fix it with a locked intramedullary nail. Apply the reamings and/or a cancellous bone graft from the posterior ilium.

**SUPRACONDYLAR AREA**

**Osteotomy with Plate and Screw Fixation and Bone Grafting**

Plate and screw fixation can be used for malunions of the shaft but is most commonly used for condylar or supracondylar malunions (1,6,29,32,34,39,42). It may be necessary in malunions of the shaft where malalignment of the medullary canal makes intramedullary nailing impossible. Many osteotomy techniques are possible, including opening wedge, closing wedge, step-cut, dome, and various types of oblique osteotomies. In most cases, shortening, angulation, and malrotation must be corrected with a single osteotomy. Closing-wedge osteotomies have the advantages of simplicity and good stability. The disadvantages are that they result in further shortening, and osteotomy site apposition is a problem when correction of significant rotation is also required. Opening-wedge osteotomies have the disadvantage of much less stability after fixation and require structural bone grafting. Union is slower than with closing wedge osteotomies, and remodeling of the graft is required. See Figure 30.13 for an illustration of open technique.

I prefer single-plane oblique osteotomies when treating combination deformities, and the dome osteotomy for isolated varus or valgus angulation in the metaphysis (33). An oblique osteotomy has the advantages of excellent stability, broad bone surfaces for union so that bone grafting is usually not required, and correction of all components of the deformity. Disadvantages are that considerable exposure of bone is required and meticulous preoperative planning and surgical execution are necessary for it to work. In about 20 osteotomies in the distal femur, I have had one failure due to nonunion, probably the result of overlengthening and devascularization of the bone ends. The technique described next is an AO osteotomy for a supracondylar malunion (Fig. 30.14).

**Figure 30.14.** A: AP radiograph of a malunion of the distal third of the femur in a 26-year-old athlete with 13° of varus, 15° of external rotation, and 1.5 cm of shortening. B: Preoperative lateral radiograph. C: Tracing of the contralateral normal femur, and the osteotomy and fixation planned for the malunion. A 12-hole plate and at least two interfragmentary screws are planned for fixation. D: Lateral tracing of the contralateral normal femur and the planned correction for the malunion. Notice that the osteotomy is at 60° to the transverse axis of the femur, which permits sliding to gain length. (The wedge removed to correct the malrotation is not illustrated.) E: Intraoperative AP radiograph of the completed osteotomy. F: Lateral radiograph of the completed osteotomy.

**Preoperative Planning** A frontal-plane or sagittal-plane osteotomy can be used; in most cases the former is better. Make tracings of the preoperative radiographs to determine the angular deformity to be corrected. Use clinical measurements to determine the amount of malrotation to be corrected. Use both clinical and radiographic assessments to determine the length to be corrected. Make a drawing of the proposed postoperative construct with internal fixation in place (Figs. 30.14A, 30.14B, 30.14C, and 30.14D).

**Technique**

- Place the patient in the supine position on the operating table. Prepare and drape the extremity to be operated on. In distal osteotomies, a tourniquet can be used. It is often useful to prepare and drape the contralateral normal extremity as well because this permits intraoperative comparison. Be certain that the pelvis is level so that leg-length determinations are accurate.
- Expose the distal femur through an anterolateral approach (see Chapter 3). Place K-wires as guide pins in the proximal and distal segments. In the frontal plane, insert one K-wire in the distal fragment parallel to the knee joint. Insert a second wire into the proximal fragment at right angles to the shaft of the femur. Verify correct position by fluoroscopy or radiograph. Place a second set of K-wires in the sagittal plane, entering the anterior aspect of the femur. These are used to measure correction in the AP plane and can also be used to ascertain rotation. Place the wires at right angles to the knee joint distally and at right angles to the long axis of the femur in the proximal fragment. Put them in direct alignment with each other rotationally. Both of these sets of wires must be proximal and distal to the osteotomy site. Measure the distance between the anterior K-wires; this will be used to determine length.
- Through the middle of the fracture site in the frontal plane, make an oblique osteotomy at 60° to the long axis of the femur. Begin distally on the anterior surface of the femur and exit posteriorly. Open the osteotomy site with bone-holding forceps or retractors. Next, remove a wedge of bone from the distal fragment. The
base of the wedge will determine correction of rotation and any deformity in flexion or extension. Experienced surgeons can remove this with a single cut. Otherwise, take the wedge for correction of deformity in the sagittal plane first and then take a side-based wedge to correct rotation. Do not remove too large a wedge. It is better to take too small a wedge initially and then to cut further. Accurate preoperative measurement, taking into account x-ray magnification, is necessary. Approximate the osteotomy site and slide the distal and proximal fragments against each other to correct varus or valgus angulation.

- At this point, overall axial alignment of the femur is corrected and only shortening remains. Apply a Lowman bone-holding clamp or other bone-holding forceps to the osteotomy site to hold it in loose apposition. Apply a femoral distractor and slowly distract the osteotomy site to gain length. Keep the knee flexed and use other precautions to avoid excessive traction on the sciatic nerve, as described earlier in this chapter. Once enough length has been obtained, temporarily fix the osteotomy site with two or three large Steinmann pins. Carefully assess the correction clinically and radiographically to ensure it is adequate.

- Begin internal fixation by inserting two or three anterior-to-posterior interfragmentary lag screws (either 6.5 mm cannulated screws or cortical screws with gliding holes) in the femur distal to the osteotomy site. The screws should engage the broad surfaces and intimate contact of the osteotomy, and union occurs rapidly. It may be difficult to document union radiographically, however, because the osteotomy often appears healed on the immediate postoperative film. Four routine views, as well as AP and lateral tomograms, are often necessary to ascertain that union has occurred. When it does occur, begin full weight bearing.

**Postoperative Care**

Initially, apply a bulky soft dressing. As soon as the patient is comfortable, remove the dressing and begin rehabilitation. Continuous passive motion may be helpful in restoring knee motion.

Allow only touch-down weight bearing until union occurs. During this period, progressive resistance exercises are possible as long as the thigh is supported on the exercise table. Avoid excessive weights. Because of the broad surfaces and intimate contact of the osteotomy, union occurs rapidly. It may be difficult to document union radiographically, however, because the osteotomy often appears healed on the immediate postoperative film. Four routine views, as well as AP and lateral tomograms, are often necessary to ascertain that union has occurred. When it does occur, begin full weight bearing.

**Crescentic (Dome) Osteotomy**

The techniques for dome osteotomies are discussed in detail in Chapter 26. The following technique is used for isolated varus or valgus deformities of the femur in the suprapatellar area (Figs. 30.16-30.18).

In the preoperative planning, be certain that a dome osteotomy will restore the normal mechanical axis of the knee, or if treating unilateral arthrosis that it will result in an appropriate shift of the mechanical axis.

- Use a direct anterior midline incision by either an anteromedial or anterolateral approach depending on the deformity to be corrected and the fixation planned.

- Perform the dome osteotomy using multiple drill points and an osteotome as described in Chapter 26. Make the osteotomy as distal as possible because this provides a larger area for the arc of the dome, which is technically easier and provides a broader surface area for union. Be certain to leave enough length in the distal fragment so that solid internal fixation with a lateral plate providing three bicortical screws of fixation in the distal fragment is possible.

- After completing the osteotomy, correct the deformity, impact the osteotomy, and secure initial fixation with one or two interfragmentary screws across the osteotomy. Apply a broad plate laterally to provide neutralization, securing bicortical fixation with three screws distally and proximally.

- Prior to closure, repeat mechanical axis determination with the fluoroscope to be certain that the goals of the osteotomy have been met.

- Do a meticulous closure of the joint capsule and muscle, and apply a sterile dressing and knee immobilizer. Drain the knee and osteotomy site.

Patients can be mobilized from bedside to a chair on the first postoperative day. As soon as the drain is removed, begin knee range-of-motion and muscle rehabilitation exercises. These osteotomies are very stable and most patients can begin 50% weight bearing with assistive devices using a knee immobilizer immediately. Until the osteotomy heals, avoid straight-leg raising and excessive stress across the osteotomy site. Healing usually occurs in 6-8 weeks, at which time progression to full weight bearing without assistive devices and full rehabilitation program can be instituted (Fig. 30.15A, Fig. 30.15B, Fig. 30.15C and Fig. 30.15D).

**CONDYULAR AREA**

Treatment of intra-articular malunions of the femoral condyles is difficult. It is best to identify malposition early and correct the deformity before remodeling takes place. Once remodeling has occurred, it becomes exceedingly difficult to realign the articular surfaces of the knee joint. Malunions of epiphyseal fractures in children involving the condyles are even more difficult because the malunion may be accompanied by growth arrest, and correct osteotomy often threatens the integrity of the physis. Specialized techniques are necessary in children (see Chapter 168, Chapter 169, and Chapter 171).

Malunion of the lateral femoral condyle usually results in varus, external rotation, and flexion deformity. Malunion of the medial condyle produces a similar deformity, but in varus. Most disabling is the malrotation that interferes with the articular surface of the patellar groove and produces malalignment of the patellar mechanism. Comminuted fractures with a transverse component produce a step-off in the articular surface that can interfere with patellar or tibial motion on the femur. Although patients can walk fairly well with the knee straight, function is impaired in flexion and during sports activities.

Correction is difficult because restoration of a normal articular surface is very difficult, and the amount of soft-tissue stripping of the fragments necessary to restore them to proper position risks avascular necrosis. Surgical techniques for medial and lateral condyles are similar.

- Place the patient in a supine position on the operating table and prepare and drape the extremity. As recommended previously, it may be advisable to drape the normal extremity as well for comparison. A tourniquet can be used.

- Use an anteromedial or anterolateral parapatellar incision long enough so that the articular surfaces of the femur can be easily seen and complete access to the fracture site gained. To achieve good alignment, it is often necessary to dislocate the patella.

- Maintain the soft-tissue attachments of the collateral ligaments, and as much joint capsule as possible, as well as the cruciate ligaments. In some distal femoral malunions, the femoral artery and vein are fibrosed to the posterior aspect of the femur. Dissect carefully in a subperiosteal manner along the posterior aspect of the femur, staying just anterior to bone to avoid injury to the neurovascular structures. Keep the knee flexed to 90° during this dissection and when the osteotomy is made.

- Identify the fracture site at the articular surface. With osteotomes, take down the malunion. Progress from the articular surface proximalward, attempting to stay in the old fracture site. A similar technique is used for transverse malunions.

- With the condyle mobile, restore the alignment of the articular surface. Often this results in incongruity in the osteotomy or fracture site and requires some

---

**Figure 30.15.** Crescentic (dome) osteotomy. AP radiograph (A) of the right knee of a 42-year-old woman who has had moderately severe genu valgum since she was a child. She was having significant lateral compartment pain that interfered with her activities of daily living. Bilateral radiographs showed moderately advanced arthritis of the lateral compartment. She was treated with bilateral dome osteotomies; this shows the right side. The black vertical line on the lateral aspect of this radiograph shows the mechanical axis between the center of the femoral head and the center of the tibial plate, which here lies completely lateral to the joint. Note the tibial femoral angle of 16° of valgus. AP (B) and lateral (C) radiographs taken at the time of surgery show a dome osteotomy in the distal femur with excellent correction of her deformity and restoration of the mechanical axis to slightly medial of normal in order to unload her lateral compartment. Note that the “cog wheel” edges of the osteotomy are impacted and the osteotomy fixed with two interfragmentary screws through a lateral plate if any micromotion exists in the osteotomy after this fixation, a small anterior plate can be added as well. AP (D) and lateral (E) radiographs taken after hardware removal approximately 2 years after the initial osteotomy show good maintenance of alignment and good preservation of the lateral joint space, with no evidence of progression of her arthritis. At the 6-year follow-up, she continues to do well with some evidence of progression of her arthritis. A similar osteotomy was done of the opposite leg with an equally good result.
carpentry to obtain good alignment of the articular surface with good closure and apposition of the fracture and osteotomy site. Most difficult to correct is rotational malalignment.

- Achieve temporary fixation with K-wires and obtain radiographs to ensure the correction is satisfactory. Internally fix the osteotomy with three or more interfragmentary 6.5 mm cancellous lag screws. In malunions, lag-screw fixation alone often is inadequate, and adding a plate to buttress the malunion is important.
- When closing, ensure that the patella is in good alignment. Use suction drains and apply a bulky soft dressing with splints. A typical case is illustrated in Fig. 30.16.

Within 2 to 3 days postoperatively, remove the drains and bulky dressing, and begin rehabilitation using continuous passive motion. With solid internal fixation, an active rehabilitation program is possible. Keep the patient on touch-down weight bearing until union occurs. Again, multiaxial radiographs and tomography may be necessary to confirm union.

In some cases, there will be sufficient degenerative changes in the knee that arthrodesis may be a better choice. Arthrodesis of the knee is so disabling, however, that I usually advise correction of the deformity followed by total knee arthroplasty.

NONUNIONS AND MALUNIONS OF THE PATELLA

NONUNIONS

Nonunions of the patella are unusual. They generally are due to nonoperative treatment of widely displaced fractures or failure of fixation, particularly as a result of infection. Treatment is unnecessary unless the patient has symptoms. A fibrous union can have acceptable function with minimal symptoms. Klassen and Trousdale (28) treated 20 patients with patellar nonunions, of whom seven were treated nonoperatively. They achieved an average knee range of motion of 120° with a Knee Society score of 83 with a function score of 75. Pain, lack of knee stability, or mechanical problems may require surgical treatment. Therapeutic choices are total patellectomy, partial patellectomy with repair of the quadriceps mechanism, or reconstruction of the patella. In nonunions, it is difficult to correct the irregularities in the patellar articular surface, so some type of patellectomy is generally indicated. Reconstruction uses the same principles of fixation and resection as described for patellar fractures in Chapter 22. Use compression screw fixation and a tension band wire. Bone graft is rarely necessary or possible, but a sliding inlay graft can be used in some cases. Of the 13 patients Klassen and Trousdale (28) treated operatively, all but one healed, achieving Knee Society scores of 94, a function score of 93, and an average knee range of motion of 109°.

MALUNIONS

Malunions of the patella result in irregularities of the articular surface. As with condylar fractures, correction is possible but difficult. Joint-surface irregularity often persists. Total or partial patellectomy may be the best choice. In active patients, preservation of the patella is worthwhile, but do not allow persistent incongruity of the articular surface to precipitate patellofemoral arthritis or perhaps generalized arthritis in the knee.

- The surgical technique is similar to that described for femoral condyle malunions. Use a long, medial parapatellar approach.
- Invert the patella. Take down the malunion with osteotomes, working from the articular surface.
- Realign the patella. Obtain solid fixation with interfragmentary lag screws and a tension band wire.

After surgery, maintain knee motion with continuous passive motion and active assisted exercises. Judicious isometric muscle exercises are beneficial. Avoid straight-leg raising. Permit weight bearing with a knee immobilizer. Union will occur in 6–12 weeks. Thereafter, institute a full rehabilitation program and allow gradual return to normal activities.

Chapter References

Nonunion of the tibial shaft is a common problem that is severe and disabling. Failure of tibial fractures to unite may lead to multiple operative procedures and prolonged hospitalization with years of disability before a union is obtained or amputation is performed. Although high rates of union have been obtained in some series of tibial fractures with simple methods, nonunion is frequently seen by practitioners treating tibial fractures (20,36,95,112,139).

Malunion of a tibial shaft fracture refers to healing of the fracture in a nonanatomic position. Functional malposition rather than cosmetic deformity constitutes an indication for surgical intervention.

The most frequently encountered problem in malunion is shortening. Shortening of less than 1 cm is acceptable. Shortening of greater than 15 mm may be symptomatic and necessitate a lift or leg-length equalization procedure. Varus and valgus angulation should be limited to less than 10°. Recurvatum is less well tolerated than anterior bowing and should not exceed 10°. Anterior bowing of less than 10° is rarely of functional significance but may be cosmetically unacceptable. Rotatory malalignment is better tolerated than varus-valgus angulation. Internal rotation exceeding 5° is noticeable, and that exceeding 10° is usually unacceptable. External rotation is better tolerated but will become noticeable when it exceeds 10° and may become functionally significant when it exceeds 15°. Pre-existing deformity such as genu varum and genu valgum, and pre-existing arthritis or joint instability may make angulation, which ordinarily would be acceptable, a problem sufficient to require correction. Experimental evidence, obtained from pressure-sensitive film, suggests that angular deformities in the distal third of the tibia are more likely to affect contact area and joint pressures in the ankle adversely, whereas proximal angular deformities have a larger impact on the knee joint (85,86,123). Although some degree of malalignment is common following tibial fractures treated nonoperatively, osteotomy is rarely indicated. Close follow-up of patients with acute tibial fractures and early intervention in cases that develop angular deformity will prevent most unacceptable malunions. Long-term clinical follow-up, however, has failed to show any adverse effect of moderate angular deformities on the subsequent development of knee or ankle arthritis (87).

INCIDENCE

Although reporting methods and definitions vary from author to author, the incidence of nonunion and delayed union can be estimated from reports published in the literature. In 22 combined series covering 5517 fractures, the incidence of nonunion was 2.5% and the incidence of delayed union 4.4% (1,20,23,25,34,36,38,51,68,73,80,95,100,106,108,112,115,124,129,130,138,140). The studies included several large series of predominantly closed tibial fractures caused by low-energy trauma. Open fractures with gross contamination and extensive soft-tissue damage have a much higher incidence of nonunion and delayed union. In series of open tibial fractures, Clancy et al. (25) have reported a 13% incidence of delayed union. Widenfalk et al. (138) have reported a 31% incidence of delayed union, and Edwards et al. (46) have reported a 41% incidence of grade III fractures requiring bone grafting to achieve union. In type II and type III open tibial fractures, Velazco et al. (135) have reported a 14% rate of nonunion. An incidence of tibial nonunions and malunions above those reported in early series should be expected by the orthopaedic surgeon practicing today in view of an increasing incidence of high-energy trauma associated with motor vehicle accidents.

CAUSES OF NONUNION

Many factors have been associated with delayed union or nonunion. Most are dictated by the injury, but others are within the surgeon's control. The incidence of nonunion, and especially of infected nonunion, increases with the severity of open fractures. The presenting factors cited as contributing to nonunion or delayed union include fracture displacement, bone loss, associated fibular fractures, comminution, and infection (41,68,73,80,95,108,128,138). Therefore, the nature of an injury plays a large role in determining the likelihood of union. A direct correlation exists between the energy absorbed by the hard and soft tissues and the complications of wound healing, including delayed union, infection, and skin slough (24,62).

The common anatomic factor that determines the rate of union of tibial fractures is the degree of preservation of the tibial blood supply. The anatomy of the tibial blood supply has been described in detail (79,94,104,126). The three vascular systems supplying the tibia are the nutrient vascular system, the periosteal vascular system, and the epiphyseal-metaphyseal vascular system. The nutrient and periosteal vascular systems are the most important in healing of tibial shaft fracture. The nutrient artery system, which arises from the entrance of the posterior tibial artery into the posterior tibial cortex, distal to the soleal line, is divided at its origin into ascending and descending branches. The nutrient vessels provide the endosteal blood supply to the tibia, which MacNab has shown to supply as much as the inner 90% of the cortex (78). Destruction of the endosteal blood supply is most extensive when the fracture occurs in the middle one third of the tibia, but the distribution of nonunions among proximal, middle, and distal thirds of the shaft appears to be equal (78,90). The periosteal blood supply receives segmental vascular contributions from the surrounding soft tissues, which, in turn, are largely supplied by the anterior tibial artery. Vessel penetration through the interosseous membrane and the posterior periosteum is abundant. The blood supply to the subcutaneous anteromedial periosteum, however, is more precarious and thus more easily destroyed. Rhinelander (104) has demonstrated that preservation of the periosteum results in cortical fracture healing through transient expansion of the periosteal blood supply to the inner cortical bone. The degree of periosteal stripping and the resultant amount of devascularized bone varies with the fracture type. Increased periosteal stripping, as seen in high-grade open fractures, contributes substantially to delayed union or nonunion.

Recent evidence has also highlighted the adverse affect of nicotine on bone healing (19,72,103). We strongly recommend that patients stop smoking before undergoing operative intervention on tibial nonunions.

Failure to manage tibial fractures properly has been shown to increase the incidence of nonunion. Distraction at the fracture site and failure to immobilize the fracture adequately are known to increase the time to union (27). Brown and Urban (20), Dehne et al. (36), and Sarmiento (112,113) have advocated early weight bearing with cast or cast brace treatment as a means of obtaining intermittent compression at the fracture site, and have reported low rates of nonunion in their respective series. Adherence to the principles of open fracture management, including aggressive multiple debridements, administration of antibiotics, and rigid immobilization of fracture
TREATMENT CONSIDERATIONS IN TIBIAL NONUNION

Optimal treatment of tibial nonunions begins with a critical assessment (Fig. 31.1). The fracture configuration and location, classification of open fracture, and history of infection of previous external fixation are essential elements of the history. Physical examination determines the status of the soft tissue, the presence or absence of a draining sinus, and the neurovascular status of the foot. Radiographically assess initial and current fracture alignment, and make note of any significant bony defect that limits the choices for managing the nonunion.

In patients with a history of an open fracture or a prior history of infection, investigate infection as one of the causal factors of nonunion. C-Reactive protein, sedimentation rate, and indium-labeled bone scans may be helpful to assess the likelihood of persistent infection. Do not administer preoperative antibiotics and obtain intraoperative cultures. Patients with active infection should undergo debridement and are frequently treated with a course of intravenous antibiotics. If a bone graft is required, stage this procedure after the infection has been treated to minimize the risk of graft infection and sequestrum formation.

Weber and Cech (135) classified pseudoarthroses into hypertrophic and atrophic varieties. The hypertrophic variety includes those that resemble an elephant’s foot, a horse’s foot, and the oligotrophic variety. These nonunions have adequate biologic potential and may go onto union by improvement in mechanical factors, such as improved stabilization or interfragmentary compression. The atrophic variety includes the dystrophic, gap, and end stage atrophic classifications. These nonunions lack adequate biologic potential and require bone grafting to stimulate successful healing.

The ultimate goal of a stable functional lower extremity should not be overlooked in attempts to achieve bone union. Amputation is a reasonable alternative to heroic efforts at gaining union in a tibia with major bone loss, infection, and posterior tibial nerve disruptions. Early amputation in those injuries in which limb salvage is inappropriate enhances patient survival, reduces pain, emotional distress, and disability, and shortens hospitalization time and costs (11,162). Limb salvage and reconstruction is indicated for salvageable injuries. Although it is more expensive and requires multiple operative interventions, better functional outcomes have been reported for limb salvage when compared with amputation (81).

Optimal treatment seeks to avoid what Müller et al. have termed fracture disease—muscle atrophy, muscle and tendon contractures, joint stiffness, and disuse osteoporosis (81). Many paths to fracture disease have been described. Prolonged immobilization in plaster has been demonstrated to result in a high percentage of fracture union, even in cases of open fractures, but it has also been associated with residual foot and ankle stiffness, knee stiffness, and muscle atrophy (82). Plaster immobilization is best limited to initial management of closed fractures and use in combination with bone grafting. Sarmento (112,113) has advocated the use of patellar tendon-bearing cast and braces, which allow knee motion, and these aids should be substituted for long-leg casts whenever possible. In addition to encouraging union, therefore, you should initiate any new intervention with the goals of minimizing immobilization and hastening return of the patient to maximum activity with a low risk of complications from the intervention.

Infection, soft-tissue defects, atrophic nonunions, and malalignment substantially alter treatment options in tibial nonunions. The closed, uninfected nonunion with an anatomic alignment requires intervention only to achieve union; posterior lateral bone graft, closed reamed intramedullary nail, and application of a compression plate with or without bone graft are all acceptable solutions to the problem. Malalignment requires osteotomy or osteosclerosis in addition to bone grafting and internal fixation. Atrophic nonunions require decortication of the nonunion site with bone grafting and internal fixation. Infected nonunions pose the greatest challenge. Acceptable approaches to infected nonunions include adequate debridement and soft-tissue coverage, in addition to bone stabilization and bone grafting.

ELECTRICAL STIMULATION AND ULTRASOUND

Electrical stimulation has been proposed as a nonoperative alternative treatment for established nonunions. Considerable laboratory and clinical evidence has been accumulated to suggest that electrical stimulation enhances fracture healing (75). Three forms of electrical stimulation have been used clinically: direct current, capacitive coupling, and inductive coupling. The direct current method requires a surgical procedure for implantation and a second surgical procedure for removal. A successful union rate of 83.7% has been reported in 178 nonunions treated with adequate duration of constant direct current. This series included a 91.5% union rate in 82 tibial nonunions treated with constant direct current (15).

A percutaneous, or seminvasive, method has been developed by Brighton et al. The cathode is inserted percutaneously directly into the nonunion site, requiring drilling across one bone cortex or fragment. Weight bearing is prohibited in the first 12 weeks of treatment (18). Complications in Brighton’s series include pin tract infection (13.8%), broken wires (13%), recurrent osteomyelitis (4.2%), cathode dislodgement (3.8%), and battery pack failure. A “corrected” union rate (excluding all patients with “suboptimal” electricity or gaps greater than half the bone diameter) of 80% was reported for tibial nonunions (14).

Inductive coupling and capacitive coupling methods can both be administered with externally applied fields. Although these methods are noninvasive, they require patient compliance. Bassett et al. reported an 87% success rate using electrical stimulation in 127 tibial nonunions (5). Brighton and Pollack reported a 77% success rate of capacitive coupling electrical stimulation in the treatment of 22 established nonunions (17).

Two double-blind series have been reported. Sharrard (119) performed a prospective double-blind trial of capacitive coupling electrical stimulation treatment of tibial delayed unions. Successful healing was achieved by twelve weeks in five of 20 patients treated with electrical stimulation compared with one of 25 patients treated with the placebo unit. Scott and King (114) performed a prospective double-blind trial of capacitive coupling electrical stimulation treatment of nonunions in long bones. Successful union was achieved in six of the ten patients treated with electrical stimulation, while none of the eleven patients treated with the placebo unit healed.

Brighton et al. (18) compared direct current, capacitive coupling, and bone graft treatment of 271 tibial nonunions in a retrospective study using logistic regression. They identified seven risk factors that adversely affect union rates: duration of nonunion, prior bone graft, prior electrical treatment, open fracture, osteomyelitis, comminuted or oblique fractures, and atrophic nonunions. In the absence of any risk factors, they reported no significant difference in the success rates of the three treatment groups. Healing rates decreased with an increasing number of risk factors. Capacitive coupling had a poorer union rate in cases of atrophic nonunions and bone graft surgery had a poorer union rate if there had been a previous unsuccessful bone graft procedure.

We consider the use of electrical stimulation in delayed unions in which patients prefer nonoperative care, when further operative intervention is contraindicated due to severe medical problems, and occasionally, as an adjunct with other forms of surgical treatment in patients with poor prognostic factors, such as smokers.

Low-intensity ultrasound has also been shown to accelerate fracture healing (32,59). The role of ultrasound in the treatment of nonunions has not been explored. This method is discussed in more detail in Chapter 26.

SOFT-TISSUE COVERAGE IN TIBIAL NONUNION

Successful management of tibial nonunions depends on viable soft-tissue coverage as well as on skeletal stability. During the past 20 years, an increased understanding of soft-tissue anatomy and physiology, as well as technical advances in tissue transfer, has improved limb salvage rates, improved function results, and
reduced the length of hospitalization for many patients. The effectiveness of aggressive debridement of necrotic tissue and attentive wound care in treating open tibial fractures was demonstrated by Dehne et al. (36) in 1961, but this treatment had the disadvantage of involving long hospital stays. In 1970, Witschi and Omer (140) reported on 84 open tibial fractures resulting from missile injuries in Vietnam. In all cases, routine wound care combined with delayed split-thickness skin grafting led to initial soft-tissue healing. Split-thickness skin grafts for more extensive deforming or avulsion injuries will not survive, however, if the recipient bed contains poorly vascularized fat or bone without peristium. Such cases often require alternative methods of coverage involving transfer of more than skin.

Ger (69) popularized and refined the techniques of muscle flap coverage, which had been previously described by other authors, for the proximal two thirds of the tibial shaft. Gastrocnemius flaps for the proximal third and soleus flaps for the middle third of the tibia have since become standard. These axially based muscle flaps provide their own vascular system and permit application of a split-thickness skin graft.

The distal third of the tibia has posed a more difficult problem, which is best approached with free-tissue transfers and the techniques of microvascular anastomoses. Weiland et al. (137) have stressed the importance of achieving a clean surgical wound before performing free-tissue transfer or any reconstructive soft-tissue procedure. Initial success rates of 76% have been reported with latissimus dorsi flaps, but further follow-up revealed recurrent sepsis in an additional 20% of cases (136). Details of these procedures and results are described in Chapter 6, Chapter 56, and Chapter 36.

Coverage of small soft-tissue defects may also be obtained by local rotational flaps. Both bipedical flaps and distally based fasciocutaneous flaps have been described to obtain coverage of the lower leg (39,43). Although these procedures avoid the complexity and morbidity of a free-flap procedure, they do not provide any additional blood supply to improve the fracture healing potential.

BONE GRAFTING

Many methods of bone grafting for tibial defects have been described. These include many forms of sliding-onlay grafts, inlay grafts, nonvascularized fibular transplants, and other techniques for creating biliobular synostosis (13,21,22,35,45,55,66,132). Cortical bone grafts have demonstrated weakness due to prolonged remodeling. They incorporate within 6 weeks of grafting, remain weak for at least 6 months, and in comparative series, have required a longer time to achieve union and have been associated with more complications than have cancellous grafts (42,63). Alternatives to cancellous bone grafting that have recently been proposed include the use of percutaneous narrow injections, human bone morphogenic protein, and synthetic bone graft substitutes (28,29,65,82). Although they are promising, these techniques are not all readily available to practicing physicians, and the precise role of each of these alternatives in a general orthopaedic practice has yet to be defined. Further details about these techniques are discussed in Chapter 6.

Cancellous bone grafting remains the single most useful form of bone graft. Anteromedial or posteromedial bone grafting is preferable for proximal nonunions (6). The posterolateral approach described by Harmon (50) is best in the distal two thirds of the tibia; it avoids the typical anteromedial open wound and places bone in the most vascular portion of the leg. In several large series, in which cancellous bone grafting was used for tibial nonunions, union rates of 87% to 100% have been reported (47,56,57,66,67,73,83,117,122). Local complications, which are uncommon, include stiffness, deformity, and loss of ankle motion. These complications have been ascribed to the initial injury but may be aggravated by further prolonged immobilization associated with bone grafting. Paresthesia in the sole of the foot and delayed vascular impairment have been reported but seem to be rare (66,67). Formation of a synostosis has been associated with, but is not clearly the cause of, ankle pain (116). Because these complications are uncommon and the union rate following posterolateral bone grafting is high, it is often used in conjunction with other procedures for angulated or infected nonunions.

Autogenous cancellous bone graft can be harvested from several locations. Some authors have advocated obtaining graft from the distal femur; however, the patient must not bear weight on the limb for 6 weeks postoperatively to protect against fatigue fractures (71). When an extensive amount of cancellous bone is required, we prefer to use the posterior pelvis because it provides the greatest quantity of graft. An acetabular reamer may be used to harvest cancellous bone graft efficiently from the posterior iliac wing, but we routinely use an osteotome and curets (110). Use of an oblique incision perpendicular to the iliac crest paralleling the fibers of the cluneal nerve has been advocated to decrease symptoms of numbness and tenderness at the donor site (22). Harvesting cancellous bone from the anterior iliac crest allows for supine positioning; however, a smaller amount of bone can be obtained. Iliac crest bone graft harvesting may result in donor site morbidity (48). Major complications have been reported to occur in 5.8% to 10% of cases, and minor complications have been reported in 10% to 39% of cases (4,4).

ANTEROMEDIAL APPROACH FOR TIBIAL BONE GRAFTING

For delayed unions or nonunions in the proximal third of the tibia, we prefer an anteromedial approach to a posterolateral approach. Owing to difficulties in management of the popliteal artery trifurcation and the vascular supply to the entire lower extremity, the former approach is safer and more easily accessible. Surgery can be performed with the patient supine, and the anterior iliac crest frequently provides enough bone graft for union to be achieved.

- The anteromedial approach provides a smaller tissue envelope for massive amounts of cancellous bone than does the posterolateral approach. The incision is frequently dictated by the injury. However, in virgin skin, make a straight vertical incision just medial to the iliac crest and straight to bone.
- Take great care in dissecting the soft tissues off the anterior tibia. The development of skin flaps will compromise soft tissue, cause skin sloughs, and may necessitate skin grafting or rotational flaps as salvage procedures.
- Once the cancellous bone has been harvested, shave the hypertrophic nonunion to recreate the normal contour of the bone, and pack the cancellous bone anteromedially and anterolaterally. Do not attempt to dissect deep into the anterior compartment along the lateral crest of the tibia; this may injure the already compromised soft tissues and vascular structures.

POSTEROMEDIAL BONE GRAFTING

A posteromedial approach is useful for nonunions in the proximal third when the anterior soft tissues are poor or a pre-existing flap makes an anterior approach problematic. In addition, there is limited space for a bone graft anteriorly; particularly if plating is necessary. Postero-medially, the approach is simple and provides exposure from the knee joint to the ankle joint. Application of a plate posteriorly works well, and soft-tissue coverage is superior to an anterior approach.

- Make a longitudinal incision along the subcutaneous posteromedial border of the tibia beginning as proximal as necessary and extending distally.
- Avoid injury to the saphenous nerve and vein. Expose the posterior tibia by subperiosteal dissection.
- Expose the tibia as far laterally as required, avoiding injury to the vessels of the trifurcation.
- Apply plate fixation or bone graft as indicated.

POSTEROLATERAL APPROACH FOR TIBIAL BONE GRAFTING

We prefer the posterolateral approach to the tibia with the patient prone. This allows a two-team approach; one surgeon can begin harvesting the bone graft from the posterior iliac crest while the other begins the approach to the tibia. This method decreases surgical operating time and provides optimal access to the posterior crest of the ilium and tibia (Fig. 31.2).

![Figure 31.2](image-url)
Depending on the level of the nonunion, make a generous skin incision from 10 cm above to 10 cm below the level of nonunion. Avoid injury to the sural nerve.

Dissect longitudinally, medial to the palpable border of the fibula, between the gastrocnemius and soleus, and flexor hallucis longus and the peroneal muscles. The fascial plane of the soleus has been entered, a fixed palpable fascia on the anteromedial border of the fibula provides a landmark for the next level of dissection. Avoid lateral stripping of the peroneal muscles from the fibula—this procedure unnecessarily compromises the regional blood supply.

Reflect the soleus and flexor hallucis longus muscles using a periosteal elevator; take care to remain on the fibula while elevating in a longitudinal direction. Once the flexor hallucis has been completely freed, pass the elevator against the fibula anterior to the posterior tibial muscle and neurovascular bundle to elevate the posterior compartment from the fibula. Be very careful at this level to avoid inadvertent entry into the posterior tibial compartment, which could injure the posterior tibial neurovascular bundle. Dissection should always begin in areas of known anatomy far away from the fracture and nonunion site.

**HINTS AND TRICKS**

- With the patient in the prone position, the interosseous membrane is deep to the fibula and runs more or less anterior to posterior (vertically). Keep this in mind because it facilitates exposure of the membrane and contiguous tibia.
- Most nonunions are fibrous; therefore, it is not necessary to take down the nonunion site.
- In difficult nonunions, strongly consider extending the fusion mass across the interosseous membrane to incorporate the fibula. The creation of a tibiofibular synostosis may ensure a stable leg even if the nonunion does not heal. The synostosis rarely compromises ankle motion.
- To avoid compartment syndrome, do not close the deep fascia.

Once the appropriate plane has been entered, carry the dissection to the nonunion site, which frequently is encased in a scar. At this point, elevate the posterior tibial compartment off the interosseous membrane with a periosteal elevator. Retract the posterior compartment, neurovascular bundle, soleus, and gastrocnemius with Bennett or Hohmann retractors.

After the nonunion has been identified, "petal" or "shingle" the shaft from 5 cm above to 5 cm below the nonunion with a sharp ½-inch osteotome. Copiously irrigate the wound, secure hemostasis, and pack the harvested cancellous bone into this compartment. After the bone graft is in place, insert a suction drain, loosely close the soleus fascia to the peroneal fascia to hold the graft in position, and close the skin in the standard fashion. Finally, apply a long-leg Robert Jones dressing, which allows easy access to the wound and drain.

Once the wound heals, most patients can be placed in a Sarmento or short-leg cast and allowed to full weight bear until union occurs. This can require up to 6 months.

**OPEN CANCELLOUS BONE GRAFTING**

Papineau (191) and Vidal et al. (131) have previously described the technique of open cancellous bone grafting for the treatment of nonunions. Cancellous bone chips are added to the wound cavity once it has been covered by granulation tissue. The cavity must be cup shaped to contain the graft. The bone graft must be kept moist as the debridement of the granulation tissue invades and vascularizes the graft. Union rates as high as 94% have been reported by Roy-Camille et al. (107), but that level of success has not been achieved by other groups treating severe tibial defects.

We do not recommend the use of this technique but prefer to use more advanced techniques with lower complication rates. Four significant drawbacks have been outlined by Edwards et al. (40). First, complete and rapid dissolution of the bone may occur if there is any focus of infection adjacent to the wound bed. Second, graft resorption or nonunion will occur if wound fixation is rigid. Third, delayed healing, which occurs especially in the posttraumatic hypovascular tissue bed and is another cause of prolonged external fixation, is common. Finally, vast ankylosis and corticalization does not occur for many months after union has been achieved. Graft fracture has been reported when an open cancellous graft is used to replace circumferential diaphyseal bone loss (53). Protected weight bearing may be necessary for as long as 2 years. Open cancellous grafting, therefore, is inferior to other available methods and should not be used for large diaphyseal defects. It may be used for circumscribed metaphyseal bone defects if more advanced techniques requiring associated soft-tissue coverage procedures can not be performed.

**BONE MORPHOGENETIC PROTEIN**

See Chapter 9 for a discussion of these promising proteins.

Numerous animal studies have shown promising results in the ability of bone morphogenetic protein (BMP) to heal critical segmental defects successfully (30,31,56,127,128,141,143,144). To date, one clinical human study of BMP has been performed on patients with tibial nonunions. BMP-7 (also known as osteogenic protein-1) in combination with purified type I collagen was compared with autogenous bone graft in the treatment of 124 established tibial nonunions in a multicenter trial. Although the radiographic appearance of union in the BMP group lagged behind the autogenous bone graft group, the ultimate clinical success rate as defined by pain-free weight bearing and lack of need for reoperation was similar in the two groups. A persistent nonunion required reoperation in 16% of the BMP group and 18% of the autogenous bone graft group (83).

**STABILIZATION**

**EXTERNAL FIXATION**

Tibial nonunions have been treated with a variety of internal and external fixation devices. External fixation is the preferred method of stabilization in cases of previous infection that might slough following surgical debridement (54). Experimentally and clinically, the single-frame anterior fixator using 4.5 mm or 5.0 mm half pins has been shown to be the best device (8,142). This form of external fixation provides free wound access, allows stabilization of bone fragments at a distance from the lesion, permits motion of adjacent joints, and encourages patient mobility. Pin tract drainage, reported to occur in 5% to 10% of all pins and responsible for removal or alteration of 1 out of 30 frames, may be minimized with compulsive local pin care (15).
Figure 31.3. A, B: The patient, a 75-year-old retired homemaker, sustained a closed tibia fracture 7 years ago. The fracture had been operated seven times previously, and the patient presented with pain and gross motion. Because of the high-risk nature of reconstruction, surgery was recommended only with the knowledge that amputation might result. Plate fixation was elected to stabilize the osteotomy to protect proximal bone for amputation if an infection occurred. C, D: On the frontal plane, a 31° valgus deformity must be corrected and the hypertrophic fibular osteotomized. The sagittal plane has a 20° apex posterior deformity, which can be corrected with a 2 cm wedge. The oblique nature of the osteotomy provides intrinsic stability to the plate fixation. The hypertrophic fibula may be used to anchor the plate screws with the severe osteopenia of the tibia. The AO/ASIF femoral distractor gives the surgeon mechanical advantage during straightening. E, F: The final result demonstrates near-anatomic alignment. The osteotomy is united, and the patient walks with a cane. To enhance stability, most screws were placed into the hypertrophic fibula, which offered better purchase than the osteoporotic tibia. Autogenous bone was harvested and packed around the osteotomy. Postoperatively, the patient was kept from weight bearing for 18 weeks and advanced as tolerated thereafter. After 1 year, she walks with a cane for support.

Figure 31.4. The angle of a single-cut corrective tibial osteotomy determines possible corrections. A pure transverse osteotomy allows only rotational correction. A long oblique osteotomy leads to primarily angular correction, with slight rotational correction. Shorter oblique osteotomies, such as the 45° osteotomy shown, allows combined rotational and angular correction. The angle of the osteotomy can be precisely determined for complex deformities.

Figure 31.5. Schematic of single-cut oblique tibial osteotomy for varus distal tibial nonunion. The deformity is entirely in the anteroposterior (AP) plane. A, B: AP and lateral views of deformity. C, D: Oblique osteotomy with an oscillating saw. E, F: Provisional single-screw fixation of osteotomy. Neutral alignment attained. G: Oscillating saw used to resect excess overlapping bone.

Preoperative Planning

Mast (79) has described three sets of drawings necessary to achieve the desired end result; and the surgical tactic.

- First, the exact nature of the deformity must be outlined with tracing paper in the frontal and sagittal planes. Only when the exact nature of the deformity is well understood in both planes can the osteotomy be planned accurately.
- Identify the central axis of the tibial shaft and angular deformity, and outline the hypertrophic callus. Closely scrutinize the status of the fibula. Superimpose the deformity drawings on the contralateral normal tibia, which serves as a template so that correct alignment can be achieved in the frontal and sagittal planes, and also allows consideration for rotational realignment.
- Second, once the deformity has been identified and both free fragments have been superimposed onto the contralateral side, plan the appropriate contour of the bone and the level of the osteotomy, and thus define the desired end result. The type of osteotomy—opening wedge, closing wedge, oblique, or a combination of these types—can be given several trial runs with tracing paper superimposed on the contralateral side.
- Consider indirect reduction methods. The femoral distractor, the articulating tensioner-compression device, and pelvic reduction forceps used in distraction mode are all helpful in obtaining length, correcting angulation, and obtaining optimal rotational alignment. If a compression plate is used, determine the size of the plate, type and direction of the screws, and the positioning of interfragmentary compression screws.

When small nonreamed locked nails are used for open fractures, delayed union and nonunion is common. Fractures that show no callus or evidence of healing by 12 weeks after fracture and nonunions are excellent indications for closed exchange nailing with a locked reamed nail. Early exchange nailing prevents breakage of the cross screws or nail, which can complicate the procedure greatly.

We recommend the following technique:

Some controversy exists concerning the role of intramedullary nailing following previous external fixation. Reamed nailing may be safely performed after short periods of external fixation before the development of pin tract colonization ( ). Deep infection rates from 19% to 66% have been reported for reamed intramedullary nailing following prior longer term external fixation ( ). The infection rate following intramedullary nailing is increased when there is a prior history of pin tract infection ( ). Because of the risk of infection, we do not recommend reamed tibial nailing following prolonged external fixation and prefer to use posterolateral bone grafting.

HINTS AND TRICKS

- Do not resect fibrous tissue in hypertrophic nonunions. Contour compression plates to fit over any callous or fibrous tissue. Stabilization of the nonunion allows calcification and conversion of the fibrous tissue into bone.
- Use interfragmentary lag screw fixation through the plate or independent of the plate whenever feasible.
- Fibrous tissue usually needs to be resected in atrophic nonunions. Re-establish the intramedullary canal by using drills or curets to debride fibrous tissue from the intramedullary canal.
- Use autogenous cancellous bone graft in atrophic nonunions
- Place the bone graft peripherally beneath healthy muscle, which will provide a good blood supply. Place no bone graft in the intramedullary canal.
- Use a sharp osteotome to “petal” or “shingle” the superficial cortex. This approach increases the surface area, elicits a “reinjury” response, and stimulates the incorporation of the bone graft.
- Third, with tracing paper or a discarded clear x-ray film, write each step of the surgical tactic and place it on the view box before the operation to assist the operating room personnel, the surgical assistant, and other surgical team members. In the preoperative plan, include special anesthesia needs, patient positioning, implants, reduction tools, dressings, and any postoperative orthopaedic appliances necessary for nursing care. Such compulsive planning allows the surgical team to be well informed and thus saves operating time and optimizes the flow of surgery.

ILIZAROV TECHNIQUE

The Ilizarov technique has been used for the treatment of angular malunions. Inconveniences associated with the need for frequent postoperative visits, as well as a relatively high rate of pin tract problems and a lower rate of major complications, has tempered enthusiasm for this technique in less complicated cases. The versatility of this method, however, may make it the salvage procedure of choice for some of the more difficult tibial malunion problems that would otherwise not be amenable to functional limb salvage. This technique may be especially useful when shortening or compromised soft tissue complicate the more readily approachable simple angular malunion. Its benefits include early weight bearing and the ability to correct contracted soft tissues gradually in addition to the bone. Preoperative planning, as described earlier, is also recommended when the Ilizarov technique is used. Further details of this technique are described in Chapter 32.

INTRAMEDULLARY NAILING

Intramedullary nailing has many applications in the treatment of the uninfected tibial nonunion. Nonreamed intramedullary nailing, as advocated by Lottes (77) for the treatment of nonunion, is a relatively simple procedure, especially if the tibia is well aligned. However, unreamed nails that are not interlocked do not provide adequate rotational control and function solely as a form of internal splint. Locked intramedullary nails have extended the indications for treatment of the initial fracture and nonunions (76).

Reamed tibial nails have a wider application than nonreamed nails, but prohibitively high infection and reinfection rates preclude their use in infected or previously infected tibial nonunions (74, 79) (Fig. 31.7). Even recent reports advocating the use of reamed intramedullary nails in the setting of previous infection document a reinfection rate of 22% to 38% although union is achieved (89, 119). In the patient with a noninfected tibial nonunion, the procedure stimulates the fracture site with the autogenous graft provided by the reamer and provides greater stabilization than does nonreamed nailing. Union rates of 95% to 100% have been reported with reamed nailing in tibial nonunions and delayed unions with no prior history of infection (12, 25, 33). Mean healing time with reamed nailing in this setting ranges from 4 to 9 months (12, 25, 33). Unlike compression plating, reamed intramedullary nailing offers the advantage of full weight bearing after treatment, in addition to allowing motion at the adjacent joints.

Figure 31.7. A to C: The patient is a young male with genu varum and a 13° proximal varus deformity of the left tibia secondary to a closed proximal tibia fracture. A vaugus-producing wedge osteotomy was performed with static locked tibial nailing and fibular osteotomy. The patient was discharged fully weight bearing. D to F: Two-year follow-up with hardware removed and the clinical result.

When using reamed tibial nails, adhere closely to the principles of management of tibial nonunions that is outlined earlier in this chapter. The tibial blood supply has usually been adequately re-established from surrounding soft tissues by the time reamed nailing for nonunion is considered. Take care to avoid stripping soft tissues, limiting surgery at the fracture site to the minimum necessary for achieving alignment. In a previously nonsurgically treated tibial nonunion, a very limited open procedure may be necessary to remove fibrous tissue and bone to align the canal. If the tibia is malaligned, a small osteotomy of the malunited fibula near the tibial fracture is frequently necessary to achieve tibial alignment. Whenever possible, perform reamed tibial nailing as a closed procedure.

Intramedullary nailing is a good option for uninfected tibial nonunions following previous unreamed nailing or a plate that has maintained canal alignment, facilitating the insertion of a reamed nail. Laboratory studies and clinical series validate this approach and show that vascularity is usually sufficiently re-established after plating to allow later intramedullary reaming (48, 69, 97). Minimize soft-tissue stripping when removing the plate. Subcutaneous plate and screw removal through multiple small incisions may be preferable to a larger incision if skin quality is poor.

When small nonreamed locked nails are used for open fractures, delayed union and nonunion is common. Fractures that show no callus or evidence of healing by 12 weeks after fracture and nonunions are excellent indications for closed exchange nailing with a locked reamed nail. Early exchange nailing prevents breakage of the cross screws or nail, which can complicate the procedure greatly.

We recommend the following technique:

- Prepare and drape the extremity in the usual fashion. Use a radiolucent operating table and a C-arm fluoroscope. A fracture table is usually not necessary.
- Remove the existing nail and cross screws or plate and screws.
- Insert a reaming guide pin.
- Ream the intramedullary to at least 2 mm larger than the nominal diameter of the canal or to a sufficient size to accommodate a nail that is 10 mm in diameter or larger, depending on the size of the patient.
- Place an AO femoral compression-distraction device with unicortical pins and compress the nonunion site.
- Perform a fibular osteotomy, if necessary (see later), to achieve compression.
- Insert the nail and lock it with two screws proximally and two screws distally.
- Perform a fibular osteotomy, if necessary (see later), to achieve compression.
- Lock the intramedullary nailing (Fig. 31.7).
- Re-establish the intramedullary canal by using drills or curets to debride fibrous tissue from the intramedullary canal.
- Place the bone graft peripherally beneath healthy muscle, which will provide a good blood supply. Place no bone graft in the intramedullary canal.
- Insert the nail and lock it with two screws proximally and two screws distally.
- Place the bone graft peripherally beneath healthy muscle, which will provide a good blood supply. Place no bone graft in the intramedullary canal.
If the canal is occluded, try to open it using "closed" technique with hand Y-handle reamers on a sharp-tipped large Kuntscher-flagged guide pin driver across the nonunion. Ream the canal proximally first to give room to work. If this procedure is unsuccessful, it may be necessary to take down the nonunion openly.

Culture the reamings and administer appropriate intravenous antibiotics until the cultures are negative.

Locate the AO femoral distractor so that it does not interfere with the crosslocking of the nail. Use it to correct angular deformities as well (Fig. 31.8 and Fig. 31.9).

**Figure 31.8.** A, B: Tibial nonunion with deformity. Intramedullary Enders nails have broken. The patient was unable to walk for more than 1 year following loss of fixation. C, D: Realignment attained with removal of small diameter nails; replacement was done with a reamed interlocked nail. Ambulation was regained within 6 weeks, and healing of the fracture was evident within 2 months. Mild valgus and recurvatum persist.

**Figure 31.9.** A common problem with broken interlocking implants associated with distal tibial delayed unions. A, B: Broken tibial nail with nonunion at the junction of the middle third and distal third of the tibia. Plate fixation had initially been used unsuccessfully to treat this fracture. The large holes in the midtibia denote the location of broken screws that had been previously removed, requiring the use of hollow-milled drills. C: Intramedullary removal of a broken nail. Removal can be achieved with commercially available instruments that are specially designed for removal of broken intramedullary nails. The fracture site is not opened. D, E: Healed fracture after intramedullary nail exchange. The long interlocking screws were inserted to facilitate retrieval in anticipation of possible screw breakage and were later removed.

**FIBULAR OSTEOTOMY**

Several authors have advocated isolated fibular osteotomy or resection for the treatment of tibial nonunions. The fibula usually heals before the tibia. With some resorption of bone at the fracture site, this process can interfere with apposition of the tibia and produce relative distraction. This is especially true with intramedullary nailing. The rationale for osteotomy is to permit the tibial fracture to compress with walking. In three series, results showed healing in 77%, with a mean time to union of 25 weeks in the first; 87% union rate, with time to union not reported in the second; and 100% union rate with a 14% refracture rate and a mean time to union of 18 weeks in the third (37,44,121). Advocates of fibular osteotomy cite the simplicity of the procedure, its isolation from a possible infected site, and its applicability in the presence of soft-tissue deficits. However, these arguments apply equally well to posterolateral bone grafting, which does not involve the additional risk of shortening and rotational deformity. Fibular osteotomy is a useful adjunct to other procedures in restoring tibial alignment, but we do not find it useful as an isolated procedure. There is no evidence that this technique used alone is effective in the treatment of infected tibial nonunions.

Our technique is as follows:

- Make a 4 to 5 cm long longitudinal incision directly over the lateral border of the fibula at the level of the tibial fracture. Avoid injury to neurovascular structures.
- Either split the peroneal muscles directly down to bone or dissect anteriorly or posteriorly in the intermuscular interval. Expose 2 to 2.5 cm of fibula by subperiosteal dissection.
- Place an anterior and posterior small sharp-tipped Hohmann retractor to protect the soft tissues.
- With an oscillating saw using a small blade, make a 45° longitudinal osteotomy. If necessary, complete the osteotomy medially with an osteotome to avoid injury to the deep soft tissues.
- Obtain hemostasis and close the wound in layers.

**HINTS AND TRICKS**

- Do not resect a section of the fibula because this procedure can lead to a symptomatic nonunion and negate the use of the fibula in future reconstructions.
- The oblique osteotomy allows shortening, and it heals rapidly.

**DYNAMIZATION OF A LOCKED NAIL**

Dynamization of a locked nail by removing the cross screws from one or both ends of the nail to permit compression of the fracture with weight bearing is a common practice, is simple, and can be performed as an outpatient procedure. Fibular osteotomy may also be necessary. Beware, however, that dynamization can also increase instability, particularly in rotation, worsening the situation. Follow these guidelines for dynamization:

- In small nonreamed nails, strongly consider exchange reamed nailing as described earlier.
- Avoid dynamization in unstable fracture patterns that will shorten excessively or become rotationally unstable. The best configuration is a short oblique fracture.
- Remove the screws from only one end of the nail farthest from the fracture.
- Permit the patient to bear weight in an appropriate orthosis.

**NONUNIONS WITH SEGMENTAL BONE DEFECTS**

Large segmental defects of the tibia are usually the result of severe open tibial fractures, the treatment of which is often associated with severe contamination, neurologic or vascular injury, and polytrauma. In the past, the treatment of choice for these injuries has frequently been amputation.

Before the popularization of Ilizarov techniques our approach to large segmental tibial defects has been initial surgical debridement, stable external fixation, and soft-tissue coverage, with late massive posterolateral cancellous bone grafting producing a tibia profibula synostosis (Fig. 31.10). Using this approach, a synostosis was created proximally and distally with internal fixation of the fibula to provide a strut for subsequent bone-grafting procedures. Achievement of a stable functional union could take up to 2 years, and multiple bone-grafting procedures were sometimes necessary. Intramedullary fixation and tibial plate fixation are associated with a higher risk of infection and, therefore, are not used in this setting. Although the length of treatment is prolonged, requiring multiple hospitalizations, massive
posterior lateral bone grafting appears to be a viable alternative in the treatment of patients with severe segmental bone loss.

Figure 31.10: A: The patient is a 26-year-old mill worker who had sustained a type III-C near-amputation of the tibia. The anterior tibial compartment and neurovascular structures were missing, leaving a major bone defect with normal plantar sensation to the foot. An amputation was advised, but the patient refused. B: The initial injury was treated with irrigation, debridement, and external fixation. After the soft tissues had been cleansed several times in the operating room, a delayed closure without major soft-tissue transfer was carried out. At 6 weeks, the patient had internal fixation of the synostosis of the tibia and fibula, and both posterior iliac crests were harvested for graft placement through a lateral skin incision. C, D: Two-year follow-up shows solid bone union and full weight bearing. The patient required a second osteosynthesis of the proximal synostosis with plate fixation and bone graft to achieve solid union. At present, he works in a steel mill, where he regularly lifts weights of 100 pounds; however, he uses a polypropylene removable orthosis to support his lack of an anterior compartment. Major bone defects can be treated with posterior lateral bone grafting as an alternative to vascularized fibular transfers or amputation.

ILIZAROV TECHNIQUE

More recently, segmental defects have been treated effectively using the Ilizarov technique of corticotomy and bone transport. The Ilizarov technique received much enthusiasm and was very popular when it was initially introduced in the United States in the early 1980s. Since then, its general use has decreased, but it remains a useful technique in specialized centers owing to its versatility. Because the Ilizarov technique is substantially different from other available techniques for treating segmental bone loss, a steep learning curve is likely to be encountered by the orthopaedist treating segmental bone loss with bone transport for the first time (29). Formal training in this technique is recommended before proceeding with any Ilizarov procedure. A relatively high rate of pin tract infections and other more significant problems are common. Good ancillary paramedical support is highly recommended. The technique is labor intensive, requiring a high level of patient compliance and frequent follow-up. Psychosocial issues and pain management often become challenging problems in the long-term care of these patients. At present, we limit the use of the Ilizarov technique to those patients for whom there are no other reasonable treatment alternatives. The Ilizarov technique for treatment of tibial nonunions and malunions is covered in greater detail in Chapter 32.

FREE MICROVASCULAR BONE TRANSFERS

Free microvascular bone transfers may be useful for osseous reconstruction following extensive resections. First reported by Taylor and associates in 1978, the technique involves the isolation and transfer of a bone segment, most commonly the contralateral fibula (3,24). The technique has the advantages of a one-stage procedure. It is relatively independent of the recipient bed and other available procedures, has a fast union rate, and has the potential for graft hypertrophy. However, the surgical procedure is long and demanding, necessitates a vascular sacrifice, may lead to graft fracture, and creates a donor bone defect that may result in instability of the contralateral foot with restricted motion of the ankle and great toe (64,90). Consider the technique for defects longer than 6 cm. There is no role for this technique in infected nonunions until the infection is completely under control, adequate soft-tissue coverage has been obtained, and drainage has been eliminated, with the patient free of all antibiotics. Hypertrophy of the fibular graft may occur with time; however, problems with fatigue fractures remain a significant complication. Further aspects of this technique are considered in Chapter 36.

CHAPTER 32

MANAGEMENT OF FRACTURES, NONUNIONS, AND MALUNIONS WITH ILIZAROV TECHNIQUES

In the second edition of this book, Operative Orthopaedics, Stuart A. Green was editor of a seven-chapter section on ring fixation and distraction techniques. To eliminate repetition and to provide a more coordinated presentation of the techniques developed by Professor G. A. Ilizarov, Dr. Green has reedited and consolidated the first five of those chapters, which now appear in this chapter as five parts. Much of the original material, both text and illustrations, has been retained, and we thank Drs. James Aronson, Dror Paley, Kevin D. Tetsworth, and J. Charles Taylor for their superb contributions to those second-edition chapters. Deborah F. Stanitski has consolidated the two second-edition chapters on pediatric applications into the new Chapter 171, located in Section IX.

A. The Biology of Distraction Osteogenesis

James Aronson

Distraction osteogenesis is a method of producing unlimited quantities of living bone directly from a special osteotomy by controlled mechanical distraction. The new bone spontaneously bridges the gap and rapidly remodels to a normal macrostructure for the local bone (1,2,3,4,5 and 6).

This method was developed and has been refined by Ilizarov in Kurgan, Siberia, since he first observed this process in one of his patients in about 1956 (3). Using ring external fixators and small-diameter (1.5–1.8 mm) wires under tension, Ilizarov has regenerated more than 18 cm of new bone from a single operative intervention, often doubling the baseline bone length (1,5,6).

These highly modular fixators can direct the new bone formation in any plane, as the distraction osteogenesis always follows the vector of applied force (13,14). Age is not a limitation so long as the patient has the potential to heal a fracture. The indications for this surgical technique are similar to those for traditional bone grafting and include limb lengthening, nonunions, pseudarthroses, and any osseous defect from trauma, tumor, or infection (12).

Distraction osteogenesis has been shown to regenerate completely vital bone, capable of bearing load, at about 1 cm of bone length per month in children, and 1 cm per 2 months in adults (10,11,18,19).

Ilizarov used the canine tibia to study distraction osteogenesis. By varying the stability of fixation, the energy of the osteotomy (i.e., the degree of vascular damage), and the rate and the rhythm of distraction, he has postulated that all four factors are critical to osteogenesis (13,14).

DEFINITIONS

Distraction osteogenesis means new bone production between vascularized bone surfaces, separated by gradual distraction. Most commonly, the bone is separated by a corticotomy and then distracted at a rate of 1 mm per day (divided into a rhythm of 0.25 mm four times per day) following a 5-day or longer latency.

Corticotomy is a low-energy osteotomy of the cortex, preserving the local blood supply to both periosteum and medullary canal.

Latency is the period of time after a corticotomy when the initial healing response bridges the cut bone surfaces, before initiating distraction.

Rate is the number of millimeters per day at which the bone surfaces are distracted apart.

Rhythm is the number of distractions per day, in equally divided increments that total the rate.

Transformation osteogenesis means the conversion of nonosseous interpositions (e.g., fibrocartilage in nonunions, synovial cavities in pseudarthroses, or muscle in delayed unions) into normal bone by combined compres and distraction forces, sometimes augmented by a nearby corticotomy.

Bone transportation means the regeneration of intercalary bone defects by combined distraction and transformation osteogenesis.

Healing index means the number of months from operation to full, unaided weight-bearing for each centimeter of new bone length.

HISTOLOGY

Histologic preparations demonstrate that the initial latency period appears to be no different from routine fracture healing, as might be expected. Fibrin-enclosed hematoma and inflammatory cell infiltration fill the gap at the corticotomy site. At the start of distraction, mesenchymal cells begin to organize a bridge of collagen and immature vascular sinusoids.

As distraction begins, the fibrovascular bridge seems to organize itself parallel to the direction of distraction. The collagen network becomes more dense and less vascular, almost resembling tendon, while the vascular channels remain at the edges closely approximated to the cut surfaces of the corticotomy segments (1,2,3,5,6 and 7).

During the first week of distraction, this central zone of relatively avascular fibrous tissue bridges the entire 6- to 7-mm gap, which is called the fibrous interzone (FIZ). Spindle-shaped cells resembling fibroblasts are loosely interspersed between collagen bundles; neither osteoid nor osteoblasts are present (Fig. 32.1). Bone mineral is distinctly absent (1,2,3,5,6 and 7).

![Figure 32.1](image)

Figure 32.1. Distraction osteogenesis, week 1. Spindle-shaped fibroblasts are interspersed among parallel bundles of collagen that bridge the two cut bone surfaces. This bridge covers the entire host bone surface (HBS), including periosteum, cortex, and cancellous bone in the medullary canal. The majority of blood vessels are located in the intramedullary region but do not cross the fibrous interzone (FIZ).

During the second week of distraction, osteoblastic cells appear in clusters adjacent to the vascular sinuses on either side of the FIZ. Collagen bundles become fused with a matrix resembling osteoid. The osteoblastic cells initially rest on the surface of these primary bone spicules and eventually become enveloped within, as the spicule is gradually enlarged by circumferential apposition of collagen and osteoid.

By the end of the second week, the osteoid begins to mineralize. These early bone spicules, called the primary mineralization front (PMF), extend from each corticotomy surface toward the central FIZ, resembling stalactites and stalagmites (5). This osteogenic process is seen uniformly covering the entire cross section of the cut bone, including periosteum, cortex, and medullary spongeosa (Fig. 32.2).
Figure 32.2. Distraction osteogenesis, week 2. As the gap widens, the local blood supply intensifies on either side of the fibrous interzone, where microcolumns of new bone are produced by clusters of osteoblasts. These new bone cones form two primary mineralization fronts (PMF) located on both sides of the fibrous interzone.

From the third week on, this process continues, with the FIZ undulating across the center at an average thickness of 6 mm. As the distraction gap increases, the bridge is formed by the elongation of the new bone spicules. The tips of the spicules have a diameter of about 7–10 microns, while their bases have diameters of up to 150 microns at the corticotomy surfaces. Each microcolumn of new bone is surrounded by large, thin-walled sinusoids; this zone is called microcolumn formation (MCF) (Fig. 32.3) (17).

Figure 32.3. Distraction osteogenesis, week 3. As distraction continues, length is gained by increasing the length of individual bone columns in the zones of microcolumn formation (MCF). The central fibrous interzone remains relatively avascular, while the large vascular sinuses continue to supply the areas of new bone formation at the primary mineralization fronts.

At the conclusion of distraction, the FIZ ossifies, creating one zone of MCF and completely bridging the gap (Fig. 32.4). During this 6-week consolidation period, the dogs studied by Ilizarov usually resumed weight bearing (1, 2 and 3, 6, 7).

Figure 32.4. Postdistraction consolidation. The microcolumns of bone and vascular sinuses bridge the fibrous interzone, leaving a uniform cross-sectional bridge of living bone tissue.

During the 6 weeks after frame removal, the osteogenic area remodels into cortex and medullary canal (Fig. 32.5). The bony columns take on the staining characteristics of mature lamellar bone, with cement lines and smaller osteocytes resting in lacunae. The fibrovascular tissue that filled the spaces around bone columns is replaced by normal-appearing marrow elements (1, 2 and 3, 6, 7).

Figure 32.5. The microcolumns of bone are easily remodeled into the cortex and medullary canal. Neovascularity has receded and bone-marrow elements fill the intramedullary spaces.

PHYSIOLOGY

Probably the most important physiologic factors in successful distraction osteogenesis are the regional and local blood supply (17). Each column of new bone is completely surrounded by large vascular sinusoids. The clusters of osteoblasts that appear at the tip of each column are in close proximity to these sinusoids. India ink injection studies with Spalteholz clearing technique demonstrate that these vessels parallel the bone columns and the distraction force; however, very few vessels actually cross the FIZ, which remains relatively avascular (1, 4).

Technetium scintigraphy of the osteogenic area shows an intensely hot region with a central cool area corresponding to the FIZ. The orderly zones of bone formation
PATHOPHYSIOLOGY

Certain conditions that reliably lead to poor osteogenesis are excessive rate, sporadic rhythm, initial diastasis, frame or bone-fixator instability, inadequate consolidation period, poor regional or local blood supply, and a traumatic corticotomy. It is easy to postulate that an initial diastasis would inhibit the formation of a primary fibrovascular bridge. Instability results in macromotion, especially shear forces that can disrupt the delicate bone and vascular channels. The importance of rate and rhythm may well involve the biosynthetic pathways on the cellular level by rate-limiting steps such as protein synthesis and mitosis. Peripheral vascular disease may limit regional vascularity, and a traumatic corticotomy can severely disturb the local blood flow.

NONINVASIVE MONITORING

During the process of distraction osteogenesis, it is helpful to assess the progress of bone formation. Early on, the surgeon can adjust the latency to enhance osteogenic potential. During distraction, rate or rhythm adjustments may be necessary to optimize osteogenesis. During consolidation, it is important to know when the osteogenic area is strong enough to remove the fixator.

At the time of the corticotomy, assess the corticotomy for completeness by intraoperative fluoroscopy, distracting no more than 2 mm, angulating no more than 10° to 15°, and rotating no more than 20° to 30°. Often, the far cortex is incompletely fractured or cut through, allowing some diastasis, but multidirectional angulation will be blocked and rotation will be eccentric. The corticotomy must be complete to allow uniform distraction. The corticotomy should be well reduced radiographically as the frame is fully assembled, to decrease local hemorrhage and to ensure that the osteogenic bridge is not compromised (Fig. 32.6). Either excess bleeding (local arterial injury) or lack of bleeding (systemic disease or local vascular insufficiency) at the time of corticotomy may indicate a local vascular deficiency. In these cases, the latency can be extended by up to 14 days; premature consolidation may occur as early as 14 days in the metaphyseal region and as early as 21 days in the diaphyseal region.

Figure 32.6. Low-energy corticotomy technique in the adult canine tibia. Subperiosteal placement of a narrow osteotome allows the cortex to be cracked on two sides while the periosteal tube and spongiosa are preserved. With a torquing maneuver, the third and final side can be separated. A temporary diastasis of 2 mm is acceptable to ensure complete separation of the cortices. The cortical surfaces should be reopposed with the external fixator and the periosteal tube closed.

Figure 32.7. A: After 7 days of distraction, the lateral view of a corticotomy shows an empty distraction gap. B: One week later. After 14 mm of distraction, the gap is filled by radiodense new bone extending from each surface toward the center (Fig. 32.7). Perform orthogonal views parallel to adjacent fixator rings and between connecting rods at each visit for comparison.

As distraction proceeds, the central FIZ remains an undulating radiolucent zone 4–8 mm wide, while more and more new bone is added from each end. The new bone should span the entire cross-sectional area of the host bone surfaces on both orthogonal views. If the new bone appears to be bulging and the FIZ is narrowing, then accelerate the distraction rate (14). If the new bone forms an hourglass appearance and the FIZ is widening, decelerate the distraction rate (9). The absence of new radiodensity by the third week of distraction may be cause for concern (2,3,8). Ultrasound can be used to diagnose cyst formation in the gap, which may require bone grafting. Ischemic fibrous tissue in the gap is an alternative explanation to delayed mineralization on the radiograph, and this may respond to slowing the distraction rate.

During consolidation, obtain plain radiography on a monthly basis until the osteogenic area has cortex and medullary canal on orthogonal views. Despite the appearance of these radiographic findings, the overall bone density may be severely reduced. Any area within the distraction gap that is less than 60% of the density of the normal side is at increased risk to buckle under normal loads.

ACKNOWLEDGMENT

I gratefully acknowledge the help of Charles Stewart, an expert bone histologist, who has persevered with enthusiasm for many exciting years of discovery.

B. Deformity Correction by the Ilizarov Technique

Dror Paley and Kevin D. Tetsworth

DEFINITION OF DEFORMITY

A limb deformity is a deviation from normal anatomy. The deformity may include abnormalities of length, rotation, translation, or angulation (Table 32.1). Several other components of limb deformity should also be considered in individual cases: deficiency, malformation, contour, circumference, and proportion.

Table 32.1. Limb Deformity Parameters

To define a deformity, we need a concept of normal anatomy for comparison. In the lower limb, this usually is evaluated from long anteroposterior (AP) and lateral (LAT) radiographs taken in the standing position. The two considerations in evaluating the frontal plane mechanical axis of the lower extremity are joint alignment and joint orientation. The normal alignment of the hip, knee, and ankle joint centers is colinear. Frontal plane deformities lead to a mechanical axis deviation, which primarily affects the knee but also affects the subtalar, ankle, and hip joints. Normally, the line of weight-bearing force from the ankle to the hip joint passes through the medial tibial spine in the center of the knee. In mechanical axis deviation, it passes medial or lateral to the center of the knee.

The second consideration is the orientation of each joint to the mechanical axis line. Each joint has a normal anatomic inclination to both the mechanical axis and the anatomic axis of the limb segment (Fig. 32.8). In the tibia, the mechanical and anatomic axes are the same, but in the femur they are different. The mechanical axis of the femur is defined as the line from the center of the hip to the center of the knee. This usually subtends a 6° angle to the anatomic axis of the femur, which runs from the piriiform fossa to the center of the knee joint. The knee joint line has been measured to be about 3° off the perpendicular, so that the distal femur is in slight valgus and the tibial diaphysis in slight varus.

Figure 32.8. The normal mechanical axis and joint orientation of the hip, knee, and ankle. The two components of the frontal plane mechanical axis are collinearity of the hip, knee, and ankle axis; and joint orientation of the hip, knee, and ankle relative to the mechanical axis in the angles shown.

The hip joint does not have as clear a reference line on the femoral side as do the other two joints. The orientation of the hip on the AP view can be characterized by the neck-shaft angle or by the line from the tip of the greater trochanter to the center of the femoral head. The radiographic projection of the neck-shaft angle, which defines the relationship of the femoral head to the anatomic axis, varies with hip rotation. The normal neck-shaft angle range is 125° to 131°. The diameter of the femoral head is about equal to the distance from the center of the femoral head to the tip of the trochanter. This defines the length of the neck of the femur. A line from the tip of the trochanter to the center of the femoral head defines the joint orientation of the hip. Its relationship to the mechanical axis does not change much with

---

rotation. This relationship is 90° ± 3° (3).

These reference lines and angles are useful in preoperative planning and in determining the deformity of each bone segment. Population norms for these lines have been measured (3). However, if the patient has a normal side that falls within the normal standard deviation, then use the specific angles from that side.

The other component of lower limb alignment is the orientation of the calcaneus to the tibia. The central axis of the body of the calcaneus is normally parallel with that of the tibia in the frontal plane. Due to the sustentaculum, the mid-body axis of the calcaneus is laterally translated relative to the mid-tibial axis (Fig. 32.9) (29).

**Figure 32.9.** Weight-bearing axis at the ankle and subtalar joints. (A) Normally, the central axis of the calcaneus is parallel and laterally displaced to that of the tibia. (B) When there is varus or valgus deformity in the ankle or subtalar joint, the heel will be inclined into varus or valgus, relative to the tibia. The amount of the deformity can be measured directly.

The acetabular alignment on the AP radiograph is defined by the sourcil, which is normally horizontal to the ground with a level pelvis (2). The center-edge (CE) angle defines the depth of the acetabulum. The normal CE angle is 20° to 30° (20). Higher values occur in protrusio acetabulum, while lesser angles are a feature of a dysplastic acetabulum. The pelvis is normally perpendicular to the spine in bipedal, equal leg-length stance. The weight-bearing axis through the pelvis to the hip joint is oriented 16° to the vertical (21).

The femoral head is oriented in 5° to 20° of anteversion from the posterior condylar axis (20). The proximal tibial articular surface has 8° to 12° of posterior tilt, while the distal tibial articular surface has 5° of anterior tilt relative to the mid-lateral axis (Fig. 32.10) (13).

**Figure 32.10.** The normal alignment and joint orientation on the long LAT view is marked. The mechanical axis line normally runs anterior to the midpoint of the femoral and tibial condyles. The inclination of the femoral neck varies between 5° and 15° of anteversion. The inclination of the proximal tibia varies between 8° and 12° of posterior tilt. The inclination of the distal tibia is approximately 5° of anterior tilt.

**EVALUATION OF LOWER LIMB DEFORMITIES**

The radiographic evaluation should parallel and complement the findings of the clinical examination (Table 32.2). Include the hip, knee, and ankle on the same radiographic view, with the patella pointing forward. A 3-ft radiograph is long enough for patients under 5’5” tall; for those over this height, a 51-in. x-ray cassette is needed to see the alignment of all three joints on one film (Fig. 32.11).

**Table 32.2. Clinical Evaluation Algorithms for Lower Limb Deformity**

**Figure 32.11.** A 51-in cassette is used to assess most adults. This provides a radiograph extending from the ground to the top of the pelvis. Notice that the patella should be centered over the middle of the femur to ensure proper alignment (left knee). If the patella points inward or outward (right knee), the alignment measurements will be misleading.
Evaluation of axial alignment may also involve radiographic assessment of fixed pelvic obliquity and scoliosis. This is best done by using blocks to equalize limb length and taking an erect AP x-ray of the pelvis and spine. Hip abduction and adduction radiographs may be necessary to rule out fixed pelvic obliquity on the basis of hip pathology and limitation of motion. Knee flexion deformity alters the alignment and length measured radiographically. Assess axial foot malalignment using a long axial radiograph that superimposes the axial view of the os calcis on the tibia. This can be useful to quantify the malalignment accurately (Fig. 32.9) (29).

Lateral alignment of the lower limb is less critical than frontal plane alignment, since it is in the plane of motion of all three joints. Obtain a long LAT radiograph of the femur and tibia in full knee extension centered over the knee (Fig. 32.10). Normally, the anterior surface of the distal femur is colinear with the anterior crest of the tibia in full extension. Similarly, a line drawn from the center of the hip to the center of the ankle will pass anterior to the midpoint of the knee on the LAT view. If lengthening is considered, the LAT view of the knee in full extension is important for evaluating knee subluxation, and for comparison in case of future knee subluxation. The midpoint of the femoral condyles on the LAT view is normally colinear with the midpoint of the tibial condyles in full extension (Fig. 32.12A). Any break in this line in full extension represents a subluxation (Fig. 32.12B) (24). If the knee subluxes or dislocates in extension, it is important to obtain a lateral radiograph in the degree of flexion where the knee reduces (Fig. 32.13).

Figure 32.12. When there is subluxation of the knee, the radiographic changes may be subtle. Subluxation of the knee can be defined on the LAT radiograph as a step in the midpoint of the femoral and tibial condyles. Normally, these two points are opposite each other (A). When there is a subluxation of the knee, the midpoint of the tibia will displace anteriorly or posteriorly away from the midpoint of the femur with the knee in extension (B).

Figure 32.13. A: The knee is dislocated in full extension. B: In 30° of flexion, the knee reduces.

The cross-table lateral of the hip is preferable to the frog-leg view in adults. Anteversion of the neck can be evaluated, as can head and neck deformities. LAT views of the ankle may be necessary in both flexion and extension to evaluate limitation of motion and its etiology (bone or soft tissue).

Torsional deformities can be quantified using some special radiographic views or computed tomography (CT) scanning (14,21). Clinical examination is still the best method to evaluate and quantify torsional deformity (Fig. 32.14) (10,21). Three-dimensional reconstruction CT scans are useful for the assessment of intraarticular deformities, especially those associated with joint deficiencies. Three-dimensional CT scans may one day be useful for planning deformity corrections.

Figure 32.14. A: Hip rotation is most accurately measured in the prone position. When the tibia is normal, the zero position is with the leg vertical. Notice that the patella points toward the examining table and the femoral condyles are horizontal. Rotation in one direction is internal; in the other direction it is external. The number of degrees is measured from the zero position. B: In the second series of diagrams, the same examination is performed for a 30° valgus deformity of the tibia. If the range of motion of the femur is judged from the tibial shaft, an incorrect assessment of 15° internal rotation (part 4) to 75° external rotation (part 1) will be made. The zero point should be selected with the patella pointing down and the femoral condyles level (part 2). The correct range of femoral rotation (45° internal to 45° external) may then be determined.

Stress x-rays, arthrographic studies, and magnetic resonance imaging (MRI) may be useful to visualize the contour of the joint surface and assess joint laxity, contracture, and luxation.

It is also important to evaluate lateral and medial laxity of the knee joint (Fig. 32.15). The joint lines of the distal femur and proximal tibia will be at an angle to each other on a standing radiograph; stress views will reveal the full extent of the laxity. If this is not corrected together with the deformity, then abnormal loading of the plateaus will continue despite limb realignment.
Figure 32.15. A: The lateral collateral ligament is lax (left). On single-leg stance during gait, the adductor moment arm leads to a varus deformity through the knee joint. The lateral joint line opens to the point that the lateral collateral ligament becomes tight (center). With descent of the fibular head, the lateral collateral ligament can be tightened to correct the articular varus deformity (right). B: The medial collateral ligament is lax (left). Associated with a valgus deformity, the tibia subluxes laterally (middle). The medial collateral ligament can be tensioned by distraction of an osteotomy located proximal to its insertion (right). The distal end of the osteotomy runs distal to the tibial tubercle to avoid pulling the patellar tendon down.

INDICATIONS FOR CORRECTION OF LOWER LIMB DEFORMITIES

Deformities of the lower limb may be symptomatic or asymptomatic. Deformity symptoms include pain and inflammation around joints, apparent or real joint restriction of motion, and gait dysfunction or alteration. Patients also present with aesthetic and psychosocial complaints regarding limb deformities.

In general, the goals in correcting a deformity are to relieve symptoms if present and to protect adjacent joints from development of osteoarthritis secondary to the deformity. Without good data about the natural history of asymptomatic deformities and their contribution to later joint degeneration, it is difficult to specify exact indications for their surgical treatment (6,9,11,16,18,21,26,30,31 and 32). Isolated rotational deformities should not be treated unless symptomatic. They should be corrected as part of a comprehensive approach to the treatment of lower limb alignment.

The following deformities should be considered for treatment, even in asymptomatic patients: distal femoral mechanical valgus greater than 5°, proximal tibial mechanical varus greater than 5°, and mechanical axis deviation greater than 15 mm. Other asymptomatic deformities should be considered for correction prophylactically if radiographic evidence of degenerative joint disease is seen or if only clinical signs are detected (e.g., a positive Trendelenburg sign in a dysplastic hip, lateral thrust in a varus knee). Other deformities that should be considered for treatment include procurvatum deformity of the distal tibia greater than 15°, recurvatum deformity of the distal tibia greater than 10°, and varus or valgus deformity of the distal tibia greater than 10° when subtalar joint motion is restricted. Although these guidelines for deformity correction are based on the available literature, each patient must be evaluated individually.

It is important to identify and treat the correct deformity and not create a deformity in an effort to treat one. The best example is distal femoral valgus. Recommended treatment for genu valgum has included distal femoral osteotomy or proximal tibial osteotomy (Fig. 32.16) (7,9,28). An isolated deformity in the femur should never be treated by a corrective osteotomy of a normal tibia. This will lead to persistent joint inclination and eventual subluxation. Cooke et al. demonstrated that for combined distal femoral and proximal tibial deformities, the best operation is a corrective osteotomy at both levels (4,5). The first step in deformity correction, therefore, is to assess the deformity by accurately defining and describing it (Table 32.1, Table 32.2); then preoperative planning begins.

Figure 32.16. A high tibial osteotomy was performed to correct a valgus deformity of the distal femur. In addition to the sloped joint orientation that was present preoperatively, the patient is now developing collapse into varus and lateral subluxation. This illustrates why a normal tibia should not be osteotomized to correct for a deformity in the distal femur.

PREOPERATIVE PLANNING

The apical level of diaphyseal deformities is obvious, while the apices of metaphyseal and especially of juxtaarticular deformities are subtle or less clear. The first step is to determine the level of the apex of the angular deformity. With diaphyseal deformities, draw a line down the concave or convex cortex proximal and distal to the apex. The intersection of these two cortical lines is the true apex of deformity. For juxtaarticular and metaphyseal deformities, a more complex system is necessary to determine accurately the level of the deformity’s apex.

We have developed a malalignment test for frontal plane mechanical axis deviation (Fig. 32.17). Required materials are a standing radiograph with the patella pointing forward, knee in extension, from hips to ankles, of both lower limbs, and a pencil, a long straight edge, and a goniometer or protractor.

Figure 32.17. The malalignment test. This test determines the origin of frontal plane malalignment. Step 0: Draw HA, the mechanical axis line of the lower limb, from the center of the femoral head to the center of the ankle plafond. If this line passes medial to the medial tibial spine, there is medial mechanical axis deviation (MAD). If it passes lateral to the center of the knee, there is lateral MAD. Step 1: Draw HK, the mechanical axis of the femur, from the center of the femoral head to the center of the knee. Draw FC, the femoral condyle line. Measure the lateral angle HKF. This should be 87° ± 2°. Outside these limits, the femur is contributing to the MAD. Step 2: Draw KA, the tibial mechanical axis line, from the center of the knee to the center of the ankle. Draw the tibial plateau line TP. Measure the medial angle AKP. This should be 87° ± 2°. Outside these limits, the tibia is contributing to the MAD. Step 3: Compare the orientation of FC to TP. These should be parallel to each other. If they diverge more than 1° to 2°, there is joint laxity contributing to MAD. A: Femoral malalignment. B: Tibial malalignment. C: Joint laxity malalignment.
If a mechanical axis deviation is detected in step 0 (referring to Fig. 32.17), then steps 1 to 3 will indicate whether the deviation is in the femur or the tibia. If lines FC and TP are not parallel, then there is an intraarticular component to the mechanical axis deviation.

**PLANNING THE LEVEL OF OSTEOTOMY AND HINGE PLACEMENT**

The optimal level for an osteotomy is usually at the apex of an angular deformity. The choice of level is influenced by the proximity to the adjacent joint, the type of fixation, skin coverage, bone quality, and, in children, the physis. A deformity apex within the bone's metaphysis or diaphysis is suitable for osteotomy and fixation. A juxtaarticular deformity apex presents difficulties with both the osteotomy and fixation. In children, correcting a juxtaarticular deformity would cause a transphysial separation, whereas in adults such a correction would necessitate a periarticular or intraarticular osteotomy. Therefore, the practical level for osteotomy is usually within the metaphysis in these deformities. For this reason, the metaphyseal and diaphyseal deformities will be grouped together under the name metadiaphyseal; the juxtaarticular type of deformity will be considered separately.

After identifying the deformed and normal bone(s) using the malalignment test, ascertain the apex of deformity. The osteotomy level can then be determined, taking into consideration the limitations imposed by the joint and physis and by the fixation method. Preoperative determination of tibial deformity with a normal femur is shown in Figs. 32.18 and 32.19.

**Step 0:**

Draw the mechanical axis line from the center of the femoral head to the center of the ankle. The malalignment test was performed to confirm that the orientation of the distal femur is normal. Step 1: Since the femur is normal, draw the line from the center of the hip through the center of the knee and extend it distally. This is the mechanical axis of the proximal femur. Step 2A: Draw a line from the center of the hip to the center of the knee, demonstrating a 45° angulation of the bone ends. Step 2B: Draw the mechanical axis line of the femur and extend it distally. This is the mechanical axis of the proximal tibia.

**Step 1:**

The deformity correction is performed on paper at the level of the apex of the deformity for a total of 26°. This realigns and overlaps the mechanical axis lines to reestablish the colinearity of the hip-knee-ankle axis. Step 3A: After opening wedge correction. This osteotomy also realigns the diaphyseal line of the convex cortex so that it is colinear. B: Tibial frame applied to correct deformity illustrated in A.

**Step 2:**

Draw the line from the center of the plafond extending proximally in line with the anatomic axis of the tibia. This is the mechanical axis of the proximal tibia.

**Step 3A:**

The deformity may be corrected by a 37° opening wedge through the growth plate, thus realigning the mechanical axis and reestablishing normal joint orientation. Step 3B: Correction of the deformity at the level of the tibial metaphysis requires a 50° correction to realign the mechanical axis. This creates a malalignment of the knee and ankle. Notice that the mechanical axis now subtends a 50° orientation to the ankle joint instead of the normal 90°. Step 3C: If only 37° of deformity is corrected, then there is persistent varus mechanical axis deviation. The knee and ankle are oriented correctly to each other, but the mechanical axis is deviated due to a persistent translational deformity (T). Step 3D: To realign the mechanical axis at the level of the metaphysis, which is distal to the apex of the deformity, the correction should include both 37° of angular correction and lateral translation in the amount of T. The magnitude of T increases as the level of the osteotomy moves farther away from the apex of the deformity. B: If the hinge is placed at the level of the osteotomy, overcorrection is required to eliminate mechanical axis deviation. Note that the rings are not parallel at the end of correction because of overcorrection. C: The apparatus is preconstructed with the hinge at the level of the center of rotation of angulation. This leads to angulation and translation. The rings are parallel at the end of correction.

Preoperative planning for a deformity of the femur with a normal tibia is shown in Figs. 32.20, 32.21, 32.22, and 32.23. When the apex of the deformity is metadiaphyseal, do the osteotomy at the level of the apex, and place the hinge at the level of the apex. The correction anulates the bone ends. When the apex of the deformity is juxtaarticular, perform the osteotomy in the metaphysis at a level different from that of the apex, and place the hinge at the level of the apex. The correction causes translation and angulation of the bone ends.
mechanical axis line at the apex of the deformity, demonstrating a 15° angular deformation. Step 3a: Correct the angular deformity through an osteotomy at the level of the apex of the deformity. The angular correction required to realign the mechanical axis is 15°. B: Apparatus before and after open-wedge correction with hinge at osteotomy level.

Figure 32.21. A: Juxtaarticular femoral deformity with a normal tibia. Step 0: Draw the mechanical axis line from the center of the hip to the center of the ankle. This line passes lateral to the center of the knee, indicating a valgus mechanical axis deviation. The malalignment test confirms that the tibial alignment is normal. Step 1: Draw the mechanical axis line from the center of the ankle through the center of the knee and extend it proximally. This is the mechanical axis of the distal femur. Step 2a: Draw the mechanical axis line of the femur on the opposite normal side. Draw the anatomic axis line of the normal side down the midshaft of the proximal femur. Measure the angle between the mechanical and anatomic axes (7° in illustration). Draw the anatomic axis of the proximal femur on the deformed side. Draw a line from the center of the hip parallel to the anatomic axis. Step 2b: Draw a line from the center of the hip extending distally at 7° to the last line. This is the mechanical axis of the proximal femur. This line intersects the distal mechanical axis line at the knee joint, indicating a juxta-articular deformity measuring 11°. Step 3a: Since it is not possible to do an osteotomy so distal, the osteotomy is performed at the level of the distal metaphysis. Correction of the mechanical axis alignment by a pure angular correction at this level requires 14°, since the osteotomy is not at the level of the apex of the deformity. As in the tibial example, this produces a slight malorientation of the hip to knee joint lines. Step 3b: The correction of only 11° results in persistent valgus mechanical axis deviation. The deformity that remains is purely a translational one of amount 7. Step 3c: The most accurate correction through a metaphyseal osteotomy is to combine 11° of angulation with lateral translation of amount 7. T increases as the distance of the osteotomy to the true apex of the deformity increases. B: Apparatus with hinge at juxtaarticular center of rotation. Angulation and translation correction occur since the hinge is at a different level from the osteotomy.

Figure 32.22. Anatomic axis method of preoperative planning for femur. Step 0: There is a mechanical axis deviation (MAD) caused by a femoral deformity. Since there is a cup arthroplasty, the center of the femoral head, which is essential for mechanical axis planning, cannot be used. Therefore, anatomic planning is used. Step 1: Draw the anatomic axis line on the normal side down the midfemur and measure the lateral angle it subtends to the knee (83°). Step 2: Draw an 83° line from the center of the knee on the deformed side. This is the anatomic axis of the distal femur. Step 3: Draw the anatomic axis line of the proximal femur on the deformed side (midline proximal femur shaft). The intersection point of the two anatomic axis lines is the center of rotation of the angulation.

Figure 32.23. Combined femoral and tibial deformities in the absence of a normal opposite side. Step 0: Draw the mechanical axis line from the center of the hip to the center of the ankle. This line passes medial to the center of the knee, indicating a varus malalignment. Step 0. The malalignment test demonstrates a deformity in both tibia and femur. Step 1: Draw a line 87° to the knee orientation line. Extend this line both proximally and distally. Step 2: Draw a line perpendicular to the ankle plafond (or distal tibial shaft) and extend this line proximally. Step 3: Correct the tibial deformity at the level of the apex of the deformity, realigning the tibial mechanical axis and reorienting the ankle and knee. Extend the normalized tibial mechanical axis proximally. Step 4: Draw the mechanical axis of the proximal femur. If there is a normal opposite femur to compare, use the angle measured from the opposite side. If there is not a normal angle, use 90°. The intersection point indicates the apex of the deformity. Step 5: The osteotomy can be performed at the level of the intersection of the axes (a) or at a lower level (b). Step 5A: Draw the osteotomy at the level of the apex of the deformity, realigning the femoral mechanical axis with that of the tibia. Since this deformity is a bowing of the femur and not truly a uniaxial angular deformity, the correction produces a sharp angulation in the cortex of the femur which may be associated with a cosmetic deformity. Step 5B: The osteotomy may be performed at a lower level combined with translation, to minimize the angulation in the shaft of the femur. This produces a better aesthetic appearance. The center of rotation of the second osteotomy (b) is still at level a.

OTHER FACTORS IN DETERMINING THE LEVEL OF THE OSTEOTOMY

Several other factors must be considered in determining the level of the osteotomy. The apex may not always be the optimal level or even a possible place to perform the osteotomy for several reasons. In developmental and congenital deformities, the deformity is often at the level of the growth plate or joint and, therefore, is inaccessible for fixation or osteotomy. Angular corrections performed as opening or closing wedges not at the level of the apex of the deformity create secondary translational deformities (Fig. 32.24). To avoid this, the bone ends must be translated either acutely or by using a translation hinge. The translation needed can be minimized by performing the osteotomy as close as technically feasible to the true apex of the deformity. An alternative technique uses a hinge at the level of the osteotomy, correcting angulation first, followed by translation by modifying the frame.
Angular malunions of the tibia lead to varying degrees of mechanical axis deviation, depending on the degree of angulation, the level of the malunion, and the magnitude and direction of any associated translational deformity. These three varus malunions differ only in the magnitude and direction of the translational component of the malunion. The center malunion has pure angulation without translation of the bone ends. The malunion on the left has the same degree of angulation combined with translation toward the convexity of the deformity. The malunion on the right has the same degree of angulation combined with translation toward the concavity of the deformity. Notice the amount of mechanical axis deviation (MAD) in all three examples. The MAD is decreased when the translation is toward the convexity and increased when it is toward the concavity. The former is called compensatory translation, whereas the latter is called aggravating translation. Notice the point of intersection of the mechanical axis lines of the proximal and distal tibia. When there is no translation, the intersection is at the level of the malunion. When there is aggravating translation, the intersection point is proximal to the malunion. When there is compensatory translation, the intersection point is distal to the malunion. The intersection point is considered to be the true apex of the angulation-translational deformity, while the malunion is considered to be the apparent apex.

In the femur, the opposite relationship exists (Fig. 32.26). By performing the osteotomy at the level of the true apex—the intersection point of the mechanical axis—the limb will realign both angulation and translation through a single hinge (Fig. 32.27). A translating hinge apex offers the added advantage of allowing an osteotomy through healthy bone rather than through a sclerotic, avascular, previously open, or infected region at the deformity’s apex.

Figure 32.24. Secondary translational deformities. A: The so-called golf club deformity of the distal femur is a result of repeated closing wedge varus osteotomies in the supracondylar metaphyseal region of the femur for the treatment of a juxtaarticular deformity of the distal femur. This produces a progressive medial translational deformity with each successive osteotomy. B: Medial translational deformities of the tibia are the result of repeated valgus osteotomies at the metaphyseal diaphyseal junction for the treatment of these juxtaarticular deformities of the tibia. In the right tibia, overcorrection was carried out to realign the mechanical axis similar to that described in Fig. 32.19, step 3B. On the left, the ankle and knee joints were reoriented but the mechanical axis was not fully corrected, leading to a persistent varus from the translational component of the deformity. C: A varus deformity of the distal tibia due to a malunion was treated by a supramalleolar osteotomy to realign the ankle to the knee joint. This correction ignores the mechanical axis deviation created by the malunion. It demonstrates again that angular correction not at the level of the apex of an angular deformity leads to a translational deformity.

Other situations in which the osteotomy is contraindicated at the apex include the presence of soft-tissue coverage problems or avascular, sclerotic, or previously infected bone (suboptimal for osteotomy). A translational correction of the osteotomy at a level above or below the apex is required.

If lengthening is a major consideration, the optimal level is in the proximal or distal metaphysis. It may be preferable to perform a metaphyseal-level corticotomy followed by a translational correction to realign the mechanical axis for both angulation and translation, or to perform two osteotomies, one for lengthening and one for deformity correction.

Malunions often present with combinations of angular and translational deformities. The translational component may either compensate or aggravate the mechanical axis deviation produced by the angular deformity. In the tibia, if translation is in the direction opposite the angular deformity, then the translation will produce a compensatory effect on the mechanical axis deviation. While this translation may not completely realign the mechanical axis, it will reduce the amount of deviation (Fig. 32.25). On the other hand, if the translation is in the same direction as the angular deformity, the mechanical axis deviation will be aggravated. The apex of the deformity in these cases is not at the malunited level of the two bone segments. Because of the translation, the true apex of the deformity will be either proximal or distal, depending on whether the translation is aggravating or compensatory. In the tibia, compensatory deformities will have an apex distal to the level of the malunion, but aggravating translational angulation deformities will have a true apex proximal to the level of the malunion.

In the femur, the opposite relationship exists (Fig. 32.26). By performing the osteotomy at the level of the true apex—the intersection point of the mechanical axis—the limb will realign both angulation and translation through a single hinge (Fig. 32.27). A translating hinge apex offers the added advantage of allowing an osteotomy through healthy bone rather than through a sclerotic, avascular, previously open, or infected region at the deformity’s apex.

Figure 32.25. Angular malunions of the tibia lead to varying degrees of mechanical axis deviation, depending on the degree of angulation, the level of the malunion, and the magnitude and direction of any associated translational deformity. These three varus malunions differ only in the magnitude and direction of the translational component of the malunion. The center malunion has pure angulation without translation of the bone ends. The malunion on the left has the same degree of angulation combined with translation toward the convexity of the deformity. The malunion on the right has the same degree of angulation combined with translation toward the concavity of the deformity. Notice the amount of mechanical axis deviation (MAD) in all three examples. The MAD is decreased when the translation is toward the convexity and increased when it is toward the concavity. The former is called compensatory translation, whereas the latter is called aggravating translation. Notice the point of intersection of the mechanical axis lines of the proximal and distal tibia. When there is no translation, the intersection is at the level of the malunion. When there is aggravating translation, the intersection point is proximal to the malunion. The intersection point is considered to be the true apex of the angulation-translational deformity, while the malunion is considered to be the apparent apex.

Figure 32.26. Varus malunions of the femur are illustrated with and without aggravating or compensatory translation. Notice that in the femur, translation toward the convexity is aggravating, whereas translation toward the concavity is compensatory. The reason for this is that by convention we refer to translation as the distal fragment being translated relative to the proximal. If we think of the proximal fragment of the femur as the one that is translating, then the rules are similar to that described in the tibia (Fig. 32.25). Notice that the translational deformity shifts the true apex of the deformity either proximal or distal to the apparent apex at the level of the malunion.
Most diaphyseal deformities can be corrected by an osteotomy at the level of the true apex. An osteotomy at the true apex corrects both angulation and translation of the malalignment simultaneously, but it does not correct any contour deformity created by the translated bone ends (Fig. 32.28). If the contour deformity is significant, then the osteotomy should be done at the level of the malunion. Translation and angulation must be corrected separately.

Determining the True Plane of the Deformity

Orthopaedic surgeons often describe angular deformities as varus, valgus, procurvatum, and recurvatum of the distal segment relative to the proximal segment. The terms varus and valgus describe angular deformities in the frontal plane; procurvatum and recurvatum describe angular deformities in the sagittal plane. Using this convention, a deformity with varus and recurvatum is described as a biplanar deformity. Careful analysis of most biplanar deformities reveals that they have but a single apex; moreover, the deformity lies in an oblique plane, somewhere between the frontal and sagittal planes (Fig. 32.29). We perceive the deformity as biplanar because the standard radiographic views are obtained in the anatomic reference planes, which may be different from the plane of angulation. Geometrically speaking, however, two lines can subtend only one plane. If we consider each bone segment as a line, these two lines can form an angle with each other only in one plane, regardless of the presence of angulation, rotation, translation, or length of deformities. A second plane of angulation can exist only if a second angular deformity at another level is introduced into these bone segments or lines.

Figure 32.27: A: Varus malunion of the mid diaphysis of the tibia with compensatory lateral translation. B: The frame was applied with the hinges at the level of the true apex of the deformity, and the corticotomy was carried out at that level. C: Distraction of the concavity led to realignment of the tibia through an open-wedge correction. Notice the simultaneous correction of the angulation and translation, as demonstrated by the colinearity of the medial tibial diaphysis. The hinges are now straight and the rings are parallel, indicating completion of the deformity correction. D: After completion of the angular correction, the parallel rings were distracted to lengthen the tibia. E: Final AP standing radiograph demonstrates the alignment of the corrected malunion. There is a persistent leg-length discrepancy of 2 cm, which was accepted because of slow healing in this patient.

Figure 32.28: A: Valgus malunion of the mid diaphysis of the tibia with aggravating lateral translation. There was a significant contour deformity created by the malunion. Preoperative planning demonstrates that the true apex of the deformity is proximal to the level of the malunion. Angular correction at this level simultaneously corrects for the translational component of the deformity. B: This leaves a persistent contour deformity that was unacceptable to the patient. C: Therefore, the alternative is to perform the correction at the level of the malunion to correct separately the angulation, translation, and the contour deformities. The radiograph demonstrates the angular and translational corrections, which were performed acutely followed by distraction to lengthen the tibia. D: The final radiograph demonstrates elimination of the angulation-translation and, as a result, of the contour deformity. The acute translational maneuver should be avoided because it contributes to delayed consolidation by disrupting the periosteum. It is preferable to correct the angulation gradually, followed by distraction to lengthen the tibia, followed by gradual translation.

Figure 32.29: A: Oblique plane deformity of the tibia. B: The AP projection of this tibia demonstrates a valgus deformity. C: The LAT projection of this tibia demonstrates a recurvatum deformity. The trigonometric exact formulae and graphic approximate formulae to calculate the magnitude (obl) and orientation of the oblique plane to the frontal plane (pln) are as follow:

\[
\text{trigonometric: } \text{obl} = \tan^{-1}\left(\frac{\sqrt{\tan^2\text{ap} + \tan^2\text{la}}}{\tan\text{ap}}\right)
\]
\[
\text{pln} = \tan^{-1}\left(\frac{\tan\text{ap}}{\tan\text{la}}\right)
\]
\[
\text{graphic: } \text{obl} = \frac{\text{ap}^2 + \text{la}^2}{2\text{ap}\text{la}} \quad \text{(Pythagorean Theorem)}
\]
\[
\text{pln} = \tan^{-1}\left(\frac{\text{la}}{\text{ap}}\right)
\]

There are several ways to determine the magnitude and true plane of a deformity in a plane oblique to the frontal plane. The simplest method is to rotate the limb until it appears straight (Fig. 32.30). The true plane of deformity is the plane where the projection of a deformed limb appears straight. The plane 90° to this projection should demonstrate the maximum angulation profile of the deformity. Radiographs taken in these two planes can be used to determine the orientation of this plane and the magnitude of the true deformity.
The orientation of the oblique plane angular deformity can be calculated using trigonometric equations or a nomogram. The graphic method requires only a pencil and goniometer to calculate the magnitude and direction of the oblique plane deformity. Bar and Breitfuss have published a nomogram to determine the true angular deformity and its oblique plane. Iliizarov plots the apical deviation from the axial midline on the AP and LAT views as x and y coordinates and determines the plane of deformity graphically. The Ilizarov apparatus allows the surgeon to make use of these calculations. By determining the true plane of deformity, the surgeon can also determine the axis of the deformity's apex. The axis of the deformity is always perpendicular to the plane of the deformity. Alternatively, the apparatus could be applied to correct the deformity in the AP plane; afterward, the hinges would be reoriented to correct the deformity in the LAT plane. This is a more time-consuming and less-efficient method, but it is accurate.

The measurement of 20° varus and 25° procurvatum were plotted on a graph. The vector obtained by the point 20–25 represents the magnitude 32° and true orientation 51.5° to frontal plane of the oblique plane angular deformity. Superimposed on this graph, the magnitudes of translation on the AP and LAT are plotted. The magnitude of the oblique plane translation is 16 mm on the LAT view and 0 to the frontal plane. The translation is measured in a plane perpendicular to the oblique plane. This confirms the radiographic findings. Notice the appearance of the apparatus in relationship to the left hinge. The hinges have been placed relative to the apex of the oblique plane deformity. Notice that the distance of the hinge rods to the central bolts differs for the medial and the lateral aspects. The patient was, therefore, protected in a patellar tendon bearing cast. The final AP (Q) and LAT (R) radiographs demonstrate the recurrence of deformity that occurred because of the premature removal of the apparatus prior to complete corticalization of the distraction callus. Notice also the ring sequestrum from one of the pin sites.

All that remains is to correct the translational deformity. By applying translational rods, the tibia was narrowed, bringing the cortical ends together side to side. The measurement of 20° varus and 25° procurvatum were plotted on a graph. The vector obtained by the point 20–25 represents the magnitude 32° and true orientation 51.5° to frontal plane of the oblique plane angular deformity. Superimposed on this graph, the magnitudes of translation on the AP and LAT are plotted. The magnitude of the oblique plane translation is 16 mm on the LAT view and 0 to the frontal plane. The translation is measured in a plane perpendicular to the oblique plane. This confirms the radiographic findings. Notice the appearance of the apparatus in relationship to the left hinge. The hinges have been placed relative to the apex of the oblique plane deformity. Notice that the distance of the hinge rods to the central bolts differs for the medial and the lateral aspects.

Figure 32.30. A: Malunion of the tibia with 20° of varus and 13 mm lateral translation. B: The LAT projection demonstrates 25° of procurvatum and 10 mm of posterior translation. C: Observation of the patient from the front demonstrates the varus deformity of the tibia. D: When the patient turns his foot inward, the varus deformity seems to disappear and the tibia appears straight. E: Examination from the side demonstrates the procurvatum deformity of the tibia. F: When the patient turns his foot inward again, the maximum angular profile of the deformity is seen. G: The maximum angular profile is captured radiographically on this LAT oblique view of the tibia. It measures 32°. H: An internal rotation AP oblique radiograph. In the plane of the deformity, the tibia appears straight. The translational component of the deformity can be appreciated on this view. I: The measurement of 20° varus and 25° procurvatum were plotted on a graph. The vector obtained by the point 20–25 represents the magnitude 32° and true orientation 51.5° to frontal plane of the oblique plane angular deformity. Superimposed on this graph, the magnitudes of translation on the AP and LAT are plotted. The magnitude of the oblique plane translation is 16 mm on the LAT view and 0 to the frontal plane. The translation is measured in a plane perpendicular to the oblique plane. This confirms the radiographic findings. J: The malunion was split obliquely. K: Notice the appearance of the apparatus in relationship to the left hinge. The hinges have been placed relative to the apex of the oblique plane deformity. Notice that the distance of the hinge rods to the central bolts differs for the medial and the lateral aspects. L: A true LAT view of the deformity showing the apparatus planes. M: In this manner, distraction of the concavity leads to realignment of the diaphysis on the LAT view of the tibia simultaneous with realignment on the AP view.

N: All that remains is to correct the translational deformity. O: By applying translational rods, the tibia was narrowed, bringing the cortical ends together side to side. P: Appearance of the callus at the time of the removal of the apparatus 23 weeks after application. Notice that there is no corticalization of the callus because of the pin sites (arrow).
When angulation and translation occur together, the plane of angulation may be the same as or different from the plane of translation. If angulation and translation are in the same plane, they can be characterized as a single apex of angulation (Fig. 32.36). If this is in one of the anatomic planes (frontal or sagittal), one view will show angulation and translation while the other shows no deformity. If both are in the same oblique plane, the center of rotation will be at the same level on both AP and LAT radiographs. If angulation and translation are in different planes 90° apart, there will be one plane with only angulation and one with only translation (Fig. 32.37). This is readily appreciated when the deformations correspond to the anatomic planes; translation only is seen on one view and angulation only on the other view. If they are in different oblique planes, then both angulation and translation are present in both AP and LAT views. To differentiate this from angulation/translation in the same oblique plane, one must examine the levels of the center of rotation of the angulation on AP and LAT views. When they are in different planes, then the center of rotation on the AP view is at a level different from that on LAT view, usually one apex above and one below the fracture level. Angulation and translation may also be in different planes that are less than 90° apart (Fig. 32.37). The graphic method of oblique plane deformity assessment can be used to plot the plane of angulation and the plane of translation on the same graph (Fig. 32.38). The difference in planes between angulation and translation can then be measured from the graph.

**ANGULATION/TRANSLATION DEFORMITIES**

When angulation and translation occur together, the plane of angulation may be the same as or different from the plane of translation. If angulation and translation are in the same plane, they can be characterized as a single apex of angulation (Fig. 32.36). If this is in one of the anatomic planes (frontal or sagittal), one view will show angulation and translation while the other shows no deformity. If both are in the same oblique plane, the center of rotation will be at the same level on both AP and LAT radiographs. If angulation and translation are in different planes 90° apart, there will be one plane with only angulation and one with only translation (Fig. 32.37). This is readily appreciated when the deformations correspond to the anatomic planes; translation only is seen on one view and angulation only on the other view. If they are in different oblique planes, then both angulation and translation are present in both AP and LAT views. To differentiate this from angulation/translation in the same oblique plane, one must examine the levels of the center of rotation of the angulation on AP and LAT views. When they are in different planes, then the center of rotation on the AP view is at a level different from that on LAT view, usually one apex above and one below the fracture level. Angulation and translation may also be in different planes that are less than 90° apart (Fig. 32.37). The graphic method of oblique plane deformity assessment can be used to plot the plane of angulation and the plane of translation on the same graph (Fig. 32.38). The difference in planes between angulation and translation can then be measured from the graph.

**TRANSLATION DEFORMITIES**

A translational deformity may also appear in two perpendicular planes (Fig. 32.35, Fig. 32.36). The direction of the true translational deformity can be calculated using the methods just described (Fig. 32.35C). Since translation is a direct linear measurement and not an angular deviation, the Pythagorean or graphic methods described are both accurate for the assessment of translation deformities in planes oblique to the frontal projection. Both the magnitude and the true plane of translation can be determined.

![Figure 32.34](image1)

**Figure 32.34.** A: Valgus malunion of the tibia with aggravating lateral translation. B: The deformity measures 22° of valgus with an apex proximal to the level of the malunion. C: On the LAT view, there is an 11° deformation, indicating that this is an oblique planar deformity with angulation and translation. D: The maximum profile of deformity is demonstrated on this oblique LAT radiograph and measures 24°. E: The radiograph in the plane of the deformity illustrates the translational component in the absence of angulation. F: Graphic determination of the magnitude and plane of the oblique deformity on a left leg graph demonstrates a 24.5° deformation oriented 26.7° from the frontal plane. (This is the same example shown in Fig. 32.29, Fig. 32.30, and Fig. 32.33.) G: The apparatus is applied so that the hinges are at the level of the true apex of the deformity which is proximal to the malunion. The corticotomy is performed at the same level. H: An open-wedge correction was carried out, realigning the mechanical axis of the lower limb. Note that all of the rings are parallel and the hinges are straight. I: On the LAT view, one can also appreciate the open wedge anteriorly with the correction of the recurvatum deformity. The rings are parallel on the lateral at the end of the correction. The follow-up AP (J) and LAT (K) radiographs demonstrate the restoration of AP and lateral alignment of the tibia.

**Figure 32.35.** A, B: Translational deformity may also be seen in two planes. This tibial nonunion has a posterior and lateral translational deformity. C: The posterior translation measures 2 cm, while the lateral translation measures 2.7 cm. When these are plotted on a graph, it demonstrates that the true translation is 33 mm in a plane oriented 36° to the frontal plane. This graph is drawn as for a right leg.
The relationship between the planes of angulation and translation has ramifications on treatment. When both are in the same plane, there is a single center of rotation point that will correct both deformities by ankylosis alone. In injuries, the hinge can be placed at this ankylosis point; after distracting the ends apart, the angulation and translation are corrected by angulation around this hinge. If there is a malunion, an osteotomy may be performed at this level with opening or closing wedge correction. This corrects both angulation and translation together (Fig. 32.27).

If angulation and translation are in different planes, then several strategies may be pursued. Angulation may be corrected at the apical level on the AP, LAT, or oblique views (Figs. 32.30). Translation, if significant, will not correct with the angulation and requires a separate correction in the LAT, AP, or oblique plane (Fig. 32.30). Alternatively, a double-level osteotomy can be performed, correcting angulation and translation in the frontal plane with one osteotomy at the AP angulation-translation point and one osteotomy at the LAT angulation-translation point. This deformity is the only true "biplanar" deformity from a single fracture level.

Malrotation may also be a component of the deformity. Rotation is simply an angular deformity in the axial plane. Since all single-level angular deformities can be resolved into a single plane, the single axis of deformity, it should be possible to resolve the rotational component together with the angulation and translation. Sangeorzan et al. and other authors have demonstrated that combinations of angulation and rotation deformities can be resolved into a single axis of deformity using complex trigonometric computations and tables (27).

This geometric problem can also be solved in a simpler fashion. This x-y-z axis deformity can be computed as a simple extension of the method detailed previously (Fig. 32.38). This method is a reasonable approximation for deformities of up to 45° in the AP, LAT, or axial directions. Since most angular deformities are much less than 45°, this computation is a useful method and does not require trigonometry or complex nomograms.

Combinations of angulation and rotation can be corrected either through a single hinge or sequentially. The correction requires a hinge that is oriented not in the transverse plane but inclined, in a vertical plane. This vertical inclined hinge will simultaneously correct the angular and rotational deformities (Fig. 32.39). If the osteotomy is done at the angulation-translation point, angulation, translation, and rotation are corrected simultaneously. The alternative, which is simpler, is to correct the angular deformity first, then to correct the rotational deformity using a derotation mechanism. While this method is more time consuming, it is easier for most surgeons to understand. However, some translational correction may be needed after derotation because of the eccentric location of the bones within the ring. The advantage of the single-hinge method is that no maltranslation results from the deformity correction.

Conventional osteotomies also make use of these principles. By producing a single osteotomy in a vertical oblique plane, a surgeon can correct all of these deformities by sliding the bone surfaces perpendicular to the plane of the osteotomy (27, 31).
MULTIAPICAL ANGULAR DEFORMITIES

A more complex situation exists when there is more than one level of angulation. Each level and each plane of deformity must be delineated for each apex. Sometimes a single osteotomy can be used to correct a multiapical angular deformity, but usually more than one osteotomy is needed. Often one of the apices is obvious, while the other is subtle. This happens when one of the deformities is diaphyseal and the other is juxtaarticular. Examples are anteromedial and posterolateral bows of the tibia (Fig. 32.40). Usually, a varus or valgus diaphyseal deformity exists with a compensatory juxtaarticular angular deformity at the level of the proximal tibial physis. Correction requires two osteotomies: angulation-translation in the proximal tibia, and angulation in the mid-diaphyseal region. These are called compensatory bowing deformities because one deformity compensates for the other. There is usually little deviation of the mechanical axis.

Figure 32.40. Anteromedial tibial bow. A: The frontal plane alignment of the tibia demonstrates an obvious varus deformity of the mid diaphysis and a subtle valgus deformity of the juxtaarticular region of the tibia. There is also a very mild distal femoral valgus and a leg-length discrepancy. B: The osteotomies were performed in the proximal metaphysis and in the mid diaphysis. The distal osteotomy is for the correction of the varus and the procurvatum deformities; the proximal osteotomy is for the correction of the juxtaarticular valgus deformity. Notice the pattern of the olive wires, which provide the necessary fulcrums and distraction points for this correction. C: The apparatus is shown in the immediate postoperative period. Each ring is oriented perpendicular to its own bone segment. The mid-diaphyseal hinge is properly located. The proximal tibial hinge was incorrectly located at the level of the osteotomy. This was one of the authors’ earliest cases before the principles of angulation plus translation for juxtaarticular deformities were completely understood. D: At the end of the correction, all of the rings are parallel and the hinges are straight. E: The AP and LAT radiographs demonstrate the realignment of the tibia on both views, as well as double level lengthening to equalize the limb length. F: The final radiograph demonstrates the realignment of the tibia with slight undercorrection of the distal angular deformity and slight overcorrection of the proximal angular deformity, which made up for the lack of translation at the proximal osteotomy. The preoperative planning of this case is illustrated in Fig. 32.44.

Figure 32.44. A: Multiapical angular deformity of the tibia with a normal femur. Step 0: Draw the mechanical axis line from the center of the hip to the center of the ankle, demonstrating minimal varus mechanical axis deviation. The malalignment test was performed, demonstrating a normal distal femoral alignment. Step 1: Draw the proximal and distal tibial mechanical axis lines. Note that the intersection point is at a nondeformed level. The intersection of these two lines is not at the level of the obvious deformity. Notice that the proximal tibia also does not lie on this line. This indicates that there is a second apex of deformity. Step 2A: Draw the line perpendicular to the middle segment of the tibia and extend this line proximally and distally. This should intersect the mechanical axis of the distal tibia at the level of the true apex of deformity. Step 2B: The same center of rotation is located by the convex cortex method. Step 3A: Correct the first deformity at the level of the obvious apex. Extend the corrected distal mechanical axis line proximally. This intersects the proximal tibial mechanical line at the growth plate. This is the second apex. The second osteotomy is of angulation and translation to realign the tibia. B: The apparatus before and after correction.

True (noncompensatory) bowing is a continuous, multiapical deformity that develops in soft bone, as is seen in rickets, Paget’s disease, and osteogenesis imperfecta (Fig. 32.41, Fig. 32.42 and Fig. 32.43). Whether due to remodeling or ongoing multiple stress fractures, these deformities demonstrate no single or double apex. While a bow can be considered to have a single apex, realignment through the apex corrects only the mechanical axis and does not improve the anatomic axis of the bone. It is preferable to perform at least two osteotomies to straighten a bowed bone. An alternative is to perform an osteotomy at a level different from that of the apex of the bow, and to combine this with a translational correction so as to eliminate some of the anatomic axis deformity.

Figure 32.41. A: Back view of an 18-year-old woman with severe bowleggedness from hypophosphatemic rickets. B: The radiographs demonstrate the severity of the preoperative deformity. Both legs do not fit on the width of a normal film, even when the legs are crossed. Notice the bowing in the femur. Notice also the lateral compartment joint laxity in the knee, which contributes to the varus deformity. C: The apparatus is shown during construction in the operating room. The femoral apparatus is applied first, followed by the tibial apparatus. The two devices need to be coordinated to allow at least 90° of free flexion of the knee. Care must be taken so that the most distal femoral and most proximal tibial rings do not collide. For this reason, incomplete rings (5/8 rings) open posteriorly are applied adjacent to the knee. D: The tibial apparatus from the frontal view. The hinges are locked at the measured deformity. The incision for the distal corticotomy of the tibia is shown adjacent to the hinge. There are two levels of fixation within the proximal and distal segments. E: At the completion of the realignment, all of the rings of both the femur and the tibia are parallel. Notice the axial increase in length from realignment of these severely bowed bones. F: After removal of the apparatus, the patient was left with a 10-cm leg-length discrepancy. The realigned limb stands in marked contrast to the uncorrected side. G: The second side was corrected after a 4-month hiatus. Notice that the left tibia was slightly overcorrected to try to compensate for the lateral knee joint laxity. On the right side, the proximal fibula was pulled down 1 cm to tighten the lateral knee joint. Notice that even in bipedal stance, the lateral knee joint is wider on the left than on the right leg. Notice also that the fibular head lies more distal on the right than on the left side. H: The final clinical appearance of both legs shows normal alignment with an excellent cosmetic and functional result.
The single level of fixation in the proximal and distal tibia and three floating levels of fixation on opposite sides of the stress fractures. Anteriorly, a sliding plate suspends the three floating half-rings. The threaded rods of this plate are used to push in the apex of the deformity. On the concave side, there are two distraction rods, of which only one can be seen on the photograph. Both a knee and an ankle Dynasplint unit were used to help prevent joint contractures. The apparatus was shown in situ at the beginning of the deformity correction. A fibular osteotomy was performed. The posterior aspect of the two nonunions can be seen to open slightly as the combined distraction and apical translation are carried out. At the end of the deformity correction, there is an opening wedge at both nonunion sites. The proximal and distal tibial rings as well as the three floating half-rings are all parallel. The apparatus was removed when a complete wall of cortical bone was seen posteriorly and when the fibula had united. This correction also equalized the patient's leg lengths. The clinical appearance is excellent.

The steps for preoperative planning of multilevel angular deformities of the femur and/or tibia are shown in Figure 32.44. The clue that there is more than one apex of angulation is that the single center of rotation determined by the intersection of the proximal and distal mechanical axis lines is at a level where there is no "obvious" angulation (Fig. 32.44, step 1). In multilevel deformities, there is usually one obvious (diaphyseal, hip, or ankle) apex and one less obvious angulation apex. The obvious apex should be corrected first. The apex of this level may be chosen based on cortical or midbone lines, or, in the case of hip or ankle deformities, we know the apex is at the center of the joint. Once the first apex of angulation is corrected, it will point to the second apex.

JOINT LAXITY DEFORMITIES OF THE KNEE

If lateral laxity of the knee is a cause of symptoms or malalignment, correct it together with the tibial or femoral varus angulation. With conventional techniques, the head of the fibula can be osteotomized and moved distally. By the Ilizarov method, the proximal fibula is pulled down to tighten (even overtighten) the lateral complex. If lateral laxity of the knee is a cause of symptoms or malalignment, correct it together with the tibial or femoral varus angulation. With conventional techniques, the head of the fibula can be osteotomized and moved distally. By the Ilizarov method, the proximal fibula is pulled down to tighten (even overtighten) the lateral complex. The clue that there is more than one apex of angulation is that the single center of rotation determined by the intersection of the proximal and distal mechanical axis lines is at a level where there is no "obvious" angulation (Fig. 32.44, step 1). In multilevel deformities, there is usually one obvious (diaphyseal, hip, or ankle) apex and one less obvious angulation apex. The obvious apex should be corrected first. The apex of this level may be chosen based on cortical or midbone lines, or, in the case of hip or ankle deformities, we know the apex is at the center of the joint. Once the first apex of angulation is corrected, it will point to the second apex.

INDICATIONS FOR DISTRACTION OSTEOTOMY VERSUS CONVENTIONAL OSTEOTOMY

An angular deformity of a bone may be corrected by opening wedge, dome, closing wedge, or angular displacement osteotomies. Both distraction and conventional methods use all of these osteotomy types. With conventional osteotomy, the correction is achieved acutely in the operating room; stability is achieved with internal or external fixation. The closing wedge technique is preferred because of the good bone-to-bone contact possible. Conventional opening wedge methods usually require a bone graft and have a higher incidence of nonunion. The dome osteotomy is a compromise between the opening and closing wedge methods and offers some adjustability. The complications with these techniques include nonunion, osteomyelitis, compartment syndrome, nerve injury, and vascular injury (8). Accuracy of correction is often a problem, especially with the closing wedge technique. Even with meticulous planning, factors such as x-ray magnification, rotated x-rays, measurement error, the thickness of the saw blade, and the expertise of the surgeon all contribute to inaccuracy with conventional methods (18). After the operation, there is no nonoperative way to adjust incomplete correction (16, 17).

Distraction osteotomies are less risky and more accurate. Since Ilizarov's technique is percutaneous, there is little risk of compartment syndrome, nerve injury, vessel injury, nonunion, or osteomyelitis. The correction is performed either acutely for small deformities or gradually for larger deformities (25). Gradual distraction prevents nerve stretch injuries, as can occur in the correction of a valgus tibial deformity. The distraction method is as accurate as one can measure on a radiograph, perhaps the greatest advantage of Ilizarov's technique. Even after acute corrections, adjustments can be made to fine-tune the correction until the exact alignment of the limb is achieved.

Oblique plane angular deformities are just as easy to correct as frontal or sagittal plane ones. More complex deformities, including rotation, translation, and limb-length discrepancy, can all be managed simultaneously. Multilevel and multibone corrections can be done since there is little blood loss and the apparatus can be applied to multiple levels and bones simultaneously. Lengthening can be performed for small and large discrepancies, as needed, at one or more levels. Associated problems of nonunion, contracture, and osteomyelitis can be treated at the same time. The apparatus allows for unrestricted weight bearing and personal hygiene; weight bearing is usually restricted with internal fixation, and bathing is difficult if a protective cast is used. The main disadvantages of Ilizarov's method are those related to external fixation, including wearing a bulky apparatus for a prolonged period, pin infections, muscle transection, loss of joint range of motion, and pain. With proper application of the device, the last three problems should be minimal. More recently, with the use of half pins instead of transfusion wires, these problems have been significantly reduced.

Of course, the distraction osteotomy is most advantageous in treating complex deformities. Nevertheless, it still offers many advantages even for simple deformities that have a good conventional alternative, such as high tibial osteotomy. The decision to use Ilizarov's distraction method rather than a conventional osteotomy and fixation depends on all of these factors, not the least of which is the surgeon's experience in the application of the distraction osteotomy.
BASIC PRINCIPLES OF DEFORMITY CORRECTION USING CIRCULAR EXTERNAL FIXATION

There are two types of constructs for correcting deformity: focal hinges, and push-pull constructs.

CENTER OF ROTATION HINGE TECHNIQUE

The basic construct for angular deformity correction using hinges consists of two levels of fixation proximal and two levels distal to the apex of the deformity (Fig. 32.45). Each level of fixation is perpendicular to either the anatomic or the mechanical axis of the bone fragment to which it is affixed. The hinge connects the proximal and distal blocks of fixation, articulating between them at the desired center of rotation for correcting the angular deformity (63).

Figure 32.45. A: Center of rotation hinge apparatus. There are two levels of fixation in each bone segment on opposite sides of the osteotomy. The rings are applied perpendicular to their respective bone segment. The hinge lies perpendicular to the ring. In this example, the hinge is applied over the apex of the deformity, with the hinge rod overlying the medial convex cortex of the tibia. On the concave aspect, there is a distraction rod connected by two twisted plates and a suspending post. The post connection to the twisted plate allows for self-adjustment of the distraction rod angle to that of the ring. B: After the correction is completed, all the rings are parallel and the hinge rods are colinear. Notice the open-wedge correction of the tibia and fibula and the change in angle between the distraction rod and the ring. C: For a juxtaarticular deformity of the tibia, the apparatus employs a translation hinge. Notice that the hinge is located over the level of the tibial physis. This is proximal to the upper ring. Two levels of fixation were achieved in each bone segment on opposite sides of the osteotomy. D: At the end of the correction there is an angulation and translation of the bone segments at the level of the osteotomy. The rings are now parallel and the hinge rod is straight. Notice again the change in orientation of the distraction rod to the rings.

If the hinge is placed at the apex of the deformity on the convex side, then distraction of the concavity will lead to an opening wedge correction (Fig. 32.34, Fig. 32.46A). If the hinge is placed at a distance from the convex side of the apex of the deformity, then lengthening will occur together with correction of angular deformity (Fig. 32.46B, Fig. 32.47). Placing the hinge on the concave side of the deformity will lead to compression of the bone ends with angular correction (Fig. 32.46C, Fig. 32.48). If the hinge is placed either proximal or distal to the level of the osteotomy, then translation of the bone ends will occur with angular correction during distraction of the concavity (Fig. 32.46D, Fig. 32.49).

Figure 32.46. A: Opening wedge hinge. The hinge is located at the level of the osteotomy overlying the convex cortex of the bone. Distraction of the concavity leads to an opening wedge correction without separation of the convex cortices of the bone. B: Distraction hinge. The hinge is located away from the convex cortex of the bone but still at the level of the osteotomy. Distraction of the concavity leads to simultaneous lengthening with angular correction. The regenerate has the appearance of a trapezoid, with a wider separation on the concave side than on the convex side. C: Compression hinge. If the hinge is located at the level of the osteotomy but on the concave side of the bone, distraction of the concavity will lead to compression of the bone ends. If the bone ends allow, this will produce a closing wedge type of correction. D: Translation hinge. If the hinge is located proximal or distal to the level of the osteotomy, distraction of the concavity will lead to translation of the bone ends. In this example, the hinge is located at the intersection point of the convex cortices of the two bones and, therefore, distraction of the concavity leads to correction of the angulation and translation of the bone ends.

Figure 32.47. Application of distraction hinges for lengthening and correction of deformity. A: A 5-year-old girl with bilateral genu varum and shortening due to meningococcemia septic emboli. She has skin grafts adherent to the bone and, therefore, distraction must be performed very gently. B: Standing radiographs show the deformities and the preoperative planning markings for the placement of olive wires. C: The apparatus has a hinge located lateral to the convex aspect of the osteotomy. To augment the stability of the fixation, the distal hinge has a threaded rod applied through the center of the anterior and posterior hinge point. This can be performed only with distraction hinges. D: Toward the end of the correction, notice the increased length achieved through the distraction hinges without lengthening on the hinge rods. All of the lengthening is performed by distraction of the concavity. Notice that this method is gentle on the skin and there were no skin problems. E: The final radiographs demonstrate 8 cm of lengthening of both tibias with realignment. Notice the bilateral triangular shaped tali. Both feet were plantigrade at the end of the correction. F: The final appearance of both legs at the end of the lengthening and correction of deformities.
Figure 32.48. Application of compression hinge. A: Valgus deformity with nonunion of knee arthrodesis site. B: The apparatus was applied with a hinge overlying the center of the knee joint so that distraction of the concavity would produce compression of the medial aspect of the nonunion and distraction of the lateral aspect of the nonunion. C: The final result demonstrates correction of deformity and union.

Figure 32.49. A: Application of translation hinge. Equinus malunion of ankle arthrodesis. B: This was treated by a supramalleolar osteotomy with application of a translation hinge. The hinge was located at the level of the calcaneotibial fusion; the osteotomy was performed 3 cm proximal to that. C: Simultaneous lengthening, angulation, and translation were carried out. Notice the position of the tibia overlying the mid foot. The entire foot has translated posteriorly to give this girl a heel and to shorten the stiff forefoot, improving her ambulation. Notice the translational pattern of the trabeculae.

Therefore, it is important to keep the hinge at the level of the osteotomy to avoid any translation of the bone ends with respect to each other, unless translation is planned as part of the correction (23). Conversely, if translation of the bone ends is desired, then the proper level of the hinge needs to be selected. The level of the hinge is also governed by the bisector line of the angular deformity (Fig. 32.50).

Figure 32.50. Determination of hinge placement level by the bisector concept. A, distraction hinge; B, opening wedge hinge; C, compression hinge.

To ensure that the desired correction is produced, the bone must be prevented from slipping along the wires (Fig. 32.51). The bone must be locked into the apparatus in such a way that the bone ends will follow the angular correction of the rings. To create such a constrained system, the appropriate fulcrum and distraction points must be built in. The position of the fulcrum and distraction points is best described as a four-point bending maneuver (Fig. 32.52). The "rule of thumbs" is used to determine the location of the fulcrum and distraction points for simple angular corrections without translation of the bone ends (23,25). In coronal plane deformities, insert olive wires in the frontal plane according to the four-point bending rule of thumbs (Fig. 32.52). For sagittal plane deformities, use transverse smooth wires in the frontal plane at all four levels of the rule of thumbs instead of olive wires (Fig. 32.53). Alternatively, threaded half-pins can serve as fulcrums for either sagittal or coronal plane deformities. It is preferable to use two olives counterposed on the same side as the fulcrum or distraction point whenever possible. In the femur, threaded half-pins often substitute for olive wires.

Figure 32.51. The principle of constraint of the apparatus to the bone. A,B: If smooth wires only are used, distraction of the concavity of a deformity will lead to slippage on the smooth wires. The bone tends not to elongate with the correction but to move toward a part of the apparatus in which there is less elongation. Therefore, the bone moves from the convex side of the apparatus toward the concave side of the apparatus. This slippage leads to incomplete correction of the bone by the time the rings are in a corrected position, and it may lead to impingement of the skin against the ring on the convex side of the deformity. C,D: Applying olive wires over the apex of the deformity prevents slipping. The concave bone and soft tissues are forced to elongate.
**Figure 32.52.** The rule of thumbs. Four-point bending is the principle of correction in angular deformities. Olive wires are placed at the fulcrum point on opposite sides of the apex of the deformity and at the distraction points at either end of the bone. The location of the olive wires can be remembered by thinking of the four point bending rule of thumbs; the olive is located at the points where the thumbs press on the apex and the index fingers press on the ends of the bone.

**Figure 32.53.** In sagittal plane deformities, the transverse wires act to constrain the system in much the same way as olives do for frontal plane deformities.

For pure frontal plane translational correction, place the olives counteropposed between blocks but on the same side of the two levels of fixation within a block (Fig. 32.54) (23). Therefore, the proximal two olive wires are on the same side and the distal two olive wires are on the counteropposed side. In this pattern, the olives act to push the bone's distal segment from its translated position toward the properly aligned proximal segment.

**Figure 32.54.** For translational deformities, the olives should be counteropposed.

For a combined angular and translational deformity correction using a hinge, the olive wires are placed in a modified rule of thumbs to effect both translation and angulation (Fig. 32.55) (23). This requires the addition of a third olive wire on the side without the hinge. The third olive wire is the translation wire that forces the translational correction simultaneously with the angular correction. If half-pins are used, they act to constrain the construct, thus replacing the need for olive wires.

**Figure 32.55.** The modified rule of thumbs helps determine the location of the olives for combined angulation translational corrections. While one fragment is held as usual between the index and thumb, the other fragment is held with the thumb and index at the same level on opposite sides of the bone and the middle finger in the previous location of the index finger. The olive pattern is illustrated in Fig. 32.46.

In preoperative planning, first determine the level of osteotomy and identify the magnitude and true plane of the deformity. Construct an apparatus to correct the deformity. Construct two blocks of fixation, each with two levels of fixation. Plan the spacing between levels according to the strategy of correction. If only angular correction is required, then make the blocks as wide as possible, with only a handbreadth separating the blocks at the level of the deformity. If significant lengthening is planned, the distance between blocks must be greater to avoid skin entrapment. In this situation, the width of each block is narrower.

Place the hinge in the axis of rotation of the angular deformity, perpendicular to the plane of deformity. In addition to the plane of the hinge axis, the level of the hinge and its function must be chosen. Place a hinge either at the level of the osteotomy or at a different level. The latter will produce a translational effect during correction. Usually the hinge is placed at the level of the deformity's apex and the osteotomy is done as close to that level as other considerations permit. The function of the hinge as opening wedge or distraction will determine its distance from the center of the ring.

Once the hinge location is determined, set the hinge at the calculated magnitude of angular deformity and lock it in that position. Place a distraction rod between adjacent rings at a point halfway between the hinges on the opposite side of the limb. The preconstructed frame is then ready for application.

**PUSH-PULL CONSTRUCTS**
The push-pull construct uses one fixed level within each bone fragment and one floating level in each bone fragment (Fig. 32.56, Fig. 32.57) (23).

**Figure 32.56.** Push construct. A: The push construct is shown applied to a procurvatum deformity of the tibia, similar to the example illustrated in Fig. 32.42. The proximal and distal rings are perpendicular to their individual bone segments. The middle half-rings are suspended from an anterior plate. The plate, connected via buckles to a perpendicular shorter plate, pivots on the ring on a hinge. The buckles allow the horizontal plates to slide up and down while the hinges allow the horizontal plate to alter its orientation to the ring as the deformity gradually corrects. The half-rings are connected by threaded rods from posts on either side of the long plate. On the concavity, there are two distraction rods connected by twisted plates and posts to allow auto-adjustment at either end. Only a single wire is needed on each of the floating half rings, and two wires are used at either end on the full ring. B: By coordinating the distraction on the concavity with the translation on the convexity, the deformity is gradually corrected. Notice that the buckles have moved toward each other on the long plate.

**Figure 32.57.** Pull construct. A: The apparatus at the beginning of the correction, with olive wires on slotted threaded rods. The olive wires pull in the apex of the deformity, much the way the push wires push in the apex of the deformity. In the minor deformity shown, conical washers are used at each end for distraction. Alternatively, a focal hinge or twisted plate at either end could be used. B: The appearance of the construct at the end of correction. C: Preoperative AP roentgenograph of a patient whose congenital pseudoarthrosis of the tibia was previously treated by a nail and onlay grafting. Note the valgus ankle and proximal migration of the fibula. D: Distraction of the stiff pseudoarthrosis using a pull construct to correct the deformity. E: Union, lengthening, and realignment were all achieved. The fibula was transported distally. It was transfixed with a screw to keep it from proximal migration and a bone graft applied to synostose it to the tibia. It remains united 2 years later. (C, D, and E from Paley D, Catafini M, Argnani F, et al. Treatment of Congenital Pseudoarthrosis of the Tibia. Using the Ilizarov Technique. Clin Orthop 1992;280:91.)

- Affix the most proximal and most distal levels to a ring, and apply distraction rods on the frame's concavity.
- On the convex side, articulate the rings with a long plate. The articulation on the plate acts as both a pivot and a sliding joint. The apex of the deformity is either pushed or pulled into the concavity.
- A push construct uses smooth wires perpendicular to the plane of the deformity (Fig. 32.56). A pull construct uses olive wires in the plane of deformity. Connect the push smooth wires to a translational apparatus. Connect the pull olive wires using a slotted threaded rod translation apparatus (Fig. 32.57).

Because there is only one fixed level within each bone segment, this construct is less stable than the hinge construct. Therefore, this frame should be applied only to relatively stable pathologies such as stiff nonunions, bowing deformities with a large resistive tension band of soft tissue on the concavity (Fig. 32.42), and bones that do not have great loads applied to them, such as the forearm.

The most stable configuration for angular deformity correction is constructed by a mix of push and hinged constructs (Fig. 32.59). Two levels of fixation within each bone segment articulated with hinges and a distraction rod on the concavity are augmented by a push construct on the apical two rings of the deformity to achieve augmented fixation and augmented constraints on the deformity.

**Figure 32.58.** Combination hinge and push constructs. A: The strongest construct of all combines the two levels of fixation of the hinge construct with the push construct. B: The construct at the end of deformity correction. C: The construct shown in (A) and (B) was applied to a congenital pseudoarthrosis, which had malunited, in an effort to fracture the bone without an osteotomy. D: Ilizarov calls this method metaphysealysis. It can be used to focus large concentrated forces on weak, narrow-diameter bone regions. Notice the fracture of the bone that has occurred. E: The final result, showing union and correction of the deformity.

**CONSTRUCT CONSIDERATIONS FOR ROTATIONAL DEFORMITIES**

Most rotational deformities are corrected by rotational modifications of the basic hinge frame. The rotational vertical inclined plane hinge, while a theoretical possibility, is usually too complex to be readily applied (Fig. 32.49). Two types of rotational corrections can be achieved with the circular frame: acute and gradual.

The rotational correction can be performed acutely by disconnecting the frame and rotating one section with respect to the other. This can be done at the time of surgery. Because acute correction is too painful in most outpatient situations, a controlled acute method is preferable. One of these methods is to angle the rods between one ring and the other and then tighten them. If all the rods are angled one or two holes over, then an acute derotation of one or two holes is achieved (Fig. 32.58A, Fig. 32.58B), resulting in 5° to 10° of derotation, depending on the ring diameter. This can be repeated every few days until the correction is completed, usually with minimal discomfort. An alternative method is to shift the wire on the ring (Fig. 32.58C, Fig. 32.58D) so as to bow each end of the wire in an opposite direction like a pinwheel, when the wires are tensioned, the bone rotates. This method is usually too complex, time-consuming, and painful, since all the wires need to be loosened...
and retensioned.

**Figure 32.59.** A: Acute rotational correction can be achieved by moving the rods around the ring the same number of holes and then acutely tightening the nuts at either end of the rods, forcing the rods to become perpendicular to the ring and thus derotating the ring. B,C,D: Acute derotation can also be performed by advancing all the wires in the same direction by the same number of holes and then tensioning them acutely. This is very difficult, time consuming, and painful, and it is rarely done.

The gradual method can be applied in one of many constructs (Fig. 32.60A, Fig. 32.60B) at a set rate and rhythm determined by bone and soft-tissue considerations. The gradual method is the safest and involves the least amount of discomfort.

**Figure 32.60.** Gradual derotation can be carried out by a variety of constructs. A: One method uses horizontal threaded rods articulating between a post on one ring and a threaded rod coming from the other ring. The threaded rod is connected by two nuts to one ring, while at the other end a buckle is attached to allow for axial support. Alternatively, a threaded rod can be connected between two posts, but this is less stable. Three of these constructs are connected around the ring. B: Another method of derotation is the ring within a ring. With this method, the proximal block is connected to the outer ring and the distal block to the inner ring. The articulation between the ring is by means of a pair of plates protruding from three or four locations. The plates are fixed to the inner ring but not to the outer ring. They sandwich the outer ring between either plate. A single horizontal threaded rod is used to motor the derotation.

Since derotation occurs between adjacent rings, the configuration’s center of rotation is at the center of these rings. If the bone is located at the center of the ring, then the derotation will occur around the central axis of the bone. In most cases, however, the bone does not lie in the center of the ring: in both the thigh and the shank, the bone is eccentrically located within the soft-tissue mass. To center the bone within a ring, a ring of very large diameter would be needed, increasing the system’s instability (Fig. 32.61).

**Figure 32.61.** A: The ring is normally centered around the leg so that there is a minimum of two fingerbreadths’ (3–4 cm) space between the inner edge of the ring and the skin. Notice that the center of the ring lies posterior and lateral to the center of the tibia. B: To center the ring on the bone, it would be necessary to use a much larger ring to allow a minimum of two fingerbreadths’ space between the ring and the skin. This leads to less stable fixation.

As the derotation occurs around the center of a ring, an eccentrically placed bone will move sideways during rotation (Fig. 32.62). External rotation of the tibia leads to lateral translation and internal rotation to medial translation (23). To a lesser extent, internal rotation is associated with posterior translation and external rotation with anterior translation. In the femur with its anterior location, the same relationships hold.

**Figure 32.62.** A: Rotation of a ring that is centered on the leg and not on the bone leads to (B) lateral translation of the bone. C: This malunion required a correction of varus and rotation. There was also a lateral translational deformity. Notice that there are two lateral translations and one medial translation of the united fragments. The result is lateral translation. D: A corticotomy at the junction of the proximal and middle thirds of the tibia was performed, and the angular deformity corrected at that level. The bone was then lengthened and derotated. Because the ring was centered on the leg and not on the bone, a medial translational deformity, which can be seen, occurred. In this particular case, this was therapeutic because it realigned the translation of the tibia. Therefore, the translational effect of the derotation in some cases can be used to achieve a desired translational correction. Since the center of the ring is posterior to the tibia, internal rotation leads to medial translation, while
external rotation leads to lateral translation. This deformity must be factored into the realignment of the leg, especially in large derotations.

If significant translation occurs with derotation, a separate translational correction may be needed after derotation with either a translation device or a derotation-translation device. The former uses a translation frame modification to move the bone into the reduced position. The latter uses the translation-rotation point to reduce the fragments (Fig. 32.63). The translation-rotation point is on the bisector of the center of each bone segment. Where this bisector crosses the ring is the location of the rotation center.

**Figure 32.63.** A: To correct the translational deformity created by a derotation, one can use either conventional translational constructs or the more accurate translation rotation point. This point is located on the ring equidistant from the center of the two bone ends. The true plane of the translation must be identified, and then a point between on the line connecting the centers of the two bones is projected to the ring as the right bisector of that line. B: A threaded rod is connected between the adjacent rings at that point and the rings are derotated around that threaded rod to rotate one bone fragment into the other. This leads to reduction in the translational deformity without loss of the rotational correction.

**TRANSLATIONAL DEFORMITY CORRECTION**

Translational deformity in combination with angulation was discussed earlier. Translation may also be corrected independently of angulation, either acutely or gradually. Acute translational correction may be achieved with olive wires and acute displacement using a wire tensioner (Fig. 32.64). Alternatively, acute correction will occur when tensioning an arced wire from both ends. Gradual translational correction can be achieved using gradual distraction on olive or arced wires using slotted threaded rods.

**Figure 32.64.** A: Acute translational correction, which can be performed by olive or arced wires. An olive wire can be pulled from the nonolive end to translate the bone fragment. B: The same effect can be created perpendicular to the wire by using the arced wire. The wire is displaced one hole in the direction of the desired translation. C: Tensioners are applied to both sides of the wire to pull out the arc and thus displace the bone into the concavity of the arc. D: For large displacements, the original Russian wire tensioners are used. E: Another acute method of effecting a translational correction is similar to the acute rotational method by displacing the threaded rods. F: The acute translational correction is performed by tightening the nuts in the threaded rods.

The most controlled way to correct translation is to use translational threaded rods articulating between parallel rings (Fig. 32.65). This allows very gradual translational movement in any direction. Unlike the rotational rods, which are oriented tangential to the ring, the translational rods are oriented parallel to each other in the direction of translation.

**Figure 32.65.** A: Gradual translational corrections are carried out by connecting horizontal threaded rods all parallel to each other. Three of these connections are necessary. B: The end of the translational correction.

**ORDER OF CORRECTIONS FOR COMPLEX DEFORMITIES**

Complex deformities may have components of angulation, rotation, translation, and shortening. In correcting combinations of deformity, the order of corrections is important. Complex deformities can be divided into two groups: those with and those without bone segments that must translate with respect to each other. Unlike lines on paper, segments of bone cannot slide past each other without colliding. Therefore, any manipulation that will lead to collision of one bone segment with another will cause obstruction and jamming of the system.

Therefore, the order of corrections can be planned depending on the likelihood of potential segment collision and jamming (Fig. 32.66). Collision and jamming may occur when translation or rotation of bone fragments is required as part of the correction. The propensity for collision and jamming depends on the configuration of the bone fragments with respect to each other and the contour of their bone ends. Of course, a transverse osteotomy through a bone with no overlap of the bone segments will allow movements of angulation, rotation, translation, and lengthening without collision and damage. On the other hand, if the two bone segments overlap, translation or angulation will be obstructed. In such a situation, the surgeon must first lengthen the limb and then correct angulation and translation together (Fig. 32.66).
Because the peroneal nerve is at the level of the fibula, it may be preferable to open the wedge relative to a 1 mm rate of the fibula rather than the tibia. In contrast, the fibula lies halfway between the distraction rod and the hinge. Therefore, at 4 mm/day distraction, the fibula will lengthen 2 mm/day.

The order of corrections also depends on the expected rate of healing of the bone or the patient. In younger children, the expected rate of healing is faster than in adults. Open-wedge angulation correction carries a risk of premature consolidation on the convex side; this would prevent subsequent lengthening. This risk is small in adults but significant in children. Therefore, the order of corrections in adults and children may be different.

In patients with no risk of jamming and collision and in whom premature consolidation is not a concern, the order of corrections is angulation, lengthening, rotation, and translation (Fig. 32.67A).

In patients with no risk for jamming and collision but at risk for premature consolidation, the order is angulation and lengthening, rotation, and translation (Fig. 32.67B).

If jamming and collision are expected, the order of corrections is lengthening, angulation, remaining lengthening, rotation, and translation (Fig. 32.67C).

It is preferable to carry out both rotation and translation through long segments of regenerated new bone, where the shearing effect of these displacements can be distributed along the soft bone and blood vessels. There is far greater shear between bone ends of an undistracted osteotomy (leading to disruption of medullary and periosteal tissues during translation or rotation) than there is between bone ends that are separated by several centimeters.

Perform translation after rotation because a translational displacement may occur during derotation of an eccentrically located bone. This displacement may be used if both the translational deformity and the rotational deformity are in the same direction. In these cases, the bone ends can be rotated, thereby correcting translation and rotation simultaneously.

If the bone is rapidly consolidating, perform the rotational correction, since rotation is possible with significantly consolidated regenerate bone. Correction of translation is difficult in the presence of advanced consolidation. Angulation is feasible even later than rotation in the face of advanced consolidation. Therefore, the order of deformity correction may need to be altered if the bone segments show evidence of premature or advanced consolidation. In these cases, the surgeon may want to correct translation first, derotate next, and finally correct the angulation.

**RATE OF CORRECTION**

The accepted average rate of distraction for osteogenesis and soft-tissue neohistogenesis is 1 mm/day in 0.25 mm intervals (12.22). In limb lengthening, all the distraction rods can be lengthened at this rate to create a separation of the bone fragments of 1 mm/day. In angular correction, a calculation must be made to obtain a rate of distraction of 1 mm/day of the osteotomy site. We use the geometric rule of similar triangles (Fig. 32.68), which allows us to calculate the rate of distraction of the threaded rods that will produce a 1 mm/day distraction rate at the level of the bone (23). As the lengthening proceeds, the rule of similar triangles must be recalculated because the distraction rod approaches the concave aspect of the bone. For small deformities this is inconsequential, but with large deformities it is significant.

**Figure 32.68.** Rule of similar triangles. The rate of distraction of the distraction rod D that will produce 1 mm of opening wedge at the concave cortex of the tibia T is calculated based on similar triangles. In the example shown, the ratio is 4:1. Therefore, it takes 4 mm of distraction at the distraction rod to produce 1 mm of opening wedge of the tibia. In contrast, the fibula lies halfway between the distraction rod and the hinge. Therefore, at 4 mm/day distraction, the fibula will lengthen 2 mm/day. Because the peroneal nerve is at the level of the fibula, it may be preferable to open the wedge relative to a 1 mm rate of the fibula rather than the tibia.
The deformity correction actually follows concentric circles (rather than triangles) that radiate around the hinge point. The calculation of the length of arc followed by the concentric circle at the radius $R$ from the hinge is an approximation of the length of time needed to correct the deformity (Fig. 32.69) (10).

**Figure 32.69.** The rule of concentric circles. Because the deformity correction is occurring around a hinge, the true pattern of correction follows the path of an arc of radius $r$ where $r$ is the width of the bone at the level of the osteotomy. Because the rate of correction is set to 1 mm/day at the concave cortex of the tibia, the length of the arc across the concave cortex is equal to the number of days it will take to correct the angular deformity. Arc length can be calculated as the number of degrees subtended by the arc divided by 360 times the circumference of the circle ($2\pi r$). For a deformity of magnitude $a$, the number of days to achieve correction of deformity is $2\pi ra/360$.

The bone is not always the tissue that determines the rate of lengthening. For example, in a contracture of the knee, correction may be adjusted so that the sciatic nerve is distracted at a maximum of 1 mm/day (Fig. 32.70). The calculation of the length $R$ is made from the center of the hinge to the sciatic nerve. Similarly, in valgus corrections of the tibia, the peroneal nerve may be the structure determining the rate of distraction.

**Figure 32.70.** Reciprocal rule of triangles. It is sometimes necessary to distract on one side of a deformity and compress on the other side. For example, in this knee contracture, the rate of distraction of the concave distraction rod is calculated by the rule of similar triangles. The rate of compression of the convex rod is a factor of $r^3$ to $r^2$, the rate of the distraction rod. In the example shown, the rate of distraction or compression is related to stretching of the most important tissue, which in this case is the sciatic nerve. The sciatic nerve is located at a distance of $r_1$ from the center of rotation. The length $r_1$ is used in the calculation of similar triangles.

Sometimes it is important to calculate not only the rate of distraction but also the rate of compression on the bone's opposite side. This can be done by the reciprocal rule of triangles (Fig. 32.71). In most cases, distracting one side at the rate of similar triangles and allowing the apparatus to self-adjust on the compression side avoids any errors of rate adjustment between the two sides.

**Figure 32.71.** Alternate method for calculating the treatment time for angular correction. A quick and simple method for calculating the total number of days of distraction until the rings become parallel is to subtract the length of the distraction rod between its connection point on the ring from the length of the hinge rods. A: When the hinge lies on the ring, the space between the rings is used as the length $d_1$. B: When the hinge lies between the rings, the lengths of the limb above and below the hinge are added ($d_1 + d_2$) and then $d_2$ is subtracted from the sum of the other two. The difference $d_4$ is then divided by the rate of distraction of rod $d_3$ to calculate the total treatment time.

Another method to calculate the time required for deformity correction is to measure the distance between the rings at the level of the hinge and the distance between the rings at the level of the distraction rod. The distance between rings at the hinge will change little before and after deformity correction if no distraction is carried out on the hinge rods. The difference between the hinge rod width and the distraction rod width divided by the rate of correction is an accurate approximation of the time needed for correction (Fig. 32.71). At the end of correction, the rings should be parallel if the apparatus was properly applied. Therefore, the difference between the distraction rod width and the hinged rod width will eventually be zero.

The rate of correction is also important for the push construct (Fig. 32.72). In the push construct, the apex of the deformity is being translated while the ends of the deformity are distracted.
Correction of a pure translational deformity should be done at a rate of 0.5–1.0 mm/day. When translation is done through a lengthy distraction gap, 1 mm/day is used; 0.5 mm/day is used when translation is done through a narrow distraction gap or through an undistracted osteotomy.

The rate of correction for a rotational deformity is about 1 mm/day at the surface of the bone. The number of degrees of rotation to keep the surface rotation rate to 1 mm/day depends on the diameter of the bone: 12° for a 1 cm diameter bone, 6° for a 2 cm diameter bone, 4° for a 3 cm diameter bone, and 3° for a 4 cm diameter bone. The rate should be adjusted for small and large bones.

The rate of rotational correction using the gradual technique depends on the ring size. The number of degrees between adjacent holes is equal to 360° divided by the total number of holes. [The count should include the solid portion of the rings adjacent to the flare (four per ring, two per half-ring).] Dividing the number of millimeters per hole by the number of degrees per hole gives the number of millimeters per degree of arc. Multiply this by the number of degrees permissible for different-diameter bones to get the rate of correction. Divide this number by three or four times per day to split the rate into a dosed rhythm of correction. In most cases, this works out to be 1 mm three to five times per day.

It is important not to exceed these guidelines except when above-average bone formation is seen. These guidelines serve to optimize the new bone formation.

C. The Technique of Circular External Fixation

Stuart A. Green

The initial experience in both Europe and North America has confirmed Ilizarov’s contention that small details of frame application can make a major difference in the clinical outcome of fractures treated by circular external fixation (1,2,8,10,11 and 12). This section reviews some of the technical details of applying a circular external fixator, using Ilizarov’s technique and modifications of it. Modern circular external fixation techniques utilize both wires and pins at multiple levels for optimum fixation of osseous fragments.

WIRE TECHNIQUE

When smooth wires are used to secure a bone fragment, a frame can slide back and forth along a limb unless two or more wires are used at each level of fixation. For maximum stability, the two wires should cross each other at a right angle. Unfortunately, anatomic constraints (neurovascular structures, muscles, and tendons) limit a surgeon’s ability to insert wires crossing at 90° within a bone at most locations. For this reason, transfixion wires usually end up crossing each other at a more acute angle, diminishing fixator stability. Therefore, to enhance fixation, a surgeon must often use more than two wires at each level or alternatively must insert additional wires oblique to, or away from, the ring’s plane.

To further improve stability, wire external fixation systems use wires with beads (“olive wires”) that abut the bone to prevent the bone from sliding along the wire, at least in the direction of the bead (Fig. 32.73). Olive wires can also be used to pull bone segments and to reduce fractures and for other applications.

Figure 32.73. Beaded wires. Original design (A) and modified design (B).

MUSCLE POSITIONING

To help maximize the functional use of the joints while a limb is in external fixation:

- Avoid synovial transfixion when possible.
- Do not impale tendons.
- Penetrate muscles at their maximum functional length.

This last rule, critical for a successful long-term application of an external fixator, means that the position of a nearby joint must change as the wire passes through the flexor and extensor muscle groups. For example, when inserting a wire from anterolateral to posteromedial in the distal femoral metaphysis, flex the knee to 90° before inserting the wire into the quadriceps, and push the wire straight down to the femoral cortex (Fig. 32.74) (13).

Figure 32.74. Flex the adjacent joint when inserting wires into the extensor surface.

- Drive the wire through the bone with a power drill. As soon as the wire emerges through the far cortex, stop drilling, extend the knee, and hammer the wire through the opposite side of the limb with the hamstrings at maximum stretch. To drive a wire through soft tissue with a mallet, either tap the wire’s end or grasp...
the wire with pliers and strike the pliers with a mallet (Fig. 32.75).

**Figure 32.75.** Tap the wire through the soft tissues on the limb's far side with a pliers and mallet.

- When inserting a wire into the lower leg, plantar-flex the foot when transfixing the anterior compartment, invert the foot when inserting wires into the peroneal muscles, and dorsiflex the foot during triceps surae impalement (Figs. 32.76, 32.77).

**SKIN CONSIDERATIONS**

The preceding steps describe the optimum placement of wires through transfixed muscle; the position of the skin is another matter. Flexing the knee during femoral wire insertion pulls the lower anterior thigh skin distally, while the posterior skin slides a bit proximally. Transfixion of anterior thigh skin during flexion (the optimum position for quadriceps impalement) might cause a limitation of knee extension, impeding ambulation and perhaps leading to a knee flexion contracture. For this reason, before wire insertion, the skin must be shifted in a direction appropriate to adjacent joint motion. In determining which way to move the skin before inserting a wire, consider the following:

- When lengthening a limb, some redundant or loose skin and subcutaneous tissue should overlap the corticotomy site, where stretching will be greatest. Thus, when inserting supracondylar wires into the femur for lengthening through a distal corticotomy, pull the skin and subcutaneous tissues proximally during wire penetration, and at the same time flex and extend the knee to shift the muscles as previously described (Fig. 32.76). Likewise, displace the skin and subcutaneous tissues distally when applying the ring proximal to the proposed osteotomy site.

**Figure 32.76.** Pull the skin proximally for lengthening before wire insertion.

- When correcting a deformity by an opening wedge corticotomy, the skin and soft tissues should be loose, if possible, on the deformity's concave side. In the case of a tibia varus correction, for example, shift the medial subcutaneous tissues downward during proximal ring application and upward while the distal ring is being applied.
- Whenever possible, select wire placement locations that normally have limited skin movement during flexion or extension of an adjacent joint, usually along the medial and lateral lines of a limb.

Proper wire insertion technique is one of the keys to successful circular external skeletal fixation. When inserting a wire, avoid necrosis of tissue caused either by “wrapping up” around the wire's tip or by thermal injury caused by heat build-up during drilling.

**DRILLING**

- Although transfixion wires are smooth, they have bayonet tips that can cause damage while spinning within soft tissues. For this reason, when inserting a wire, push it straight down through the soft tissues to the bone (Fig. 32.77). Begin drilling when the wire's tip is at the bone's surface.

**Figure 32.77.** Hold the wire with a wet gauze to stabilize it during insertion.

- Stop drilling intermittently to prevent heat build-up. Cool the wire with irrigating solution during drilling, especially when penetrating dense cortical bone. As soon as the wire emerges from the bone's opposite side, stop drilling, and drive the wire through the limb's soft tissues with a mallet and pliers (Fig. 32.78A). If a wire emerges with blackened bone on its tip, then the wire has burnt the bone; remove the wire, cool it, and reinsert it elsewhere. Do not use a burnt bone hole for external skeletal fixation, as the bone around the hole has no resistance to invading microbes.

When using a power drill to insert a transfixion wire, the wire's flexibility may cause the wire to bend, reducing the accuracy of wire placement. While it seems appropriate to “chuck up” the wire closer to its tip, such a maneuver may nick the wire, leading to early breakage if the nick is located anywhere between the fixation bolts. Instead, grasp the wire with a 2×2 gauze pad soaked in antibiotic solution close to its blunt end and stabilize the spinning wire.

**SKIN TENSION**

- After inserting a wire, but before attaching it to a frame, check the wire–skin interface for evidence of tension while the limb is in its functional position—the knee extended, the ankle at neutral, and so forth. Skin tension creates a ridge of flesh on one side of a wire (Fig. 32.78A). To eliminate this tension on the side of a wire tip, withdraw the wire tip slowly (with the pliers-and-mallet technique) until the point drops below the skin surface (Fig. 32.78B). Shift the skin to a more neutral location and advance the wire until it penetrates the skin in an improved position (Fig. 32.78C).
Dealing with skin tension. **A:** Tension at a wire site. **B:** Withdraw the wire and allow the skin to shift. **C:** Drive the wire through the skin in a new position.

If skin tension exists on the insertion side of a wire (Fig. 32.79A), snap off the wire’s blunt end obliquely to create a point (Fig. 32.79B) and advance the wire to below the skin surface by the pliers-and-mallet method on the limb’s far side (Fig. 32.79C). Adjust the skin with the point below the skin (Fig. 32.79D). Tap the wire back through the skin after a skin-position adjustment (Fig. 32.79E).

Occasionally, another technique is needed to minimize wire–skin interface tension: modifying fixation after an acute deformity correction. For example, when a fixator is applied to manage a congenital coxa vara, part of the correction can be done immediately after subtrochanteric osteotomy. The skin, however, may be pulled distally on the transfixion wires as a valgus subtrochanteric angle is established. If this occurs, shift the skin upward after the correction and insert additional wires or pins before removing the ones causing the skin tension. Release any residual skin tension with a scalpel.

**FIXATION TO A RING**

Tensioning a wire when securing it to a ring will straighten any bend or curve in the wire. Soft tissues on either side of a bent wire may suddenly be stretched during wire tensioning, causing intense postoperative pain. Thereafter, the stretched soft tissues can become necrotic, providing nutrition for microorganisms that enter the limb through the wire holes. For this reason, do not bend a wire toward the frame during fixation; instead, use washers, posts, and other hardware to build up to and capture the wire where it lies (Fig. 32.80).

With the Ilizarov apparatus, a wire passing over the center of a ring’s hole is affixed with a cannulated fixation bolt (Fig. 32.81A). A wire passing between two holes along the surface of a ring is secured with a grooved fixation bolt (Fig. 32.81B). Other ring fixators on the market use similar techniques for preventing wire deflection during tensioning.

**WIRE TENSIONING**

The overall stability of the bone fragments within the configuration depends to a considerable extent on the amount of tension on the wires. Tensioning a wire axially stiffens it mechanically; with enough tension, a transfixion wire behaves like a stiff pin. Moreover, a deflection load applied to a tensioned wire (by weight bearing, for
example) increases wire tension even further, enhancing wire stiffness and resistance to additional deflection. When the deflection load is released, the wire usually springs back to its original position, although some permanent plastic deformation might occur. This mechanical behavior of tension wires stimulates osteogenesis in a bone-defect site, according to Ilizarov.

- Tension a wire with either a spring-loaded wire tensioner or by the fixation bolt method (winding the wire around its own fixation bolt). When using these methods, be sure to fix the wire securely to the ring on the limb’s opposite side. A smooth wire can be tensioned on either side of the limb, but an olive wire cannot. If the olive wire is meant to serve as a stabilizing element in the assembly, fasten the wire to the ring on the olive side, with the olive firmly abutting the bone. If the olive is to pull a bone fragment into position before fixation, do not secure the olive side of the wire until the maneuver is completed.
- A spring-loaded dynametric wire tensioner (Fig. 32.8) is simple to use; both the barrel-shaped and pliers-shaped models are calibrated. Tension the wire to between 100 and 130 kg on a full ring, and to about 90 kg when the wire is spanning an open ring or on a pair of posts elevated from a ring’s plane.

Figure 32.82. Spring-loaded wire tensioner.

- With the fixation bolt method (Fig. 32.83), the wire is twisted around its own fixation bolt, tensioning it. The maneuver requires two hands, one for the nut and the other for the bolt. Have an assistant hold the ring stable.

Figure 32.83. Manual wire tensioning. A: Initial position. B: Final position.

- After fixing the wire to the ring on the opposite side, tighten the nut until the wire is loosely gripped. Next, rotate the fixation bolt and its nut together, twisting the wire 90° around its own fixation bolt. Because the wire displaces slightly with this method, try to displace the wire slightly during initial fixation so that it will be straightforward through the tissues when tensioning is complete.

ANATOMIC CONSIDERATIONS

Transfixion wires endanger neurovascular structures if inserted without regard to cross-sectional anatomy. In 1981 I published a “zone system” atlas for pin placement to help ensure safe application of Hoffman pins, and I now use this atlas for inserting transfixion wires (3). Other atlases are also available for this same purpose.

FEMUR

In the Classic Ilizarov Method, The Proximal Femur Is Secured With Anteroposterior Wires, And These Wires Are Attached To A Large, Thick, Curved Plate Surrounding The Patient's hip and pelvic area (14). The patient must use a special bed that incorporates a cut-out mattress to allow the posterior portion of the frame to be suspended while the patient is flat on her back.

When inserting wires into the femur, there are several basic problems. First, the bulk of the soft tissues causes difficulties, especially posteriorly, in the buttock. Second, the neurovascular bundles—especially the superficial femoral artery—can be damaged during wire insertion. The vessel is medial to the femur in its proximal third and posterior to the bone in the thigh’s distal third. A safe practice is to mark the location of the vessel after palpating the femoral pulse. Third, the sciatic nerve prevents direct AP wire insertion. The proximal wires must cross at a fairly narrow angle in the upper thigh.

- When inserting wires into the proximal femur, mark the skin with the hip ring arch in an overcorrected (compensated) position, higher anteriorly and laterally.
- During femoral lengthening, the femur tends to angulate into varus with the apex of the deformity anterolateral. To correct this problem, the arch must be applied in a position that anticipates such a deformity. As lengthening proceeds, the arch is gradually rotated downward, becoming progressively more perpendicular to the bone’s mechanical axis during elongation.
- Insert the first olive wire from anteromedial to posterolateral two fingerbreadths lateral to the femoral artery. Insert a second olive wire from back to front, 15° medial to the first wire. The posterior olive on this wire prevents the entire frame from displacing anteriorly while the patient lies in bed. A third wire is often inserted between the first two. Push all three of the proximal femoral wires through the soft tissues down to bone without drilling, and tap the wires through the soft tissues with pliers and mallet once the tip emerges through the opposite cortex.
- To stabilize a hip during femoral lengthening—especially a hip that might sublux or dislocate—it may be necessary to insert wires into the supraacetabular or iliac portion of the pelvis. Leave these wires in place (not allowing movement) until lengthening is complete. Thereafter, the wires are removed and hip motion is commenced.
- When an unstable deformity is in the middle third of the femur, a four-ring configuration may be necessary, with two rings above the deformity and two rings below it.
- For the distal femur, insert wires into either the transverse or the coronal plane. When selecting the transverse plane, cross the wires at an angle of no less than 60°. Likewise, insert olives from both directions for enhanced stability. In many situations, the distal femur can be stabilized with wires in the coronal plane; such wires permit greater freedom of knee motion than do wires that impale the hamstrings and the quadriceps.
- Whether the first pair of crossing wires is transverse or coronal, use at least one more drop wire to complete a distal femoral mounting. To improve distal femoral fixation, insert this wire some distance away from the first two, usually toward the level of the condyle or fracture.

TIBIA

With the classic Ilizarov mounting for tibial lengthening, one ring with two crossed wires and a supplementary drop wire is used proximally, and a similar combination is used distally (15). The stretched soft tissues help stabilize the limb. More complex problems, such as a mobile synovial pseudarthrosis of the mid tibia, require far more stable configurations using three, four, or even more rings. Likewise, a deformity correction at two levels requires at least three rings. The proximal ring for a tibial mounting usually incorporates a wire that passes through the fibular head and into the tibia to prevent subluxation of the proximal tibia–fibula joint during lengthening or deformity correction. A second wire through the tibia crosses the fibula wire, paralleling the medial face of the tibia. A third transverse drop wire is inserted across the tibia into the location used for skeletal traction. Additional wires are inserted as needed for greater stability. Distally, the tibia–fibula joint during lengthening or deformity correction. A second wire through the tibia crosses the fibula wire, paralleling the medial face of the tibia. A third transverse drop wire is inserted across the tibia into the location used for skeletal traction. Additional wires are inserted as needed for greater stability. Distally, the tibia–fibula joint during lengthening or deformity correction. A second wire through the tibia crosses the fibula wire, paralleling the medial face of the tibia. A third transverse drop wire is inserted across the tibia into the location used for skeletal traction. Additional wires are inserted as needed for greater stability. Distally, the tibia–fibula joint during lengthening or deformity correction. A second wire through the tibia crosses the fibula wire, paralleling the medial face of the tibia. Many modern configurations use half-pins for diaphyseal bone fixation. In this way, muscle impalement with transfixion pins or wires is avoided.

Forearm. Consult a cross-sectional anatomy atlas at the time of wire insertion.

The configuration for a forearm mounting depends on the pathology. In some cases, the two forearm bones are secured together with wires transfixing both the radius and the ulna. In other mountings, each bone has its own separate fixator, with one frame rotating within the other. Transfixion wires are particularly dangerous in the calcaneus to ensure good bone stock plantarward of the wires. When correcting a cavocalcaneal deformity, insert the wires lower in the bone to ensure a maximum stock of osseous tissues cephalad to the wires.

The insertion of forefoot wires also depends on the nature of the problem. To overcome forefoot abduction, keep the olive on the medial side of the foot; to correct forefoot adduction, place an olive on the foot's outer edge.

In general, insert metatarsal wires through the first and fifth metatarsals, passing under the necks of the second, third, and fourth. In certain circumstances, it may be necessary to insert additional wires into other metatarsal bones, especially when correcting a severe supination deformity. Pass these wires from the plantar surface of the foot out through the neck of the third or fourth metatarsal, exiting in the dorsolateral surface of the foot.

Many foot mountings use a three-point-bending principle to correct an adductovarus foot. The first and third points of force application (olives) are on the medial side of the calcaneus and first metatarsal, respectively. Place the counterpressure olive wire on the lateral side of the cuboid (or talar neck or other midfoot bone).

**HUMERUS**

In the humerus, the proximal and distal ends of the bone can be secured with three wires each. To insert wires through the proximal humerus, abduct the arm 90° and externally rotate it 20°. Drive olive wires from both the anterior and posterior directions. The third wire is a drop wire off the plane of the ring.

In the distal humerus, insert olive wires crossing in the frontal plane, one from the lateral supracondylar ridge and one from the medial supracondylar ridge (Fig. 32.84). A drop wire (perpendicular to the bone's axis) completes the configuration. Extend the elbow when inserting wires anteriorly and flex the elbow when inserting wires in the posterior side of the limb. When a humeral mounting requires three levels of fixation, wires crossing in the mid-humeral area should be inserted with regard for the location of the neurovascular bundles, especially the radial nerve.

![Figure 32.84. Distal humeral fixation with wires crossing in the coronal plane.](image)

In the distal humerus, when the elbow is flexed, the anterior lower-arm skin moves proximally while the posterior skin moves distally; with elbow extension, these tissues move in the opposite directions. Between the flexor and extensor surfaces, however, a fairly stable tissue plane exists, around which the upward-downward movement of the anterior and posterior tissues revolves. This plane of limited skin movement lies along the medial and lateral supracondylar ridges of the humerus, an ideal location for transfixion wire placement. Unfortunately, the distal humerus flattens and widens at the elbow. Two supracondylar transfixion wires (in the same transverse plane) will not have enough of an angle between them for stable fixation; it is better to cross the wires in the frontal plane.

- Insert the wires into both epicondyles, exiting the humerus proximally at the medial and lateral supracondylar ridges. Take care not to transfix either the ulnar or radial nerves. A third wire straight across from one supracondylar ridge to the other completes the mounting.
- After all wires are in place, flex and extend the elbow: there should be no block in either direction. A mechanical block to full extension means that one or more wires has entered the olecranon fossa of the distal humerus; such a wire must be repositioned.

**FOREARM**

The configuration for a forearm mounting depends on the pathology. In some cases, the two forearm bones are secured together with wires transfixing both the radius and the ulna. In other mountings, each bone has its own separate fixator, with one frame rotating within the other. Transfixion wires are particularly dangerous in the forearm. Consult a cross-sectional anatomy atlas at the time of wire insertion.

**Pin Technique—Operative Technique**

Many modern configurations use half-pins for diaphyseal bone fixation. In this way, muscle impalement with transfixion pins or wires is avoided.

- Avoid creating a cantilever system with pins perpendicular to the bone. Instead, our half-pins are splayed out in different directions and different planes, with some inserted obliquely into each bone segment (Fig. 32.85).
Furthermore, try to mount the half-pins as circumferentially around the bone as possible, attempting to gain purchase where the osseous surface is located subcutaneously (Fig. 32.86). The tibia and ulna are particularly suited to this type of mounting, because these bones are subcutaneous through their length (5).

The femur and humerus have subcutaneous surfaces proximally and distally. For juxtaarticular mountings, continue to use wires. Three or four wires can be easily inserted into fragments that are unsuitable for half- or full-threaded pins.

Titanium pins, although not as stiff as steel pins, seem particularly well tolerated by both bone and soft tissues. If a titanium pin site does become septic, we rarely observe the extensive inflammatory reaction (involving adjacent portions of the limb) that we have noted with steel implants. Occasionally, a threaded titanium pin becomes strongly bonded to bone, suggesting bone-to-metal bonding similar to the type of fixation that may occur with titanium total joint implants.

Titanium is more flexible than steel; hence, when correcting deformities with titanium half-pin configurations, more pin bending than one would expect with stainless-steel half-pins is noted. Therefore, use 5 mm titanium pins for tibial and humeral mountings and 6 mm titanium pins in the femur. For substantial lengthenings, steel pins have proven superior because of the added stiffness.

There are several reasons for using a circular configuration with the half-pins (4). First, whenever a rotational deformity requires gradual correction, a circular external fixator is the only apparatus that allows counterrotation of the configuration's sections. Second, a circular frame permits application of hinges and distractors anywhere around the circumference of a bone (Fig. 32.87). In this way, a hinge axis can be placed wherever needed to produce the desired bone-fragment angulation. Third, a circular fixator gives the option of using wires—especially olive wires—when needed for interfragmentary compression, reduction of fractures, or juxtaarticular fragment fixation.

PIN INSERTION

Since fixators are in place for many months, meticulous pin technique is needed to ensure long-term fixation. When inserting half-pins, take the following measures, which should be used for routine external skeletal fixation as well (3,4 and 5):

After making the skin incision, use a mosquito clamp to spread the tissues down to the bone (Fig. 32.88).

Next, use a joker or narrow periosteal elevator to elevate the periosteum from the bone at the pin site (Fig. 32.89). This measure reduces periosteal damage caused by the spinning drill bit.
Use a drill sleeve and trocar with tangs (or points) that can be driven into the bone, ensuring both stability of the sleeve and less interposed soft tissues during drilling (Fig. 32.90).

Figure 32.90. Sleeve and trocar system for pin insertion.

Irrigate the drill bit with a cold irrigating solution during drilling.
Use a stop-and-start drilling motion to prevent the drill bit tip from overheating (7).
When penetrating dense cortical bone, periodically remove the drill bit from the sleeve and wipe out bone chaff from the flutes—another measure to prevent overheating.
Use a depth gauge and insert a properly sized half-pin with a hand-held driver.

The use of half-pins in place of wires offers an added dimension to Ilizarov’s methods (Fig. 32.91). Since we have been using half-pins for our mountings, problems with physical therapy (inhibition of muscle and joint action by wires) and pin sepsis have greatly improved (Fig. 32.92, Fig. 32.93) (6).

D. Tension-Wire External Fixators for Acute Trauma

J. Charles Taylor

Although others have used highly tensioned small-diameter wires with external frames, G. A. Ilizarov in Kurgan, Siberia, was foremost in the development of techniques to treat a variety of orthopaedic problems, including fractures, nonunions, and deformities, using an innovative modular circular external fixator with tensioned wires. This section discusses the use of the Ilizarov method in the management of acute fractures and their complications.

BIOMECHANICS

Many changes in external fixation design and use occurred in the 1980s, foremost of which is the shift toward half-pin frames and maintenance of the frame in place until union occurs in unstable fractures. The benefits of axial micromotion for fracture healing and bone remodeling have been well documented, leading to the techniques of dynamization and staged dismantling of half-pin fixators to improve fracture healing (9,17).

The Ilizarov frame is about 25% as stiff as uniplaner and biplaner fixators in the axial direction, while maintaining approximately equal stiffness to bending and torsional loads (4,13). These mechanical characteristics allow the beneficial effects of axial micromotion without the deleterious effects of torsional and translational shear.

Wire diameter and tension are the most important factors affecting frame stability (13). Other factors influencing frame stiffness are size, number, and location of the rings; divergence of the transfixing wires; use of olive wires; and distraction or compressive loads at the fracture or nonunion site (1,4,8,19). Intrinsic biomechanical factors unique to each patient include weight, cortical continuity, and integrity of the soft tissues.

Awareness of three axes–three rotations geometric analysis of fracture deformities has recently served as the basis for a new generation of external skeletal fixators that, in their most basic form, consist of two rings connected to each other by six struts. The struts can be manually lengthened or shortened in accordance with a pattern determined by a computer program that calculates the displacement of fragments secured (with pins and wires) to the rings. The coordinate information is determined by precise measurements from properly oriented x-ray views of the limb. The Taylor Spatial Frame is the first of such devices (14).

FRACTURE MANAGEMENT

The use of a circular external fixator for acute trauma of the upper and lower extremities is common in Russia and parts of Western Europe, and increasingly in North America (7). Metaphyseal fractures may have extension into the articular and diaphyseal regions, greatly increasing the complexity of their management. To define better these complex injuries and to clarify treatment options, a new classification scheme (Fig. 32.94) is offered. The main metaphyseal injury is characterized as stable (S), unstable (U), or with diaphyseal extension (D). The three subgroups are 0, for absence of intraarticular extension; 1, for nondisplaced (2 mm or less) intraarticular extension; and 2, for displaced (more than 2 mm) intraarticular extension.

Figure 32.94. SUD classification of metaphyseal fractures accounting for increasing degrees of instability and intraarticular extension.

In most cases, the metaphyseal injury precludes stabilization by intramedullary fixation. Treatment options are limited to closed methods, pin external fixation, tensioned-wire external fixation, and open reduction and internal fixation.

With progression from type S to type D, treatment shifts toward external fixation and away from open reduction. On the other hand, with progression from subgroup 0 to subgroup 2, open reduction becomes indicated. Acceptable reduction of the intraarticular portion of the fracture complex must be obtained. If reduction of the intraarticular portion of the fracture to less than 2 mm is not obtained with traction, recommend open reduction and internal fixation. The diaphyseal extension in type D fractures makes open stabilization an extensive procedure. For type D-2 fractures, perform an open reduction with limited internal fixation of the articular segments with cancellous screws, and then neutralize the metaphyseal and diaphyseal regions with external fixation. This method cannot make up for poor articular reduction, however.

The presence of a Gustilo type I or II open wound does not alter basic treatment guidelines. However, a type III wound, especially IIIB, favors stabilization with an external fixator. Less exposure is needed if performing a limited open reduction and external fixation, decreasing the amount of soft-tissue dissection, and limiting local vascular injury.

Stabilization of short periarticular fragments is possible with a circular external fixator. Because the wires are tensioned and supported circumferentially, a “trampoline” of fixation is provided (Fig. 32.95). Spanning the knee or ankle for 4 to 6 weeks is necessary on occasion, especially with elevation of the joint surface and bone grafting. Fixation is rigid enough to allow early motion and partial weight bearing.
An open fracture with extensive bone loss is another indication for the Ilizarov method in acute trauma. The unstable fracture, soft-tissue defect, and bone loss are all managed successfully with one device and method. The first step in the management of these complex fractures is to determine if the limb is salvageable. A dysvascular, insensitive extremity does not function better than a prosthetic limb. Other relative indications for circular fixation in acute trauma are open fractures, unstable closed fractures, and fractures with compartment syndrome.

Time-to-union is probably related to the quality of reduction and restoration of normal alignment (9). Accurate apposition and alignment at the time of initial application of a simpler trauma frame is easier than the use of articulated frames with subsequent reduction. Most fractures can be treated to union in the external fixator, but those of lower energy and more stability can be converted to functional bracing as healing of soft tissue allows.

Technique for Fracture Stabilization

The key to success with any circular fixator is preoperative planning. Assembling frames preoperatively greatly reduces intraoperative time.

- Obtain full-length anteroposterior (AP) and lateral x-ray films of the limb, including the joint above and that below. These full-length radiographs are used to select rods of proper length and approximate ring location.
- Determine ring size on the uninjured extremity. Two fingerbreadths (2–3 cm) clearance is necessary for tibial mountings (Fig. 32.96), and two or three fingerbreadths (about 3 to 6 cm) clearance is necessary for the femur (Fig. 32.97). Rings that are too large cannot support the transfixing wires adequately, and they impair osteogenesis (6).

- Because of the anatomic constraints of safe wire placement, 90° divergence is usually unobtainable (5,6,10). A second level of fixation in each segment improves the frames' stiffness to AP bending and torsion. Use two rings on large fragments, and a ring and drop post for smaller fragments.

Lower Extremity

Midfemur is the most proximal level to accommodate a complete ring comfortably.

- Accomplish fixation to the proximal femur by half-pins attached to femoral arch bars. Connect these arch bars to the remainder of the construct by rods and offset brackets. Make the most proximal arch bar a short arc to prevent interference with the abdomen when the hip is flexed.
- The entire lower extremity can be treated with a simple cylindrical frame from mid femur to the ankle, as shown in Figure 32.98. The thigh dictates ring size, which is usually one or two sizes larger than that normally used for the tibia. Make the frame parallel to the tibia on AP and lateral views. Center the femur at the level of the patella and align it in anatomic valgus with respect to the frame.

- When the frame is confined to the femur, use a 5/8 ring as the distal femoral ring to allow full flexion at the knee (Fig. 32.99). This 5/8 ring may be attached to a...
complete ring with heavy-weight sockets and may be made more resistant to deformity when tensioned wires are applied to the open section ring. The most proximal ring in a tibial mounting can be a $\frac{5}{8}$ ring attached to a complete ring, allowing maximal flexion and providing two levels of fixation (Fig. 32.100).

**Figure 32.99.** Femoral mounting using a $\frac{5}{8}$ ring to allow full knee flexion.

**Figure 32.100.** Tibial mounting using a $\frac{5}{8}$ ring to allow full knee flexion.

- Include the foot in the frame for open fractures to prevent contractures and soft-tissue motion at the fracture site (2). Pilon fractures may require foot fixation for fracture stability. Remove the foot frame after soft-tissue healing, unless it is necessary for fracture stability. With injury to the peroneal nerve or anterior and lateral compartments, consider temporary incorporation of the foot to prevent equinus contracture. A stable foot mounting consists of two half-rings joined by plates with threaded extremities (Fig. 32.101). These special plates prevent the foot frame from distorting when the wires are tensioned. Usually the same size of half-rings are used for the tibial frame and for the foot frame.

**Figure 32.101.** Foot mounting using two half-rings coupled by two plates with threaded extremities.

- Select the frame size to allow 2 to 3 cm of clearance between the inner edges of rings and skin (11). Swelling and dependent edema create late changes in extremity dimensions and must be anticipated. More clearance is needed posteriorly for the lower extremity, and the femur requires more room for swelling than the leg. Figure 32.96 and Figure 32.97 show typical clearances for tibial and femoral frames.

**Upper Extremity**

- The Omega ring or ring with curved extremities is useful for the proximal humeral mountings, decreasing soft-tissue irritation and providing relatively more holes for the critical low-divergence mountings of the proximal humerus (Fig. 32.102). The safe angle between pins or wires is relatively small for short fragments, requiring two wires for fixation on the ring and a wire below or above the others. At the level of the distal humerus, the $\frac{5}{8}$ ring allows full elbow flexion (Fig. 32.103).

**Figure 32.102.** Aerial view of the shoulder, demonstrating an omega ring for proximal humeral fixation.

**Figure 32.103.** Lateral view of the elbow with a $\frac{5}{8}$ ring at the level of the epicondyles to allow full elbow flexion.
On a forearm mounting, a \( \frac{3}{4} \) ring may be used on the dorsum of the proximal forearm to allow full elbow flexion. Provide fixation of the distal humerus by mediolateral wires in a short arc in the coronal plane, fixed to posts above and below the ring (Fig. 32.104). Fix the proximal humerus with anterior posterior wires in a small arc in the transverse plane.

**Figure 32.104.** Humeral mounting showing anteroposterior fixation of the proximal fragment and mediolateral fixation of the distal fragment. (Inset) Short arc of fixation achieved with drop posts above and below the ring.

**TECHNIQUE FOR TIBIAL FRACTURES**

- Position the patient supine on a fracture table with traction placed through an os calcis pin. Place the injured extremity in the 90°–90° intramedullary nailing position (Fig. 32.105) or straight traction in the heel-to-toe position.

**Figure 32.105.** Supine position for application of external fixation or tibial nailing.

- Elevate the buttocks support on the fracture table on the injured side, placing the extremity in neutral rotation with the patella pointing straight toward the ceiling (Fig. 32.106), allowing true AP and lateral orthogonal x-ray imaging.

**Figure 32.106.** A: Supine position on the fracture table. B: Use of buttock support to internally rotate proximal limb.

- Alternatively, place the patient on a radiolucent table extension using the external fixator for traction and reduction. Longitudinal traction reduces most fractures to within 10° or 15° of anatomic alignment.

The addition of hinges to the trauma frame, in our experience, has been unnecessary. Avoid excessive or prolonged traction to prevent neurologic or vascular injury.

- After prepping and draping the extremity, disconnect the ring connection bolts on one side of the preassembled frame and swing the frame open. Place the frame around the extremity and reassemble it, with adequate soft-tissue clearance and with coupling bolts aligned parallel to the crest of the tibia in AP and lateral planes (Fig. 32.107).

**Figure 32.107.** Reference position of Ilizarov frame parallel to crest on anteroposterior (AP) and lateral views, with connecting bolts superimposed on AP view.

- To use this frame to treat the fracture in Figure 32.108A, hold the frame in this position with proximal and distal transverse reference wires placed parallel to the knee and ankle (Fig. 32.108B).
Figure 32.108. A: Unreduced diaphyseal fracture. B: Proximal and distal coronal plane reference wires inserted parallel to the joint at the proximal and distal extent of proposed frame. C: Ilizarov trauma frame “clamshelled” around the leg. D: Reference wires tensioned with slight residual deformity. E: Residual deformity corrected with arched wire technique. Parts F through J: show a cross section demonstrating the arched wire technique of residual deformity correction. F: Unreduced fracture fragments. G: An olive wire is inserted into one fragment. H: Arch the olive wire the amount necessary to reduce the fragment on the lateral view, and attach it loosely to the ring with wire fixation bolts. I: Slowly tension the wire until the fragment is reduced on the AP view with the trailing nut subsequently tightened. J: Further tension the wire to achieve final correction of AP displacement, and then tighten the leading nut.

As the wires are secured to the frame and tension is applied (Fig. 32.108C), further correction of the fracture in the coronal plane is achieved (Fig. 32.108D).

An alternative method for these initial steps is to suspend the frame with ordinary suction tubing placed around the extremity and secured to the frame with towel clips. Eccentrically cant the proximal and distal rings until they are parallel to the knee and ankle joints. After secure fixation with at least two wires to the proximal and distal rings, bring these two rings back parallel to their counterparts in the center of the frame, further reducing the fracture.

Achieve final fracture reduction with arched olive wires or traction on half-pins (Fig. 32.108E). For final correction of the residual displacement in the coronal plane (Fig. 32.108F), place an olive wire in a transverse fashion if safe (Fig. 32.108G), apply tension without securing it tightly to the frame, and pull the fragment toward the tensioner.

Use image intensification to verify adequate reduction. To compensate for parallax curves on the image intensifier, place an olive wire longitudinally on the extremity as an alignment guide to confirm the reduction.

After adequate correction is obtained in this plane, secure the wire to the frame on the olive side. If further correction is needed in the sagittal plane, connect the olive wire in an arched fashion (Fig. 32.108H). As the wire is tensioned, final correction is achieved (Fig. 32.108I, Fig. 32.108J).

Eliminate any residual distraction (Fig. 32.108).

Figure 32.109. Place the fracture under compression if axially stable, to eliminate residual distraction.

In rare cases, two olive wires placed from opposite sides perpendicular to the fracture plane can reduce and compress the fracture (Fig. 32.110). This pattern of wire placement may not always be safe. In such a case, treat these fractures with lag screw fixation followed by external fixator placement (Fig. 32.111).

Figure 32.110. A: In an unusual case, a minimally displaced articular fracture is amenable to reduction and fixation with opposing olive wires. B: Opposing olive wire. C: Additional wires are necessary for stability.

Figure 32.111. A: A more universal technique of open reduction and limited internal fixation with a lag screw than that shown in Figure 32.110. B: The plane of fixation provided by subsequent wires. C: Divergence—and thus stability—are maximized within anatomic limits.

Use axial computed tomography (CT) scans in preoperative planning to help determine the more appropriate method.

We usually avoid interfragmentary screws or wires in the diaphyseal region, as interfragmentary fixation in the diaphysis region is counterproductive to the axial flexibility of the Ilizarov external fixator; ideally, this promotes secondary fracture healing. I avoid interfragmentary screws or wires in the diaphysis because I have experienced delayed unions and nonunions with their use.

Treat pilon fractures with significant shaft extension by first mounting the proximal tibia and foot in anatomic rotation, alignment, and apposition. Place a dummy ring just distal to the most distal ring fixing the proximal shaft fragment.

Maintain distraction to achieve as much reduction as ligamentotaxis provides (Fig. 32.112).
Figure 32.112. Place pilon fractures under gentle traction after fixation of the proximal tibia and the foot.

- Elevate depressed articular fragments and fill large subchondral voids with autogenous graft.
- Maintain interfragmentary reduction with wires, which are subsequently attached to the dummy ring after that ring is translated into position (Fig. 32.113). Tension the wires and relieve any excessive traction.

Figure 32.113. After reduction and interfragmentary fixation with Ilizarov wires, attach the wires to a ring and add tension.

- Protect pilon and plateau fractures requiring bone grafting for 4 to 6 weeks by constructs spanning the joint.

SUBACUTE FRACTURE MANAGEMENT

Reconstructive soft-tissue procedures are possible with circular tensioned wire fixators. Typical fracture frames are made up of four threaded rods linking four complete rings. Temporary removal of one rod allows 180° access to the leg for bone grafting delayed unions or for vascular access for free flaps (Fig. 32.114). Removal of the anterolateral rod allows access to the dorsalis pedis artery, and removal of the posteromedial rod allows access to the posterior tibialis artery.

Figure 32.114. A: Axial view of the limb showing 180° access to the anterolateral surface if a single anterolateral rod is removed for a rotation flap or free flap with the anterior tibial artery as donor. B: Axial view of limb showing 180° access to the posteromedial surface if a single posteromedial rod is removed for a rotation flap or free flap with the posterior tibial artery as donor.

In open fractures with bone loss, consider the circular external fixator for the primary treatment. Conventional treatment consists of debridement and delayed coverage with a rotation or free flap and possible internal or external fixation followed by autogenous bone grafting. Using a tensioned wire fixator, the wound undergoes the same serial debridement of all necrotic tissue (Fig. 32.115); if there is no exposed bone, exposed muscle can be covered with a split-thickness skin graft (Fig. 32.116). Later, the bone defect can be filled by performing a corticotomy and bone transport (Fig. 32.116). The tendency of soft tissue to move with the transported bone, and the normal tendency of split-thickness grafts to contract, fill in the soft-tissue and bone defects, eliminating the need for rotation or free flaps. If less than 2 cm of vascularized bone is exposed after debridement, consider further shortening of fragment ends to avoid the necessity for flap coverage. Then a simple skin graft can be used as described previously.

Figure 32.115. Open tibial fracture with devitalized bone, muscle, and skin.

Figure 32.116. A: Open fracture following debridement, with bone loss but no exposed bone. B: Split-thickness skin grafting of the soft-tissue defect and corticotomy in preparation for bone transport to obliterate the bone defect. C: Subsequent bone transport with regenerate bone filling the bone defect. D: Completion of transport and obliteration of bone defect.
If a significant amount of vascularized bone remains exposed after debridement, use a free or rotation flap (Fig. 32.117A). At the time of flap coverage, make a corticotomy, and prepare a fragment for transport into the bone defect (Fig. 32.117B, Fig. 32.117C). Although Ilizarov recommended a metaphyseal corticotomy for transport, diaphyseal corticotomy and transport of shorter fragments has also been successful.

**Figure 32.117.** A: Open tibial fracture following debridement, with exposed viable bone requiring a rotation or free flap. B: Bone transport through the flap with formation of regenerate bone. C: Completion of transport with obliteration of the bone defect.

**PITFALLS AND COMPLICATIONS**

With careful determination of safe zones by level of fixation, acute neurovascular injury with transfusion wires is rare. In the immediate postoperative period, an unusually painful wire should be suspected of passing through a larger nerve and should be removed. Late neurovascular injury is exceedingly rare unless bone transport is performed or there is gross motion between bone fragments. This usually occurs during a reconstruction rather than with simple immobilization of a fracture. Flexion contractures of the knee and ankle occur less frequently with fracture treatment than with lengthening and can be prevented by active exercises and weight bearing in the frame.

The management of pins and pin sites is discussed earlier in this chapter and in Chapter 11.

Frame modification involving loosening of tensioned wires is uncomfortable for patients. Anesthetics are usually required. Swelling and dependent edema must be anticipated with circumferential external fixators; anterior soft-tissue clearance need not be as great as posterior. The rings can be quite close to the anterior thigh on the initial femoral mounting because dependent edema distends posteriorly. Few patients can sleep in positions other than supine with a femoral frame. For a typical adult tibial application with a distance of 36 cm between proximal and distal rings, the frame shifts 2 cm if the frame is canted only 3°.

- Accurately position the frame before it is attached to bone with tensioned wires. Place proximal and distal reference wires at the most proximal and distal points of attachment of the frame using an image intensifier (12).
- Insert reference wires in the coronal plane parallel to the joint, and attach the frame to these wires, establishing sufficient soft-tissue clearance at each end. Insert subsequent wires between these two extremes, further constraining the bone frame construct.
- If skin impinges on the frame near the end of treatment, slip thin pieces of cardboard, with a slot for the wires, between the skin and the frame. This prevents pressure necrosis against the edge of the rings by increasing the area of contact (Fig. 32.118, Fig. 32.119). If skin impinges on the frame early in the treatment, frame modification is almost always necessary. If problems exist at several rings but only along a short arc segment of each ring, shift the frame toward the impingement by reattaching all wire fixation bolts in new holes away from the impingement. If the skin impinges on a single ring, modify that ring by introducing two short plates between the ends of the half-rings, creating an “ellipse” oriented with its major axis toward the impingement (Fig. 32.120). Alternatively, use a saw to remove a segment of a ring if it will not affect stability.

**Figure 32.118.** Soft-tissue impingement on an Ilizarov ring.

**Figure 32.119.** Pressure is decreased over the metal ring by using a thin cardboard shim as a temporizing measure late in treatment.
Salvage major problems of circumferential impingement at several levels by constructing a larger frame around the first frame. Position the rings of this larger frame at exactly the same levels. Straighten curled wire ends and attach wires to the outer frame at both ends. Loosen the wire fixation bolts on the smaller frame, and disassemble the smaller frame. Cannulated wire fixation bolts from the smaller frame may be taped against the new frame to prevent them from moving about. This modification can be performed without loosening wires or losing reduction.

E. Ilizarov-type Treatment of Nonunions, Malunions, and Posttraumatic Shortening

Stuart A. Green

“Restorative traumatology” is Ilizarov's name for the branch of orthopaedic surgery that deals with the treatment of trauma residuals. Indeed, Ilizarov's techniques for causing new bone formation within a widening distraction gap now offer patients the hope of having an injured limb restored to normal in ways never before thought possible (7, 9, 10, 11 and 12). Skeletal defects, for example, can be eliminated without the need for bone grafting. Many types of nonunions can be stimulated to unite by gradual distraction of the fragment ends. Malunions of all sorts can be corrected, and posttraumatic limb shortening can be overcome.

To accomplish these goals, the surgeon must have a clear idea of the nature of the pathologic process responsible for the patient's problem. For example, a nonunion of long bone may be atrophic, hypertrophic, or a true synovial pseudarthrosis; the treatment plan differs for each type of failed bone healing (6). A malunion in valgus or varus may also have a rotational component and malalignment of the mechanical axis as well. See Chapter 26 for more details.

The following sections describe the principles of treatment of nonunions, malunions, and posttraumatic shortening with circular fixation devices.

NONUNIONS

A stiff (hypertrophic) nonunion is usually accompanied by pain on motion of the nonunion and a feeling of resistance to manual deformation at the fracture site. Roentgenograms of a stiff nonunion reveal proliferation of callus growing out from the fragments on both sides of the fracture line.

A loose (atrophic) nonunion moves easily during manual examination of the fracture site. The patient often experiences little or no pain. On roentgenograms, the fracture site may show either the features associated with an atrophic nonunion (no evidence of callus formation) or the characteristics of a synovial pseudarthrosis (rounding-off and sclerosis of the bone ends).

Grouping atrophic nonunions and synovial pseudarthroses together into the same category may seem, at first, unusual. However, both types of nonunions demonstrate similar difficulties with healing and require exploration and bone grafting of the nonunion site at the time an external fixator is applied. In an atrophic nonunion, the surgery focuses on freshening up the atrophic bone ends and removing any nonviable tissue from the fracture site. A synovial pseudarthrosis requires resection of the synovium and pseudocapsule, removal of the fibrocartilage covering the bone ends, and reopening of the intramedullary canals.

Stiff (hypertrophic) nonunions—so-called fibrous nonunions—usually heal with stable interfractionary compression. If the nonunion is transverse (perpendicular to the bone's longitudinal axis), compression with either external or internal fixation will stimulate union. Many nonunions, however, are oblique and often combined with malalignment of the bone fragments in angulation, rotation, displacement (of the mechanical axes), and shortening. When any or all of these deformities are associated with a nonunion, the ilizarov method permits gradual correction of all deformities, either simultaneously or in succession. In many cases, gradual distraction of a hypertrophic fibrous nonunion will stimulate osteogenesis in a manner similar to the new bone formation within a widening distraction gap. Before distraction, however, the nonunion site must be compressed 7 to 14 days, a procedure that Ilizarov claims stimulates the bone-growth process.

The treatment strategies described in this section focus on nonunions with viable bone ends that are not accompanied by sepsis.

ATROPHIC NONUNIONS

Ilizarov has an interesting approach to atrophic and oligotrophic nonunions. He performs a corticotomy of the involved bone at a site where the surrounding soft tissues are healthy, then gradually transports the intercalary segment through the limb. This strategy is followed even when there is no segmental defect or shortening. For this reason, the regenerate new bone at the corticotomy site is often no more than 1 or 2 mm long. Nevertheless, Ilizarov claims (good) results with this tactic, based on two principles: first, the corticotomy increases the limb's local vascularity (a stimulus to healing); and second, the corticotomy serves to decrease the lever arm at the nonunion site by creating a temporary floating segment (between the corticotomy and the nonunion). This floating segment will more readily unite at the nonunion site under the influence of compression. We prefer to bone graft atrophic nonunions and use the circular fixator to eliminate shear forces at the nonunion site by using...
counterpulling olive wires above and below a nonunion with an obliquity of greater than 30°.

**ANGULATED NONUNIONS**

**ASSESSMENT**

Before treating an angulated nonunion, determine the true plane of the deformity as well as the displacement of the deformity's apex from the original mechanical axis of the bone. Likewise, determine the true angle and plane of the deformity, the amount of rotational malalignment, and the direction and magnitude of any displacement of the fragments by applying the principles described by Paley and Tetsworth in the earlier section, Defority Correction by the Ilizarov Technique. An appropriate configuration must be designed to correct the deformities and in the end achieve interfragmentary compression across the nonunion. Likewise, determine if the shortening is a result of angulation or the consequence of a true loss of limb length.

To determine if correction of an angular deformity alone will restore limb length, use one of the following two methods.

In the first method, make a tracing of the radiograph of the bone in the projection that demonstrates the maximum angulation. Cut out the tracing, transect it through the apex of the deformity, and straighten it out. Measure the length of the corrected cutout and compare it to a comparable roentgenogram of the contralateral limb.

In the second method, obtain roentgenograms of both limbs in the same projection, using the view that maximizes the angular deformity on the injured side. Draw a line on the convex side of the deformity from a fixed landmark on the bone's proximal end (such as the corner of the joint line) to the apex of the deformity. Draw a second line from the apex of the deformity along the deformity's convex edge to a landmark on the opposite edge of the bone (such as the tip of the medial malleolus). Add the lengths of these two lines together, and compare the sum to the length of a line from the same landmark on the uninjured limb. If there is no true shortening of the bone, then the length of the convex side of the deformed bone should equal the length on the corresponding side of the normal bone. If it does not, lengthening will be needed.

**CORRECTION**

In principle, the apparatus is applied with each ring perpendicular to the bone segment attached to it. In this way, the fixator configuration mimics the deformity. In actual practice, a mounting should exaggerate the deformity, with the rings tilted slightly into the deformity's concavity. During correction, resistant soft tissues deform the wires, causing the bone fragments to lag behind the rings during movement of the frame; the wires or pins of the configuration will bend as the rings displace faster than the bone fragments.

During application of the external fixator (according to the principles outlined in Section C), place a pair of hinges at the level of the apex of the angular deformity. Arrange this pair of hinges so that their central bolts form an imaginary line perpendicular to the plane of the deformity. The distance of this imaginary line from the apex of the bone's deformity depends on how much lengthening must accompany the angular correction. If, for example, eliminating the angulation results in normal limb length, then the imaginary rotation axis of the hinges should correspond exactly to the apex of the deformity (Fig. 32.121). In this manner, the regenerate bone resulting from the deformity correction will fill an "opening wedge" triangular gap. If, on the other hand, substantial lengthening is needed, moving the configuration's axis of rotation away from the deformity's apex along a line that bisects the deformity results in a trapezoid-shaped gap between the bone ends when the deformity is fully corrected (Fig. 32.122).

![Figure 32.121. Correction of angulation. A: Scheme of correction. The black dot is the axis of rotation of the configuration. B: Severe varus deformity with hypertrophic nonunion. C: Configuration for correction. D: New bone formation during distraction and correction.](image1)

![Figure 32.122. Correction of angulation with simultaneous lengthening. A: Scheme of correction. The black dot is the axis of rotation for the configuration. B: Standard method of correcting a deformity by lengthening the hinges on the concave side of the deformity. C: Less stable configuration with a distractor attached with two twisted plates. D: Configuration for stiff nonunion using a pusher mechanism.](image2)

If any displacement accompanies an angular deformity—a common combination—the axis of rotation for the configuration's hinges are not on the bisector line of the deformity's angle, but at a point corresponding to the intersection of the mechanical axes of the bone fragments (Fig. 32.123). If lengthening is required along with correction of angulation and displacement, move this rotation point a distance away from the bone that is proportional to the lengthening needed.

![Figure 32.123. Scheme of correcting angulation and displacement. The black dot is the axis of rotation for the configuration.](image3)
OBLIQUE NONUNIONS

ASSESSMENT

The plane of a nonunion is often oblique to the bone's mechanical axis. Moreover, the two main fracture fragments are often not along the same weight-bearing line, even when the overall alignment of the limb is satisfactory (Fig. 32.124). In this situation, longitudinal compression with an external fixator (or by weight bearing) is likely to retard, not enhance, bone healing. The fixator will either hold the bone fragments apart if the frame is rigid (Fig. 32.125) or permit excessive shear at the nonunion site if the frame is dynamic, especially if the obliquity of the nonunion exceeds 30°.

Figure 32.124. Scheme of oblique nonunion with displacement and shortening.

Figure 32.125. Lengthening an oblique nonunion may increase the distraction gap.

CORRECTION

To promote union in oblique hypertrophic nonunions, realign the fracture fragments, making their mechanical axes collinear, and obtain interfragmentary (usually side-to-side) compression of the nonunion. This combination of interfragmentary compression, axial realignment, and stability is well known to surgeons who use plates and screws to treat nonunions. When an external skeletal fixator is used, the reduction must be as good as that achieved with a plate and screws.

Since hypertrophic nonunions are stiff, reduction and realignment of the fracture fragments must occur gradually, using the apparatus to achieve reduction. Often, a push configuration using long plates in the mounting is needed to apply sufficient force on the deformity's apex.

Occasionally, the limb's alignment can be manually corrected while the patient is anesthetized, a maneuver that simplifies the frame considerably. When performing the manual correction, do not create a triangular gap on the deformity's concave side, as that will never be able to contribute to osseous healing.

Use axial interfragmentary compression when the limb length equals that of the contralateral side, and when the nonunion is transverse: simple axial compression will promote healing. With increasing obliquity of the nonunion site, modify the configuration to neutralize shear forces. Obtain interfragmentary compression by inserting counterpulling olive wires that traverse the limb from opposite directions (Fig. 32.126). Insert these wires either through the site of the nonunion itself or at some distance above and below it. Ilizarov recommends placing the wires through an oblique nonunion if there has been no history of sepsis. Clearly, such wires not only ensure interfragmentary compression but also help stabilize the nonunion that they cross.

Figure 32.126. Lengthening must be combined with interfragmentary compression, shown here with counterpulling olive wires.

Anatomic considerations generally limit the use of side-to-side olive wire interfragmentary compression to fracture lines in the sagittal plane, since the wires enter and exit the limb on its medial and lateral sides. When a nonunion is in the coronal plane, however, interfragmentary compression with olive wires would require the wires to enter or exit the limb in the anteroposterior direction. In most anatomic locations, such wires can be dangerous. For this reason, achieve interfragmentary compression of oblique coronal plane nonunions by inserting wires mediolaterally into each fragment and attaching the wires to rings or half-rings (Fig. 32.127). Connect these rings to the rest of the configuration in a manner that permits front-to-back interfragmentary compression at the nonunion site. If necessary, incorporate one or two long plates in the configuration to serve as a base for pushing and pulling the rings.
OBlique nonUNIONS WITH SHORTEnING

ASSESSMENT

Oblique nonunions associated with limb shortening usually result from either comminution at the fracture site, angulation, or displacement of the mechanical axes of the major fragments (Fig. 32.128). In the latter two cases, once the fragments are made coaxial, the shortening is eliminated.

When there has been a substantial comminution at the fracture site, there may actually be several nonunions responsible for the problem. Often, such injuries have been maintained in rigid external or internal fixation that inhibits osseous healing. When the fixator is removed, the fracture tends to gradually collapse as the scar tissue at the site of injury stretches. In some cases, one or more fracture lines may eventually unite, leaving only one site of retarded bone healing.

CORRECTION

Distracting a hypertrophic nonunion after first compressing it stimulates osteogenesis. Anecdotal clinical experience of orthopaedic surgeons in Western countries suggests that bone formation with this technique is somewhat unpredictable. A more reliable strategy is to compress the nonunion (either longitudinally or side-to-side, depending on the obliquity of the fracture line) and lengthen the bone elsewhere—through healthy tissue—to overcome any residual limb shortening.

TRANSLATIONAL MALALIGNMENT

ASSESSMENT

As mentioned earlier, both angular deformities and oblique fracture lines are often associated with translation of the mechanical axis of the distal fragment with respect to that of the proximal fragment. Not only does such a malalignment retard osseous healing, but even if the bone did eventually heal in a malaligned position, the weight-bearing line would fail to pass through the centers of nearby joints, leading to either chronic joint pain, degenerative osteoarthritis, or both.

Determine the amount of translational displacement by drawing a line through the mechanical axis of each major fragment and measuring the distance between the lines after correction of angulation at the nonunion site. Be sure that the roentgenographic projection used for the measurement shows the displacement at its greatest.

CORRECTION

When translational deformities coexist with angulation, the combined deformity can be eliminated by locating the center of rotation of the hinge axis at the proper place with respect to the fragments, as described in the previous section. When displacement exists without angulation, mutual translation of the fragments is accomplished by incorporating a translation assembly into the configuration. The mechanism for a translation assembly is simple yet elegant: Fix three pairs of horizontal rails to the respective rings with posts (Fig. 32.129). The entire configuration must be sturdy enough to prevent axial displacement during horizontal translation.

ROTATIONAL MALALIGNMENT

ASSESSMENT

Malrotation often accompanies the angulation, displacement, and shortening affecting both nonunions and malunions. With the Ilizarov method, rotational malalignments are usually corrected last, after angulation, displacement, and shortening (Fig. 32.130). The reason for this is that the major bone fragments must be
aligned along the same axis to correct malrotation. Moreover, this axis must be in the center of the configuration. In this way, the bone fragments will rotate around a line passing through the center of the fixator's rings and the marrow canals, rather than through an axis that does not pass through either. Were the fragments to rotate around an eccentric axis, one fragment would displace transversely with respect to the other during rotation.

**Figure 32.130.** Sequence of correction of rotational malalignment. Angulation is corrected first, and then displacement is addressed.

One of the advantages of using a circular external fixation system is the ability to rotate one ring with respect to another. When unilateral half-pin fixators are used to treat nonunions and malunions, this capacity for gradual rotational correction does not exist, no matter how adaptable the fixator may be.

**CORRECTION**

There are at least three different rotation assemblies. The most stable one uses sliding buckles as the interconnection between the rotating ring and the rest of the frame. The “motor” that provides the power to turn one ring with respect to another is made from a horizontal threaded rod spanning the space between the buckle and a post connected to the movable ring (**Fig. 32.131**).

**Figure 32.131.** Rotation assemblies. **A:** Nested rings, with the inner ring securing the wires. **B:** Buckles-and-bushings rotation assembly. **C:** The bone fragments must be coaxial—and in the center of the configuration—for counterrotation.

Another rotation mechanism is made from three horizontal threaded rods located between the two rings that must move with respect to each other. One end of each rod is connected via posts to the upper ring; the other attaches to posts on the lower ring. Decreasing the distance between the posts on each rod rotates one ring with respect to the other.

A third mechanism for counterrotation of the rings is constructed by placing one ring within another (**Fig. 32.131**). A pair of clamps made out of two short plates holds the pair of rings together. In clinical use, the wires are connected to the inner ring and the fixator to the outer one. A single horizontally oriented threaded rod attached with posts to each ring will motor the revolution of the inner ring with respect to the outer one.

One final point: With some limb segments—the lower leg and the forearm—the bones are eccentrically placed within the soft tissues. The tibia, for instance, is anterior and medial in the shank’s cross section. Placing a fixator around the lower leg would result in a mounting that rotates around an axis in the soft tissues, rather than the correct location through the center of the bone. Turning one ring with respect to another in this situation would cause more displacement than rotation. For tibial mountings, therefore, a ring for a rotation assembly must be quite large with the bone—not the leg—centered within the frame (**Fig. 32.132**).

**Figure 32.132.** Frame for correction of shortening, malrotation, angulation, and displacement.

**SEGMENTAL DEFECTS**

**ASSESSMENT**

Segmental defects may be caused by bone loss at the time of trauma, removal of nonviable fragments at initial debridement, or resection of necrotic bone during the care of an infected fracture. When a segmental defect is present, any angulation, rotation, translation, or combination of displacements can easily be corrected through the soft tissues at the level of the defect. For this reason, circular frame configurations designed to deal with segmental defects are usually rather simple: The configuration is tubular, with the connecting rods of the frame parallel to each other and to the bone’s mechanical axis.

**CORRECTION**

To eliminate the defect, make a corticotomy through healthy bone some distance from the defect; then pull the intercalary segment between the defect and the corticotomy through the tissues until the defect is closed (1,4,8,12,13,15). At the corticotomy site, new bone forms during distraction (**Fig. 32.133**).

**Figure 32.133.** Frame for correction of shortening, malrotation, angulation, and displacement.
If the defect is smaller than 2.5 cm, it can be compressed acutely after appropriate debridement, and the bone can be lengthened through a corticotomy elsewhere.

It is unwise to acutely close a skeletal defect that is more than 2.5 cm, since the redundant soft tissues surrounding the defect tend to bulge when the fragments are brought together, creating an unsightly appearance to the leg and kinking both lymphatic and venous drainage. As this redundant skin is trapped between the wires, it cannot contribute to lengthening of the limb through another section of the bone. Therefore, the patient is left with a peculiar-looking limb with bulky redundant tissues at one level and tight, stretched skin at another. With this problem in mind, when dealing with a segmental defect of more than 2.5 cm, leave the soft tissues at length and eliminate the defect by gradual transport of the intermediate segment.

A segment of bone can be pulled through a limb with a transport ring and cross-wires, or with oblique directional wires. A transport ring and an attached pair of cross-wires is the most stable way to pull a bone fragment through tissue (Fig. 32.134). Unfortunately, the wires must cut through the skin and soft tissues as the ring and its attached bone segment move through the limb. At the end of bone transport, however, the crossed wires serve to enhance compression at the point of contact between the intermediate fragment and the target fragment.

When oblique directional wires are used to move a bone segment through a limb, there is far less cutting of tissues, since the wires start out nearly parallel to the limb's axis (Fig. 32.134). Unfortunately, such oblique wires often do not provide enough pressure at the end of bone transport to ensure stable interfragmentary compression between the intermediate fragment and the target fragment. For this reason, a pair of cross-wires connected to a ring must be attached to the intermediate fragment at the end of bone transport to enhance compression at the point of contact. In such a case, a second operation is required.

No matter how the intermediate fragment is pulled through the limb, it is obvious that the proximal fragment, the intermediate fragment, and the distal fragment must all be in line with each other lest the intercalary fragment miss its target. Although such a requirement seems simple, in actual practice the bone fragments tend to sag posteriorly on the operating table while a frame is being applied. Be sure to check the final alignment of the bone fragments on long x-ray films before the patient leaves the operating table.

Although frames can be modified on an out-patient basis afterwards, this is not preferred. A fragment of bone can be moved within its ring by detaching the transfixion wires from their fixation bolts and moving the wires over one or two holes on the ring.

The final general consideration in planning treatment for a skeletal defect deals with the shape of the bone ends at the docking site (Fig. 32.135). Unfortunately, it is difficult to match bone ends on opposite sides of a skeletal defect so that they fit well together when a defect is closed. The most predictable healing occurs when one fragment impales the marrow cavity of the other (Fig. 32.136). Of course, the surgeon must trim a point on the transported segment for such impalement to be possible. Regardless of the shape of the bone ends, we do not hesitate to insert a bone graft around the contact point between the transported and the target fragments whenever we suspect that healing will be delayed.
correction of displacement can accompany rotation, especially if the mechanical axes of the major bone fragments are not located within the center of their respect to each other. As a general principle, begin counterrotation of fragments after correction of angulation and restoration of limb length. In many situations, Rotational malalignments—usually seen combined with other deformities—must be corrected with an assembly that permits the corresponding rings to rotate with the apparatus. Translation. Such frames are fairly complicated, since the translation mechanism involves multiple horizontal threaded rods connected to adjacent rings on both sides of the apparatus. Angulation and axial displacement also can be corrected in separate steps, using a fixator configuration that incorporates assemblies for both angular correction and automatically results in translation of the bone fragments. The geometry of correction in this manner was described earlier in this chapter by Paley and Tetsworth. The apex of any malunion deformity is located at the intersection of the mechanical axes of the principal fragments. In angulated malunions without concomitant displacement, the intersection point is at the level of the old fracture line. When displacement accompanies angulation, the intersection of the axes of the fragments is not at the fracture line, but at some point above or below the level of injury. Placing a corrective osteotomy at the level of the apex of the deformity corrects angulation of the fragments but does not improve translation of their mechanical axes. To correct such displacement, the cortical osteotomy must be level proximal or distal to the hinge axis at the apex of the deformity. When the level of the corticotomy and hinge axis of the configuration are not at the same level, correcting angulation of the fragments but does not improve translation of their mechanical axes. To correct such displacement, the cortical osteotomy must be level proximal or distal to the hinge axis at the level of the corticotomy site after the intermediate fragment has completed its journey. When there has been loss of bone substance, overlap, translation, or some other combination of factors resulting in both angulation and true shortening of the bone, Most malunions combine elements of not only angulation and shortening, but also translation (displacement) of the mechanical axes of the fragments, and rotation as well. Sometimes these deformities are not as apparent as angulation and shortening, but, unless the surgeon is aware of associated malalignments, the correction will be less than ideal. To determine if true osseous shortening accompanies angulation, follow the recommendations in the above section on angulated nonunions. When there has been loss of bone substance, overlap, translation, or some other combination of factors resulting in both angulation and true shortening of the bone, correcting the angulation and realigning the bone's mechanical axis will not result in restoration of limb length without using a directional hinge or a translation hinge, or lengthening after deformity correction. Certain common fracture patterns tend to produce consistent malunion deformities. For example, a distal tibial fracture with associated fracture of the fibula that has healed in a shortened position and angulated into valgus usually demonstrates external rotation of the distal tibial fragment and foot and lateral displacement of the distal fragment’s mechanical axis compared to that of a proximal fragment. Malunions with varus of the tibia frequently are rotated inward and displaced medially. The apex of any malunion deformity is located at the intersection of the mechanical axes of the principal fragments. In angulated malunions without concomitant displacement, the intersection point is at the level of the old fracture line. When displacement accompanies angulation, the intersection of the axes of the fragments is not at the fracture line, but at some point above or below the level of injury. Placing a corrective osteotomy at the level of the apex of the deformity corrects angulation of the fragments but does not improve translation of their mechanical axes. To correct such displacement, the cortical osteotomy must be level proximal or distal to the hinge axis at the level of the corticotomy site after the intermediate fragment has completed its journey. When the level of the corticotomy and hinge axis of the configuration are not at the same level, correcting angulation automatically results in translation of the bone fragments. The geometry of correction in this manner was described earlier in this chapter by Paley and Tetsworth. Angulation and axial displacement also can be corrected in separate steps, using a fixator configuration that incorporates assemblies for both angular correction and translation. Such frames are fairly complicated, since the translation mechanism involves multiple horizontal threaded rods connected to adjacent rings on both sides of the apparatus. Rotational malalignments—usually seen combined with other deformities—must be corrected with an assembly that permits the corresponding rings to rotate with respect to each other. As a general principle, begin counterrotation of fragments after correction of angulation and restoration of limb length. In many situations, correction of displacement can accompany rotation, especially if the mechanical axes of the major bone fragments are not located within the center of their
corresponding rings.

**CORRECTION**

After you fully understand the nature and complexity of the various deformities that require correction, make cutouts of the bone segments and perform the surgery with paper and tape before the actual operation.

To plan the correction, start with full-length roentgenograms of lower-extremity problems and corresponding films for upper-limb malunions. Also obtain roentgenograms of both the involved and normal bones in multiple projections, one of which shows the maximum deformity in profile, the view perpendicular to the true plane of the deformity. If there are two or more deformities in the bone that are oriented in different planes, then obtain separate roentgenographic projections of each deformity in its maximum profile. With long tracing paper, make cutouts of the abnormal bone and perform the osteotomies at appropriate levels to correct the deformity. In complex cases, make the tracings on large clear acetate sheets, using separate pieces for the proximal and distal fragments. In this way, the traced fragments can be rotated with respect to each other, using a thumbstick as the hinge axis. Moving the thumbstick around in different locations outside the contours of the fragments will often reveal the correct location of the point of rotation for correction of both angulation and displacement.

Once the fixator is in place, correction of malunions follows the principles of general deformity correction with the ilizarov method.

**POSTTRAUMATIC SHORTENING**

**ASSESSMENT**

A leg-length discrepancy alters gait, interferes with spinal mechanics, may require unainly shoe lifts, and often embarrasses the patient. Before the introduction of the ilizarov methods, a posttraumatic leg-length discrepancy in an adult was usually managed with either a shoe lift, shortening the contralateral limb, or in rare instances lengthening with an open osteotomy and multiple surgeries. The discovery of bone’s capacity to regenerate in a widening distraction gap has revolutionized the care of posttraumatic limb-length inequality (16).

Restoring length to a limb shortened by trauma presents fewer problems than elongating a congenitally short limb, for the following reasons. First, before injury, the neurovascular structures were at full length; with elongation, these structures are restored to their original status. Second, posttraumatic shortening usually involves a loss of length of 3–7 cm, whereas congenitally short limbs often demonstrate far greater inequality. Third, the skin and soft tissues are often redundant after posttraumatic shortening and therefore easy to lengthen.

In some situations, however, lengthening for posttraumatic shortening may present significant problems, especially if there is extensive scar tissue, preexisting microvascular repair, transposition flap surgery, or injury to neurovascular structures, muscles, or tendons. Also, damaged joints, internal fixation devices, disuse osteoporosis, articular contractures, head trauma, and other problems may complicate restoration of limb length for posttraumatic shortening.

**CORRECTION**

In principle, lengthening of a traumatically injured limb follows the same methods used for limb elongation associated with other kinds of pathology. Apply a stable external skeletal fixator and perform a corticotomy through healthy bone surrounded by normal soft tissues (2,3,5). After a delay of 5–7 days, lengthen the limb using ilizarov’s guidelines. If the soft tissues around the corticotomy level are suboptimal, prolong the latency up to 14 days.

Distract the limb at a rate of 1 mm per day in four divided doses. Manage any delay of new bone formation in the distraction gap by slowing the rate of distraction to 0.5–0.75 mm per day (a distraction frequency of 0.25 mm every 8–12 hr). Concomitant deformities must be corrected during lengthening following the principles described in preceding sections.

Intensive physiotherapy must accompany any limb-lengthening program. Treat any joint that develops a contracture vigorously. Progression of a flexion contracture of the knee, for example, can lead first to posterior subluxation of the tibia on the femur, and then to frank dislocation of the knee joint. Likewise, lengthening a femur with either a valgus hip deformity or a shallow acetabular roof can lead to subluxation or dislocation of the hip.

A decline in the patient’s ambulatory capacity during elongation (or deformity correction, or any other application of an external fixator) must be investigated and corrected. Often, pin or wire site sepsis is the problem. Muscle impalement or pain caused by irritation of tendons or synovium also interferes with gait. Contractures limit ambulation. Decreased weight-bearing leads to osteoporosis, a cause of pin or wire loosening. The loosened implants lead to fixator instability, which causes further pain and infections. This vicious cycle must be stopped as soon as it appears. Check for fixator stability and range of joint motion at each visit. Ask the patient about pain and any reasons for a decline in the ability to walk. If necessary, admit the patient to the hospital for intensive physiotherapy (primarily muscle stretching).

Stop the lengthening for a week if necessary. Change any infected pins or wires if sepsis cannot be controlled with antibiotics.

If none of these measures work, do not continue lengthening. Instead, stop or even back up a bit and allow the bone to mature. Six or 8 months later, when joint function has been restored to normal and the patient is fully ambulatory, repeat the lengthening.

Vascular insufficiency is the result of altered blood flow significant enough to compromise cellular perfusion and function, and ultimately to cause cellular injury or
death. Clinical symptoms of abnormal perfusion include pain, cold intolerance, numbness, ulceration, and gangrene. Symptomatic vascular disorders of the upper
extremity interfere with health-related quality of life and diminish function. More than 10% of the general population and 20% to 30% of postmenopausal women suffer
from abnormal microvascular flow secondary to trauma, congenital deformity, systemic processes, or genetic influences. This chapter presents an approach to the
diagnosis and management of vascular disorders.

ACUTE ARTERIAL INJURIES

TRAUMATIC ARTERIAL INJURIES

Penetrating injuries account for more than 80% of acute vascular injuries to the upper extremity (7). Acute arterial trauma may accompany high-energy fractures or
dislocations, and these injuries require careful evaluation (51). The management of arterial injuries has improved dramatically since the late 1940s. During World War
II, only 3 of 2471 known reported cases of acute arterial repairs by end-to-end anastomosis were successful (15).

Today, trained surgeons skilled in the use of the operating microscope, microvascular instruments, and microsuture can achieve excellent vascular patency and
replantation of complete upper extremity amputations. Thrombosis following the repair of noncritical arterial injuries, however, is common, even with the sophisticated
microvascular techniques performed by experienced vascular surgeons. Successful management of acute vascular disorders requires (a) an understanding of the
physiology of symptoms associated with vascular trauma; (b) a thorough knowledge of the pertinent vascular anatomy (Fig. 33.1) (2,12); (c) an assessment of
associated injury to soft tissue, bone, and nerve; and (d) an appreciation of the natural history of the treated and untreated injury.

Figure 33.1. The superficial palmar arch is completed by branches from the deep palmar arch, radial artery, or median artery in 78.5% of patients; the remaining 21.5%
are incomplete. The deep palmar arch is completed by the superior branch of the ulnar artery, the inferior branch of the ulnar artery, or both in 98.5% of patients.

Classification

The three common patterns of arterial injuries are complete transection (Type 1), partial transection (Type 2), and nontransection (Type 3). These injuries can be
further defined as either critical, wherein the absence of arterial reconstruction will produce tissue necrosis requiring amputation, or noncritical, wherein tissue survival
is independent of arterial reconstruction (Table 33.1 and Table 33.2). Chronic arterial injury and vasospastic problems may also be classified (Table 33.3 and Table
33.4).

Table 33.4. Chronic Arterial Dysfunction: Wake Forest Classification of Occlusive, Vasospastic, and Vasoocclusive Disease

Physiology of Arterial Injuries and Subsequent Symptoms

Complete vessel division (Type 1) by trauma causes immediate retraction of the transected arterial ends away from the site of injury. Vasoconstriction, intraluminal thrombosis, and compression from surrounding soft-tissue hemorrhage result in a cessation of arterial bleeding, depending in part on the diameter of the vessel. The thrombosis usually propagates proximally and distally to a patent branch not more than several centimeters from the zone of injury. The amount of retraction and zone of injury determine whether end-to-end repair or interposition grafting is required to restore perfusion. Occasionally, arteries that are lacerated and transected completely by sharp bone fragments may be tethered by the fragments; retraction is prevented, and the result is uncontrolled hemorrhage.

Partial arterial injuries (Type 2) are most often secondary to lacerations from sharp glass or knives or bone fragments. Iatrogenic injuries may follow diagnostic arterial cannulation for hemodynamic monitoring, arterial blood sampling, or angiography, or they may result from inadvertent puncture with drill bits or screws (see later). The injured portions of the vessel wall retract and constrict, but because of the segment of vessel that remains intact, this retraction serves to enlarge the defect and increase the bleeding. Distal ischemia may not occur because of persistent flow or collateral circulation, but hemorrhage is typically much greater than with complete transection and may not stop with directly applied pressure. Although the normal coagulation mechanism may control bleeding, the thrombosis may develop a communication with the arterial lumen and stabilize (heal), expand (false aneurysm), or develop a communication with an adjacent injured vein (arteriovenous fistula (AVF)).

Nontransection arterial injuries (Type 3) occur from blunt direct trauma or indirect shock waves from a high-velocity missile and may produce complete or partial flap tears of the intima or intramural hemorrhage; both diminish lumen diameter and compromise flow. Potential sequelae may include thrombosis, periadventitial constriction, and aneurysm; all may occur with or without ischemia and may not be immediately symptomatic. After complete occlusion by thrombosis, recanalization can occur and may restore circulation without symptoms or may rethrombose and produce distant emboli.
Symptoms (pain, numbness, paraesthesias, weakness) following acute arterial injury are based on the adequacy of the collateral circulation, posttraumatic sympathetic tone, and vasomotor control mechanisms (Fig. 33.3). In the presence of adequate collateral circulation and normal vasomotor control, patients with arterial injuries infrequently require vascular reconstruction (noncritical injury). An underlying neurologic, soft-tissue, or osseous injury, however, may alter sympathetic control in the remaining intact vessel or vessels, resulting in ischemic symptoms from an otherwise insignificant injury. Therefore, adequate anatomic vasculature may be compromised by inappropriate functional control that produces vasospasm, arteriovenous shunting, and resultant hypoperfusion. In the presence of inadequate collateral circulation, arterial injury results in distal ischemia that increases sympathetic tone, produces additional arterial spasm, decreases tissue perfusion, induces ischemia, and escalates symptoms. The effects of an arterial injury may be magnified in the presence of a concomitant nerve injury or underlying vasomotor control abnormality.

Natural History

Although pulseless extremities may survive on small collateral and subdermal plexus flow, there is uniform agreement that the surgeon should revascularize one or both forearm vessels if both the radial and ulnar arteries are disrupted, if the vessels in the distal extremity are suitable, and if the patient’s overall condition permits. During World War II, amputation (critical injury) after arterial injury occurred in 26% of brachial artery injuries requiring ligation below the origin of the profunda brachia and in 55% of injuries above this level. The amputation rate after ligation of both radial and ulnar arteries was 39%, whereas for single-vessel injuries the amputation rate dropped to 5%—an indication that the majority of single-vessel injuries are noncritical (25).

In the absence of osseous or neural injury, nonrepaired single vessels with adequate collateral circulation do not produce significant symptoms, do not impair function, and do not initiate significant cold sensitivity. Blood pressure decreases in the digits served by the damaged vessel in spite of a compensatory increase in the flow of the parallel artery (22). Symptoms depend on associated injuries and the ability of the remaining vasculature to respond appropriately to stress (39). The effect of a nonrepaired noncritical vessel on the completeness of nerve recovery following neurorrhaphy and the effect of the nerve injury on the function of remaining parallel microvasculature is unclear; data are conflicting.

Diagnosis

Diagnosis of arterial injuries requires a high index of suspicion based on the history of the injury. Vascular injury may occur after penetrating wounds (80%) or fractures and needs to be considered when patients have injuries to adjacent neural structures. Initial physical examination may include profuse external bleeding (62%), hypotension (18%), expanding or pulsatile hematomas, thrills, bruits, and decreased peripheral pulses (43). A distal pulse is not a reliable sign of vascular integrity, however, and it is palpable in approximately one quarter of patients with a brachial artery disruption and in 50% of patients with an isolated radial or ulnar artery injury (23). Distal to arterial disruption, a palpable pulse may be secondary to retrograde flow through collateral circulation or wave transmission through the injured segment. The Allen test, which may be obtained using Doppler ultrasound, is the most accurate and reliable indicator of arterial patency in the hand and can document the direction of flow and the quality of the collateral circulation (2).

Noninvasive diagnostic techniques include hand-held Doppler ultrasound, pulse echo real-time ultrasonography, color duplex Doppler imaging, and radial or digital blood pressures (Table 33.5). As noted, when performed with and without parallel vessel compression, Doppler evaluation can detect the presence and direction of flow, whereas digital pressures can quantify the amount of flow when referenced to the brachial artery in the form of a digital brachial index (DBI) or radial brachial index (RBI). A DBI or RBI of 0.7 or less indicates inadequate flow and supports medical and surgical intervention; heavily calcified vessels, as seen in patients with diabetes, may produce higher pressures, which must be considered (8).

Table 33.5. Direct Vascular Evaluation
Invasive diagnostic techniques include arteriography. Its role in acute extremity trauma, however, remains controversial (3, 20). For most critical penetrating arterial injuries, the preceding assessments dictate obvious and appropriate surgical intervention. Arteriography is sought preoperatively if (a) surgery may compromise the patient or the extremity, (b) multilevel arterial damage is possible or probable (e.g., shotgun wound), and (c) extensive thrombosis or embolism is of clinical concern (e.g., injection or cannulation injuries). Relative indications for arteriography after blunt trauma include (a) suspicion of a proximal traction injury or distal occlusion (thrombosis or embolism), (b) detection of a partial arterial injury (e.g., intimal flap), and (c) suspicion of a false aneurysm.

Intraoperative assessment is required in all critical injuries but may also be required in cases in which the extent of damage and quality of collateral circulation are in question. Collateral flow can be assessed by the backflow from the injured vessel, qualitatively by the pulsatile flow or by quantitative measurement of the retrograde blood pressure (23, 25). Although excellent retrograde flow (DBI >0.7) confirms adequate collateral circulation, poor flow may be transient secondary to vasospasm or hypotension and not predictive of collateral flow postoperatively. Alternative intraoperative measures available are qualitative assessment of capillary refill (22) or pulp turgor, and quantitative digital plethysmography or laser Doppler flowmetry.

**Indications for Surgical Reconstruction**

Reconstruction is indicated in all cases of critical arterial injuries, assuming the absence of additional injuries or problems. Absolute indications for noncritical arterial injuries are not well defined, but relative indications include injuries in which additional flow would help to maintain pulsatile digital flow capable of responding to stress. Another relative indication is the presence of injury to adjacent neural structures (i.e., ulnar artery and nerve).

**Surgical Reconstruction**

To obtain reliably patent anastomoses, the surgeon must use the proper instruments, appropriately sized needles, suture materials of appropriate diameter, adequate magnification, and meticulous microsurgical technique.

**Instrumentation**

The selection of microsurgical instruments is, in part, at the surgeon’s discretion. Instruments should be simple, corrosion resistant, and fabricated with nonglare material, and they should approximate accurately (Fig. 33.4). Scissors and needle holders should have nonlocking spring mechanisms and should be long enough to rest comfortably in the thumb-index finger web space. Sufficient length is important to minimize intrinsic muscle fatigue, decrease hand tremors, and help minimize technical errors.

**Figure 33.4.** Basic microsurgical instruments. A: Tying forceps may be used for tissue manipulation and suture handling and tying. B: Specialized forceps may be used to dilate vessels as well as to manipulate tissue and to handle sutures. C: Straight or adventitial scissors and curved or dissecting scissors (inset) are used for dissection, tissue preparation, and suture transection. D: Needles may be manipulated with curved or straight forceps or specialized needle holders.

**Figure 33.5.** Microclamps. A large variety of microclamps capable of holding 0.3 to 2.0 mm vessels is available.

**Forcesps**

Smoothly functioning forceps capable of holding without tearing are essential, with tip sizes ranging from 0.2 to 0.6 mm. Jeweler’s forceps (straight #5 and #3) traditionally have been used as microsurgical forceps; however, their small tips are easily distorted, rendering them ineffective. Additionally, they are unavailable in lengths greater than 10 cm. Forceps made specifically for microsurgery are longer, constructed with forged or case-hardened metals, have improved durability, and are not sharp. A variety of specialized forceps are available for vessel dissection, stretching, and tissue manipulation.

**Scissors**

Microscissors are extremely important. Ideally, they should be 15 to 18 cm long, and their tips should be of forged or case-hardened metal. Adventitial scissors are straight; dissecting scissors have a gentle curve. Tips may be pointed or slightly blunted; the latter are preferable for less experienced surgeons, because they decrease the possibility of damage to vessels. Handles may be straight, rounded, or flared. Many of the newer microscissors are counterbalanced to improve their feel and maneuverability.

**Needle Holders**

Most microsurgeons prefer specialized needle holders with finely forged tips that have smooth action, such as jewelers forceps. Longer needle holders (15 to 18 cm), which are easier to handle and control than short ones, help minimize false needle passes, inadvertent vessel wall penetration, and trauma. Needle holders come with straight or curved jaws. A gently curved jaw facilitates handling, allowing the surgeon to roll the handle between the thumb and forefinger to rotate the needle through the vessel wall. Locking needle holders are not used with needles smaller than 150 to 200 μm. Locking and unlocking may bend the needle and tear vessel walls.

**Clamps**

Single and double clamps are available in several sizes for vessel approximation or hemostasis (Fig. 33.5). Vessel clamps are designed to hold the vessel, to prevent bleeding, and to allow rotatory approximation. Disposable single and double clamps of varying sizes and pressures are now available and are suitable for 0.4 to 2.0 mm vessels. Specialized clamps include stay suture–holding frames, adjustable tension devices, and clamps with variably angled blades. The ideal clamp has enough tension to hold the vessel without damage and jaws 1.5 to 2.0 times wider than the diameter of the vessel. A clamp that exerts excessive pressure will damage the intima and media, and produce or increase the likelihood of thrombosis. Avoid using double-bar clamps to overcome tension during vessel approximation. Clamps are designed as anastomotic aids to facilitate vessel positioning, hemostasis, and suture management; they are not designed to overcome tension.

**Figure 33.6.** Custom vessel dilators or smooth probes (e.g., lacrimal duct probes) are often helpful, but they may damage the intima if their surfaces are rough or if they are mishandled. Instruments to provide counterpressure are useful to facilitate needle passes in difficult situations or to avoid inadvertent penetration and tethering of the vessel.
End-to-End Vascular Repair

Inspecting the vessel carefully under high power identifies wall or intimal damage that would compromise patency. Resect abnormal vessels before repair.

- End-to-End Vascular Repair
  - Perform a primary end-to-end repair, without placing excessive tension on the anastomotic site if possible. In sharp, nonsegmental injuries or when minimal artery has been resected, it is possible to achieve a tension-free anastomosis after resection of damaged vessel ends by moderately mobilizing the artery proximally and distally.
  - Colored background material improves visualization and handling of suture, decreases glare, and improves contrast.
  - Perform the anastomosis with or without vessel approximating clamps, which are used to hold the vessel in position, not to overcome excessive tension. It is easier to gain access to the anastomotic site by orienting the bar clamps with the open end away from the surgeon (Fig. 33.7).
  - Under the operating microscope, adjust tension, expose the vessel, irrigate the lumens with heparinized saline, and remove debris or loose adventitial tissue.
  - After ensuring that the vessel is not twisted and that tension is not excessive, place stay sutures at 120°. Approximate the front wall by halving the distance with a triangulation technique (Fig. 33.8).

Remove the periadventitial tissue to reveal the vessel wall and lumen to prevent debris from interfering with passing or tying of sutures.

- Place but do not tie sutures if lacerated flexor tendons are adjacent to or would interfere with vascular anastomoses; after vascular repair, tendon approximation is possible without additional dissection. The possibility of damaging the vessel repair is thereby minimized. Performing tendon repair before vessel anastomosis may make exposure of the anastomotic site more difficult because of finger, hand, or wrist position, or because of the location of the tendon.

Vessels may be placed in a bar clamp to facilitate positioning, control bleeding, and maximize ease of repair.

- Place the vessel in an approximating clamp and repair it end to end (Fig. 33.7). Manage undue vessel tension by the use of reversed interposition vein grafting, in situ vein grafting with valvulotomy, antegrade vein grafting with valvulotomy, proximal and distal arterial mobilization, acute arterial lengthening, or bone shortening.

End-to-End Vascular Repair

- Explore wounds under loupe magnification using a tourniquet to provide a bloodless field.
- Use extensile incisions that incorporate traumatic wounds. If it is clinically indicated, perform fasciotomies. Identify transected and injured structures proximally and distally in normal tissue. Mobilize and tag them with vascular tapes or loops.
- Excise dead and necrotic tissue, and trim wound margins.
- Identify the periadventitial plane of the injured vessel proximally and distally to the transection site to allow rapid and safe dissection. Dissect vessels from surrounding tissues and place atraumatic vascular clamps on either side of the repair site.
- Ligate branches from the damaged artery in the proximity of the transection or cauterize with a bipolar cautery, leaving a 0.5 mm stump (Fig. 33.6). Manipulation of the media or intima is thereby minimized.

- Under the operating microscope, adjust tension, expose the vessel, irrigate the lumens with heparinized saline, and remove debris or loose adventitial tissue.
- Identify the periadventitial plane of the injured vessel proximally and distally to the transection site to allow rapid and safe dissection. Dissect vessels from surrounding tissues and place atraumatic vascular clamps on either side of the repair site.
- Ligate branches from the damaged artery in the proximity of the transection or cauterize with a bipolar cautery, leaving a 0.5 mm stump (Fig. 33.6). Manipulation of the media or intima is thereby minimized.

- Place but do not tie sutures if lacerated flexor tendons are adjacent to or would interfere with vascular anastomoses; after vascular repair, tendon approximation is possible without additional dissection. The possibility of damaging the vessel repair is thereby minimized. Performing tendon repair before vessel anastomosis may make exposure of the anastomotic site more difficult because of finger, hand, or wrist position, or because of the location of the tendon.

- Inspect both portions of the vessel to determine if the intima and media are suitable for anastomosis. Hemorrhage within the media, intimal disruption and multiple stellate leaks, or telescoping of the intima are ominous findings and require additional resection back to the level of normal vessel. Intimal damage itself is an important but not definitive factor in long-term patency. Intimal damage, however, the most easily recognizable external sign of local trauma, may indicate significant additional damage and is associated with a higher rate of thrombosis. It is good practice to resect the vessel to see relatively normal intima.

- Place the vessel in an approximating clamp and repair it end to end (Fig. 33.7). Manage undue vessel tension by the use of reversed interposition vein grafting, in situ vein grafting with valvulotomy, antegrade vein grafting with valvulotomy, proximal and distal arterial mobilization, acute arterial lengthening, or bone shortening.

- Perform the anastomosis with or without vessel approximating clamps, which are used to hold the vessel in position, not to overcome excessive tension. It is easier to gain access to the anastomotic site by orienting the bar clamps with the open end away from the surgeon (Fig. 33.7).
- Under the operating microscope, adjust tension, expose the vessel, irrigate the lumens with heparinized saline, and remove debris or loose adventitial tissue.
- After ensuring that the vessel is not twisted and that tension is not excessive, place stay sutures at 120°. Approximate the front wall by halving the distance with each suture, using a triangulation technique (Fig. 33.8).

- Rotate the bar vessel–approximating clamp 180° (open end toward surgeon) and approximate the back wall in a similar fashion.
- Minimize size or spacing discrepancies by applying tension to the adjacent sutures as you tie and triangulate the first throw of the knot (Fig. 33.9). Gently dilate the end of the smaller vessel, and cut it obliquely (not to exceed 30°). Perform end-to-side anastomosis, V-section, and closure of the end of the larger vessel.
longitudinal slit opening of the end of the smaller vessel, or interposition of appropriate graft material (Fig. 33.9).

Figure 33.9. Compensatory technique for size discrepancy. (A) End-to-side, (B) V-excision and closure, (C) V-opening, and (D) vein graft.

- Repair forearm level injuries with nonabsorbable 7-0, 8-0, or 9-0 sutures, and repair distal vessels with 9-0, 10-0, or 11-0 sutures.
- When the anastomosis is complete, inspect it and remove the clamp. Additional sutures may be necessary, but early leaks often stop spontaneously or you can stop them by placing fat over the anastomosis. Spaces of 0.3 mm or less between sutures generally do not require additional sutures. Technical errors in performing anastomoses can also cause turbulence and thrombosis (Fig. 33.10). Confirm patency by direct observation or by patency testing (Fig. 33.11).

Figure 33.10. Technical errors in anastomosis are shown. Side wall (A), back wall (B), failure to penetrate full vessel (C), uneven lateral placement (D), and uneven approximation of intima (E, F).

Figure 33.11. The technique for patency testing is illustrated. A: Using minimal pressure, the vessel is occluded distal to the anastomosis. B: Blood is milked from the vessel, which flattens between the forceps. C: The proximal forceps is released, and blood fills the flattened area.

Vascular Grafts for Arterial Repair Use vein grafting to overcome excessive tension when, after appropriate debridement, you cannot mobilize the damaged vessel to achieve end-to-end reapproximation (27). Although it requires two anastomoses, vein grafting does not significantly lower patency rates, even when this procedure is used in more severe injuries. Several types of bypass grafts are reversed interposition veins, nonreversed in situ valvulotomized vein segments, noncritical arterial grafts, and synthetic or allograft material.

Reversed Interposition Autologous Vein Grafting

- For injuries to the radial artery, ulnar artery, or proximal superficial arch injuries, use the cephalic vein from the forearm, the distal saphenous or lesser saphenous vein, or a dorsal vein from the foot; they are equally effective (27, 37, 40). The volar forearm is an excellent source of veins for the digital vessels.
- To harvest veins, use longitudinal incisions, multiple transverse incisions, or endoscopic techniques. In general, longitudinal incisions allow meticulous vascular dissection, identification, and ligational branches, thus minimizing accidental injury to superficial nerves and facilitating the procedure. Harvest a segment of vein 15% to 20% longer than the measured defect. Ligate all branches with 4-0 or 5-0 suture, and coagulate them with bipolar cautery or microclip branches to prevent leakage (Fig. 33.6).
- Dilate the vein to inspect for injury, to compress valves, and to detect wall defects or unligated branches; if damage and problems persist after repair, harvest a new vein.
- At the time of surgery, dissect and mobilize the ends of the severed artery, and position vascular clips for later rapid identification. Typically, the vein graft is reversed and placed in position, but nonreversed valvulotomized veins may be used.
- Perform the more difficult anastomosis first because the extra degree of freedom allowed by the mobility of the vein graft makes repair easier and prevents technical errors. Repair the anastomosis as described above. Discrepancies in size are common with vein grafting; they can be overcome by using the techniques previously discussed or by using nonreversed valvulotomized grafts (Fig. 33.6 and 33.9).

In Situ and Nonreversed Vein Grafting The primary indications for in situ and nonreversed vein grafting are (a) the need for a large (greater than 7 cm) graft segment, (b) multiple distal anastomoses, and (c) significant size discrepancies between the proximal and distal ends. This type of grafting prevents the large discrepancy in lumen size at both ends found with reversed vein grafting and provides natural branching for multiple distal grafts. Incise all valves before revascularization. The risk of accidental vein damage is the limiting factor with the use of this type of grafting. Historically, many microvascular surgeons preferred reversed interposition vein grafting; new valvulotomes, endoscopic techniques, and documented efficacy support the judicious use of nonreversed valvulotomized vein grafts, however.

Arterial Grafts Despite theoretical advantages of a better size match, freedom of orientation, longer theoretical patency, and ease of dissection, few adequately sized donor arterial grafts are available and the use of arterial grafts is limited. If reconstruction of one artery is contraindicated and sufficient undamaged vessel is available, use it as an interposition graft.

Temporary Shunting Use temporary shunting to prevent or minimize prolonged warm ischemia. Use commercially available shunts or heparinized Silastic catheters. A variety of carotid endarterectomy shunts are available and are sized (e.g., 3 mm distal, 3 mm proximal) to fit 2.5 to 5.0 mm vessels. Smaller vessels can be shunted using neurosurgical ventriculoperitoneal shunts; however, these shunts require the surgeon to stabilized them with either suture ligatures or vascular keepers or clamps. Perform minimal dissection to avoid iatrogenic damage, place the shunts, and perfuse the distal extremity. Do a fasciectomy if overt or impending compartment syndrome exists.

Conclusions The need for arterial reconstruction requires an assessment of the adequacy of the collateral circulation and is based primarily on clinical judgement. Preoperative and intraoperative assessment of color, capillary refill (22), turgor, and back bleeding combined with quantitative measures of perfusion provide an estimate of the adequacy of the collateral circulation. Consider arterial reconstruction as part of a patient-oriented plan. Assuming that limb salvage is appropriate, circulation is restored in critical injuries or in the presence of poor collateral circulation (27). A DIB of 0.7 is a relative indication for reconstruction (refer to the discussion
PHYSIOLOGY OF CHRONIC ARTERIAL INJURY AND SUBSEQUENT SYMPTOMS

CHRONIC ARTERIAL INJURIES

management.

fasciotomy for elevated compartment pressures, as needed. Perform revascularization and thrombectomy if it is technically possible and clinically indicated. Repeat

distal small vessel occlusion may respond to heparinization. It is important to monitor the patient for signs or symptoms of compartment syndrome. The need for repair of a noncritical lacerated

tuberculosis, embolectomy, and resection of the thrombosed segment and surgical reconstruction.

The patient's medical status dictates management of ischemia following cannulation injuries. In critically injured patients, evaluation may require exploration of the

organization and may be contraindicated following cannulation events due to coexisting illnesses in this patient population.

Arterial injection injuries occur in the workplace or are secondary to medical procedures. They may also be self-inflicted during drug abuse. Distal ischemia can occur

pseudoaneurysm formation, (b) creation of AVFs, and (c) acute thrombosis with possible distal embolization. Despite a 23% incidence of occlusion of the radial artery

ARTERIAL INJURIES DUE TO CANNULATION

Natural History

Complications arising from indwelling arterial catheters and cardiac catheterization most frequently involve the brachial and radial arteries (4,31,47,53). Repeated

injury to the arterial lumen following attempts to obtain blood from the artery causes vessel lacerations and intimal flaps and an increased likelihood of (a)

Diagnosis

Vascular insufficiency causes pallor, decreased capillary refill, petechiae, and, later, pain. Bedside assessments can be performed using the Allen test or evaluation

with a Doppler device. Arteriography is rarely indicated and may be contraindicated following cannulation events due to coexisting illnesses in this patient population.

Treatment

The patient's medical status dictates management of ischemia following cannulation injuries. In critically injured patients, evaluation may require exploration of the

involved vessel in the intensive care unit or operating room under local anesthesia. Management options include one or more of the following: thrombolytic therapy, thrombectomy, embolectomy, and resection of the thrombosed segment and surgical reconstruction.

In an acute situation, expose the involved vessel and assess the extent of injury. Results following exploration, primary repair, patch grafting, and vein grafting are

excellent, and wound complications are infrequent and manageable. Consider thrombolytic therapy for patients without complicating medical conditions but not in the

immediate postoperative period following extensive nonvascular surgery.

Conclusions

The loss of a radial pulse without ischemic symptoms distally is not an indication for emergency surgery. In an awake and alert patient, monitor the extremity clinically.

In an anesthetized or unconscious (e.g., head injury) patient, objective monitoring through use of the Allen test, placement of temperature probes, Doppler imaging with

hand-held instruments, color duplex instruments, and laser perfusion instruments, or by measuring distal pressure (DBI) is recommended. Arteriography is indicated to

answer specific clinical questions or to explain contradictory findings (20). Suspicion of proximal pathology unrelated to the cannulation injury is an indication for

arteriography.

If symptoms and signs suggest vascular compromise, use heparin unless it is contraindicated. The use of thrombolytic agents is contraindicated in the presence of

pseudoaneurysm, vascular laceration, and in most postoperative conditions (e.g., following heart surgery). In the presence of persistent distal ischemia (45), active

bleeding, or aneurysm, surgical exploration is indicated to determine the extent of arterial damage. Surgery can include resection and ligation, arterial reconstruction,

and thrombectomy or embolectomy.

ARTERIAL INJECTION INJURY

Natural History

Arterial injection injuries occur in the workplace or are secondary to medical procedures. They may also be self-inflicted during drug abuse. Distal ischemia can occur

following injection of a variety of pharmaceutical products (e.g., barbiturates, propoxyphene, and nonparenteral narcotics). Severe vascular events occur following

workplace injury involving solvents, paint products, and lubricants injected through high-pressure devices, but fortunately intraarterial injection is infrequent. Injection

injuries can result in acute, severe extremity ischemia on the basis of secondary vasospasm, chemical endarteritis, arterial blockage by acid crystals, activation of the

clotting cascade, and localized compartment syndromes.

Diagnosis

Clinical history includes exposure to a high-pressure tool, a high-risk medical procedure, or drug abuse. Swelling, numbness, and discoloration often accompany

symptoms of acute arterial insufficiency. Injection wounds often appear innocuous, but the combination of the mass of injected material, chemically induced

inflammation, and increased interstitial pressure (compartment syndrome) may produce secondary vasospasm, thrombosis, and skin and soft-tissue necrosis.

Diagnostic tests include Doppler evaluation, color duplex imaging, arteriography, and interstitial (compartment) pressure measurements. See Chapter 45 for more
details.

Treatment

Unfortunately, end-artery occlusion within microvascular beds is common, and systemic anticoagulation is the only option. Treatment options include vasodilators, thrombolytic agents (e.g., urokinase) (55), steroids, heparin, and low-molecular-weight dextran. Surgical management includes revascularization of injured and

requires an understanding of the principles, fasciotomy, and, in some cases, amputation. Revascularization is difficult because of frequent involvement of small and distal vessels and diffuse

distal vascular injury. If a discrete and reconstructable obstruction or obstructions exist, however, early exploration and embolectomy or thrombectomy or arterial repair

(or both) is indicated. Associated compartment syndrome of the digits, hands, or forearms is common and an indication to perform immediate fasciotomy.

Author's Preferred Approach

Clinical examination should include Doppler ultrasound evaluation, which may provide definitive information. Perform contrast arteriography to determine whether or not

reconstructable segmental occlusion is present and to evaluate the extent of distal microvascular compromise. Management depends on the etiologic agent, the

location of the insult or insults, and the extent of damage. Treatment may involve one or more techniques, which may be performed sequentially or simultaneously.

Manage diffuse thrombosis and embolism involving vessels of any size with thrombolytic therapy (e.g., urokinase), oral vasodilators, and close observation. Discrete,
distal small vessel occlusion may respond to heparinization. It is important to monitor the patient for signs or symptoms of compartment syndrome. Perform a

fasciotomy for elevated compartment pressures, as needed. Perform revascularization and thrombectomy if it is technically possible and clinically indicated. Repeat

arteriography is often necessary to document the extent of large vessel versus small vessel involvement and to evaluate the effects of medical thrombolytic

management.

CHRONIC ARTERIAL INJURIES

PHYSIOLOGY OF CHRONIC ARTERIAL INJURY AND SUBSEQUENT SYMPTOMS
Occlusive disease of the upper extremity may result from trauma, atherosclerosis, proximal embolic events, systemic disease, and hypercoaguable states. Significant arterial occlusion produces ischemia, vasospasm, and stress-induced symptoms; venous involvement may produce cyanosis and edema. Symptoms and signs depend on the existence of collateral vessels and normal functioning vasomotor and autonomic mechanisms (Table 33.2). Symptomatic chronic vascular events produce pain, cold sensitivity, and numbness and may cause ulceration, fibrosis from segmental cell death, and gangrene. The relationship of trauma to occlusive disease is well documented in laborers who use their palms as a hammer (49) or in individuals who participate in activities that expose them to repetitive palmar stress (e.g., baseball catchers).

Although the histologic picture, pathodynamics, and clinical consequences of atherosclerosis and chronic trauma are frequently similar, the etiologic mechanisms and prognosis differ. For example, postrumametral ulnar artery thrombosis has a much better prognosis than does Buerger's disease. Repetitive trauma may produce localized thrombosis on the basis of periadventitial scarring and compression (19). Alternatively, trauma may cause intimal damage and expose the media, disrupt the internal elastic lamina, and expose endothelial collagen. The result can include aneurysmal dilatation, mural thrombosis, complete occlusion, and distal embolic events. This process is worsened in the presence of a hypercoaguable environment and stasis. In the presence of atherosclerosis or systemic disease, vessels appear to be more susceptible to trauma, and occlusion or aneurysm is more frequent. Regardless of the etiology, level, or extent of occlusion, the adequacy of collateral flow and sympathetic tone (Table 33.2) will affect clinical outcome and must be factored into a clinically useful classification (Table 33.3 and Table 33.4).

### POSTTRAUMATIC ULNAR AND RADIAL ARTERY THROMBOSIS

#### Natural History

Compromise of the ulnar artery and proximal superficial palmar arch is the most common type of upper-extremity occlusion and has been described as ulnar artery thrombosis or hypophyseal hammer syndrome (37,40). Symptoms of pain, cold sensitivity, numbness, and weakness occur following thrombosis, occlusion, or distal embolization of the ulnar artery within the confines of Guyon's canal (Figs. 33.12). Signs include the presence of a pulsatile or pulseless mass, absent flow through the ulnar artery by Allen's test, decreased ulnar sensibility, nailbed changes, decreased refill, diminished turpoe, ulceration, and gangrene. Fortunately, ulceration and gangrene rarely occur. Ulnar artery thrombosis occurs most frequently in male laborers in the fifth decade of life. Patients often have a history of using the palm of the hand as a hammer and of using tobacco products.

![Figure 33.12](image)

**Figure 33.12.** A 52-year-old man sustained repeated trauma to the hypothenar area of his left hand. He presented with pregangrenous changes in his little finger. The arteriogram shows complete occlusion of the ulnar artery and superficial palmar arch with no flow to the proper digital artery to the little finger. The deep arch provides filling of the common digital artery to the ring and little fingers as well as the long and ring fingers, but there is no flow past the middle of the proximal phalanx in the proper digital artery on the radial side of the little finger. At surgical exploration, the ulnar artery, superficial arch, radial proper digital artery to the little finger, and proper digital artery to the ulnar side of the little finger were found to be thrombosed. B: Schematic depiction of the surgical findings in the same hand. The black areas represent areas of thrombosis; the cross-hatched areas represent areas of intimal damage. The reversed interosseous 18 cm vein graft from the contralateral foot is shown next to the hand. C: One end of the graft was sewn end to end to the ulnar artery proximal to the area of intimal damage, and the other end was Anastomosed end to end to the proper digital artery on the radial side of the little finger; one limb was placed end to end into the superficial palmar arch. Follow-up at 1 year (including Allen testing, high-resolution real-time ultrasonography, and Doppler evaluation) showed that the vein graft was patent. Symptoms were decreased, the finger ulceration had healed, and the patient was working. (From Koman LA, Urbaniak JR: Ulnar Artery Thrombosis. *Hand Clin* 1985:1:311, with permission from W.B. Saunders Co.)

Throughosmosis of the radial artery, deep arch, and common digital vessels may also occur. Radial artery thrombosis often involves the deep branch of the radial artery within the anatomic snuffbox and is seen in women with collagen vascular disease.

#### Pathophysiology

Human skin microcirculation comprises nutritional papillary capillary beds and nonnutritional thermoregulatory vessels. Distribution of flow between and within these beds varies by anatomic region (Fig. 33.13). Under normal conditions in the digits, 80% to 90% of total flow passes through thermoregulatory beds. In pathologic states, however, cellular hyperperfusion may result secondary to decreased total flow, abnormal distribution of nutritional and thermoregulatory components of flow, or both. Symptoms secondary to anatomic damage (e.g., arterial thrombosis) are managed by either increasing collateral flow or restoring arterial flow (Table 33.3 and Table 33.7). Symptoms secondary to abnormal functional (physiologic) control require alterations in vasoconstrictive and vasodilatory tone that, in turn, have a direct effect on collateral flow, total flow, and the distribution of flow between the nutritional and thermoregulatory beds.

![Figure 33.13](image)

**Figure 33.13.** A schematic diagram of a microvascular bed from the skin surface is shown. Nutritional perfusion occurs in papillary capillaries and is dependent on appropriate arteriovenous shunting. Excessive shunting through arteriovenous anastomoses (AVA) prevents or limits (shunts) nutritional flow. Nutritional flow can also be reduced by arteriole vasoconstriction and a decrease in total flow. (Reproduced from Koman LA, ed. *Bowman Gray School of Medicine Orthopaedic Manual*. Winston-Salem, North Carolina: Wake Forest University Orthopaedic Press, 1985, with permission.)
Valvulotomized vein grafts may be used from the parallel forearm vessel or from the brachial artery to a distal artery (although they are infrequently used, bypass grafts occasionally are necessary in the upper extremity). Reversed interposition, expendability of internal mammary arteries and the radial artery. Therefore, the use of a contralateral radial artery graft for a critical upper extremity vascular problem is possible after resection of the most diseased segment. A critical evaluation of anastomotic sites is crucial; if a compromised vessel is included in the reconstruction, the likelihood of rethrombosis is high. For this reason, reversed interposition autologous vein grafting is most frequently used, as described above.

End-to-end repair is possible after resection of the most diseased segment. A critical evaluation of anastomotic sites is crucial; if a compromised vessel is included in the reconstruction, the likelihood of rethrombosis is high. For this reason, reversed interposition autologous vein grafting is most frequently used, as described above.

Classification of vascular injury based on anatomic and physiologic pathology aids in the selection of appropriate treatment options (Table 33.3 and Table 33.7). Most patients with secondary vasospasm and occlusive disease have adequate collateral circulation (Group II A and II B) and require minimal intervention, such as calcium channel blockers or mild sympatholytics (Algorithm 33.1). Surgical options decrease vasocostrictor tone, restore blood flow, or both. Surgery to decrease abnormal sympathetic tone includes resection and ligation of the thrombosed segment (Leriche sympathectomy), adventitial dissection (peripheral or periarterial sympathectomy), and cervicothoracic sympathectomy. Periarterial or peripheral sympathectomy is considered a salvage procedure and is reserved for otherwise unreconstructible disease with or without adequate collateral flow.

Assuming (a) technical feasibility and (b) a positive risk–benefit ratio, arterial reconstruction is appropriate in selected patients with adequate circulation (Group II A and II B) and is the treatment of choice for patients with inadequate circulation (Group II B and III B). Physical findings following surgical exploration that support the use of arterial reconstruction include (a) absence of a parallel arterial limb; (b) two-level or greater occlusion that compromises potential collateral flow; thrombosis extending beyond the origin or origins of common digital vessels; and (c) incomplete deep and superficial arches (49). Group II B patients, with secondary vasospasm and inadequate circulation, require the restoration of arterial flow for maximal recovery (39). Methods to restore arterial flow include use of thrombolytic agents and a variety of reconstructive arterial surgery techniques.

Thrombolytic therapy is indicated in embolic events, nonembolic thrombosis of the subclavian and ulnar artery, and intraarticular injection injury with medium vessel occlusion. Perforation thrombolysis by introducing a percutaneous catheter proximal to the thrombus and introducing a thrombolytic agent, typically urokinase, a tissue plasminogen activator. Monitor therapy clinically and with serial arteriograms. Twelve to 72 hours of treatment may be necessary, followed by 3 to 6 months of anticoagulation therapy. Thrombolytic therapy is performed using interventional radiology or cardiology consultants, selective catheterization into or just proximal to the thrombosis is optimal, and a more acute occlusion may respond more dramatically than a chronic condition. The current agent of choice is urokinase, with the dose based on the patient's body weight, response to infusion, and the position of the catheter.

Embolectomy is valuable in selected patients and is used in conjunction with thrombolytic agents (i.e., urokinase) or following proximal resection of thrombosed areas and arterial reconstruction. The use of embolectomy catheters within the hand and digits is difficult and may produce vascular damage. The choice of a Fogarty catheter is based on the size of the arteries involved. In general, catheters 1 to 1.5 mm in diameter are used within the distal palm, whereas 2 to 3 mm catheters are appropriate at the wrist and forearm level. It is difficult to introduce embolectomy and thrombectomy catheters distal to the midpalm or distal palm without causing injury; carefully assess the risk–benefit ratio for the patient. After successful embolectomy, administer systemic anticoagulation therapy for 5 to 7 days. Administer intraoperative heparin by bolus (2,000 to 3,000 units), followed by a continuous infusion of heparin based on body weight. A typical 70 kg patient receives 600 to 1,000 units/hour. Obtain daily clotting studies and adjust dosage accordingly. Follow this systemic therapy with an oral anticoagulant (Coumadin) if it is clinically indicated.

In selected individuals, arterial reconstructive procedures have the potential to improve symptoms, to aid in healing, and to prevent premature amputation. End-to-end repair is rarely indicated or possible because of excessive tension at the repair site after removal of damaged artery. In instances in which vessels are tortuous, end-to-end repair is possible after resection of the most diseased segment. A critical evaluation of anastomotic sites is crucial; if a compromised vessel is included in the reconstruction, the likelihood of rethrombosis is high. For this reason, reversed interposition autologous vein grafting is most frequently used, as described above (Fig. 33.12 and Fig. 33.13).

The use of in situ and nonreversed interposition vein grafts requires incising the valves. The exposure and technique are similar to those for reversed interposition grafting, with the exception of vein placement and valvulotomy (Fig. 33.13). The use of expendable donor arterial grafts is not described for upper extremity reconstruction. Current data in the thoracic literature, however, support the use of arteries in preference to veins for coronary artery bypass and supports the expendability of internal mammary arteries and the radial artery. Therefore, the use of a contralateral radial artery graft for a critical upper extremity vascular problem provides an alternative to vein grafting.

Although they are infrequently used, bypass grafts occasionally are necessary in the upper extremity. Reversed interposition, in situ valvulotomized, or nonreversed valvulotomized vein grafts may be used from the parallel forearm vessel or from the brachial artery to a distal artery (Fig. 33.14).
Patients with inadequate distal arterial reconstitution or poor outflow secondary to arteriosclerosis, or end-stage vasoocclusive or embolic disease may be treated with arterialization of venous flow (26,34). This procedure attempts to bypass the valves in the venous system by reversing flow through arteriovenous anastomoses to nutritional vascular beds (26,34). The proximal artery is identified, branches of the in situ venous system are ligated, valves are incised, and arterial flow is established through the venous system to the metacarpal phalangeal level. Theoretically, the delivery of systemic arterial flow to vessels of 150 µm or smaller renders distal valves relatively incompetent, allowing flow reversal within the microcirculation, and perfuses nutritional capillaries retrograde through arteriovenous anastomoses. Salvage procedures are occasionally appropriate and involve transfer of omental free tissue to resurface and revascularize ischemic distal areas, nourished by proximal arterial and venous anastomoses.

Operative Technique (Occlusive Disease)

- Explore the involved arterial tree through an extensive incision. Excise damaged and compromised arterial segments, and reconstruct using end-to-end repair or reversed interposition grafting.
- End-to-end repair is difficult to achieve unless the segment involved is short and tortuous. Do not perform repair with the vessel under tension.
- Use interrupted 7-0 to 9-0 sutures on appropriately sized needles to achieve anastomoses. If grafts are necessary, choices include antegrade veins with incised valves, arterial grafts, prosthetic grafts, or, more commonly, reversed interposition vein grafts.
- Expose vessels, evaluate the vasculature, and initiate resection and ligation or repair. It is important to identify and excise damaged areas of artery. Often, areas of the vessel that remain patent have damaged internal elastic lamina and are at risk for future thrombosis.
- Resecting a central vessel segment that includes patent branches proximally and distally increase the probability that undamaged vessels are repaired.
- Harvest the appropriate-sized graft from either the upper or lower extremity. Although the cephalic and basilic veins are suitable, the distal saphenous vein at the ankle to midcalf level for ulnar artery and brachial lesion is optimal for ulnar artery lesions. The cephalic vein—if adequate—is used in radial artery occlusion. In selected patients who lack appropriate donor veins, the contralateral radial arterial may be an option.
- Grafts, either in situ, or the valves incised, or reversed, are appropriate. In situ grafts overcome the size discrepancies created by reversed grafts, with the larger proximal end needing to be anastomosed to the smaller distal artery. Multiple terminal branches are common in antegrade grafts with incised valves but are more difficult to find in reversed vein grafts.
- To accomplish in situ and bypass grafts using a valvulotomized vein, perform end-to-end repairs with an operating microscope. The grafts must be tensioned appropriately to prevent kinking.
- In short uncomplicated grafts involving the ulnar artery and superficial arch, it is appropriate to complete both end-to-end repairs before deflating the tourniquet.
- When reconstructing the radial artery within the anatomic snuffbox, perform the distal anastomosis (to the deep arch and princeps pollicis) before performing the proximal repair in order to facilitate the anastomosis.
- In larger or more complex grafts, deflate the tourniquet briefly in order to confirm flow through the vein graft.
- Use an operating microscope unless there is a clinical contradiction.
- After completing the more difficult anastomosis, if possible, trim the graft to size (10% longer than the defect), distend it with heparinized physiological saline (10 to 50 units/ml), and place it in its new bed in the wrist or palm. Take care not to twist the graft. Use 8-0 or 9-0 nylon suture on 100 to 135 µm needles for distal repair.
- Manage vessel size discrepancies using the most appropriate technique.
- If two or more distal anastomoses are necessary, accomplish end-to-end and end-to-side repairs in a series of steps. Complex reconstructions may be achieved by end-to-side anastomoses proximally and distally. Y grafts, and bypass grafting (Fig. 33.15).

Postoperative Care

- Give systemic intraoperative heparin as one or two 2,000 to 5,000 unit boluses immediately before releasing the tourniquet. Irrigate all vessels with heparinized balanced solution.
- After all the anastomoses are complete, deflate the tourniquet, remove the clamps, and check the repair or repairs for patency and leaks. After obtaining hemostasis, close the wound in a single layer from wrist to digits. Place a single Silastic 7-French drain adjacent to but not touching the vein graft, if necessary.

Conclusions

Environmental modification, biofeedback, and pharmacotherapy are helpful in most patients with occlusive vascular disease and may ameliorate signs and symptoms secondary to pathologic vasospasm in patients with adequate primary and collateral circulation (Algorithm 33.1). When required, arterial reconstruction can reduce symptoms of pain, improve function, increase distal arterial perfusion, promote healing of ulcerations, and prevent gangrene in extremities with inadequate collateral circulation (Algorithm 33.2). Successful reconstruction of occlusive lesions proximal to unreconstructible lesions increases total digital flow and nutritional flow.
distal to inoperable digital occlusions while simultaneously decreasing symptoms, increasing function, and positively affecting health-related quality of life (59). In contradistinction, symptomatic improvement from Leriche (44) or peripheral sympathectomy procedures in patients with diffuse vasocclusive digital disease occurs via an increase in the ratio of nutritional to total flow without increasing total microvascular perfusion.

EMBOLISM

Natural History

Embolism of the upper extremity often originate in the heart, subclavian artery, and superficial palmar arch. Upper extremity embolic events account for less than 20% of arterial emboli, and 70% are of cardiac origin. Cardiac emboli are created by mural thrombi that form after myocardial infarction or in association with atrial fibrillation. In general, cardiac emboli are large and affect the brachial artery, whereas emboli of arterial origin (noncardiac) are smaller, affecting wrist-level and digital-level vessels. Most emboli originate in the subclavian artery; they are commonly produced by mural thrombi secondary to thoracic outlet compression and poststenotic dilatation. Emboli from aneurysms or thrombotic events in the wrist and palm occur in and affect primarily the common and proper digital arteries.

Pathophysiology

In contradistinction to occlusive disease, which may be insidious in onset, embolism often produces acute pain, pallor, and palselessness. Paralysis occurs rarely and only after lesions proximal to muscle units; thus, it is not present in distal events. Secondary vasospasm may compromise undamaged collateral flow, and necrosis is commonly followed by ulcerated digits. The classic blue finger progresses to white and then black. The degree of damage depends on the amount of embolism, the extent of undamaged collateral vessels, the presence or absence of continued embolic events, and the source of the emboli.

Principles of Treatment

As in occlusive disease, the goal in the treatment of embolism is to restore pulsatile flow and to normalize the distribution of the components of the flow.

Diagnosis

Acute changes in upper extremity flow affecting multiple terminal vessels suggest embolic events. Symptoms of pain, pallor, pulselessness, and paralysis are not specific, but an acute onset suggests an arterial origin. By performing a complete history and a physical examination: obtain consultations for evaluation of embolic events and echocardiogram. The extent and location of the occlusion can be determined rapidly by segmental pressure measurements, arteriography and color duplex imaging can pinpoint the embolic source. Arteriography using conventional techniques or magnetic resonance imaging is important to determine the extent of the damage (16).

Treatment

Embolectomy followed by anticoagulation using heparin sulfate is the treatment of choice for large emboli. After embolectomy, initiate anticoagulation with heparin followed by Coumadin for approximately 3 months. Reperfusion injury following revascularization may result in a compartment syndrome requiring release. Embolism of arteries in the hand and the excision of embolic sources may require surgical explorations. For acute situations that do not respond to heparinization, use urokinase or streptokinase (17,53).

Conclusions

For patients with acute signs and symptoms of embolism, we perform arteriography immediately. If lesions are found, we initiate thrombolytic therapy. If appropriate, we perform embolectomy, surgical reconstruction, or both.

ANEURYSM

Natural History

Aneurysms are either false or true. False aneurysms or pseudoaneurysms occur most frequently following penetration of the vessel wall, with subsequent hemorrhage and extravasation. The resultant hematoma in the soft tissues becomes organized, fibrosed, and recanalized. The lumen of this false vessel is in continuity with a true vessel and is distinguished from it by the absence of endothelial lining.

True arterial aneurysms result from injury to the vessel causing gradual dilation into a more uniform shape, compared with the saclike appearance of a pseudoaneurysm. Whereas false aneurysms commonly result from penetrating traumatic and iatrogenic incidents, true aneurysms occur most frequently in areas of arterial circulation that are exposed to repetitive trauma (e.g., the distal ulnar artery and superficial arch).

The incidence of false aneurysms following penetrating trauma is unknown. False aneurysms of the upper extremity accounted for 27% of all of the false aneurysms recorded in the Vietnam vascular registry (52). Aneurysms of the ulnar and digital vessels are evenly distributed between the true and false type, and ulnar artery aneurysms comprise the largest group of both true and false aneurysms (52). False aneurysms are frequently encountered in the axillary, brachial, anterior interosseous, and radial arteries but may also involve the radial artery within the anatomic snuffbox, the palmar arch, and the digits.

The time interval between the trauma and the clinical evaluation of an aneurysm may vary considerably between 2 weeks and 12 years. The natural history of both true and false aneurysm is characterized by a slow progression leading to thrombosis, the production of emboli, or both. The effect of thrombolytic agents on the natural history is unknown. However, the degree of turbulence in the re-created aneurysm and any abnormal coagulation properties are similar to the pretreatment state and rethrombosis is possible. In fact, because the components of Virchow's triad for thrombosis (stasis, turbulence, and hypercoagulability) is present, reocclusion is likely to occur.

Diagnosis

An aneurysm is usually a painless, palpable mass; signs and symptoms occur secondary to mass effect or vascular insufficiency (13). Symptoms of localized pain from soft-tissue and neural compression can occur secondary to a mass effect; distal signs and symptoms occur most frequently from embolization.

Aneurysms are readily identified by Doppler ultrasonography, color duplex scanning, and B mode imaging. Arteriography, the gold standard, can define the extent of damage: delineate distal embolic events; differentiate the aneurysmal mass from an arteriovenous malformation, neural tumor, or malignancy; and, most important, aid in preoperative planning by assessing collateral flow and determining the possibility of reconstructing distal vessels (18).

Treatment

The traditional treatment options for aneurysms include (a) resection and ligation, (b) excision of the damaged wall and patch graft, (c) resection with end-to-end repair, and (d) resection with interposition graft. The choice of treatment is determined by evaluating collateral flow and vasomotor tone. Resection of the aneurysm has been found effective, along with proximal and distal ligation of a noncritical radial or ulnar artery aneurysm; brachial vessels or critical vessels, in general, however, require arterial reconstruction. The long-term benefit of thrombolytic agents is unknown.

Conclusions

Aneurysmal dilatation produces turbulence, thrombosis, recanalization, and embolism. Because of the risk of thrombosis and distal embolization, surgical treatment of both true and false aneurysms is recommended. Aneurysms may occur in the presence of adequate or inadequate circulation and may be accompanied by distal ischemia and embolic disease. If collateral flow is adequate, providing uniform digital pulp microcirculatory perfusion, either resection plus ligation of the aneurysm or arterial reconstruction is appropriate. When collateral flow is inadequate or occlusive, or embolic events occur distal to the aneurysm, arterial reconstruction using end-to-end repair or reversed interposition vein grafting or other techniques is advised. (See previous discussion of preoperative and intraoperative assessment and treatment techniques.) Until further data are available, we feel that thrombolytic therapy is relatively contraindicated in the treatment of upper extremity aneurysms.
ACQUIRED ARTERIOVENOUS FISTULA

Natural History and Pathophysiology

AVFs occur following trauma, infection, or iatrogenic trauma from catheterization or hemodialysis. Distal ischemia and neurologic symptoms are created by shunting, which causes a so-called steal phenomenon. Although most patients tolerate AVFs for dialysis, complications are common (11,46). Following end-to-end and end-to-side anastomosis of the radial artery to the cephalic vein (radiocephalic AVF), digital blood flow to the thumb may be reduced by up to 40% secondary to proximal shunting (steal phenomenon) (11). Arterial insufficiency is produced if distal perfusion decreases below a critical volume (DBI = 0.5). Dialysis-associated steal syndrome (DASS) occurs in 1% of side-to-side radiocephalic fistulas and in 6.4% of patients who have undergone forearm loop grafts (50a). The incidence increases significantly in the presence of pre-existing occlusive disease distal to the shunt.

Shunts may cause high-output cardiac failure characterized by progressive cardiomyopathy, fatigue, and dyspnea on exertion and may produce a higher than expected incidence of median and ulnar neuropathy. The incidence of median mononeuropathy following radiocephalic AVF approaches 70%—significantly higher than the 2% incidence in the contralateral hand. Neurologic symptoms are produced by neural ischemia, elevated interstitial pressure, diminished systolic pressure in the presence of pre-existing elevated carpal canal pressure, and venous distention compressing neural structures. Shunt reversal or banding may alleviate symptoms of arterial insufficiency secondary to inappropriate shunting, but neurolysis of involved nerves may be required.

Diagnosis

On examination, a thrill or bruit is frequently present. A combination of neural or ischemic symptoms (whether due to a steal phenomenon or emboli) and the presence of an AVF support the diagnosis, which may be confirmed by an assessment of digital flow. A DBI of 0.5 to 0.7 is a harbinger of impending cell death and necrosis. Stress testing may be helpful to delineate the pathophysiology. An assessment of nutritional flow may be diagnostic. Arteriography is required to differentiate between aneurysm and thrombosis, to document emboli, and for preoperative planning.

Treatment

Management options for symptoms secondary to AVF include sympatholytic agents, banding, and ligation. Surgical ligation of the venous limb of the shunt, leaving the artery intact, may be required if banding (decreasing shunt diameter) is inappropriate. The persistence of excessive arteriovenous shunting may produce severe neurologic and ischemic sequelae, which may require (a) shunt revision, (b) banding or ligation of the shunt, or (c) neurolysis of compressed nerves, or a combination thereof.

Banding or narrowing of the shunt increases the resistance through the shunt, increases blood flow distally in the digits, and may reverse symptoms if the shunt is 4 mm or more in diameter. Shunts smaller than 3 to 4 mm, however, may not produce sufficient flow for effective dialysis. Banding is indicated if the ulnar artery is patent and occlusion of the radial artery distal to the fistula causes a documented increase in distal perfusion. It is also indicated if occlusion of the venous limb increases digital flow and banding allows adequate flow for dialysis. Occlusion of the radial artery distal to side-to-side fistulas eliminates retrograde steal and increases thumb blood pressure significantly (11). Documentation of digital blood pressure before and after occlusion of the radial artery below the fistula provides valuable information in symptomatic patients with a DBI of less than 0.64 (Algorithm 33.3)

Conclusions

Treatment must be patient oriented and must take into account the importance of vascular access in the dialysis-dependent patient. Decisions require the combined input of the patient, nephrologist, vascular access surgeon, and the hand surgeon. In general, severe symptoms following an AVF require surgical intervention. In the presence of pre-existing or acquired occlusive disease distal to the AVF, severe symptoms are frequent and are alleviated most effectively by elimination of the vascular steal, by minimizing abnormal sympathetic tone, and by arterial reconstruction of occlusive disease.

The treatment of ischemia in patients with AVFS is difficult and requires the involvement of the patient, the nephrologist, and the vascular surgeon. Symptoms often include (a) necrotic digital tips requiring amputation, (b) cyanotic digits, and (c) neurologic impairment. Digital blood pressures and peripheral nerve conduction velocity (PNCV) measurements guide the decision. Temporary occlusion of the radial artery distal to the shunt reduces symptoms and improves capillary refill (22) and the DBI is less than 0.5, we consider banding or ligation of the shunt. If PNCVs are abnormal and the DBI is greater than 0.7, associated neurologic complaints may be reduced by neurolysis with excision of any venous compressive structure. If PNCVs are normal, distal perfusion is poor, the DBI is less than 0.5, and graft reversal represents an unacceptable burden, consider bypass grafting from the brachial artery to a vessel distal to the fistula (Algorithm 33.3).

ARTERITIS

Natural History and Pathophysiology

Arteritis of the upper extremity is encountered in thromboangiitis obliterans (TAO), giant cell arteritis, Wegener's granulomatosis, Takayasu's arteritis, polyarteritis nodosa, and collagen vascular disease, and it is seen in association with neoplastic disease. TAO (Buerger's disease) is an inflammatory occlusive disease of small and medium-sized vessels (9). Classic clinical characteristics include lower extremity involvement in young, predominantly male smokers (33). The male-to-female ratio of patients with TAO, however, is declining, with older patients more frequently seen and upper extremity involvement more common (41). Although arteriographic differentiation from atherosclerosis is relatively obvious, TAO is difficult to differentiate from scleroderma and collagen vascular disease. Histologically, arterial or venous thrombosis with lymphocytic and polymorphonuclear leukocyte infiltration into the thrombus and vessel wall is observed. If the patient quits smoking, disease progression decreases and the need for amputation is less likely.

Diagnosis

Arteriographic findings typical of TAO include (a) small and medium vessel involvement, (b) segmental occlusive disease, (c) distal disease greater than proximal, (d) collateralization bypassing occlusive segments, and (e) normal proximal (e.g., brachial) vessels.

Principles of Treatment

- Improve nutritional flow to improve the response to stress.
- Correct inappropriate arterial-venous shunting.
- Increase proximal and distal perfusion.

Preoperative Management

All nonoperative management to maximize total and nutritional perfusion falls under the rubric of preoperative management. Use calcium channel blockers and other pharmacologic or mechanical means, including biofeedback, to decrease sympathetic tone, decrease abnormal shunting, and increase nutritional flow.

Preoperative Planning

Preoperative planning in cases of arteriolar insufficiency requires (a) an understanding of the vascular anatomy and (b) an assessment of physiologic control. Therefore, studies to evaluate the form and function of the vascular tree are important and should include an estimate of

- Total flow—before and after stress [temperature and laser Doppler flow (LDF)],
- Nutritional flow (LDF, vital capillaroscopy), and
- Vascular anatomy (arteriography or magnetic resonance angiography) (16,20). Surgery should then be planned to
- Decrease sympathetic tone and increase nutritional flow by periarterial sympathectomy, and
- Increase total and nutritional flow by arterial reconstruction and periarterial sympathectomy (Table 33.7).

Operative Technique
Direct treatment toward the relief of vasospasm and the restoration of anatomic channels by using vascular reconstruction, if necessary. The techniques used here are identical to those in acute and chronic reconstruction.

**VASOSPASTIC DISEASE**

**PATHOPHYSIOLOGY**

Under normal conditions, arterial vasconstriction maintains blood pressure by the peripheral modulation of vascular resistance, directing blood to nutritional capillary beds, providing appropriate thermoregulatory control, and preventing excessive blood loss after trauma. However, inappropriate vasoconstriction may produce symptoms of pain and cold intolerance, interfere with health-related quality of life, and result in ulceration, gangrene, or both. Pathologic vasospasm produces inappropriate arterial and venous tone that persists in the presence of physiologic demands for increased flow or contrary to specific cellular metabolic needs. Inappropriate cold sensitivity, the most common symptomatic manifestation of vasospastic states, is frequent and affects 5% to 10% of the general population and 20% to 30% of premenopausal women. Vasospastic states are defined as primary (Raynaud's disease) in the absence of an identifiable etiology or secondary (Raynaud's phenomenon) in the presence of a causal condition (Table 33.8).

Symptoms in vasospastic conditions result from inadequate vascular structure, inappropriate vascular control mechanisms, or both. Adequate tissue perfusion requires delivery of blood to nutritional capillary beds in sufficient quantity to fulfill metabolic needs, appropriate oxygen-carrying capacity, and diffusion of oxygen through intravascular spaces to functioning cellular structures. In the majority of patients, oxygen and metabolic-carrying capacity within the vascular system is adequate. In the absence of intravascular fibrosis and cell death, symptoms are secondary to inadequate delivery of blood products at a cellular level (ischemia). Vasospasm decreases total flow, shunts blood through nonnutritional thermoregulatory pathways, or, in some cases, does both.

**CLASSIFICATION**

Although vasospastic disease, occlusive disease, and vasocclusive disease are interrelated, they are physiologically distinct (Table 33.4). Group I patients have idiopathic Raynaud's disease, which is characterized by normal vascular architecture, no identifiable underlying etiology, and the presence of vasospasm. Group II patients exhibit Raynaud's phenomenon that may be secondary to vascular injury and may be classified as either (a) those with normal collateral flow or (b) those with abnormal collateral flow. Group IV patients without pre-existing or acquired structural or vascular abnormality have secondary vasospasm after sustaining an injury to nerves, soft tissue, bone, or any combination thereof. These categories provide criteria that allow treatment to be based on anatomic and physiologic considerations.

The clinical manifestations of vasospastic states result from inadequate nutritional perfusion, insufficient delivery of oxygen and metabolites to cellular structures, and the development of an anaerobic and acidic tissue environment. Raynaud's phenomenon classically has three stages that progress from normal to blanched (white) to cyanotic (blue) to rubrous (red). Sympathetic hyperactivity stimulated by exposure to cold or other stresses initiates intense vasospasm with cessation of arterial inflow and the production of a white, blanched, and cool digit (stage 1). Stasis within the digit produces deoxygenated, pooled blood that appears cyanotic or bluish and produces the characteristic blue hue seen in stage 2 of the phenomenon. The rubor (redness) in stage 3 is secondary to reactive hyperemia from a rebound vasodilation initiated by the ischemia; reperfusion is associated with burning pain, dysesthesias, or both. Therapeutic approaches are designed to increase microvascular flow and maximize capillary perfusion.

**DIAGNOSIS**

Take a complete history, perform a physical examination, and order appropriate laboratory studies (35). Pursue a diagnostic strategy to delineate physiologic events (i.e., vessel structure, vascular function and control, and intravascular blood components) and to determine precipitating local or systemic processes or disease (e.g., collagen vascular disease, arterial occlusion, neurovascular compression, hematologic abnormality, trauma, smoking, drugs or toxins, central nervous system disease, or primary vasospasm). Specifically, diagnostic goals should

- Differentiate vasospastic from vasocclusive states.
- Separate Raynaud's disease from secondary Raynaud's phenomenon.
- Evaluate the effects of structural compromise versus functional impairment.

The existence of nonhealing ulcers and impending gangrene, which are associated with unilateral Raynaud's symptoms, is presumptive evidence of thrombosis or embolism.

Evaluate pulses, and look for trophic change, ulcerations, and infections. Wrist-level and digital Allen testing is a valuable screening test for distal occlusive disease and may be enhanced by digital plethysmography and measurement of segmental arterial pressures. Check capillary refill, turgor, skin integrity, and sensitivity. Perform appropriate nerve conduction studies if there is a suspicion of neurologic dysfunction and neurologic symptoms. Use laboratory tests to look for hematologic or collagen vascular abnormalities.

The noninvasive vascular evaluations outlined previously may be employed in order to delineate the structural and functional influences on perfusion of the upper extremity. Digital plethysmography and temperature measurements with and without stress are most commonly used. Pressure gradients of greater than 20 mm of mercury between two levels in the same extremity or between the affected and contralateral extremity, or a DBI or an RBI of 0.7 or less, suggest stenosis or occlusion (8,48).

Collagen vascular disease can be diagnosed using vital capillaroscopy to document pathognomonic capillary morphologic changes including telangiectasias, abnormal capillary budding, and blunting, dilation, or deformation of papillary capillaries. At present, vital capillaroscopy is the only clinical method to assess directly the nutritional components of digital blood flow. A quantitative and qualitative assessment of digital perfusion is necessary to make an appropriate diagnosis and to plan medical care. Detailed assessments of digital temperature, laser Doppler flowmetry measurements of cutaneous perfusion, and vital capillaroscopy before and after stress allow a determination of the extent of arterovenous shunting, the adequacy of nutritional flow, and an estimate of total flow available (65,86-89).

Laser Doppler flowmetry reflects nutritional perfusion and provides data regarding thermoregulatory flow components. Combined temperature and plethysmographic data correlate with total perfusion (38). Allen testing and pulse volume recordings provide data regarding vascular structure, which may be delineated morphologically by contrast arteriography or—if available—magnetic resonance angiography (16,20). Structural data, complemented by stress testing, provide a functional assessment of extremity flow. A combination of both structural data and functional information is mandatory for optimal evaluation (38).

Contrast arteriography provides the best overall assessment of vascular pathology and structural integrity. Indications for arteriography include potential surgical intervention, unilateral Raynaud's phenomenon, progressive gangrene or ulceration, suspected occlusive or embolic disease, and clinical concerns regarding vascular structural integrity. For patients with decreased perfusion or vasospasm, use isosomotic contrast agents to enhance diagnostic capability and vasodilation through
intraarterial agents (e.g., tolazoline or nitroglycerine) or regional anesthetic block (e.g., axillary block). Vasospasm prevents visualization of vasculature that is otherwise adequate structurally, and the incurred diagnosis that could result may affect treatment plans.

**INDICATIONS FOR TREATMENT**

The majority of patients can be managed without surgery. The treatment of vasospastic disorders must be individualized. Management options include medical therapy, biofeedback, digital sympathectomy, and microvascular reconstruction. Patients with vasospastic symptoms, abnormal autonomic control, and absence of occlusive disease (Group I, Raynaud's disease), frequently respond to nonsurgical modalities and improve spontaneously over time. For patients in Group II (Raynaud's phenomenon) and Group III (occlusive disease), structural and functional information guides treatment decisions. With inadequate collateral circulation (Groups IIB and IIIB), vascular reconstruction is indicated, if possible. Although nonsurgical methods or peripheral sympathectomy may reduce patient symptoms, the prognosis is guarded. Patients in Group IV (secondary vasospasm or normal vasculature) improve with correction of the initiating traumatic event or with appropriate pharmacologic intervention.

**PRINCIPLES OF TREATMENT**

- Decrease inappropriate vasospasm by nonsurgical management, if possible.
- Improve nutritional blood flow in the absence of occlusive disease using, in order (a) calcium channel blocker, (b) biofeedback, (c) oral pharmacologic agents, and (d) peripheral sympathectomy.
- In the presence of combined occlusive and vasospastic problems, correct reparable occlusive disease with or without peripheral sympathectomy (PAS). In the absence of reparable occlusive disease consider, in order (a) peripheral (peripheral) sympathectomy, (b) phenol or alcohol percutaneous proximal sympathectomy, (c) spinal cord stimulators, and (d) arteriovenous reversal. (Note that the up-regulation of peripheral receptors 6–12 weeks following traditional cervicothoracic sympathectomy may reexacerbate clinical complaints.)

**PREOPERATIVE MANAGEMENT**

**Environmental Modification**

Environmental modification includes advising the patient to stop smoking, avoid cold environments, alter activities to eliminate those that precipitate symptoms, and use protective garments. Cessation of smoking is the most important of these modifications. Patients who live in cold climates have more significant symptoms, which may be ameliorated by the use of mittens or hand-held heating devices. A distinct relationship exists between cold exposure of the head and neck and the reflex vasospasm of hands and feet. Advise patients to use scarves and hats.

**Biofeedback**

Biofeedback involves instruction in methods that allow the conscious regulation of autonomic body processes. External monitors are used initially, allowing patients to observe how they can elevate their digital temperatures by changing their rate of breathing or thought processes. Biofeedback significantly alleviates symptoms in patients with groups I, IIA, IIIB, and nonneural Group IV etiology, but it is less effective in patients with Group IIB and Group IIIB symptoms (21).

**Pharmacologic Management**

The goal of pharmacologic intervention is to interrupt or to mitigate sympathetic hyperactivity associated with vasospastic and vasoocclusive disease. Pharmacologic intervention works best in patients with adequate collateral circulation and redistributes flow to nutritional capillary beds by decreasing inappropriate shunting (Fig. 33.13). At present, calcium channel blockers are the drugs of choice for vasospastic symptoms, provide the most reliable palliation of symptoms, have an acceptable level of side effects, and present an excellent risk–benefit ratio (34). Calcium channel blockers prevent calcium influx in vascular smooth muscle and diminish sympathetically driven vasconstriction. Nifedipine, 10 to 30 mg bid, or in long-acting form (30 to 60 mg qd), and amlopidine besylate (Norvasc), 5 to 10 mg qd, are the drugs employed most frequently. Other drugs include:

- Triyclic antidepressants (amlotrilamine, 25-75 mg QHS)
- Serotonin reuptake inhibitors (fluoxetine hydrochloride [Prozac], 20 mg qd; sertraline [Zoloft], 25 to 50 mg qd, and paroxetine [Paxil], 20-50 mg qd)
- Sympatholytic drugs (prazosin hydrochloride, 1 to 2 mg bid to tid; terazosin hydrochloride, 1 to 2 mg qd; clonidine, 0.1 mg bid or by transdermal patch).

**OPERATIVE TECHNIQUES**

Surgical options may restore near-normal physiologic function or provide short-term to intermediate-term palliation. Group IV patients with nonvascular injury seldom require surgery. Successful surgical intervention depends on the underlying etiology, the extent and location of vascular insults, and the extent of irreversible end-organ damage. Surgical options include reconstruction of occluded thoracic vessels and modulation of sympathetic tone (Table 33.7).

**Alteration of Sympathetic Tone**

Sympathetic tone may be altered by proximal cervicothoracic sympathectomy, Leriche sympathectomy (resection of thrombosed or occluded vessels and ligation) (44), or peripheral periartrial sympathectomy (19,38,54).

Proximal (cervicothoracic) sympathectomy decreases sympathetic tone and improves peripheral blood flow by permanent ablation of the cervical sympathetic trunk and may be performed through an axillary or cervical incision, or by endoscopic technique. Chronic sympathectomy secondary to cervicothoracic interruption of sympathetic fibers decreases total peripheral flow and produces upregulation of distal alpha-adrenergic receptors. It also decreases the efficacy of subsequent peripheral sympathectomies. This procedure, which is often immediately effective, lasts only 6 to 12 weeks in many patients and, after that time, may increase sympathetic tone. Temporary posterior cervicothoracic sympathectomy by phenol injection under computer tomography control is reversible and may be of benefit during collateral vessel maturation.

Peripheral (periartrial) sympathectomy may be performed by a variety of techniques (32). Classically, Leriche observed that resection of a thrombosed segment of occluded artery with ligation proximal and distal stumps decreases abnormal sympathetic tone and improves distal perfusion through collateral circulation. Therefore, peripheral sympathectomy is performed by excision of thrombosed arteries with or without arterial reconstruction. In the presence of Group IIA occlusive disease and secondary vasospasm, the structurally adequate but abnormally functioning circulation will respond and deliver adequate distal flow to fulfill metabolic requirements. However, in Group IIB occlusive disease, there is inadequate collateral flow and sympathectomy will be inadequate to restore microvascular perfusion. In primary vasospastic conditions with or without occlusive disease (Groups IIA and IIB), peripheral sympathectomy of digital vessels or wrist-level vessels may be necessary to decrease optimally abnormal tone. The Leriche sympathectomy may be combined with multiple-level peripheral sympathectomy and arterial reconstruction.

1. A Leriche sympathectomy involves the excision and ligation of a thrombosed segment of artery, which interrupts the sympathetic connections from the peripheral nerves to the peripheral arteries as well as the sympathetic fibers that travel on and within the adventitia of peripheral arteries (69). It is preferable to begin in an area of near-normal tissue and to continue the dissection into the area of occlusion. In the case of the ulnar artery, transect the nerve of Hente as well as other connections with the ulnar nerve while protecting the ulnar nerve.
2. Peripheral sympathectomy decreases spasms in the collateral circulation and decreases inappropriate arteriovenous shunting, thereby increasing nutritional flow. If collateral circulation is inadequate or if there are multiple levels of occlusion, a Leriche-type sympathectomy may not provide sufficient palliation.
3. With a digital sympathectomy technique (Flatt and Wilgis) (33,53), digital arteries and nerves are identified through Brunner zigzag incisions from the distal palmar crease to the midportion of the proximal phalanx. All connections between the digital nerve and artery are transected, and the adventitia of the digital artery is stripped from the artery under the operating microscope (19).
4. A palmar or hand sympathectomy technique (Koman) (38) is used to achieve a sympathectomy of all four digits and the thumb. A description of the procedure follows:
   - Expose the radial and ulnar artery, the superficial arch, and the three common volar digital arteries by means of three palmar incisions: two parallel 3 cm longitudinal incisions at the wrist and an oblique incision in the palm (Figs. 33.16).
Figure 33.16. Schematic representation of periarterial sympathectomy of the hand using longitudinal incisions to expose the radial and ulnar artery and an oblique incision in the palm to expose the superficial arch and the origins of the common volar digital arteries (Koman technique) is shown. A separate incision (not shown) may be used over the anatomic snuffbox to expose the radial artery. After initial dissection under loupe magnification, the operating microscope is used to strip the adventitial filters from the vessels and to sever connections with parallel peripheral nerves. (Reproduced from Koman LA, ed. Bowman Gray School of Medicine Orthopaedic Manual. Winston-Salem, North Carolina, Wake Forest University Press, 1997, with permission.)

- Transect the connections between the radial and ulnar arteries and their respective nerves over a 3 cm segment. Dissect the adventitia of the radial and ulnar artery under the operating microscope over a length of 2 cm.
- Similarly, after exposure of the proximal portion of the superficial arch and the origins of the three common volar digital arteries, all connections from the peripheral nerves to the arteries are severed, and all periarterial adventitia containing neural tissues is dissected free.
- If there are significant symptoms in the thumb, make a fourth dorsal incision in the anatomic snuffbox, and expose and mobilize the deep branch of the radial artery and the origin of the deep arch. Remove the adventitia (Fig. 33.16) (19).

Arterial Reconstruction

Arterial reconstruction is indicated in patients with refractory symptoms and inadequate collateral circulation (Group IIB and IIIIB) (32,33). Vascular reconstruction in Group IIA and IIIA patients should be individualized as described previously. The goal of surgical reconstruction is to increase digital perfusion pressure and nutritional flow in ischemic digits (38-40) by (a) end-to-end repair, (b) interposition grafting, or (c) bypass grafting of the occluded vascular areas. Also important is functional modification of sympathetic tone resulting from the peripheral sympathetic association with the vascular resection. Successful arterial reconstruction in patients with underlying collagen-vascular disease increases total digital flow and nutritional flow, diminishes symptoms, and promotes healing of ulcers (38-39).

In extremities with inadequate collateral circulation or unreconstructible distal occlusion, successful reconstruction of a concurrent proximal occlusion increases total digital flow and nutritional flow, decreases symptoms, and allows ulcers to heal (39). In contradistinction, Leriche resection of the proximal occluded segment combined with peripheral digital and palmar sympathetic improves nutritional flow by the elimination of inappropriate arteriovenous shunting but does not increase total flow (38). The technique for reconstruction is similar to that used in occlusive disease.

AUTHORS' PERSPECTIVE

The selection of treatment modalities is determined by pathophysiology, and the treatment goal should be directed at appropriate distribution of digital flow to provide adequate nutritional capillary flow sufficient to meet metabolic demands under stressed and nonstressed conditions. Treatment decisions are aided by a knowledge of structural and functional characteristics and the classification of the vasospastic state (Table 33.4). For example, Raynaud's phenomenon with inadequate circulation (Group IIB) is the condition most refractory to treatment and Group IIB patients have the highest incidence of ulceration. Conversely, patients in Group I (Raynaud's disease) and Group IV (secondary vasospasm from a nonvascular injury) have the best prognosis, rarely have ulcerations, progress infrequently to gangrene, and often respond to oral medications or biofeedback and improve spontaneously.

Environment modification, pharmacologic agents, and biofeedback are often effective in Group I (Raynaud's disease), Group IIA (Raynaud's phenomenon with adequate circulation), and Group IV (secondary vasospasm without arterial compromise). These patients have normal vasculature, but abnormal vascular reactivity secondary to abnormal sympathetic control. In patients with inadequate collateral circulation or inadequate circulation (Groups IIB and IIIIB), the prognosis is guarded unless arterial reconstruction can be successfully achieved. The use of periarterial sympathectomy in patients with inadequate circulation is a salvage procedure.

Selection of candidates for periarterial sympathectomy is controversial. An increased digital temperature or pulse volume recording and decreased symptoms after wrist or digital block with lidocaine or bupivacaine confirm abnormal sympathetic tone and that sympathectomy will provide palliation. Of note, in response to sympathetic blockade, patients with vasocclusive disease and inadequate collateral circulation are unlikely to be able to increase digital temperatures—a reflection of total flow. In a percentage of these extremities, however, nutritional flow is maximized, inappropriate arteriovenous shunting is decreased, ulcers heal, and symptoms decrease. This group of patients benefits the most from periarterial sympathectomy. The surgeon must have a thorough knowledge of the diagnostic tests and their interpretation to identify them (38). Although surgical statistics would be improved by eliminating this group of patients, some of whom do not have sufficient flow to respond successfully, it is this group of patients that needs a palliative procedure the most. The role of arteriovenous reversal in vasculopathic disease represents an additional modality and deserves investigation. Although short-term relief is dramatic, long-term efficacy has not yet been demonstrated in the peer-reviewed literature.

REPLANTATION

Successful clinical replantation of completely severed limbs has been possible for nearly 40 years. The first successful reattachment of a completely severed human limb was reported by Malt et al. in Boston in 1962 (55). Komatsu and Tamai (56) have been credited with successful replantation of a completely severed digit in 1965. Zhong-Wei et al. (57) reported the successful replantation of a severed digit the same year. Over the past three decades, several microsurgery centers throughout the world have achieved greater than 80% success rates in replanting severed digits, hands, and major limbs (83-88,101,102). Additional experience, subspecialization in microsurgery with the increased knowledge and skill in reconstructive surgical skills in this field, improvements in microscopes, ultrathin needles, microsuture materials, and other new and improved instruments have made replantation the procedure of choice for the management of many amputations (1,4,11,82,88,89).

The most important factor determining the patency of the anastomosis and survival of the replanted or revascularized part is the technical adequacy of the microvascular repair (82). Successful microsurgery requires familiarity with the operating microscope and microsurgical instruments and the careful handling of small vessels and surrounding tissues. These skills must be learned in the animal laboratory, not in the clinical operating room. After the surgeon has demonstrated proficiency in the repair of microvessels and nerves, in the animal laboratory, then these skills may be transferred to the operating room. In addition, replantation of amputated parts should be done by surgeons who are thoroughly trained in surgery of the upper extremity and hand and who have had sufficient clinical experience to be able to predict the outcome following replantation of a severed part.

INDICATIONS FOR REPLANTATION

Among the factors that must be considered in deciding to replant an amputated extremity are the predicted morbidity to the patient; survival of the replanted part; functional outcome of the reconstructed limb; and the overall financial burden to the patient, insurance carrier, or society (83). The predicted function after replantation should be better than that of a prosthesis or amputation revision. Because the ultimate functional result may be unpredictable, the decision of whether to replant an amputated part is often difficult, even for the experienced reconstructive surgeon.

Replantation experience does help in the selection process. Based on the experience of more than 1,800 attempted replantations over a 25-year period by my colleagues and me, we have developed criteria for proper patient selection. The surgeon must understand that not only viability but also recovery of useful function determine success in replantation.

Factors that influence the selection process include the following:

- Level of amputation
- Severity of injury (guillotine versus crush or avulsion)
- Warm and cold ischemia times
- Age of patient
- Segmental injuries
- General health of patient
- Vocation
- Predicted rehabilitation

It is generally unwise to allow patients or families to make the decision regarding replantation because they will usually request replantation even in cases where there is little chance of survival or function of the replanted part. The final decision must rest with the surgeon in collaboration with the patient. Social, ethnic, and religious beliefs about the significance of loss of the amputated part do influence the surgeon's decision regarding replantation, however.

No listing of indications or contraindications for replantation is rigid or absolute, and the criteria, although generally similar for most replantation surgeons, vary with individual experience (83). Future experience with replantation and technological advances in externally powered prostheses are likely to further alter these criteria. On the basis of this standard, good candidates for replantation are those with amputations of the following types:

- Wrist (Fig. 34.1)
Figure 34.1. Good candidates for replantation include amputations at the level of the wrist. A,B: A complete amputation at the wrist level in a 21-year-old man. C,D: The amount of digital flexion (C) and extension (D) seen in this patient 3 years following successful replantation. (From Porubsky GL, Urbaniak JR. Limb and Digital Replantation. In Flye MW, ed. Principles of Organ Transplantation. Philadelphia: WB Saunders, 1989.)

- Partial hand (through metacarpal level of palm) (Fig. 34.2)

Figure 34.2. A,B: Complete amputation of the left index and long finger through the metacarpals in a 20-year-old man. The amputated part was reattached as a composite. C,D: Flexion (C) and extension (D) 1 year later. The patient lacks 5 mm of touching the distal palmar crease with the index finger and 4 mm with the long finger. He returned to work as a meatcutter 3.25 months after the injury.

- Thumb (Fig. 34.3)

Figure 34.3. A: Dominant thumb of a 16-year-old boy was avulsed by a nylon rope. B,C: Replantation resulted in less than 5 mm of two-point sensory discrimination and individual interphalangeal and metacarpophalangeal flexion and extension. (From Urbaniak JR. Replantation of Amputated Hands and Digits. American Academy of Orthopaedic Surgeons Instructional Course Lectures, Vol. 27. St. Louis: CV Mosby, 1978.)

- Multiple digits
- Forearm
- Almost any body part of a child
- Elbow and above elbow (only sharply severed or moderately avulsed)
- Individual digit distal to the flexor superficialis insertion

Even though these are not necessarily rigid indications for replantation, if all other factors are favorable one should attempt replantation of these amputated parts.

Successful replantations at the level of the palm, wrist, and distal forearm result in good hand function (65,66,77,94,101) (Fig. 34.1). Usually, amputations proximal to the midforearm level are of a crushing or avulsing nature, which produces considerable muscle trauma. Myonecrosis and subsequent infection are common problems with this type of replantation, particularly at the elbow or brachial level; therefore, be extremely selective in choosing replantation at these levels.

Make every effort to salvage the amputated thumb in patients of all ages. A replanted thumb is far better than any type of reconstructed thumb to replace one that has been amputated (5,31,58,68,73,95) (Fig. 34.3). Attempt replantation even as far distal as the nail base if vessels for revascularization can be located. If the patient is healthy, there is no upper age limit (33,75).

When multiple digits are amputated, a decision must be made about whether to replant all or just some of the digits (67,82). The digits that are least damaged may be transposed to the most useful or least injured amputation stumps (2,71). For example, if the thumb and index finger have been completely amputated in a crushing injury and the distal thumb has irreparable distal vessels, transpose the amputated index finger to the thumb stump. This alteration should result in excellent thumb function and cosmetic acceptability.

The level of the amputated digit influences the decision for replantation. Amputations at or distal to the interphalangeal joint of the fingers or the interphalangeal joint of the thumb can be successfully replanted if dorsal veins can be located on the amputated part (21,25,26,36,41,43,54,59,75,81,91,98). As a general rule, at least 4 mm of dorsal skin proximal to the base of the nail plate must be present for locating veins suitable for repair.

We replant amputations distal to the superficialis insertion; an excellent functional result can be achieved, and the operating time is not long (usually less than 4 h) (33,87). Replantations at this level are usually successful (greater than 90% viability rate), provide a good appearance, are not painful, allow good function, eliminate the potential for painful neuromas, and permit an early return to work (usually less than 3 months) (16,33,87).

In children, attempt to replant almost any amputated body part because, if the reattached part survives, useful function can be predicted (20,84).

Just as indications for replantation are not absolute, neither are contraindications. Injuries generally not considered ideal for replantation include:

- Amputations in patients with other serious injuries or diseases
- Amputations at multiple or segmental levels
- Severely crushed or avulsed parts
- Amputations in which the vessels demonstrate arteriosclerosis
Amputations in mentally unstable patients
Amputations with prolonged warm ischemia time (more than 6 h)
Individual finger amputations in the adult at a level proximal to the superficialis insertion (proximal interphalangeal joint or proximal)

Severe crushing or avulsing amputations can often be salvaged with the use of vein grafts to replace the injured vessels (3,9,85); however, there are no methods for replacing the most distal vessels in the amputated part. Because arteriosclerotic plaques on the intima often preclude functional patency following the reanastomosis of small vessels, the arteries of older patients must be thoroughly evaluated under the microscope before reattachment. In addition, patients with diabetes mellitus may have diseased blood vessels, which would lessen the likelihood that repaired vessels will remain patent. Again, the experienced microsurgeon can determine the potential success of an anastomosis by studying the vessel structure under a high-powered microscope.

Although it is possible to reconstruct amputations that have been severed at multiple levels (for example, in the phalanges and midpalm or at the elbow and above the elbow, in the same patient), replantation is usually not recommended because the time commitment is large and the predicted outcome is uncertain (8).

The patient's mental stability is a component of the decision regarding replantation. Mental instability is not uncommon in patients who sustain completely amputated upper extremities, but it is often difficult to determine the patient's mental stability during the limited preoperative assessment stage.

Based on assessment of isolated digital replantation, we recommend not replanting the isolated finger amputation proximal to the flexor superficialis tendon insertion. Although the cosmetic result is excellent, the overall function of the hand is usually not improved; in fact, this digit sometimes gets in the way. Special considerations, such as for musicians, young women, and children, do influence selection, however (72,87). The patient with a replanted index finger that was amputated at the base will usually bypass the replanted digit to oppose the thumb to the long finger.

The surgeon must explain to the patient and family the chances of viability, length of surgery and hospitalization, anticipated functional outcome, predicted loss of time from work, and cost compared with an amputation revision. Equipped with all of this information, most patients and families will insist on replantation; therefore, the ultimate decision rests with the surgeon. On many occasions the final decision cannot be made until the vessels of the amputated part are carefully evaluated under the operating microscope.

SURGICAL TECHNIQUE OF REPLANTATION

PREPARATION OF THE AMPUTATED PART AND PREOPERATIVE CARE

Preservation of the Amputated Part

Preoperative physiologic storage of amputation parts is essential to achieve success in replantation. Generally, if the warm ischemia time of the amputated part exceeds 6 h, do not attempt replantation. If the amputated part contains muscle, the ischemia time is much more critical. Muscle is extremely sensitive to ischemia, compared with tissues such as skin, bone, and tendon (22,23).

Cooling reduces metabolic acidosis, muscle autolysis, and bacterial growth. All amputated parts should be cooled during the transportation to a replantation center. If the part is cooled, successful replantation is possible with cold ischemia times up to 12 h, or even longer if it is a digit; we have successfully replanted amputated digits with cold ischemia times up to 30 h. However, transportation of the amputated part and the patient should be as rapid as possible.

The amputated part may be preserved by one of the following two basic methods:

1. Wrap the part with gauze moistened with Ringer's lactate or saline solution and place it in a plastic bag, which is then placed on ice.
2. Alternatively, immerse the part in Ringer's lactate or saline solution in a plastic bag and place this bag on ice.

Both methods result in equal viability rates at 24 h, but we prefer the immersion method for the following reasons (92):

1. The part is less likely to become frozen (frostbitten).
2. The part is less likely to be strangled by the wrappings.
3. Instructions are easier to explain to the primary-care physician.
4. Maceration secondary to immersion is not a problem.

**Instruments**

The microsurgery instruments are described in detail in Chapter 33, so only the equipment essential for replantation surgery is mentioned here. A great variety of expensive microsurgery instruments are unnecessary; the appropriate instruments must be available, however, and the working ends must be well maintained for precision handling of the small microstructures, fine needles, and suture material (Fig. 34.4) (11,83,88). Basic replantation surgery instruments include the following:

Figure 34.4. Basic microsurgery instruments for replantation. Left to right, bottom row: Micro-Pots (angled) scissors, spring-loaded curved tipped microscissors, spring-loaded needle holder, two jeweler's forceps, 30-gauge blunt needle syringe for irrigation. Top row: Lacrimal duct dilator (below), latex background material (above), microclip approximator (below), Van Beek nerve approximator (above), and small cotton absorbent sponge sticks.

- Surgical loupes of 3.5× to 4.5× are necessary for the initial debridement, exploration, and dissection of the amputated part and injured extremity.
- An operating microscope with magnification to at least 20× is essential. Preferably, the operating microscope should have a beam splitter and a double head that allows the surgeon and the first assistant to visualize the same microfield. Foot controls for focusing, zoom magnification, and horizontal xy movement are ideal. We use the microscope for the repair of any vessels distal to the axilla.
- Microinstruments should be at least 10 cm long to allow the handles to rest comfortably in the thumb–index webspace. Instrument handles at least 15 cm long are recommended for all microsurgery instruments to increase the versatility of the instruments when operating in deep fields.

Essential instruments include the following:

- A spring-loaded needle holder and spring-loaded microscissors
- Two sets of jeweler's forceps
- A microtipped dilator (lacrimal duct dilator)
- A microirrigator (30-gauge smooth-tipped needle)
- Various sizes of (approximator) microclips mounted on some type of bar

The less complex the microclip the better; I prefer the disposable type with two plastic tips mounted on a metal sliding bar. The use of a new clip or microapproximator
for each procedure better assures a constant pressure of less than 30 g/cm. Other helpful equipment includes:

- Small hemoclips to tag the vessels and nerves and to use when isolating or harvesting vessels
- A small-tipped bipolar cautery, essential in isolating and mobilizing the vascular structures to be repaired.

Some type of colored rubber background material is useful in highlighting the vessels and suture material. I prefer a yellow background material, particularly if the lighting is low.

The level of the replantation determines the selection of needle and suture size for the vascular repairs. Table 34.1 suggests the appropriate needle and suture size for amputations at the wrist level or distal. An 8-0 or even 7-0 suture may be used proximal to the elbow.

### INITIAL MANAGEMENT OF THE AMPUTATED PART AND PATIENT

#### Anesthesia

Most replantations can be performed under axillary block with bupivacaine, a long-acting local anesthetic. Regional anesthesia is favored because of the peripheral autonomic block, which increases vasodilation and peripheral blood flow (22). Some inhalation anesthetics may result in vasospasm and diminished peripheral blood flow. General anesthesia is necessary in the uncooperative patient or for children 12 years old or younger. Keep the operating room warm at all times to diminish peripheral vasospasm caused by cooling of the body temperature.

#### Team Responsibilities

It is advantageous for the replantation team to divide into two subteams (here designated teams A and B) when the patient and the amputated part arrive in the emergency room. This practice is more critical with major limb replantations. Surgeons without microsurgical experience may help prepare the amputated part and patient; however, they must be experienced in dissecting the small vessels lest irreparable damage may occur. They may, however, be quite helpful in the bone trimming, bone fixation, and tendon repair and subsequent wound coverage.

#### Team A Responsibilities

Team A responsibilities include the following duties and surgical techniques:

- Immediately transport the amputated part to the operating room for initial cleansing with Hibiclens and sterile Ringer’s lactate solution.
- Place the prepared amputated part on a bed of ice covered with a sterile plastic drape. If multiple digits are involved, these may be cooled by storage in a refrigerator or under ice packets until the appropriate time for replantation. Care must be taken not to freeze them.
- Under the operating microscope or with operating loupes (depending on the size of the amputated part), carefully debride the part or parts and identify and tag the nerves and vessels with small hemoclips. This identification and tagging of the neurovascular structures will save time when microsurgeons have to work in a bloody field at a later time. The ease in locating the tagged structures, particularly in multiple amputations, is definitely beneficial in the later stages of replantation, particularly if the procedure is lengthy and fatiguing.
- Make bilateral longitudinal midlateral incisions, which provide the most rapid and best exposure of the neurovascular structures on the digits (Fig. 34.5). Place the incisions slightly toward the dorsum so that both the dorsal and palmar skin flaps can be reflected to locate the veins, nerves, and arteries with ease.

### Figure 34.5. A: Bilateral longitudinal midlateral incisions. B: Neurovascular bundles exposed palmarly and veins exposed dorsally. (From Urbaniaj JR. Replantation in Children. In Serafin D, Georgiade NG, eds. Pediatric Plastic Surgery. St. Louis: CV Mosby, 1984:1168.)

- Using magnification, isolate the digital nerves and vessels for a distance of 1.5 to 2 cm and tag them.
- Identify the dorsal veins on the amputated part by reflecting the entire dorsal flap of skin and dissecting the subdermal tissue. In the amputated digit, locating and labeling the veins may be delayed until after arterial anastomosis, which makes identification of veins easier because of the backbleeding, particularly if the patient and amputation stump are ready to receive the amputated part. If the patient is not yet prepared to receive the amputated part, however, then search for the veins at this time to reduce the overall operating time.
- Continue additional debridement after isolation and labeling of the neurovascular bundles.
- Shorten and trim the bone appropriately on the amputated digit.
- Insert an intramedullary Kirschner wire retrograde in the amputated part so the part is prepared for immediate reattachment. If the bone is closely surrounded by soft-tissue structures, a 16-gauge hypodermic needle serves as an excellent protector guide for the 0.45 Kirschner wire.

#### Team B Responsibilities

Team B’s activities are concurrent with those of team A. Team B’s responsibilities include the following tasks and techniques:

- Thoroughly evaluate the patient in the emergency room with a physical examination, radiographs of the chest and injured extremity, cardiogram, complete blood count, blood chemistries, urinalysis, blood type and cross-match, and activated partial thromboplastin time.
- Begin intravenous fluids and administer intravenous antibiotics and tetanus prophylaxis if indicated. Insert an indwelling urethral catheter if a long procedure is anticipated.
- Using magnification and tourniquet ischemia, debride the stump and locate and label the neurovascular structures in a manner similar to the preparation used by Team A on the amputated part.
- It may be difficult to locate the subcutaneous veins on the stump, particularly for the inexperienced surgeon. Because successful replantation depends on the patency of an adequate number of veins, this is a critical point of the operation. Isolating veins in the digit may be tedious and requires meticulous dissection and careful handling of these small structures. After one good vein is located in the subcutaneous layer, this vein may serve as a guide to direct the surgeon to similar veins in the same subdermal plane.
OPERATIVE SEQUENCE

The sequence of repair of the severed structures in replantation will vary slightly depending on the level of amputation (digit versus levels proximal to the wrist) and type of injury (sharp versus avulsion). The technique of replanting amputated digits is described first because these amputations are much more common than the more proximal amputations. The variations in technique used for major limb replantations are described subsequently.

Repair for digit and hand replantation takes place in the order indicated in Table 34.2.

Once the vessels and nerves are located and tagged, protect these neurovascular structures during the debridement. Do not, in haste to reestablish blood flow, compromise on the irrigation and debridement. A thorough wound debridement is essential. A pulsating jet lavage is useful in severely contaminated major limb replantations. Excise all necrotic and potentially necrotic tissue, particularly muscle.

All structures are repaired primarily, even if primary nerve grafting is necessary for approximation of the severed nerves. It is much easier to make repairs at the time of the initial reconstruction than to reoperate secondarily through the repaired structures of the replanted part.

BONE SHORTENING AND STABILIZATION

Never anastomose arteries, veins, and nerves under tension. Sufficient bone must be resected to ensure the ease of approximation of normal intima in the vascular anastomosis. Additionally, bone shortening allows easier skin coverage of the repaired veins, particularly on the dorsum of the digits. The amount of resected bone depends on the type of injury. In an avulsion or crushing type of injury, more bone must be resected until normal intimal coaptation is possible without tension. For the digit, it is usually necessary to resect 5 to 10 mm of bone; in amputations proximal to the hand, 2 to 3 cm of bone resection may be indicated. In the avulsion type of injury, even more bone resection is done. If it appears that a great deal of bone must be resected in the digit or in partial hand amputations, use vein grafts to make up the deficit in the arteries and veins rather than doing excessive bone shortening.

Many replantation surgeons emphasize that bone shortening is seldom necessary, and instead they recommend vein grafting when there is considerable intimal damage (52). Bone shortening should usually be chosen over vein grafting, however, because there is often concomitant damage to the nerves and other soft tissues. These injured structures can be more easily managed after bone shortening. However, do not hesitate to perform vein grafts when they are indicated (for example, when the loss of a potentially functional joint may result from bone shortening). This is particularly true for a child, for whom excessive bone resection should be avoided because it results in the excision or potential damage to the epiphysis and joint. Do not hesitate to perform interposition vein grafts when they are necessary; it is quicker, easier, and less frustrating to perform an interposition graft than to redo a difficult anastomosis several times, or even one time.

In replantation of the thumb, most of the bone shortening is done on the amputated part to preserve maximal length on the stump in case replantation fails. This is not always possible, as, for example, when attempting to preserve joint function. Several methods of bone fixation are available (Fig. 34.6) (41, 79, 86, 97):

- Longitudinal intramedullary Kirschner wire or wires
- Longitudinal intramedullary Kirschner wire plus oblique Kirschner wire to prevent rotation
- Crossed Kirschner wires
- Interosseous wiring
- Intramedullary screw or bone peg
- Miniplates and screws
- Tension band technique.

All these methods may be used to stabilize replantations; however, certain methods may be preferred in specific areas, such as near the joint or epiphyseal plates. When possible, it is preferable to perform bone stabilization in a digit with double axial Kirschner wires because the lowest nonunion and complication rates occur with this method (97). This is the easiest and quickest method when a motorized drill is used for careful pin placement. A large-bore hypodermic needle (16-gauge) is often used as a guide to prevent the surrounding soft tissue from wrapping up near the bone ends. In more than 1,800 replantations, we have experimented with all methods of bone stabilization and prefer single or double axial Kirschner wire fixation for the following reasons:

- Speed and simplicity of the technique
- Minimal bone exposure required
- Minimal skeletal mass needed for fixation
- Ease of reshortening or readjusting the bone approximation if deemed necessary
- In children, the likelihood of physeal damage is minimal with a single well-centered intramedullary longitudinal pin. A second axial intramedullary pin is frequently used for better stability (62).

Crossed Kirschner wires can cause potential damage in the repaired neurovascular bundles, either by contact or by tethering of the vessels or the protective retaining ligaments. I prefer crossed Kirschner wires for arthrodesis of joints. A chevron bone cut aids stabilization when crossed Kirschner wire fixation or the tension wiring is
A thorough description of the microvascular technique is given here, and further details are presented in Chapter 33. Anastomose the arteries after bone fixation and primary tendon repair. Use a suture method in primary flexor tendon repair, with the following recommendations:

- The Tajima suture method is excellent for primary flexor tendon repair in replantation surgery (Fig. 34.7).

With the Tajima method, sutures can be placed in each end of the tendon initially, and the approximation secured any time during the procedure.

- This delayed coaptation has the advantage of allowing the digit to be held in full extension for better vascular and nerve repair, particularly in the area of the proximal phalanx.

Some primary repairs of flexor tendons in replanted digits may require subsequent tenolysis; however, do not do a tenolysis for at least 3 to 6 months after the primary repair.

If a delayed flexor tendon repair is necessary, it may be safely performed as long as 3 months after the initial replantation or revascularization. Usually the two-stage silicone rod method is indicated.

**VASCULAR REPAIR**

**Arterial Repair**

A thorough description of the microvascular technique is given here, and further details are presented in Chapter 33. Anastomose the arteries after bone fixation and primary tendon repair. Use a suture method in primary flexor tendon repair, with the following recommendations:

- The Tajima suture method is excellent for primary flexor tendon repair in replantation surgery (Fig. 34.7).

With the Tajima method, sutures can be placed in each end of the tendon initially, and the approximation secured any time during the procedure.

- This delayed coaptation has the advantage of allowing the digit to be held in full extension for better vascular and nerve repair, particularly in the area of the proximal phalanx.

Some primary repairs of flexor tendons in replanted digits may require subsequent tenolysis; however, do not do a tenolysis for at least 3 to 6 months after the primary repair.

If a delayed flexor tendon repair is necessary, it may be safely performed as long as 3 months after the initial replantation or revascularization. Usually the two-stage silicone rod method is indicated.
extensor and flexor tendon repair. The recommended number of arteries to repair is as follows:

- With the digit, it is advisable to repair both arteries when possible.
- At the palm or at the wrist level, anastomose all available arteries to increase the chances of survival (56). Some microsurgeons recommend the repair of only one digital artery to diminish the operating time; however, we have demonstrated that both vessels, even in multiple digital amputations, should be anastomosed to increase the survival rate (52).

Preparation of the Arteries

- Free the arteries from their surrounding connective tissue for a distance of 1.5 to 2 cm. Perform this dissection under the microscope with microsurgical instruments. Small branches from the arteries may be safely coagulated with bipolar cautery.
- Dissect a severed artery until normal intima is visualized under high-power magnification. Only normal intima must be reconnected (Fig. 34.8).

![Image](https://example.com/image.png)

**Figure 34.8.** Preparation of the vessel. A: The damaged portion must be resected until normal intima is visualized under high-power magnification. B: Minimal adventitia is stripped to make the lumen clearly visible.

- If vessels with normal intima cannot be approximated, further bone shortening is necessary; preferably, however, use interpositional vein grafting.
- The two most critical factors in achieving successful microvascular anastomosis are the surgeon's skill and expertise and the ease of coaptation of normal intima to normal intima with minimal tension.
- Assess the most distal and proximal portions of the exposed vessels to ensure there is no damage to the media or surrounding adventitia. Such an injury indicates the need for further arterial resection and vein grafting.

To establish blood flow:

- After sharply trimming the opened end of the proximal stump and enlarging it with jeweler's forceps or a dilator, an excellent pulsating blood flow must occur.
- Active spurting blood in a digital vessel should produce a persistent stream of at least 5 cm for about 20 to 30 seconds.

If sufficient blood flow cannot be obtained, proceed as follows:

- Do not use this vessel for repair.
- Take steps to relieve the proximal vasospasm that is present.
- Be certain that the patient is not hypotensive, hypovolemic, cold, acidic, or in pain, because all these factors introduce unwanted vasospasm.
- Perform thorough irrigation of the proximal lumen with warm heparinized Ringer's lactate solution to relieve vasospasm.
- If it is certain that no proximal mechanical block exists, place papaverine in a 1:20 solution with normal saline directly on the proximal vessel or gently insert it into the lumen with a blunt needle. This maneuver usually provides an excellent pulsatile flow that lasts for at least 30 min.
- Exercise caution when using papaverine or similar dilating agents because the flow induced may be temporary and flow may be induced in vessels with damaged intima.

After excellent flow is established in the proximal stump:

- Insert the two vessel stumps into the approximating microclip. Coapt the ends without tension.
- If undue tension is present, use an interpositional vein graft obtained from the palmar forearm.
- Trim the vessel ends with sharp straight scissors so that no adventitia covers the ends of the lumen.
- Carefully dilate the lumen of each end with jeweler's forceps or a lacrimal duct dilator.
- Irrigate the lumen with heparinized Ringer's lactate solution and reinspect the intima for complete normalcy.
- Just before beginning the anastomosis, give an intravenous bolus of 3,000 to 5,000 U of heparin (decrease this dose in young children).

Suture Technique

- Apply two stay sutures of 10-0 monofilament nylon 180° apart. Do not tie the sutures too tightly because this will produce necrosis of the vessel wall.
- The distance from the needle insertion to the cut end of the vessel should be about one or two times the thickness of the arterial wall.
- Do not pinch or touch the intima with the jeweler's forceps.
- After the application of each knot, carefully irrigate the anastomosis site with heparinized Ringer's lactate and examine it to ensure the suture does not pierce the back wall.
- After the anterior wall is repaired, turn over the clip approximator and again examine the lumen under high-powered magnification to ensure that all sutures are properly placed.
- Place additional sutures in the back wall in a similar manner.
- Usually six to nine sutures are required to repair an artery 1 mm in diameter.
- In the small distal vessels, particularly in children, sometimes only four or five sutures are necessary for the anastomosis.

Postanastomosis Observations Within a few minutes after completion of the initial arterial anastomosis, the fingertip will begin to turn pink if there is adequate perfusion. Capillary refill should be excellent, and pulp turgor good. If the amputated part has been without blood flow for several hours and has been cooled for a prolonged period, a return of adequate perfusion to the distal part will be delayed. Under these circumstances, proceed with repair of the digital nerve and the opposite digital artery. In addition to warming the replanted part, this waiting period is often all that is necessary to achieve adequate distal perfusion.

**Tourniquet Use**

A pneumatic tourniquet around the upper arm may be used safely for each vascular anastomosis. The tourniquet is helpful in diminishing blood loss as well as decreasing operating time. If the microsurgery is skillfully and rapidly performed, the patency rate will not be affected by the ischemia.

Release the tourniquet at the conclusion of each anastomosis to ensure that the anastomosis is patent and blood flow is strong. The tourniquet may be inflated or deflated many times during the procedure for nerve, artery, and vein repair.

If all is going well and the operative field is not obscured by blood, then a tourniquet is unnecessary.

**Microclips**

- Because all available microclips produce some degree of vessel wall damage, do not apply them for more than 30 min (72).
- In a crushing or avulsion injury, and if the procedure is lengthy, consider giving serial doses of heparin (500 to 1,000 U every hour) intravenously. Adjust this dosage for children.
- After completion of the anastomosis, release the microclips; the blood flow across the anastomosis site should be immediate.
Shifting Arteries and Vein Grafts

In some avulsion or crush injuries, undamaged arteries may be shifted. For example, in a ring-finger avulsion, the proximal ulnar digital artery may be shifted to the distal radial digital artery if these ends are less traumatized. In most instances, however, a vein graft is used if the distal artery is salvageable.

- For reattachment of veins that have been avulsed or amputated, I prefer to use an interpositional vein graft from the ulnar digital artery of the amputated thumb to the first dorsal metacarpal artery, or to the dorsum of the hand, for an end-to-side anastomosis into the radial artery at the wrist. For expediency, the reversed vein graft is often anastomosed to the ulnar digital artery of the detached thumb before bone fixation.
- The final stage is the connection of the proximal end of the vein graft into the artery. We use interpositional vein grafts in about 20% of our replantations to obtain reapproximation of healthy arteries and veins. The palmar aspect of the wrist contains veins 1 to 2 mm in diameter that are appropriate for revascularization of digits.
- Hint: If the use of vein grafts is anticipated, harvest the vein grafts from the forearm in the initial steps of replantation, using loupe magnification before bringing in the operating microscope, in an effort to save time.

Venous Repair

In general, attempt to repair two veins for each artery. It may be necessary to mobilize or harvest veins to achieve this ratio. Venous anastomosis is trying to repair veins under tension. If vein harvesting does not allow coaptation without undue tension, then vein grafts must be used. Following this principle will elevate the patency rate and diminish the surgeon’s frustration as well.

Technical Steps

- The technique of vein repair is similar to that for arterial repair with only a few exceptions.
- Generally fewer sutures are necessary at the anastomosis site because the blood flow through the venous system is not as strong as through the arterial system.
- Because the walls of the veins are more fragile than those of the arteries, minimize the application time of microclips.
- The distance from the needle insertion to the cut in the vessel should be two to three times the thickness of the wall.
- Use constant irrigation of the suture line with warm heparinized lactate solution to float the thin walls apart.
- Do not waste time repairing the very small veins, instead, connect only the largest veins. One large repaired vein is more reliable than two smaller repaired veins.

Options When Dorsal Veins Are Absent

Occasionally in distal digital replantations it may be impossible to locate a suitable dorsal vein. Various available options are as follows:

- Arteriovenous shunt. If successful flow through a repaired digital artery is established, retrograde flow from the unrepaired distal contralateral artery may be seen. In the absence of a suitable vein in the distal part, connect this digital artery to a proximal vein (arteriovenous shunt). This procedure is successful in about half of the attempted cases in providing sufficient venous drainage.
- Removal of the nail plate. Removing the nail plate allows venous oozing from the nail bed. Every 1 or 2 h, have a physician, nurse, or family member stroke the nail bed with a cotton-tipped applicator to stimulate bleeding from the nail bed. In the interim, apply heparin-soaked pledges to the exposed nail matrix.
- Surgical leeches. Surgical leeches have been successfully used when venous congestion is apparent. Place the leeches, which are readily available from various biological companies, on the failing part until they become engorged with blood; remove them and replace with fresh leeches every few hours.
- Venocutaneous fistula. The venocutaneous fistula technique involves the construction of a temporary venous return bypass using a venous graft. Anastomose the proximal side of the venous graft to a vein at the dorsum of the stump. Then suture the distal end of the graft to the skin around a punch wound on the volar side of the replanted fingertip.

Figure 34.10. The venous cutaneous fistula, a technique for reducing venous congestion in replanted fingertips when distal dorsal veins are not present. A cut is made in the volar pulp, and the vein graft extends from this bleeding fistula to an easily located dorsal vein on the proximal stump. (Modified from Kamai K, Sinokawa Y, Kishibe M. The Venocutaneous Fistula: A New Technique for Reducing Venous Congestion in Replantation Fingertips. Plast Reconstr Surg 99:171,1997.)

- Periodic massage. Periodic massaging of the distal segment to enhance venous drainage improves the venous outflow temporarily but is usually not successful in achieving viability of the part if it must be continued more than a day or two.
- Skin grafts. When there is an absence of skin on the dorsum of the replanted digit, cover the anastomosed veins with a split-thickness or full-thickness graft.
- Venous flaps. If there is a deficit of veins in addition to subcutaneous tissue and skin, cover the defect by a venous flap. This flap may be based on a proximal pedicle from an adjacent digit or freely harvested from the dorsum of the hand or foot or volar forearm. A vein graft with its covering of subcutaneous tissue and skin serves as a conduit for venous return as well as skin coverage.

All of these options to enhance venous drainage are inferior to a dorsal vein repair if it is feasible.

Should the Arteries or Veins be Anastomosed First?

Some surgeons prefer to repair the veins before the arteries to decrease blood loss and maintain a bloodless field for better vision. By judicious use of the tourniquet, however, the artery may be repaired first and a dry field maintained. This sequence provides the advantage of earlier revascularization and allows easier location of the most functional veins, detected by their spurring backflow. Additionally, if the veins are repaired first, and a subsequent arterial anastomosis fails to show adequate arterial inflow, the surgeon has wasted valuable time on a nonsalvageable part.
Variations of Repair

In some difficult replantations, such as distal to the interphalangeal joint or deep in the thumb–index webspace, the back wall inside-out technique is favored over the conventional two-stage microanastomosis (1). Use this method in cases where limited exposure of the vessel ends may preclude the possibility of inverting the vessel for back wall repair.

Introduce the needle into one vessel end from the outside in, withdraw it, and pass it from inside out on the other vessel. Begin the repair with the back wall and, by alternating sutures, work the knots toward the front wall.

In some fingertip replantations, a reversed vein graft is sutured to the digital artery of the amputated fingertip before bone fixation. This sequence allows for better exposure and an easier anastomosis (49).

Various coupling devices, laser methods, and even tissue cements have been developed for small vessel repair, but none has proven as successful as interrupted suture methods (44,45,72).

NERVE REPAIR

Nerve repair in replantation is usually not difficult because the bone has been shortened, and no tension should be present at the suture line.

Technical Steps

- Attempt primary repair in all replantations, when feasible.
- If direct end-to-end repair is impossible, then use primary nerve grafts.
- The median antebrachial cutaneous nerve of the ipsilateral extremity is ideal for primary nerve grafting in the digital nerve (62).
- The nerves from a discarded segment such as a severely damaged digit may be used to bridge the gap.
- The Van BEEK nerve approximator (Fig. 34.4) is extremely helpful in repair of nerves in difficult areas.

Using the Operating Microscope

- Cut the nerve ends sharply until pouting fascicles are seen on each stump.
- Align the fascicles on the freshly cut nerve ends and approximate the ends without undue tension, using 8-0 to 10-0 monofilament nylon or polypropylene (prolene).
- Epineural repair after obtaining geographic fascicular alignment is the best method for the digital nerves.
- Only two or three epineural sutures are necessary; more sutures are used in proximal injuries, where the nerve is larger.
- Fibrin glue may be helpful but really does not save time in replantation (44).

SKIN COVERAGE AND DRESSING

After all of these structures have been repaired and successful revascularization of the replanted part has been ensured, meticulous hemostasis is essential. Failure to obtain complete hemostasis can lead to multiple postoperative problems and failure of the replant.

- Loosely approximate the skin with a few interrupted nylon sutures. Usually the midlateral incisions are not closed to allow for decompression of the digital vessels. Excise all potentially necrotic skin, and place no tension on the skin during the closure. Cover the vessels without constriction from the overlying skin or sutures. A local flap or split-thickness graft may be necessary, even for digital vessel coverage. Large defects may be covered by "flow-through" arterialized venous flaps or pedicled venous flaps (27,42,60,80). Fasciotoomies are indicated if the slightest pressure or constriction occurs.
- Cover the wounds with small strips of gauze impregnated with petrolatum or antibacterial grease. Never place these strips in a continuous or circumferential manner around the replanted part. Although it is preferable not to cover the replanted part with any dressing or splint, to allow free drainage and early active motion, this is usually not feasible because some type of protective dressing is necessary. The ideal dressing is bulky and uniformly compressive but not constrictive.
- Extend the plaster splints above the elbow to prevent proximal slippage while the hand is being elevated (Fig. 34.11). Apply plaster splints on one side of the hand (usually on the palmar aspect) so that the dorsum of the hand can be inspected if there is a postoperative problem. If flexor tendons have been repaired, however, place the splints dorsally to prevent unwanted pull of the flexors against the rigid plaster.

**Figure 34.11.** Digital temperature is monitored with a telethermometer and small surface probes. These quantitative skin temperature measurements have proven to be the most reliable indicators of replantation status.

- Then elevate the extremity in the bulky compressive dressing by a soft (Styrofoam) cradle boot. Keep the fingertips exposed for application of temperature probes and frequent clinical observation. The environment of the bulky compressive dressing seems to be well suited to the replanted part; often, blood flow increases to the fingertips at the conclusion of the dressing application.
- Do not change the dressing for about 10 days (particularly in children) because anxiety and discomfort produced by the dressing change often incite potentially irreversible vasospasm in the replanted part (22). If there is excessive bleeding into the dressing, change the dressing immediately to prevent constriction from the blood-soaked dressings.

MAJOR LIMB REPLANTATION

The amputation of major limbs (proximal to the wrist or lower extremity) is less common than amputation of digits or parts of the hand. In replantation of limbs amputated proximal to the wrist level or of amputations of a lower extremity below or above the knee, principles similar to those for digit replantation are used with minor modifications. The major difference is related to the increased amount of muscle tissue involved. Because more muscle mass is present in a major limb amputation, the duration of ischemia of the detached part is more critical. Whereas amputated digits that have been detached for 30 to 36 h may be replanted with a high degree of success, an amputated arm at the elbow area is in jeopardy if it has been avascular for 10 to 12 h, even with appropriate cooling. Rarely are major limbs cleanly severed; therefore, the muscle damage is usually quite severe. Extensive muscle debridement of both the detached part and the proximal stump is essential to prevent myonecrosis and subsequent infection. This problem, associated with major limb replantation, seldom occurs in digital reattachment (46).

SHUNTING

- If the amputated part and the patient arrive in the operating room more than 4 h after injury, initiate immediate blood flow into the detached part. This is best accomplished by using some form of shunt, such as a Sundt (Huger Shulte Corporation, Galeta, CA) or ventriculoperitoneal shunt, to obtain rapid arterial inflow from the proximal vessel to the detached part (61) (Fig. 34.12).
Relatively early active joint motion is encouraged in most replantations (the replantation. Permit no smoking by the patient or in the patient’s room, and all efforts should be made to keep the patient tranquil (difficulty with blood flow to the replanted part, then bed rest is advised for 3 to 5 days. If the patient is vigorous or energetic, however, allow activity a day or two after
Bed rest or ambulation is determined by the activity level or desire of the patient. If the patient is anxious and chooses to remain in bed or appears to be having
ACTIVITY
digit, appropriate methods of management must be undertaken immediately.

MONITORING
Debride any necrotic tissue to prevent infection. In general, no anticoagulation is used for major limb replantations.

POSTOPERATIVE MANAGEMENT AND REHABILITATION
Most patients with digital replantations are hospitalized for 7 to 8 days. Major limb replantations, of course, require longer periods, depending on the severity of the injury. Intelligent, careful postoperative management is essential to achieve a high success rate in replantation surgery (23).

ENVIROMENT
Keep the replanted part elevated in the bulky dressing, and keep it warm at all times. The patient should stay in a warm, comfortable room during the first week. If the recovery room is cooler than normal room temperature, place a patient heater or a warmer over the patient. Keep the patient’s room at a minimum of 72°F (22°C) and prevent cool air drafts.

ANTICOAGULATION AND ANTIMBIOTICS
The use of anticoagulation therapy remains controversial. A few surgeons use none or perhaps only aspirin and di-pyridamole; some use all or various combinations of anticoagulants (11,52,67,104). We prefer some type of anticoagulation for all patients. Heparin is generally not indicated in clean-cut amputations that are replanted or if the anastomosis was technically easy and the blood flow was immediately brisk. In these patients, we use aspirin, 300 mg, and dipyridamole, 50 mg, twice daily as well as 500 mg of intravenous low-molecular-weight dextran for 1 week. In addition, we give chlorpromazine, 25 mg three or four times daily, for a tranquilizing effect as well as to provide peripheral dilation. This drug is valuable in relieving vasospasms secondary to anxiety, which occurs particularly in children. In children, the dose is reduced to 10 mg three to four times daily by mouth.

If the injury is of the avulsing or crushing type, give intravenous heparin, 1,000 units every hour, in adults for 7 days. Adjust this dosage in children, giving about 100 U/kg for 4 h. Adjust this according to the activated partial thromboplastin time, which is maintained at 1.5 times normal. If bleeding occurs into the dressing, adjust the dosage and change the dressing immediately to prevent constriction. Do not use heparin prophylaxis in amputations proximal to the wrist level. Give appropriate antibiotics for 1 week.

ACTIVITY
Bed rest or ambulation is determined by the activity level or desire of the patient. If the patient is anxious and chooses to remain in bed or appears to be having difficulty with blood flow to the replanted part, then bed rest is advised for 3 to 5 days. If the patient is vigorous or energetic, however, allow activity a day or two after the replantation. Permit no smoking by the patient or in the patient’s room, and all efforts should be made to keep the patient tranquil (15).

Relatively early active joint motion is encouraged in most replantations (17,18,69); because the dressing is not changed for at least 10 days, however, immediate early
motion is limited. In the patient who has had a replantation distal to the superficialis insertion, encourage movement of the digit the following day because there is really no stress on the flexor or extensor tendons. Otherwise, begin protective active motion against rubber bands and flexor and extensor outriggers, supervised by a hand therapist. 1 to 2 weeks after the replantation. Especially for replantation patients who live far from the treatment center, if more than one digit has been replanted or a major limb has been replanted, keep the patient in the hospital or in a nearby motel so that daily therapy can be supervised by hand therapists.

PITFALLS AND COMPLICATIONS

ACUTE COMPLICATIONS

Acute failures are secondary to inadequate perfusion (39). Often the surgeon can predict which replantation will have a postoperative problem with perfusion. Some examples include:

- Replantation in children under 10 years of age
- Crush and avulsion injuries
- Ring avulsion injuries
- Poor proximal flow observed before the arterial anastomosis
- Intermittent or inconsistent distal flow despite a technically good anastomosis

When these signs of jeopardy are present, extra postoperative efforts are necessary to enhance the chances of survival. Intravenous heparin is particularly beneficial in these difficult replantations.

Regional Sympathetic Block

The use of an indwelling silicone catheter to administer a regional sympathetic block is particularly helpful. Insert a #5 silicone urethral stent beside the median or ulnar nerve (depending on the digits revascularized or replanted) to permit regional block to be given in the postoperative course. The catheter exits from the dressing and has a stopcock attached so that a nurse can give 5 mL of 0.25% bupivacaine hydrochloride every 6 to 8 h. This drug provides regional block anesthesia to diminish vasospasm and alleviate pain. This procedure is particularly rewarding in children because it obviates the use of axillary or brachial block if postoperative spasm develops. In the postoperative period, we have rarely given an axillary or brachial block since the early 1980s.

Management of the Failing Replant

If the reattached part appears in jeopardy in the immediate postoperative period, as indicated by decreased skin temperature, loss of capillary refill, diminished pulp turgor, or abnormal color, immediately take the following steps:

- Inspect the dressing to rule out any type of constriction. Administer intramuscular narcotics prior to inspection.
- Depress or elevate the hand to improve the vascular status, depending on whether the problem is arterial or venous.
- Give an intravenous bolus of heparin (3,000 to 5,000 U), which often incites recovery.
- Give chlorpromazine to diminish anxiety and decrease vasospasm, if necessary.
- Ensure that the patient is adequately hydrated and that the hematocrit is normal or near normal.
- Alter the environment of the patient's room (for example, increase the temperature and remove smokers or other agitating factors), if necessary.
- Make all efforts to calm the patient, especially a child, as pain, fear, and anxiety may initiate peripheral vasospasm.

Return to Operating Room

If normal perfusion does not return after these management measures, return the patient to the operating room. Once this decision is made, do so within the first 4 to 6 h after the loss of adequate perfusion. Seldom have we found reexploration to benefit the patient if it occurs more than 1 to 2 days after replantation. If the patient is returned to the operating room within the first 12 to 48 h, however, many potential failures can be salvaged by redoing the vein graft, removing the thrombus, and usually grafting a previously unrecognized damaged vessel segment.

SUBACUTE COMPLICATIONS

Although infections occur frequently in digital replantations, loss of a replanted digit is rare secondary to infection. The most common infections are pin tract infections, which usually occur more than 4 weeks after the replantation and are easily managed by removing the pins and putting the patient on antibiotics. We have seldom found it necessary to admit a patient to the hospital for pin tract infections.

Infection is more common and more serious in major limb replantations. The presence of large amounts of muscle that have been rendered ischemic increases the likelihood of infection. To ensure adequate muscle debridement, return all major limb replantations to the operating room in 48 h for a “second look” procedure. At this time, inspect the wounds thoroughly and debride any muscle necrosis that has progressed since the first procedure. Infections in major limb replantations may not become apparent until the second week (most commonly in 8 to 10 days); if the infection involves the vascular anastomosis, failure is almost inevitable.

CHRONIC COMPLICATIONS

The most common chronic complications are cold intolerance, tendon adhesions, and malunion.

Cold intolerance is an almost universal complaint in patients who have undergone digital replantations. However, cold intolerance is not unique to digital replantation and occurs with almost equal incidence in other severe hand injuries, including amputations that are not replanted (29). Cold intolerance is related to the adequacy of digital reperfusion; for this reason, try to maximize the number of arterial repairs. Cold intolerance diminishes with time and usually resolves by 2 years (67). Pain is rare in successfully replanted limbs.

Because both the flexor and extensor tendons are usually repaired in replantations, tendon adhesions are common, with diminished motion. If this is severe, tenolysis may be performed as early as 3 months after replantation.

Malunion is most often seen after transmetacarpal replantation. These complex injuries require multiple tendon, vessel, and nerve repairs, and if care is not taken during bone fixation, rotational malunion may occur. Every effort should be made to properly align digits before replantation. Another form of malunion can occur in multiple digit replantations for which it is difficult to identify the various digits at the time of surgery. It may become apparent later that one digit has been exchanged for another. This is primarily a cosmetic problem and does not result in any diminished function.

Nonunion is not a common problem after replantation; it has been reported to occur in only 2% to 9% of digital replantations (39). Usually nonunions are asymptomatic, and I have yet to operate on a patient for a nonunion of a digital replantation.

RESULTS

Most replantation centers can now achieve better than 80% viability in replantation of completely severed parts. Our team has achieved 77% viability in replantations and 92% in revascularizations of more than 1,800 amputations.

By applying the principles presented in this chapter, the experienced and proficient microsurgeon should be able to achieve at least an 80% overall viability rate in replantations. The results, based on our own long-term follow-up as well as reports from major replantation centers, should be as follows:

- The active range of joint motion should be about half of normal, depending on the level of injury.
- Cold intolerance is a definite problem that usually subsides within 2 years.
- Nerve recovery is comparable to the repair of an isolated, severed peripheral nerve (19).
- Cosmesis is usually better than any amputation revision or prosthesis (29).
- Near-normal growth may be anticipated in amputations through the diaphyseal region of children. If the injury involves the epiphysial plate, growth will almost always be retarded, although excessive growth has been reported (64,65,67).

- Cold intolerance is an almost universal complaint in patients who have undergone digital replantations. However, cold intolerance is not unique to digital replantation and occurs with almost equal incidence in other severe hand injuries, including amputations that are not replanted (29). Cold intolerance is related to the adequacy of digital reperfusion; for this reason, try to maximize the number of arterial repairs. Cold intolerance diminishes with...
• The best results are obtained in replantations of the thumb, a finger distal to the insertion of the superficialis tendon, and the hand at the wrist level.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Autologous tissue transplantation describes the surgical technique used to transfer tissue from one location in the body to another using the operating microscope and techniques of microvascular surgery to perform small vessel anastomoses. Free flaps include isolated transfer, composite tissue transfer, and functioning free muscle transfer. Structural transfers such as vascularized bone grafts or toe transplantation for hand reconstruction are also included in this group of procedures. Specific tissue transfers such as vascular and neural grafts are also an integral part of the microsurgical reconstruction armamentarium. Although such “grafts” do not involve large amounts of tissue, they are considered tissue transplantation and thus are included here in the discussion of free tissue transfer.

Microsurgery for extremity reconstruction began more than three decades ago with the introduction of the operating microscope for anastomosis of blood vessels, 

Microsurgical reconstruction and the vital role it plays in orthopaedic surgery is credited to the efforts of many investigators who identified new donor sites, expanded indications for free tissue transfer, and constantly improved microsurgical techniques. In particular, the contributions of Mathes and Nahai (82) in summarizing the clinical application for muscle and musculocutaneous flap should be acknowledged, as well as the pioneering work of Ian Taylor (108), Harry Buncke (17), Harold Kleinert (65a), Robert Acland (2a), Bernad O’Brien (88a), and Fu Chan Wei (115a).

Orthopaedic surgeons perform reconstructive procedures in all fields of their practice. For example, the simultaneous management of fractures and associated soft-tissue injury—the so-called orthoplastic approach—is now accepted treatment for extremity trauma. It allows optimal repair processes to take place for bone and soft tissue while avoiding the adverse sequelae of failed fixation, sepsis, and, ultimately, amputation. The orthopaedic trauma surgeon should appreciate the importance of anatomy, specifically being cognizant of intravenous planes and vascular territories (angiosomes) during dissection (108). Delicate soft-tissue handling and an awareness of the blood supply to muscle, fascia, and skin will prevent the orthopaedist from inadvertently damaging tissue, which may result in necrosis and exposure of either bone or implants that requires coverage with free flaps. Expendable repair of soft tissue is important in the care of the injured extremities. It facilitates further reconstruction, such as bone grafting or tendon transfers.

A thorough understanding of free tissue transfer includes understanding the rationale for tissue transplantation, the timing of the transplant, and what transplant should be selected. The orthopaedic surgeon should have an understanding of the current techniques of reconstructive microsurgery and be able to obtain appropriate reconstructive consultation for patients.

**DEBRIDEMENT**

The French word debridement implies the removing of soft tissues and bone that are nonviable, with hope of preventing infection. Before the era of free tissue transfer, debridement was often limited because removing tissue of questionable viability led to the exposure of vital structures such as bone. Surgeons were reluctant to make the traumatic defects larger by “radical debridement.” Now, in contrast, free tissue transfer of large, well-perfused flaps is readily available and allows radical debridement and necrectomy. Debridement is required both in acute trauma situations and for chronic wounds that have resulted from either the improper handling of soft tissue or infection.

**DEBRIDEMENT OF THE ACUTE WOUND**

- In a fresh wound (such as a Gustilo 3B or 3C tibial fracture), perform the debridement with the tourniquet either up or down. Our preference is to begin the...
Debridement with the tourniquet up because hemorrhage and ooze can stain tissue, making it difficult to distinguish viable tissue from nonviable tissue that has been exposed to adjacent bleeding. Also see Chapter 12.

- Decide what should be debrided according to the appearance and consistency of the different tissues. Healthy tissue in the exanguinated extremity is bright and homogenous in color. Damaged tissue has foreign bodies, irregular tissue consistency, and an irregular distribution of dark red stains, indicating hematoma or contusion. Remove all nonviable tissue. The border of the debridement should include healthy tissue. Remove avulsed skin and muscle from the base of avulsed flaps.
- Let down the tourniquet and assess contractility, bleeding, color and consistency of tissue such as muscle tissue to determine viability of tissue.
- Wash exposed bone with antibiotic solution. Free bone fragments are usually removed.
- Ligature severed vessels and, if they are not vital, excise to normal appearing margins. If they are vital, restore continuity with interposition vein grafts.
- Nerves are the only structures in which the debridement is more conservative. The epineurium can be carefully removed, with fascicles remaining intact.

### CHRONIC WOUNDS

The treatment goal for the chronic wound is to treat the wound as a tumor and excise it in its entirety to the level of normal tissue planes (Fig. 35.1; see also Color Fig. 35.1). Excise all scar tissue. Bone debridement can be difficult, because it can be challenging to distinguish the viable bone and healthy callus from necrotic and inflamed areas. Techniques such as computed tomography (CT) scans, bone scans, and magnetic resonance imaging (MRI) may be helpful in preoperative planning for bone debridement.

![Figure 35.1. Chronic wound following a tibial 3B injury. Proximal muscle is covered with granulation tissue. There is evidence of desiccated, infarcted tendon and chronic granulation tissue in the base of the wound. This wound required extensive debridement and free flap reconstruction.](https://example.com/figure351.png)

At the conclusion of wound debridement, normal tissue planes should be visualized. If this is not possible, then a second-look procedure in which the debridement process is repeated is strongly advised. Re-debride no later than 48 hours, and preferably at 24 hours after the initial debridement (65).

### MICROSURGICAL RECONSTRUCTION

Sir Harold Gillies, considered as one of the fathers of modern reconstructive plastic surgery, used the motto “replace like with like.” The interpretation of this principle with regard to free tissue transfer is that the reconstructive microsurgeon transplants autogenously vascularized tissue into defects that are the result of trauma, tumor, infection, or congenital defects.

Consider free tissue transplantation for any tissue deficit that cannot be treated by an adjacent tissue rearrangement, skin grafting, or local pedicle flaps. Select free tissue transplantation in instances in which there are “composite deficiencies,” such as skin and bone or muscle and skin. Furthermore, free tissue transplantation may be considered for functional restoration that obviates the need for tendon transfer or nerve grafting, as in brachial plexus injuries, in which free muscle transplantation is performed for functional muscle restoration.

### RECONSTRUCTIVE LADDER

To understand the role of free tissue transfer in orthopaedic surgery, one must understand the concept of the “reconstructive ladder” (Fig. 35.2). It represents an increasingly complex solution for soft-tissue problems, with the ultimate goal being reconstitution of the soft-tissue envelope. The reconstructive algorithm, or ladder, is used to select treatment for damaged soft tissues. This algorithm should be used in the setting of acute or chronic soft tissue injury, with or without fractures. In addition, it can be applied to chronic conditions such as osteomyelitis, nonunion, or tumors (63).

![Figure 35.2. Reconstructive Ladder. HBO, hyperbaric oxygen.](https://example.com/figure352.png)

Coverage can be in the form of a skin graft, local tissue transfer, adjacent tissue transfer, regional tissue transfer, or free tissue transfer, which represents the most complex rung on the reconstructive ladder and is the subject of this chapter. As microvascular success rates have improved over the last three decades, the certainty in which tissue can be transplanted to provide coverage as well as function has been enhanced to an expected success rate of more than 95%. Free flaps facilitate solutions to complex soft-tissue problems, with the ultimate goal being reconstitution of the soft-tissue envelope.

Debridement is the first step in the process of the reconstructive ladder. After adequate debridement, it may be possible, such as in minor hand injuries, to close a wound primarily. This is known as primary closure (the first rung). This is rarely done in the treatment of open fractures because of associated soft-tissue loss, the degree of contamination, or the possible uncertainty as to the adequacy of debridement.

Delayed primary closure (the second rung) can be considered for reasons such as returning to the operating room in 24 to 48 hours after edema subsides, or if there is uncertainty about the safety of the wound closure (gunshot wounds or farmyard injuries). A wound may be left open to heal by epithelialization and wound contraction, as in the so-called secondary intention healing. This is the third rung of the reconstructive ladder. This may be applied to small donor areas, such as for skin grafts, or in abrasions over muscle compartments that have small areas that can rapidly epithelialize, obviating the need for skin grafts.

The next rung on the reconstructive ladder is the use of split or full-thickness skin grafts, either meshed or unmeshed. Skin grafting successfully closes many wounds in the extremities, particularly those that are beyond primary or delayed primary closure. The wound bed must be well vascularized with a smooth pink bed of granulation tissue for the graft to take. Grafts will work on fat, muscle fascia, and even intact periosteum. It is important that wound beds be cleaned before grafting to avoid flap loss by infection. Immobilization of the graft is crucial for a good “take of the graft.”

More complex wounds—for example, those that contain exposed vital structures such as nerves and arteries, bone that is devoid of periosteum, or those that have...
insufficient vascularity and soft tissue to support skin grafts—require the importation of well-vascularized tissue to achieve wound closure. This may be accomplished by either local or distant flaps, which are the next rungs of the reconstructive ladder.

Rotational flaps, such as muscle, skin, fascia, or a combination of these types, can provide much-needed vascularized tissue and allow dead space to be obliterated and the wound to be closed without tension. These options may be limited because of the wound location or regional donor site deficiencies. In this instance, free tissue transplantation must be considered.

The highest rung on the reconstructive ladder uses free tissue transfer, possibly in combination with lower rungs of the ladder, such as skin closure, skin grafting, or rotational flaps. An example would be the use of a soleus myoplasty in the middle third of the tibia as well as requirements for distal third of the coverage. A muscle free flap, such as the latissimus dorsi, could be considered in such a case.

The reconstructive ladder has many rungs. The reconstructive surgeon may go from one level to another and, in many instances, may simultaneously use techniques from different levels of the ladder for different problems. Familiarity with options on the reconstructive ladder will help the reconstructive surgeon plan limb salvage and avoid the adverse sequelae that results from improper soft-tissue handling.

**FREE TISSUE TRANSFER AT THE UPPER EXTREMITY**

**INDICATIONS: TRAUMA, SEPSIS, AND TUMOR**

One of the main advantages of free flaps for hand reconstruction is that they allow early mobilization of the hand following injury. This feature decreases limb edema and postoperative stiffness. Free flaps allow the possibility of composite tissue reconstruction in one stage by transferring various combinations of nerve, bone, tendon, skin, and muscle at once. Free flaps can be contoured and cut to fit any defect precisely. Most important, microvascular free tissue transfers have enabled us to adhere more closely to one of the basic principles of any reconstruction effort, as set forth by Gillies—“replace losses in kind”—by allowing us to reconstruct these defects with tissue that is most similar to the lost tissue.

Patients who undergo mutilating upper extremity trauma often have the greatest need for free tissue transfers (Fig. 35.3; see also Color Fig. 35.3A). Trauma to the hand requires resurfacing using skin, muscle, or free fascial flaps. In the treatment of upper extremity trauma, patients who cannot be treated by conventional techniques such as skin grafting, local flaps, or distant flaps are candidates for free tissue transfer. When possible, it is desirable to import tissue rather than to use island pedicle flaps, which will further compromise upper extremity vascularity. For example, the radial forearm flap, if used for dorsal hand coverage, renders an already compromised limb more compromised. This method requires sacrifice of the radial artery. A fibula osteoseptocutaneous flap can also be used in cases of trauma of the upper extremity (Fig. 35.4; see also Color Fig. 35.4C).

**Figure 35.3.** (See Color Fig. 35.3A.) (A) Gunshot wound to upper extremity with soft-tissue defect and exposure of tendons. (B) The patient required skin flap coverage. (C) An anterolateral thigh flap was selected for coverage. Donor site after skin grafting. (D–F) Function of extremity at 1 year.

**Figure 35.4.** A: (See Color Fig. 35.4C.) Gunshot wound to the distal forearm. The patient originally had debridement and skin graft coverage to the forearm. B: On the night of injury, the patient was treated with an external fixator. C: He subsequently had bony reconstruction with an osteocutaneous fibula transfer. D: Pronation. E: Donor defect is acceptable, with the skin graft covering the distal leg. F: Final radiograph with fibula in place.

Upper extremity tumors that involve compartment resections are best treated with free tissue transfer; specifically free muscle, skin, and free bone flaps (Fig. 35.5; see also Color Fig. 35.5A).

**Figure 35.5.** Chondrosarcoma of the humeral shaft in a 9-year-old boy. A: A radiograph shows an eccentric lesion. B: An osteocutaneous fibula was taken with a small monitor paddle to ensure vascularity of the bone. C: An external fixator was used to hold the osteocutaneous fibula in place. D: Final function at 1 year. (See Color Fig. 35.5E) E: Radiographs at 1 year showing hypertrophy of the fibula graft and preservation of growth plates.

Upper extremity sepsis includes bone infection involving large intercalary segments either in the humerus or the forearm. The vascularized fibula transplant is an excellent method for reconstruction of such defects. Soft-tissue sepsis can usually be controlled and treated with local debridement and grafts, unless there is massive
necrosis requiring coverage, in which case select a free skin or muscle flap selected.

A large selection of free tissue transfers for hand reconstruction is available. One of the most commonly used flaps in hand reconstruction is the lateral arm flap; this is a fasciocutaneous flap that is a good choice for coverage of the dorsal or palmar defects. It is thin, easy to dissect, and associated with few complications (52).

Hand wounds resulting in palmar or dorsal defects can also be covered with a free temporoparietal fascia flap. This flap has a very low morbidity and a small scar because no skin is taken with the fascia. The flap can be taken as a double-layered flap, incorporating both the superficial and deep temporoparietal fascia on the superficial temporal vessels (47). The dorsalis pedis flap, scapular, parascapular, groin, and lateral thigh flaps can be used to cover defects on the palm and dorsum of the hand (14).

**TOE-TO-HAND TRANSFER**

Perhaps the best example of composite tissue transplantation is toe transplantation. Toe transfers include vascular, neural, osseous, tendinous, and nail components as part of the composite.

Microvascular toe transplants are believed to be superior to fingers or thumbs reconstructed by other techniques because the toe includes a sensate pulp with nail support, a near-normal appearance, and an active flexion mechanism of the transplanted toe (Fig. 35.6).

Both the great and the second toe have roles in toe-to-hand transplantation. Each transplant has advantages and disadvantages. The decision of which toe to transfer is based on several considerations: the patient's desire, donor morbidity, aesthetic aspects, as well as the part of the hand where the toe is needed. The patient should be informed that the donor morbidity from a great toe harvest (from a cosmetic and functional standpoint) would be greater than that of removing the second toe.

In a mutilated hand, where only a thumb is present, there is a need for an opposable post at the fourth and fifth digit so that the thumb and post can oppose each other. In such a case, it is more appropriate to take the second toe; bilateral second-toe transfers, or double-toe transfers, rather than the great toe (Fig. 35.7).

Thumb reconstruction by great-toe transplantation can be considered if at least one third of the proximal portion of the first metacarpal bone is present.

Second toe—thumb transplantation is indicated when a large discrepancy in size exists between the great toe and the thumb, when the loss of the great toe is not acceptable, or when the level of amputation is proximal to the proximal third of the first metacarpal and a considerable length of the metacarpal is necessary to provide adequate length. Second-toe or multiple-toe transfers also are indicated in a hand from which all fingers have been lost and there is no ulnar post against which the thumb can oppose. In this situation, two second-toe transfers may enhance the grip strength and the ability to manipulate fine objects. Partial toe transfer of the second toe can be used for reconstruction in cases of the amputation of a finger at the level of the distal interphalangeal (DIP) joint or even the nail itself. The distal aspect of the second toe can provide, in these cases, a pulp, sensibility, nail plate, and osseous length, which eases the patient's self-consciousness (15).

Microvascular reconstruction of the distal digits by partial toe transfer includes pulp flaps, which are used for volar thumb and finger resurfacing. There are three major indications for pulp transfer: (1) acute loss of the digital pulp, (2) unstable skin resulting from previous pulp reconstruction with skin graft or local flap, and (3) posttraumatic distal insensitivity with pulp atrophy and distal neuroma with no possibility of nerve anastomosis (35).

If nail transfer is done, it should be based on at least one artery through one hemipulp and venous drainage through the dorsal skin proximal to the nail. A careful history as to whether there has been any damage to the foot in the lifetime of the patient will eliminate the need for an arteriogram. Doppler imaging can trace the pathway of the dorsalis pedis artery in cases in which the artery location needs to be found (52, 57).

**MICRONERVEAL RECONSTRUCTION OF THE UPPER EXTREMITY**

Peripheral nerve repair and brachial plexus reconstruction following injuries have evolved parallel to the development of microsurgery. In many cases of peripheral nerve injury, primary repair may not be possible for many reasons, including direct loss of nerve tissue from trauma, retraction of nerve stumps following delay in repair, or resection of the nerve for a primary nerve tumor or surrounding malignancies. Repair of the gap by primary closure with tension is avoided because tension hinders regeneration by encouraging gapping at the repair site with subsequent scar adhesion formation, as well as reducing blood flow in the repaired nerve (27). Nerve allografting is possible now owing to the advances in immunosupression, although clinical application of peripheral nerve allografting remains under experimental investigation (112).

Different procedures using microsurgical techniques have been described for brachial plexus reconstruction. Some of these techniques include nerve crossing procedures, free muscle transfer, and more recently, a combined technique of double free muscle and multiple nerve transfers. This procedure involves transferring the first free muscle neurolized by the spinal accessory nerve for elbow flexion and finger flexion, a second free muscle transfer reinnervated by the fifth and sixth intercostal nerves for finger flexion, and neurotization of the biceps brachii muscle via its motor nerve by the third and fourth intercostal motor nerves to extend and stabilize the elbow. Restoration of hand stability is obtained through the suturing of the sensory rami from the intercostal nerves to the median nerve (30).
transferred muscles include latissimus dorsi, rectus abdominis, and gracilis. The gracilis muscle is considered to be the best option by many surgeons.

**VASCULAR RECONSTRUCTION OF THE UPPER EXTREMITY**

The orthopaedic surgeon, in particular the hand surgeon, may encounter pathology that requires the understanding of free tissue transfer techniques. These transfers are not the classic transfers used in daily orthopaedic practice; thus, the subject will be mentioned briefly.

**Intimal Injuries**

Intimal injuries due to trauma from cannulation and indwelling devices are relatively common and can lead to thrombosis and resultant ischemia. The problem at the wrist is associated with arterial cannulation, especially in the 20% of the patients that have an incomplete vascular arch. Despite acceptable results with thrombolytic agents, we recommend prompt surgical exploration and resection of the thrombosed segment. Frequently, the gap needs to be reconstructed using reversed interpositional vein grafting (a form of tissue transfer) (68).

**Ulnar Artery Thrombosis**

Repetitive trauma to the hands may cause intimal damage and progress to thrombosis of the ulnar artery. Historically, management of ulnar artery thrombosis has been controversial. Treatments have included pharmacologic management, sympathectomy, thrombectomy, and arterial reconstruction. There has been a trend toward surgical management, and in the great majority of cases, we recommend this course of treatment (69). Resect the thrombosed segment of the artery and reconstruct the artery. This is best accomplished by means of a reverse interposition vein graft harvested from the forearm.

As the age of our population increases, the hand surgeon will care for more patients who experience the ravaging effects of diabetic angiopathy and peripheral vascular disease involving the upper extremities.

Together with improvements in conservative and pharmacologic treatments, the surgical approach to these diseases will evolve and will more frequently use techniques involving microsurgery and free tissue transfers such as free omental transfer to insulate skin to provide vascularity to the hand (68).

**FREE TISSUE TRANSFER IN THE LOWER EXTREMITY**

**INDICATIONS**

**Trauma**

In recent years, increasing emphasis has been placed on open reduction and internal fixation in the management of fractures. The importance of good soft-tissue coverage to maintain the vascularity of bone fragments has also been emphasized. New methods of fracture fixation have evolved, such as indirect reduction and minimal internal fixation, that respect fracture biology and protect soft tissues.

The simultaneous management of soft-tissue injury and fractures, the so-called “orthoplastic approach,” coordinates repair processes for bone and soft tissue and avoids the adverse sequence of exposed internal fixation, bone sepsis, and possible amputation.

The main indications for salvage of a severely damaged limb include any limb in a child, and in adults, those with potentially intact sensibility. Nerve injuries do not preclude salvage but should be distal enough to permit the return of some function (primarily sensory) within a reasonable amount of time. Conversely, complex lower limb injuries with nerve damage are frequently considered for amputation, because the return to a functional status with an appropriate prosthesis is usually more rapid (63).

Advanced age should not be a contraindication to the limb salvage. Careful preoperative patient evaluation and perioperative monitoring can reduce morbidity and mortality rates to be comparable to those of younger patients. Lower extremity microvascular reconstruction can be performed safely and successfully in the elderly patient (66).

Initially debride the devitalized and contaminated tissue and stabilize fractures. Patients with severe limb injury will often have sustained major vascular injury in the area of the trauma. Assess leg perfusion clinically and, if needed, consider an arteriogram if the zone of injury is large and it is in the region of potential microvascular anastomosis.

The timing of definitive wound management (such as free tissue transfer) in the injured extremity is usually determined by the general condition of the patient and the condition of the wound. The bacterial status of the wound, type of fracture, different types of tissues involved in the injury, and the exposed structures are factors that influence the timing of wound closure. In severe extremity trauma with soft-tissue loss and exposure of the underlying structures, cover the wound as early as possible. Acute coverage by day 5 to day 7 is generally accepted as having a good prognosis in terms of decreased risks of infection, flap survival, and healing of the fracture. If the wound can be radically debrided at the first setting, it can be covered immediately with a free flap (39) (Fig. 35.8; see Color Fig. 35.8A).

![Figure 35.8](Image)

**Figure 35.8.** (See Color Fig. 35.8A.) Trauma to the lower extremity emphasizing the importance of early coverage. A: Patient was treated with debridement and external fixator. B, C: At 48-hours, a one-stage reconstruction was performed with a nonvascularized iliac crest bone graft for the intercalary defect of the forefoot followed by a free scapular flap. D: One year after the reconstruction.

Base the choice of flap used for wound coverage on the size of the wound, type of tissue deficit, state of the wound (the colonization, amount of cavitation), location of the injury, and the length of the pedicle needed. Place the anastomosis in a “safe zone” where recipient vessels have not been damaged by the initial trauma. This is not always feasible. Therefore, plan to perform anastomosis outside the zone of injury, either proximally or distally. The concept of “zone of injury” refers to the inflammatory response of the soft tissue of the traumatized lower limb, which extends beyond the gross wound and results in perivascular changes in the blood vessels. These changes include increased friability of the vessels and increased perivascular scar tissue. Both of these changes can contribute to a higher failure rate, especially in lower-limb free tissue transplantation, presumably due to a higher rate of microvascular thrombosis (5).

Most surgeons avoid the zone of injury by extensive proximal dissection of the recipient vascular pedicle, and some use vein grafts in lower limb reconstruction. Isenберg (49) demonstrated that clinical acceptability of the recipient pedicle (vessel wall pliability and the quality of blood from the transected end of the vessel) was more important than the distance from the wound. Reconstructions of the traumatized leg can be challenging owing to the fact that both bony stabilization and soft-tissue coverage are required for a successful functional outcome. Free tissue transfer using microsurgical techniques has allowed surgeons to salvage traumatized extremities in patients who would formerly have required
Examples include a myocutaneous innervated latissimus dorsi for finger flexion or an osteocutaneous fibula flap for an intercalary bone defect that also has a free tissue transfer. Defects of bone and soft tissue that require microsurgical reconstruction. Local flaps generally do not provide adequate coverage, and many times, the only option is a free flap coverage. Tumors of bone and soft tissue have increased in the lower extremity due to the increased use of microsurgical techniques. Advances in skeletal reconstruction and fixation have improved the treatment of patients with osteomyelitis and large (greater than 6 cm) segmental bone defects. In the past, despite successful treatment of osteomyelitis, some patients have required amputation owing to chronic nonunions. Now, once the bone infection is treated, vascularized bone transplants or bone lengthening with the Ilizarov device facilitates reconstruction and provides structural stability for limb function. The current management of soft-tissue sarcomas or resections greater than 25 cm³ or those on the distal third of the leg, ankle, or foot. For these defects, free muscle transfers are preferred. The advantages of using the free muscle flaps such as latissimus dorsi, serratus anterior, and rectus abdominis compared with the local pedicled muscle flaps such as the gastrocnemius muscle are that they provide greater bulk (filling larger wounds), have longer pedicles (increasing flexibility in muscle positioning), and carry larger diameter vessels (facilitating the microanastomoses).

**Orthopaedic Sepsis**

Osteomyelitis and Infected Joint Prosthesis  Osteomyelitis is now a treatable disease. The Cierny-Mader classification guides treatment. The management of dead space after sequestrectomy relies heavily on the technique of free tissue transfer. Free muscle flaps provide coverage for the debrided bone and soft tissue, obliterate dead space, improve vascularity, and enhance leukocyte function.

Advances in skeletal reconstruction and fixation have improved the treatment of patients with osteomyelitis and large (greater than 6 cm) segmental bone defects. In the past, despite successful treatment of osteomyelitis, some patients have required amputation owing to chronic nonunions. Now, once the bone infection is treated, vascularized bone transplants or bone lengthening with the Ilizarov device facilitates reconstruction and provides structural stability for limb function. See Chapter 32, 33, 34, and 35.

Local muscles traditionally had been used to treat chronic osteomyelitis, and free flaps have been described more recently for this use. Local gastrocnemius and soleus muscle flaps are still used for coverage of smaller wounds on the upper and middle thirds of the leg, respectively. However, local muscle flaps will not reliably cover defects greater than 25 cm³ or those on the distal third of the leg, ankle, or foot. For these defects, free muscle transfers are preferred. The advantages of using the free muscle flaps such as latissimus dorsi, serratus anterior, and rectus abdominis compared with the local pedicled muscle flaps such as the gastrocnemius muscle are that they provide greater bulk (filling larger wounds), have longer pedicles (increasing flexibility in muscle positioning), and carry larger diameter vessels (facilitating the microanastomoses).

**Infected Implants**  Infection is the most serious potential complication in total joint arthroplasty, and the risk is increased with compromised wound healing. Clinical risk factors for compromised wound healing include diseases such as rheumatoid arthritis, peripheral vascular disease, chronic renal failure, and diabetes. Other risk factors include irradiation, steroids, immunosuppressive therapy, multiple previous surgeries, and malnutrition. When they are exposed, orthopaedic prosthetic materials become colonized with bacteria, and in the majority of these cases, rapid intervention is required to salvage the extremity and prevent osteomyelitis. Removal of the prosthesis, debridement, closure with a muscle flap and delayed insertion of a new prosthesis constitute the preferred treatment. Free muscle transfers not only provide coverage of the defect but also provide a well-vascularized tissue in close proximity to the new prosthesis.
lateral arm flap, tensor fascia lata flap, and radial forearm flap may be used to provide sensibility, but they may lack the bulk and thickness required for cavitary tissue cycle is possible only if the foot can fit into a regular or slightly modified shoe, is pain free, and ideally has some sensibility. Neurosensory flaps such as dorsalis pedis, subject of significant forces during running and toe off in the normal gait cycle.

The plantar skin has unique properties. It is thick and heavily keratinized, designed to resist high stress, and it is anchored to underlying bones and ligaments by thick fibrous connective tissue. The plantar surface acts as a shock-absorbing system for the foot, helping to minimize horizontal and vertical shear forces by its multidirectional fibrous septae.

PLANTAR SKIN RECONSTRUCTION

Dryness and cracking of a hypertrophied skin graft, especially at the flap–foot skin interface, is less of a problem with skin flaps compared with free muscle flaps and can provide a durable and stable weight-bearing plantar surface for walking. It also achieves an excellent aesthetic result without the need for debulking. Although free tissue transfer adds extra time and technical complexity to the tumor operation, it may also lead to a decrease in amputation rates by decreasing wound complications. In addition, it allows the oncologic surgeon to obtain adequate margins of resection, which may favorably influence amputation rates by contributing to a decrease in local recurrence.

PRINCIPLES FOR THE FOOT AND ANKLE

Despite advances in limb reconstruction in the last several years, resurfacing of the foot remains one of the most difficult reconstructive problems. Not only is it necessary to reestablish soft-tissue integrity but also the treatment plan must include attention to bony architecture and foot deformities that can be caused by muscle imbalance. Each anatomic region of the foot has certain characteristics that will influence selection of the free tissue transfer for reconstruction. The dorsum of the foot and the ankle require thin pliable soft-tissue coverage for exposed tendons that are devoid of paratenon, bones, or joints. The weight-bearing surface of the foot (the plantar skin) is unique with respect to its dermoepidermal histologic characteristics, the unique subcutaneous tissue in the heel pad, adherent dermal septae to the underlying plantar fascia, and the ability to withstand constant pressure and shear forces.

Providing coverage along with protective sensibility can be achieved with a free neurosensory flap such as the radial forearm flap. Free muscle flaps are used when bulk is necessary to obliterate dead space such as in osteomyelitis, severe crush injuries with extensive soft-tissue loss, and for weight-bearing surfaces. However, muscle flaps can often be bulky and, if they are not contoured properly, may prevent the use of normal shoes.

The radial forearm flap offers several potential advantages over other fasciocutaneous flaps and muscle flaps for resurfacing the foot and ankle. It meets most of the prerequisites for the “ideal” foot flap: it provides a large amount of well-vascularized, thin, and pliable soft tissue; it is easy to harvest; and it has large consistent vessels and a long pedicle. Furthermore, it facilitates the restoration of normal (original) foot contour by replacing “like-with-like,” allowing patients to wear normal shoes, and can provide a durable and stable weight-bearing plantar surface for walking. It also achieves an excellent aesthetic result without the need for debulking. Dryness and cracking of a hypertrophied skin graft, especially at the flap–foot skin interface, is less of a problem with skin flaps compared with free muscle flaps covered with split-thickness skin grafts. In addition, it has the potential for sensory reinnervation. Possible disadvantages include an unsightly donor site scar, especially in a young woman, and donor site skin graft breakdown with flexor tendon exposure.

PLANTAR SKIN RECONSTRUCTION

The plantar skin has unique properties. It is thick and heavily keratinized, designed to resist high stress, and it is anchored to underlying bones and ligaments by thick fibrous connective tissue. The plantar surface acts as a shock-absorbing system for the foot, helping to minimize horizontal and vertical shear forces by its multidirectional fibrous septae. The plantar surface of the foot can be divided into three distinct areas, each with special requirements for replacement.

The instep skin in the normal foot is not subject to high stress and, in many cases, it has been used as a donor tissue for plantar resurfacing. Forefoot skin is the subject of significant forces during running and toe off in the normal gait cycle.

Base the decision to proceed with foot salvage on whether the foot will function better than a prosthesis after the reconstruction is complete. Achieving a normal gait cycle is possible only if the foot can fit into a regular or slightly modified shoe, is pain free, and ideally has some sensibility. Neurosensory flaps such as dorsalis pedis, lateral arm flap, tensor fascia lata flap, and radial forearm flap may be used to provide sensibility, but they may lack the bulk and thickness required for cavitary tissue.

Figure 35.11. A: Osteosarcoma of the tibia requiring resection of the anterior tibial compartment. Patient required (B) latissimus free flap (C) and a free fibula for reconstruction. (D) Final reconstruction with simultaneous ilizarov, free latissimus dorsi myocutaneous flap, and free vascularized fibula flap. (E) Fibula in place as an intercalary graft compressed and held by an ilizarov frame. (F) Final result at 1 year. The fibula hypertrophied, and fusion was performed into the talus with the fibula.

Figure 35.12. Patient with popliteal mass presented with acute peroneal palsy. A: Diagnosis was neurosarcoma. B: Tumor defect after biopsy and local radiation. (See Color Fig. 35.12B). C: Harvest of free rectus abdominus myocutaneous muscle flap. D: Postoperative result with radiation catheters in place under the flap. E: Results at 1 year.
defects. Larger flaps such as muscle flaps that do contour better cannot be innervated. Thus, there is no ideal transfer. A review of flap options should be done for each patient. The specific complications include wound breakdown because of mechanical instability and excessive sheer forces, ulceration, formation of calluses, hypertrophic scarring, and intrinsic muscle imbalance (62).

VASCULAR AND DIABETIC FOOT

Nonhealing wounds of the extremities are common in patients with diabetes and peripheral vascular disease. The magnitude of the problem is enormous; statistics indicate that 14% of these patients are hospitalized an average of 6 weeks per year for foot problems, and more than 80% of amputations are performed on diabetics. The contralateral limb of one with an ulcer is at risk for further ulceration, and there is a 50% chance of loss of the opposite leg within 5 years (43). Care of these patients requires a close collaborative effort between the orthopaedist, the peripheral vascular surgical team, and the microsurgical team to optimize rapid and accurate assessment of the vascular problem, and to determine the most appropriate and timely plan for wound care and the most reliable method for revascularization. The results of macrovascular and microvascular anastomoses are comparable to those for nondiabetic patients undergoing the same procedure (63). Patients treated with cutaneous free flaps have less morbidity than patients treated with muscle free flaps (69). The radial forearm free flap is ideal for treatment of relatively small wounds of the foot and ankle. It provides cutaneous tissue with a lengthy vascular pedicle and a donor site that can often be closed primarily.

Despite the multiple medical problems of diabetic and dysvascular patients, surgical mortality has not been found to be higher in cases of microsurgical reconstruction procedures performed alone in these patients or in combination with macrovascular vascular reconstruction (43). Once the extremity has been revascularized, the most appropriate method of reconstruction can be carried out for defects of the foot in a well-vascularized limb. For those patients in whom the macrovascular blood supply is intact and without apparent compromise but who have large, unhealthy, colonized wounds, particularly if they involve tendon or bone, free flap coverage is indicated. Free tissue transfer techniques are ideal in these situations because (1) they are able to resurface any size defect; (2) they allow aggressive resection of the wound to eliminate colonized, fibrotic, unhealthy tissue; (3) the flap can help revascularize the foot; and (4) the defect is replaced with healthy nondamaged tissue (Fig. 35.13).

Diabetic and dysvascular patients require a high degree of vigilance to avoid problems both locally and systemically, with a much closer observation of the donor sites and recipient sites to preclude wound healing problems.

Because many diabetic and dysvascular patients are candidates for amputation before flap transfer (which was often offered as a last option before limb loss), these procedures do not increase the rate of limb loss, but can only increase the limb salvage rate (Fig. 35-14; see also Color Fig. 35.14A, Color Fig. 35.13B).

The question of the cost/benefit ratio of such procedures has yet to be determined. Certainly in this era of cost-containment, the arguments against such “expensive” and sophisticated procedures versus straightforward amputation cannot be ignored. Although the exact cost of leg salvage in such a group of patients is difficult to determine, it may be less expensive than the combined cost of hospitalization, prosthesis fitting, rehabilitation, and disability payments.

A high degree of success can be achieved only by extremely careful patient selection. In the face of systemic complications, one must also exercise proper judgment and abort attempted reconstruction to ensure patient survival.

Chronic venous ulcers can also be treated with microsurgical tissue transfers. In the appropriate patient with localized disease, a dual surgical approach including wide excision of the ulcer and surrounding liposclerotic tissue bed, and coverage with a free flap containing multiple competent microvenous valves, may improve the underlying pathophysiology. In patients with complex ischemic or infected wounds from diabetes, free tissue transfer as an adjunct to lower extremity vascular reconstruction can help in obtaining a salvageable functional limb, thus presenting a viable alternative to amputation (41-75).

STUMP COVERAGE

Despite the success achieved in limb-salvage procedures, a high number of amputations are performed as a result of major trauma, tumors, diabetic ulcers, and in cases when the patient is too ill to survive a lengthy operation. The level of amputation itself is an important factor for consideration. In cases of lower limb amputation, below-knee amputation is associated with faster rehabilitation compared with above-knee amputation. Below-knee amputees require less rehabilitation time, have a more natural gait, and can engage in more physical activities (6). The choice for the level of amputation is determined by the need to cover the stump with appropriate soft tissue stable enough to resist breakdown in a prosthesis. Skin grafting of amputation stumps, especially in lower limbs, provides only wound coverage, and usually does not meet the need for adequate padding. In cases for which a local flap is not available, free flaps should be considered. These flaps can provide coverage of the stump, and if microneural coaptation is performed, sensation of the stump can be achieved. That may assist proprioception within the prosthesis. An amputated limb may provide donor tissue, such as in traumatic below-knee amputations (Fig. 35.15).

donor site morbidity (114). Fillet foot flaps are useful for salvage of below-knee level amputees.

PREOPERATIVE CONSIDERATIONS

SELECTION OF TISSUE TRANSPLANTATION

Free flaps can be categorized into two different types. Isolated tissue transplants include muscle, skin, fascia, bone, or flaps. The more common composite tissue

The type of tissue deficiency and surface requirements will determine the type of flap to be selected. Tissue transplants are selected with respect to donor site

recipient morbidity, recipient site requirements, vascular pedicle length, and anticipated aesthetic result. For example, a myocutaneous latissimus dorsi flap should not be

transplanted to the dorsum of the foot due to its bulk and the fact that the donor tissue does not match the dorsum of the foot. Other flaps, such as an isolated skin flap

(radial forearm flap or lateral arm flap), are a better transplant. Similarly, to fill dead space after sequestrectomy of an infected tibia, a lateral arm flap, which is a small

skin flap of approximately 5 × 7 cm is not appropriate owing to its lack of bulk and the fact that the muscle flaps, rather than skin flaps, are known to be more effective

in the treatment of osteomyelitis. The use of a skin paddle with composite tissue transfers can be done for either contouring or as a monitor for perfusion of the flap.

Not all flaps are selected to replace missing tissue. There are instances in which tissue coverage exists but it is insufficient in texture or quality. A soft-tissue envelope

may need to be augmented, such as using a scapular flap to resurface a knee with unstable skin as a first stage before a total knee replacement. There are free flaps that

are performed purely for aesthetic reasons, such as the resurfacing of extremities. This is an unusual use of free tissue transfer, and it is used only in special

cases. A combination of the above-mentioned selection factors determines free flap selection.

RECIPIENT VESSELS

Specific preoperative assessment in microsurgical procedures frequently includes angiography to evaluate the vasculature of the recipient site. The need for

angiography, however, especially after trauma, is debatable. The vast experience gained in reconstructive microsurgery has enabled us to become familiar with the

“vascular” anatomy in all regions of the body to optimize the selection of recipient site vessels. A meticulous clinical evaluation (with Doppler mapping) can provide

valuable information without the need for recipient-site angiography (71).

The proper selection of recipient vessels is essential for the success of free tissue transfer, especially when the transfer is to the lower extremity. However, general

agreement on which vessels to use has not yet been reached. Conflicting data have been reported on the survival and outcome of the transferred flaps, depending on

the vessel used or the location of anastomosis proximal or distal to the zone of injury. For example, the anterior tibial vessels may be preferred for their easy

accessibility, whereas the posterior tibial vessels are strongly advocated by others.

Park et al. (91) developed an algorithm for recipient vessel selection in free tissue transfer to the lower extremity. Based on their experience, the most important factors

influencing the site of recipient vessel selection were the site of the injury and the vascular status of the lower extremity. The type of flap used, method, and site of

microvascular anastomosis are less important factors in determining the recipient vessels.

TIMING OF FREE TISSUE TRANSFER

The timing of the wound closure using microsurgical techniques is important. In severe injuries of the lower extremity with associated soft-tissue defects, early

aggressive wound debridement and soft-tissue coverage with a free flap within 5 days has been found to reduce postoperative infection, as well as decrease flap

failure, nonunion, and chronic osteomyelitis (19,20). Godina (39) emphasized the importance of radical debridement and early full-thickness soft-tissue coverage either
decubitus or within the first 72 hours.

Lister and Scheker (70) reported the first case of an emergency free flap transfer to the upper extremity in 1988; they defined the emergency free flap as a “flap transfer

performed either at the end of primary debridement or within 24 hours after the injury.” Yaremchuk and colleagues (118) recommend that flaps be transferred between

7 and 14 days after injury after several debridements. The argument in favor of this approach is that the zone of injury, which often may not be apparent at

presentation, can be determined by serial debridements performed in the operating room over several days.

When deciding to perform a primary closure with a free flap, two key factors should be considered: the presence of an exposed vital structure and the risk of infection.

A vital structure is defined as “one that will rapidly necrose if not covered by adequate soft tissue” (21). The decision of what constitutes a vital structure depends on

circumstances. Tissues such as vessels, nerves, joint surfaces, tendons, and bone denuded of periosteum may desiccate, die, and lead to infection when they are left

exposed for long periods of time. When considering primary versus delayed coverage, take into account the risk of leaving the vital structure exposed and what

functional deficit would occur if it were lost.

The risk of infection is the second important factor that should be considered because it may jeopardize the limb, the quality of the functional recovery, or the free flap.

As the risk of infection increases, the wisdom of primary closure with a free flap is reduced. Debridement of the wound is the most powerful surgical tool to reduce the

risk of infection of the wound. If radical debridement is not possible, then it is not safe to perform primary free flap transfer. Another perspective is that the capability to

perform free tissue transfer allows the surgeon increased freedom to perform radical debridement and may actually reduce the risk of infection (85). The mechanism of

injury, the elapsed time since injury, and the degree of contamination of the wound determine the risk of wound infection. In an acute, sharp noncontaminated injury,

when closure would be routinely performed if there were no skin loss, there seems to be little reason not to consider an emergency free flap.

PATIENT PREPARATION

Microsurgical procedures are major surgical procedures. Carefully evaluate the cardiovascular and pulmonary status. Nutritional assessment is of particular importance

because this will influence healing, particularly in trauma and tumor patients. In elective cases, patients in a high-risk category may need preoperative nutritional

supplements (7).
The commonly used fasciocutaneous free flaps are the lateral arm flap, radial forearm flap, scapular flaps, dorsalis pedis and groin flaps.

**LATERAL ARM FLAP**

The lateral arm flap (Fig. 35.16) can serve as an innervated fasciocutaneous flap or as a deepithelialized subcutaneous fascial flap. The lateral arm flap is based on the posterior radial collateral vessels (PRCA). The artery is a direct continuation of the deep brachial artery. The draining veins of this area are the venae comitantes of the PRCA. The pedicle length is approximately 7 cm. The external diameter of this artery is usually 1.5 to 2.0 mm but sometimes can be smaller, even 0.8 mm. The vein’s diameter ranges from 2.0 to 2.5 mm. The anatomy of this vascular pedicle is constant, in contrast with the medial arm flap, which has a more variable vascular supply.

Preliminary tissue expansion will increase the flap dimensions; more important, it will allow direct closure of the donor defect (Figure 35.17). The bone in the radial forearm flap can lead to fracture of the radius.

The radial forearm flap can include tendons and segments of the radius. The dimensions of the skin flap is approximately 8 × 15 cm². The surface marking that is important in planning is a line that joins the deltoid insertion with the lateral epicondyle (this line marks the lateral intermuscular septum and the course of the PRCA). Design a flap with this line as the central vascular axis. Include the deep fascia in the flap. It also can be harvested based on the PRCA pedicle alone. This is advantageous in cases in which thin well-vascularized coverage is required and for coverage of areas where tendon gliding is required.

The distal territory is thin and is innervated by the lateral brachial cutaneous nerve of the arm; it is often hairless. In addition, vascularized bone (humerus) may be harvested with this flap for composite reconstruction.

The periostal blood supply from the PRCA will allow a vascularized bony segment 10 cm long and 1 cm wide to be included with the skin flap.

- Position the patient supine. Drape the arm to allow free movement; position the arm on an arm table or across the chest. A tourniquet is recommended but sometimes is difficult to maintain during proximal dissection.
- Begin dissection with a posterior incision to the triceps muscle fascia.
- Raise the flap subfascially and suture the skin to the fascia to prevent shearing.
- Elevate the posterior fascia to expose the lateral head of the triceps. Continue dissection to the anterior border of the triceps muscle. Here, the fascia dives deep and inserts into the humerus. Perforators are now seen in the septum.
- Make an anterior incision down to fascia. Incise the anterior fascia over the brachialis and the brachioradialis muscle, following the level of the periosteum of the humerus.
- Ligate the distal continuation of the PRCA.
- Separate the fascial septum as close as possible to the periosteum. Follow the vascular pedicle proximally under the triceps muscle into the spiral groove.
- Separate the lower cutaneous nerve from the radial nerve.
- Separate the lower cutaneous nerve from the radial nerve.
- Position the skin incision and continue a subfascial dissection toward the vessels.
- Begin dissection on the lateral side of the arm and dissection toward the radial side of the arm.
- Make the skin incision and continue a subfascial dissection toward the vessels.
- Make the skin incision and continue a subfascial dissection toward the vessels.
- Begin dissection with a posterior incision to the triceps muscle fascia.
- RAISEflaps from distal to proximal and isolate the vessels proximally. Dissect under the pedicle and isolate the pedicle distally.
- RAISEflaps from distal to proximal and isolate the vessels proximally. Dissect under the pedicle and isolate the pedicle distally.
- RAISEflaps from distal to proximal and isolate the vessels proximally. Dissect deep to the deep fascia, elevating the flap from the underlying muscle. Combined flaps can include tendons and segments of the radius.
- RAISEflaps from distal to proximal and isolate the vessels proximally. Dissect deep to the deep fascia, elevating the flap from the underlying muscle. Combined flaps can include tendons and segments of the radius.

**RADIAL FOREARM FLAP**

The radial forearm flap (Fig. 35.17) is a thin, well-vascularized fasciocutaneous flap on the ventral aspect of the arm. This flap was widely used in China before it was popularized in the Western literature (88,105). The flap is based on the radial artery, which can achieve a 20 cm pedicle and has a diameter of 2.5 mm. This pedicle length facilitates microsurgical anastomosis out of the zone of injury. The venous drainage is through the venae comitantes of the radial artery, but the flap can include the cephalic vein, the basilic vein, or both. The flap can contain the lateral antebrachial cutaneous nerve or the medial antebrachial cutaneous nerve and serve as a neurosensory flap. The size of the flap can be 10 × 40 cm². A portion of the radius can be included as a vascularized bone with this flap (29). The advantages of this flap are its long pedicle and potential sensory innervation. The quality of the bone from the radius is mainly cortical and not of any substantial volume (107). Including the bone in the radial forearm flap can lead to fracture of the radius.

The radial forearm flap is innervated by the posterior brachial cutaneous nerve, a proximal branch of the radial nerve (C5—6), giving the flap potential as a sensate flap. Additional sensory supply comes from the posterior antebrachial cutaneous nerve, which divides at the distal upper arm, with the upper branch supplying the posterior inferior upper arm and the lower branch supplying the lateral side of the arm and elbow (82).

The lateral arm flap is thinner and is innervated by the lateral brachial cutaneous nerve of the arm; it is often hairless. In addition, vascularized bone (humerus) may be harvested with this flap for composite reconstruction.

Surgical anatomy of the lateral arm flap.

The lateral arm flap is innervated by the posterior brachial cutaneous nerve, a proximal branch of the radial nerve (C5—6), giving the flap potential as a sensate flap. - Separate the fascial septum as close as possible to the periosteum. Follow the vascular pedicle proximally under the triceps muscle into the spiral groove.
- Separate the lower cutaneous nerve from the radial nerve.
- Separate the lower cutaneous nerve from the radial nerve.
- Position the skin incision and continue a subfascial dissection toward the vessels.
- Begin dissection on the lateral side of the arm and dissection toward the radial side of the arm.
- Make the skin incision and continue a subfascial dissection toward the vessels.
- Make the skin incision and continue a subfascial dissection toward the vessels.
- Begin dissection with a posterior incision to the triceps muscle fascia.
- RAISEflaps from distal to proximal and isolate the vessels proximally. Dissect under the pedicle and isolate the pedicle distally.
- RAISEflaps from distal to proximal and isolate the vessels proximally. Dissect under the pedicle and isolate the pedicle distally.
- RAISEflaps from distal to proximal and isolate the vessels proximally. Dissect deep to the deep fascia, elevating the flap from the underlying muscle. Combined flaps can include tendons and segments of the radius.

**Fig. 35.16. Surgical anatomy of the lateral arm flap.**

**Fig. 35.17. Surgical anatomy of the radial forearm flap.**

Preliminary tissue expansion will increase the flap dimensions; more important, it will allow direct closure of the donor defect (76).

- Position the patient supine, with the arm on a hand table. Preoperatively, evaluate the vascular supply to the hand by an Allen test and a Doppler scan, and confirm the circulation through the ulnar artery. A line drawn from the center of the antecubital fossa to the radial border of the wrist where the radial pulse is palpable represents the course of the radial artery. Center the flap over the course of the vessels. The more distal the flap design, the longer the pedicle.
- Make the skin incision and continue a subfascial dissection toward the vessels.
- On the distal part of the flap, identify the brachioradialis and flexor carpi radialis tendon. The radial artery and venae comitantes will lie along the ulnar side of the brachioradialis and along the radial side of the flexor carpi radialis tendon. The cephalic vein will lie radial to the brachioradialis.
- Bypass the pedicle and isolate the pedicle distally.
- RAISEflaps from distal to proximal and isolate the vessels proximally. Dissect deep to the deep fascia, elevating the flap from the underlying muscle. Combined flaps can include tendons and segments of the radius.
- RAISEflaps from distal to proximal and isolate the vessels proximally. Dissect deep to the deep fascia, elevating the flap from the underlying muscle. Combined flaps can include tendons and segments of the radius.

If the radius is harvested as vascularized bone, less than 40% of the cross section of the radius should be harvested, and the wrist and forearm should then be put in a...
cast for 3 to 4 weeks. Avoid injury to the peritenon covering the tendons of the flexor carpi radialis, brachioradialis, and finger flexors because its loss can lead to skin graft failure and even loss of the tendons.

In most cases, the donor site requires a skin graft for closure, which leaves a scar in a visible place.

**SCAPULAR AND PARASCAPULAR FLAPS**

The scapular flap (Fig. 35.18) is probably the workhorse of skin flaps. It is a thin, usually hairless skin flap from the posterior chest and can be deepithelialized and used as subcutaneous fascial, pedicled, or free flap.

**Figure 35.18. Surgical anatomy of the scapular flap.**

The flap is perfused by the cutaneous branches of the circumflex scapular artery (CSA) and drained by its venae comitantes. The CSA is a major tributary of the subscapular artery; it is the artery supplying blood to the scapula, the muscles that attach to the scapula, and the overlying skin. The length of the pedicle is 5 cm, and the diameter of the artery is 2.5 mm. The vascular pattern of this territory makes it possible to raise multiple skin flaps on a single vascular pedicle or to harvest the lateral border of the scapula as an osteocutaneous flap for a complex reconstruction.

The cutaneous territory can be 20 × 7 cm² and can be divided in two components: a horizontal territory (horizontal scapular flap) and a vertical territory (parascapular flap) based on the branches of the CSA after the vessel courses through the triangular space.

Innervated by the lateral posterior cutaneous branches of the intercostal nerves, this flap has no potential for being used as a sensate flap. Preliminary expansion of the territory of the scapular flap will increase the flap dimensions and permit direct donor site closure.

**Parascapular Flap**

- Position the patient midlateral or in an oblique position. Elevate the flap retrograde.
- Start with a low medial incision. Identify the epifascial plane. Elevate the fascia cranially beneath the deep fascia, to the area of the triangular space.
- Complete the skin incision (the upper part). Carefully retract the flap medially. Identify the junction of the parascapular and horizontal branches of the circumflex scapula vessels.
- Divide the horizontal branches and dissect the circumflex scapular pedicle into the triangular space. Identify the thoracodorsal or scapular artery.

**Scapular Flap**

- Use the same dissection strategy as for the parascapular flap.
- Start the dissection laterally and proceed toward the triangular space.
- As in the parascapular flap, the vascular pedicle can also be identified first in the course of the dissection.

Some surgeons favor the identification of the vascular pedicle as the first step of the dissection, especially in cases of microvascular transplant. Accomplish this with palpation of the triangular space and confirmation of pedicle location with a Doppler probe. Two approaches are available for scapular and parascapular flap elevation and preparation for the microvascular transplantation: lateral (initial pedicle identification) and medial (retrograde flap dissection). This flap can be combined with other flaps based on subscapular blood supply, and this may greatly facilitate certain complex reconstructions. These reconstructions include the latissimus dorsi and serratus anterior flaps, which can supply additional skin, muscle, and bone (rib), if necessary (93-98,100).

The primary indication for the scapular flap is a defect requiring a relatively thin, large cutaneous flap (10). These kinds of defects are often found in the foot (93). The osteoseptocutaneous free scapular flap reconstruction has been described in the lower extremity (100).

**DORSALIS PEDIS FLAP**

The dorsalis pedis flap (Fig. 35.19) is a thin sensate fasciocutaneous flap from the dorsum of the foot. It is based on the dorsalis pedis artery, which originates from the anterior tibial artery and its venae comitantes (73). The length of the pedicle is 6 to 10 cm, and the diameter of the artery is 2 to 3 mm. The nerve supply comes from the branches of the deep and superficial peroneal nerves. The size of the flap is 6 × 10 cm², and it can be raised as a skin flap alone or in combination with the second metatarsal bone as an osteocutaneous flap or in combination with first- and second-toe transfer (63).

**Figure 35.19. Surgical anatomy of the dorsalis pedis flap.**

- Position the patient supine with a tourniquet around the thigh.
- Make a distal incision for identification of the first dorsal metatarsal artery with subsequent retrograde dissection of the flap. Divide the first dorsal metatarsal artery and branches of the deep peroneal nerve to the first web space.
- Continue the dissection from distal to proximal in a plane just deep to the deep peroneal nerve and first dorsal metatarsal artery. This plane is just above the peritenon of all the extensor tendons.
- Then continue the dissection proximally up to the proximal head of the metatarsal. At that level, the deep perforating branch of the dorsalis pedis artery is encountered.
- Make the medial incision of the flap and elevate the medial part of the flap with the greater saphenous vein and the dorsal venous arch included in the flap.
- Over the tarsal bones, identify the dorsalis pedis artery. Divide the deep branch and incise the rest of the skin completely.
With the upper incision completed, open the extensor retinaculum and identify the dorsalis pedis artery, its two venae comitantes, and nerve. Divide the extensor hallucis brevis muscle at the level of the extensor digitorum longus tendon to the second toe. Take care to preserve the paratenon on the remaining tendons to provide a bed for the skin graft.

The flap can be used in the upper extremity to cover joints and tendons, and in microvascular transplant of metatarsophalangeal joints in children (78).

The donor site morbidity is of concern with the use of this flap; it can include difficulties in primary healing with the need for skin grafts, and complications of lymphedema, and hypertrophic scarring of the foot (69).

GROIN FLAP

The groin flap (Fig. 35.20) provides a large skin and subcutaneous tissue territory based on the superficial circumflex iliac artery (SCIA) and vein (SCIV). The length of the pedicle is 2 cm, and the diameter is 1.5 mm. The dimension of the flap is approximately 10 × 25 cm².

The flap can be modified, including the sheets of external oblique aponeurosis for reconstruction of a tendon-like structure to replace the Achilles tendon or reconstruction of the calcaneus with a composite graft including the groin flap and iliac crest bone (113).

The complexity of the vascular anatomy and the small diameter of the superficial circumflex iliac artery make this flap less popular than other free skin flaps (25).

TEMPOROPARIETAL FASCIAL FLAP

The temporoparietal fascial flap (Fig. 35.21) can be used as a fascial or fasciocutaneous flap. The fascia covers the temporal muscle extending over the temporal fossa and lies superficial to the deep temporal fascia covering the temporalis muscle. It continues as the galea beyond the limits of the temporal fossa.

Vascular pedicle: The superficial temporal artery (STA) is the terminal branch of the carotid artery. The length of the artery is 4 cm, and the diameter of the artery is 2 mm. The course of the vessels is on the fascia from the preauricular area into the temporal fossa. The sensory nerve supply comes from the auriculotemporal nerve.

The size of the flap is 12 × 9 cm² (1).

Preoperatively, identify the course of the vessels with a Doppler probe and mark the incision lines parallel to hair follicles.

Position the patient supine, with the head tilted slightly to the opposite side.

Start the incision by raising a pretragal skin flap, extending the incision toward the vertex of the skull over the temporal fossa.

Identify and spare the superficial temporal vein anterior and remain superficial to the STA. Identify the STA.

Dissection proceeds cephalad deep to the hair follicles. Avoid damaging the superficial temporal vein and the frontal branch of the facial nerve.

After cephalad completion of the dissection, incise the flap. Lift from the deep fascial plane toward the auricle.

After complete dissection, leave the flap for observation of perfusion.

This flap is ideally suited for covering small defects of the foot, ankle, Achilles tendon, and hand. The minimal thickness of this well-vascularized flap prompts some authors to describe the technique as a "microvascular transplantation of a recipient bed" (13). This flap is useful for burns, particularly when joint spaces or tendons are exposed after debridement (23).

MUSCLE FLAPS

The following sections on each donor muscle flap include information on (1) the muscle's origin and insertion, function, vascular supply, innervation, and pedicle length; (2) the flaps size, functional loss on removal, and elevation; and (3) any special problems that may be encountered in their use.

The classification of muscle type is based on five patterns of muscle circulation (81). A muscle for free tissue transfer must be able to survive on one vascular pedicle that is dominant and that will support the entire muscle mass. Classification is as follows:

- Type 1: one vascular pedicle (extensor digitorum brevis, tensor fascia latae).
- Type 2: dominant pedicle and minor pedicles (abductor hallucis longus, gracilis).
Type 3: two dominant pedicles (rectus abdominis, serratus anterior).
Type 4: segmental vascular pedicles (none).
Type 5: one dominant and secondary vascular pedicles (latissimus dorsi, pectoralis major, pectoralis minor).

Unclassified potential transfers include fillet flaps and combination flaps such as the latissimus dorsi–serratus anterior muscle flap based on one dominant pedicle (thoracodorsal artery).

**Latissimus Dorsi Flap**

The latissimus dorsi is a type 5 muscle (major pedicle and multiple segmental vessels) (Fig. 35.22). The dominant pedicle is the thoracodorsal artery and venae comitantes, which originate from the subscapular artery and vein. Secondary pedicles are two rows (lateral and medial) of four to six perforating arterial branches and venae comitantes taking origin from the posterior intercostal and lumbar arteries and veins. The length of the major pedicle can be as long as 8 cm and the arterial diameter as large as 2.5 mm. The artery enters the deep surface of the muscle in the posterior axilla, 10 cm inferior to the latissimus muscle insertion into the humerus (9).

*Figure 35.22. Surgical anatomy of latissimus dorsi muscle flap.*

The motor nerve supply is the thoracodorsal nerve (C6–C8), and the sensory innervation of the skin is supplied by multiple cutaneous branches of the intercostal nerves. Generally, this is not used as a sensate flap.

The latissimus dorsi is the largest transfer available, with a muscle surface area of 25 × 35 cm² and skin territory of 30 × 40 cm² (60).

The latissimus dorsi is an expandable muscle flap because function is preserved by the remaining synergistic shoulder girdle muscles.

- Position the patient midlateral, with the arm elevated 90°.
- Begin the dissection with an incision along the lateral muscle border.
- First, identify the muscle border and its relationship to the serratus muscle. Next, identify the pedicle and follow the pedicle to its origin in the axilla.
- Free the anterior border of the muscle and raise the flap from a ventral to dorsal direction to the spine. Take care to coagulate or ligate the perforating vessels.
- Next, divide the muscle distally as required. Raise the muscle in the cranial direction.
- Next, ligate the serratus branch of its artery.

For extensive wounds, the latissimus can be transplanted simultaneously with the serratus muscle, on a single vascular pedicle (36). The latissimus is commonly used in reconstruction in lower extremities for large defects (97, 102). A combined flap including the ninth and tenth ribs as vascularized bone transplanted for simultaneous coverage and tibial bone reconstruction is possible but not commonly used (74).

**Serratus Anterior Flap**

The serratus anterior muscle is a thin, broad, multidigitated muscle on the lateral chest wall between the ribs and scapula. The muscle is supplied by two pedicles, the serratus anterior branch and the lateral thoracic artery. The length of each one of the pedicles is 6 to 8 cm, and the diameter of the artery is 2 to 3 mm (Fig. 35.23).

*Figure 35.23. A: Skin incision for a serratus anterior flap. B: Surgical anatomy of a serratus anterior flap.*

The motor innervation is supplied by the C5–C8 roots of the long thoracic nerve and the T2–T4 segmental intercostal nerve supply for sensory innervation. The vascular pedicle as well as the motor nerve separates into fingers of muscles corresponding to the slips of the serratus. The size of the serratus anterior is 15 × 20 cm².

A musculocutaneous flap of 5 × 15 cm² can be elevated (8).

- For a fascia flap, place the patient in a lateral position, and elevate the arm 90°.
- Make a slightly curved incision along the lateral border of the latissimus muscle.
- Next, identify the muscle border and the serratus arcade. Determine if the thoracodorsal pedicle is intact and find the entrance points of the motor fibers into the muscle. Outline the flap size on the muscle surface.
- Release the muscle from the thoracic wall. Preserve the three proximal slips to avoid winging of the scapula. The entire muscle is never taken because of the risk of winging of the scapula. Preservation of at least the upper five and preferably six slips and their innervation will decrease or totally eliminate winging of the scapula.
- Dissect the thoracodorsal pedicle to the length required.
- Transfer the flap.

Basing the serratus on its blood supply, and using the thoracodorsal artery makes it possible to elevate a combined latissimus dorsi and serratus anterior flap (44) (Fig. 35.24). The serratus is useful as a free flap for coverage or as an innervated functional muscle.
The gracilis muscle is a type 2 muscle (dominant pedicle and several minor pedicles.) It is a thin, flat muscle that lies between the adductor longus and sartorius muscle anteriorly and the semimembranosus muscle posteriorly. The dominant pedicle is the ascending branch of medial circumflex femoral artery and venae comitantes. The length of the pedicle is 6 cm, and the diameter of the artery is 1.6 mm. The minor pedicles are one or two branches of the superficial femoral artery and venae comitantes. Their length is 2 cm and diameter is 0.5 mm (38).

Motor innervation is by the anterior branch of the obturator nerve, which is located between the abductor longus and magnus muscles, and it usually enters the muscle above the level of the dominant vascular pedicle. The anterior femoral cutaneous nerve (L2–L3) provides sensory innervation to the majority of the anterior thigh.

This muscle functions as a thigh adductor. The presence of the abductor longus and magnus makes it an expendable muscle.

The size of the muscle is 6 × 24 cm². The skin territory is 16 × 18 cm², but the skin over the distal half of the muscle is not reliable when the flap is elevated, based on its dominant vascular pedicle with division of the minor vascular pedicles. In obese patients, the musculocutaneous flap may be too bulky, necessitating use of a skin graft placed on the muscle.

The size of the muscle is 6 × 24 cm². The skin territory is 16 × 18 cm², but the skin over the distal half of the muscle is not reliable when the flap is elevated, based on its dominant vascular pedicle with division of the minor vascular pedicles. In obese patients, the musculocutaneous flap may be too bulky, necessitating use of a skin graft placed on the muscle.

- Position the patient supine, with hip and knee flexed and leg abducted. Draw a line between the pubic tubercle and medial condyle of the femur.
- Because the muscle is 2 to 3 cm posterior to the line, make an incision 2 to 3 cm posterior parallel to this line. Identify and preserve the greater saphenous vein (anterior to the incision).
- Incise the fascia and identify the gracilis muscle medially and posterior to the adductor longus muscle.
- Divide the muscle distally.
- Ligate the minor pedicles.
- Proceed with dissection cephalad. Retract the adductor longus proximally. Expose the pedicle 6 to 12 cm distal to the pubic tubercle. Protect the medial cutaneous nerve on the surface of the adductor magnus.
- Clip or ligate small branches.
- Divide the muscle superiorly.
- If a skin island is included in the flap, it will be located over the middle or proximal portion. Make the incision down to the fascia, and include the fascia lata in the dissection.
- The rest of the dissection is similar to the dissection of the muscle alone.

An advantage of this flap is the length of the pedicle and the ease of harvesting the flap with the patient in the supine position (86). One of the complications of using this flap is the abdominal defect, which may lead to weakness and, possibly, hernia formation.

**Gracilis Flap**

The gracilis flap is the abdominal defect, which may lead to weakness and, possibly, hernia formation.
Tensor Fascia Lata Flap

The tensor fascia lata (TFL) is a type 1 muscle (one pedicle). The origin is anterior 5 to 8 cm from the outer edge of the anterior superior iliac spine, immediately behind the origin of the sartorius. The insertion is the iliotibial tract of the fascia lata. The dominant vascular pedicle is the ascending branch of the lateral circumflex femoral artery, which arises from the profunda femoris and vein comitantes. The length of the pedicle is approximately 7 cm, and the diameter of the artery is 2 to 3 mm. Motor innervation comes from the superior gluteal nerve, and sensory innervation comes from the cutaneous branches of T-12. The size of the muscle is approximately 5 × 15 cm², and the skin territory can be 7 × 22 cm² to 9 × 26 cm² (6).

- Position the patient supine and prep the entire lower extremity so that the hip can be adducted, ab ducted, and rotated during elevation. Make the initial incision for elevation of the flap along the anterior, posterior, or distal border of the flap.
- After the distal incision, identify whether the fascia lata below the skin. The TFL muscle can be identified after the dissection advances more proximally.
- Extend the anterior and posterior incision from below upward toward the anterior superior iliac spine and the border of the iliac crest.
- Identify the terminal branches of the lateral circumflex femoral artery 10 cm below the anterior superior iliac spine and continue to dissect deep to the rectus femoris to develop a long vascular pedicle.
- Continue the dissection above the pedicles to separate the TFL from the underlying gluteal muscle.
- Then complete the upper incision, transect the muscle, and prepare the flap for microvascular transplantation.

Communications between the origin of the muscle and the outer lip of the anterior iliac crest allow transplantation of the muscle with vascularized bone. The flap can be transferred as a functional unit and can be useful for foot and lower leg coverage (75).

FIBULA FLAP

The fibula flap can be raised as an osteoseptocutaneous or isolated bone segment. The length of the bone can be up to 25 cm. The dominant pedicle is the peroneal artery and vein. The length of the pedicle is 2 cm; the diameter of the artery is up to 2.5 mm, and the vein diameter is 3 to 4 mm.

The course of the pedicle is posterior to the fibula through or beneath the flexor hallucis muscle. The sensory nerve supply is via the superficial peroneal nerve.

The skin territory is located on the lateral leg, and the size of the flap can be 8 × 15 cm². The skin blood supply is based on septocutaneous and musculocutaneous perforating vessels.

- Position the patient supine, with a tourniquet placed on the thigh. Center the skin island over the middle third of the fibula with the long vertical axis over the posterior edge of the fibula.
- Make the incision around the anterior part of the skin island through the crural fascia to the peroneus muscle.
- Dissect subfascially toward the posterior intermuscular septum.
- Perform a distal osteotomy and proximally distract the distal end of the fibula with a clamp.
- Divide the interosseous membrane and expose the peroneal vessels.
- Perform a proximal osteotomy and dissect the vessels to their origin.
- Check the perfusion after releasing the tourniquet.

OSTEOCUTANEOUS ILIAC CREST FLAP

A composite (osteomusculocutaneous, osseous muscle) transfer can include the superior anterior iliac crest with overlying skin, and a portion of contiguous muscle can be harvested.

The blood supply is the deep circumflex iliac artery (DCIA) and venae comitantes. The pedicle length is 6 to 8 cm, and the artery diameter is 2 to 2.5 mm. Skin territory can be 6 × 12 cm². A branch of T-12 supplies the skin portion of the flap.

- Place the patient in a supine position. Design the skin island along the iliac crest extending from the anterior superior iliac spine (ASIS) posteriorly for the desired length.
- Make the first skin incision in the upper margin of the flap, exposing the external oblique muscle fibers posteriorly along with the fascia. Dissect the skin in a loose areolar plane toward the iliac crest, taking care not to injure any musculocutaneous perforators.
- Incise the external oblique muscle approximately 2 to 3 cm parallel to the iliac crest.
- Identify the inguinal canal and retract the spermatic cord or round ligament medially and superiorly.
- Make incision through the posterior margins of the skin paddle and advance to subfascial dissection of the soleus muscle to the posterior intermuscular septum.
- Posteriorly, continue the dissection toward the flexor hallucis muscle. At this point, it is important to identify the peroneal artery and vein and the motor nerve.
- Identify the terminal branches of the lateral circumflex femoral artery 10 cm below the anterior superior iliac spine and continue to dissect deep to the rectus femoris to develop a long vascular pedicle.
- Close the donor site in layers to prevent abdominal herniation (101).

OMENTAL FLAP

The omentum is a visceral structure containing fat and blood vessels within a thin membrane. It extends from the stomach to the transverse colon and beyond, covering the anterior peritoneal contents.

The omentum has two dominant pedicles: a right gastroepiploic artery and vein with a length of 6 cm and an artery diameter of 2 to 3 mm, and a left gastroepiploic artery and vein with a pedicle length of 4 cm and artery diameter of 2 mm. The omentum may be as large as 40 × 60 cm².

Prior intraabdominal surgery may preclude use of the omental flap because of extensive omental inflammatory adhesions.

The pliability and rich lymphatic network of the omentum make it ideal to fill cavities and fight infection. The omentum is particularly ideal for obliteration of irregular dead space cavities and thus has been effectively used in providing coverage after sauzeration for chronic osteomyelitis (111).

- Place the patient supine.
- Release the areolar attachments of the omentum from the transverse colon so the omentum remains hanging on the greater curvature of the stomach. Return the omentum to the inferior abdominal cavity and expose the anterior paired layer attachments to the greater curvature of the stomach.
- Next, divide the short vascular branches between the gastroepiploic arch and the greater curvature of the stomach.
- Identify the terminal branches of the lateral circumflex femoral artery and vein. As the dissection approaches the ASIS, the ascending branch passes through the transversus abdominis muscle, coursing superiorly between this muscle and the internal oblique muscle.
- Divide the interosseous membrane and expose the peroneal vessels.
- Perform a proximal osteotomy and dissect the vessels to their origin.
- Close the donor site in layers to prevent abdominal herniation (101).

Insert a nasogastric tube for 24 to 48 hours after the operation to decompress the stomach. This prevents gastric distention, which, among other things, might dislodge any of the vascular ligations along the greater curvature.
POSTOPERATIVE CARE

Postoperative care of free tissue transfer patients requires that patients be adequately hydrated. Maintenance of proper body temperature and hematocrit is also important. We do not routinely heparinize or use anticoagulation.

In addition to clinical observation, flaps are usually monitored with a laser Doppler for a minimum of 5 days. Although the immediate postoperative period of 24 to 48 hours is critical, there have been late occasional failures; thus, continue laser Doppler monitoring for 4 to 5 days.

Elevate the patient’s extremities at all times to augment venous return. Do not allow patients who have undergone surgery of the lower extremity to ambulate postoperatively for a minimum of 3 weeks. The ischemia of the flap to the wound bed, the selection of muscle or skin, and the “take” of the skin graft are factors contributing into the timing to determine dependency of the lower extremity. Those patients who have reconstruction around the foot and ankle are most prone to increased venous pressure and resultant edema of the flaps. This edema can result in the dehiscence of the free flap from the surrounding tissue bed. For this reason, require patients who have undergone surgery on an extremity to keep their limbs elevated and use bed-to-chair transfers for a minimum of 3 weeks. Some experimental data suggest that this timing can be shortened. However, it is our experience that this is the amount of time it takes for the flap to mature and develop a sufficient venous return to withstand the hydrostatic pressure associated with standing.

Before proceeding with any other reconstruction such as bone grafting (such as in a case of open tibia fracture or tendon transfers), all wound surfaces must be epithelialized. There must be no edema, cellulitis, granulation tissue, or sinus tracts that could compromise the next stage of reconstruction. For example, in cases of a free muscle flap in the distal third of an open tibia fracture that ultimately requires bone grafting, it is essential that all skin grafts be totally epithelialized to decrease skin colonization of bacteria. Our preference is to remove the external fixator, clean the pin sites, and place the patient in a cast until the pin tracts heal. The flap can be then elevated, and an arterogenous bone graft can be safely performed.

The donor site should be given the same attention as the recipient site during the postoperative period. Complications of the donor site include hematoma, seroma, and sensory nerve dysfunction and scar formation.

MONITORING

Monitoring of free tissue transfer is essential to ensure transplant success. Many different monitoring devices and techniques have been used with varying levels of success.

An ideal flap monitoring should satisfy several criteria. It should be harmless to the patient and the flap, objective, reproducible, applicable to all types of flaps, and inexpensive. It is important that any monitor be capable of prolonged monitoring and respond rapidly to circulatory changes. Postoperative monitoring techniques can be grouped in four categories: (1) clinical evaluation, (2) direct vessel monitoring, (3) indicators of tissue circulation, and (4) metabolic parameters related to perfusion.

Clinical Evaluation

Clinical evaluation remains the standard by which all methods of monitoring need to be measured. This process involves observation of skin color, temperature, capillary refill, and bleeding characteristics. Clinical observation fulfills many of the criteria of the ideal monitoring system. It is cheap, readily available, and can provide a dynamic picture. The disadvantages are the need for experienced personnel, and its use being confined to monitoring surface skin flaps and muscle flaps. Changes are often initially subtle, and by the time they are clinically apparent, salvage of the flap may be impossible because of irreversible tissue damage.

Direct Vessel Monitoring

Direct vessel monitoring can be done by electromagnetic flowmeters. Readings are based on measuring the electric potential induced by blood flow. The ultrasonic Doppler measures sound waves reflected from columns of moving blood cells. Thermocouples measure the temperature difference between preanastomotic and postanastomotic sites on the vascular pedicle using two microthermocouples.

Circulation Monitoring

Measurements based on monitoring the change in the temperature of the skin are used as indicators of the blood flow in skin. Photoplethysmography is based on the change of the amount of light reflected during change in the local cutaneous blood volume, and laser Doppler flowmetry is based in the same general principles as ultrasound Doppler but measures the frequency shift of light rather than sound waves reflected from moving red blood cells. Pulse oximetry continuously monitors both pulsatility and oxygen saturation. This measurement defines blood flow.

Metabolic Monitoring

Transcutaneous oxygen monitoring and invasive measurements of PO₂ check the perfusion of tissue transplantations based on metabolic parameters. Levels of tissue oxygen tension have been monitored in flaps and have been shown to reflect the quality of capillary circulation.

Monitoring is usually performed in an intensive care unit setting or a step-down setting, depending on the condition of the patient. It is standard practice in our center to routinely monitor patients in an intensive care unit for the first 24 hours because this is when the problems most frequently occur following free tissue transfer.

Absolute values of laser Doppler measurements, patterns, and trends of flow can give valuable information about the dynamic perfusion range of blood flow over time. Low absolute values of perfusion, as well as relative change to the initial flow, are alarming signs, and require immediate clinical evaluation of the flap.

Based on our experience with laser Doppler monitoring we suggest classifying the perfusion in one of the following four groups with a corresponding diligence of observation.

1. If the perfusion is within or above the established range, maintain a normal degree of observation.
2. If the observed flow is somewhat low based on available tables of normal blood flow, continue clinical observation.
3. If the absolute flow is lower than 0.4 laser Doppler flow units (LDF) units for 30 minutes, institute a maximally aggressive clinical observation (alert level 3; “red alert”) and strongly consider exploration. This is typically inconsistent with viability of the flap regardless of flap type, recipient site, or blood flow history.
4. If the absolute flow is lower than 0.4 laser Doppler flow units (LDF) units for 30 minutes, institute a maximally aggressive clinical observation (alert level 3; “red alert”) and strongly consider exploration.

In cases of abnormal laser Doppler values, rule out artifact. Falsely low readings can occasionally be the result of a probe becoming detached from the flap. However, low readings can also be caused by hypotension, hypothermia, and hypoxemia. Therefore, it is important to examine closely not only the laser Doppler equipment but also the general condition of the patient. Falsely elevated measurements can be caused by vibration, motion of the probe or tissue, location of the probe over a large vessel, or extreme variation in the hematocrit.

FLAP FAILURE AND MANAGEMENT

Success of free tissue transfer should be on the order of 95% to 99%. Acute complications occur usually in the first 48 hours and include venous thrombosis, arterial thrombosis, hematoma, hemorrhage, and excessive flap edema.

Arterial insufficiency can be recognized by decreased capillary refill, pallor, reduced temperature, and the absence of bleeding after pin prick. This complication can be caused by arterial spasm, vessel plaque, torsion of the pedicle, pressure on the flap, technical error with injury to the pedicle, a flap harvested that is too large for its blood supply, or small vessel disease (due to smoking or diabetes). Management of arterial compromise requires prompt surgical intervention to restore the blood flow. Pharmacologic intervention includes vasodilators, calcium blockers, and anticoagulants for flap salvage presenting with arterial insufficiency.

Venous outflow obstruction can be suspected when the flap has a violaceous color, brisk capillary refill, and normal or elevated temperature, and produces dark blood

after pin prick. Venous insufficiency can occur due to torsion of the pedicle, flap edema, hematoma, or tight closure of the tissue over the pedicle. The venous outflow obstruction can result in extravasation of the red blood cells, endothelial breakdown, microvascular collapse, thrombosis in the microcirculation, and finally, flap death. Given the irreversible nature of the microcirculatory changes in venous congestion that occurs even after short periods of time, venous compromise must be recognized as early as possible.

These complications can occur alone or in any combination. The clinical observation and monitoring of the patient (such as with laser Doppler) should alert the surgeon, who has to decide between conservative and operative intervention. Conservative treatment may include drainage of the hematoma by the bedside release of a few sutures to decrease pressure. In cases of venous congestion, leeches may be helpful if insufficient venous outflow cannot be established despite a patent venous anastomosis (Fig. 35.26; see also Color Fig. 35.26). The leeches inject a salivary component (hirudin) that inhibits both platelet aggregation and the coagulation cascade. The flap is decongested initially as the leech extracts blood and is further decongested as the bile wound oozes after the leech detaches (110).

Figure 35.26. (See Color Fig. 35.26). Venous congested flap treated with leeches.

TREATMENT OF FAILURE

Occasionally, free flaps, despite early return to the operating room for vascular compromise, do fail. Options for management include the performance of a second free tissue transfer, noting the technical or physiologic details that led to initial failure. Most of the time, free tissue transfers that fail are due to technical errors in judgment, whether they be flap harvest, compromise of the pedicle during the harvest, improper microvascular technique during anastomosis, improper insetting resulting in increased tissue tension and edema, or postoperative motion of the extremity resulting in pedicle avulsion. Although this is rare, it does occur.

The operating surgeon must then decide how to manage this patient, based on several factors. Obviously, if a patient required a free flap in the first place, a second free flap should be considered. If a decision is made not to redo the flap, it could be left in place using the so-called “crane principle” in hope that underlying granulation will be sufficient such that skin grafting can be performed once the necrotic flap is removed.

The Crane principle can be applied to cases where a local flap or free tissue transfer fails in part or totally. The failed flap serves as a biologic dressing or eschar over the wound bed. If there is no infection, leave the eschar on the wound bed and observe for healing, evidenced by the formation of granulation tissue under the eschar. Ultimately, the eschar can be removed and, with an appropriate granulation bed, the wound can be skin grafted, obviating the need for another free tissue transfer. If a granulation bed is not produced, consider a second flap. Occasionally, failed free flaps are left in place, provided that there is no infection. With some wound contraction and granulation tissue taking place over time, the flap is removed and a skin graft can be performed to reepithelialize the wound.

Delayed debridement of unsalvageable free flaps can be considered for noncritical wounds and may obviate the need for a second free tissue transfer to obtain wound closure (116).

We believe that a necrotic flap can become a source of sepsis and further compromise local tissues. Remove necrotic nonviable flaps and apply a temporary wound dressing, such as a bead pouch or wound Vacuum Assisted closure device (KCI Company, San Antonio, Texas). Occasionally, when flaps fail in severely compromised extremities, consideration can be given to amputation in that the morbidity of a second free tissue transfer and perhaps the resultant extremity state renders the extremity less favorable for salvage and more favorable for amputation. If a second free flap is considered, avoid the errors that led to the initial flap compromise. It is prudent to obtain an arteriogram, evaluate the coagulation profile, and research other issues that lead to failure.

AESTHETIC CONSIDERATIONS

Providing patients ultimately with a functional limb after free tissue transfer is most important. Careful selection of the flap as well as consideration of donor scar management can result in a satisfactory aesthetic result (Fig. 35.27). The use of tissue expanders can help by decreasing donor site morbidity, as well as the need for debulking of flaps, which can result in an improved cosmetic result (24).

Figure 35.27. Scapular flap for aesthetic reconstruction of the lower extremity. A: Defect on lower leg. B: Post-operative flap.

ILIZAROV APPARATUS AND MICRO SURGERY

There has been interest in combining free tissue transfer with the Ilizarov apparatus. The combination of Ilizarov and microsurgical techniques can be classified in four categories as follows.

Type 1 consists of the use of ilizarov as an external fixator for bone stabilization in cases of open fractures. In these cases, adequate bone stock is present and will consolidate, usually without a bone graft, provided soft tissue coverage is achieved. Request for coverage may occur after the orthopaedic traumatologist places the Ilizarov frame and recognizes the need for augmentation of the soft-tissue envelope. Trends toward a multidisciplinary approach in lower extremity trauma care involve orthopaedic and plastic surgeons coordinating efforts at the time of the initial evaluation of the patient, which allows planning of emergent or early coverage (within 3 days) and proper pin and ring placement. If the procedure is planned properly, frames can be partially disassembled (for example, connecting rods removed) to allow access to wounds, pedicles, and space for hands to perform microsurgery. Free tissue transfer in these cases provides only coverage. The frame provides definitive fracture care, with options for progressive dynamization by frame disassembly, decreased rigidity, and increasing load to allow bone healing to occur. An example of a type 1 Ilizarov-microsurgery combination would be a comminuted distal third fibia fracture with an open wound.

The second combination of ilizarov-microsurgery (type 2) is the application of the Ilizarov frame after placement of the flap for treatment of nonunion or malunion. Although the Ilizarov method can treat deformities or malunion without free tissue transfer, a large group of patients undergo initial stabilization with plates or conventional external fixators. These patients then undergo coverage with free flaps. The soft tissue heals, but the bone does not heal or develops deformity. If this is
Type 3 involves injuries that have soft tissue as well as bone defect, for which the Ilizarov frame can be used to treat the initial fracture by stabilization, followed by callosity dissection after the soft tissue has healed. Two scenarios exist: (1) limb length and alignment are initially achieved the night of injury, and (2) corticotomy and free tissue transfer are performed at about 48 hours after the injury. The bone is transported through the maturing free flap, with the bone defect treatment spanning a few weeks to months, obviating the need for bone graft. The second option involves acute shortening of smaller defects, with primary bone healing under compression at the fracture site, in addition to performing the corticotomy at the time of flap coverage such that the initial fracture is compressed and the corticotomy is distracted ultimately to gain limb length with consolidation of the ilia at that time. Microsurgery is performed to reconstitute the soft tissue in these cases. The surface area in such cases and the volume of flaps are diminished so that morbidity of the donor site is decrease of flaps are diminished so that morbidity of the donor site is decreased. For example, in a large soft-tissue injury in an open tibia fracture, the latissimus dorsi may have been previously selected for coverage. By acutely shortening the limb and decreasing the soft-tissue defect, a gracilis or slip of serratius may be adequate. This fulfills the need for soft-tissue coverage with an easier flap with less morbidity.

In type 4 reconstruction, the Ilizarov frame is used as a definitive fixation for vascularized bone grafts used for bone defects that exceed more than 6 cm. The osteosynthetic fibula is our choice in such cases. Complications such as nonunion or delayed union, stress fractures, and prolonged time for bone remodeling have all been diminished using the Ilizarov technique.

In the instances of osteomyelitis, the soft tissue can be managed with free tissue transfer, and the Ilizarov frame can be used to bridge unstable defects requiring conventional or vascularized bone grafts. We have used the combination of a free vascularized fibular graft and the Ilizarov frame very successfully in instances of femur and tibia defects. Both microsurgical and Ilizarov technique have the capabilities to stand alone in solving limb reconstructive problems and should do so in specific cases. However, in patients considered for limb amputation, these combined techniques can be used to salvage extremities with good functional outcomes.

FUTURE TECHNOLOGY

The search continues for new techniques that will result in faster and easier methods for microvascular anastomosis. Staplers may have a more important role in microsurgery in the future. They shorten the operating time and have proven to be safe (137). The vessels suitable for this technique must be chosen carefully, and the surgeons using this technique should also be experienced in conventional microsurgery.

It is expected that the time-consuming use of interrupted sutures will be replaced more and more by running sutures. Furthermore, refinements in laser welding and the development of new tissue glues may take over the role of sutures. The operating microscope itself may also vanish in time. Many microsurgeons prefer to use high-magnification loupes, in which they are able to achieve good results (103, 104). Furthermore, advances in video technology now enable the surgeon to view a microsurgical field on a monitor in three dimensions without looking through microscope eyepieces.

ENDOSCOPIC HARVESTING

Following the introduction of endoscopic techniques in almost every field of surgery, the application of endoscopic techniques for reconstructive microsurgery represents the natural evolution of this trend. Less postoperative pain, smaller scars in the donor area, better visualization of the operative field with the magnified video, and better hemostasis are only a few of the advantages of these techniques. These advantages have been reported in a recent series of patients in which latissimus dorsi harvesting was analyzed comparing endoscopic techniques and the traditional technique (69). Successful microvascular transplantation of gracilis muscle harvested with endoscopic guidance has been reported (34, 106).

Prefabrication of flaps allows custom flaps to be constructed based on what is required for a specific defect. The exploration of this new frontier may increase the possibility of reconstructive capabilities and decrease the donor morbidity of classical reconstructions. Depending on the specific application of the prefabrication, one or more of the following advantages may be offered:

- Specific preferred blocks of tissue that are not naturally perfused by anatomically well-defined axial vessels or by a reliable pedicle that is easy to transfer may be used. One example is skin flaps that need to be very thin (the axial pedicles of all known flaps enter from the deep side, and a significant amount of subcutaneous tissue must be incorporated).
- A larger flap of specialized tissue may be transferred by manipulating the vascular territory of the flap. Examples include pretransfer delay of a cutaneous flap to include a larger skin island or pretransfer expansion of a flap to generate an additional amount of tissue. By extending the limits of perfusion, delay allows the transfer of a much larger amount of tissue than would be allowed by the original pedicle.
- The morbidity of a donor site can be reduced. Examples include pretransfer expansion of a flap to allow primary closure of the donor site and transfer of the lower abdominal skin based on an induced pedicle that spares the rectus muscles and the integrity of the abdominal wall.
- A satisfactory functional status of the replacement part may be ascertained before transfer. Thus, that which had been a lengthy multiple-stage posttransfer reconstruction can be converted into an elegant, single-step transfer of a finished functional part or organ.

FLAP PREFABRICATION

Current clinical methods of flap prefabrication can be considered to be based on one or more of the following fundamental principles of reconstructive surgery:

- Delay or expansion (Fig. 35.28).

Grafting: pretransfer grafting of flaps is necessary when complete graft take is mandatory to the success of the reconstruction, and when posttransfer grafting is neither feasible nor practical.

Vascular induction using staged flap transfer. This method is based upon the well-established principle of staged flap transfer, for which the “vascular carrier” is the contemporary microvascular refinement of the old wrist carrier. The concept is that a small flap of muscle, fascia, intestine, omentum, or even an arteriovenous bundle or fistula can become a “vascular carrier” and can be induced to provide an alternative blood supply through neovascularization to a larger block of tissue after a relatively short staging period.

A fourth method of flap prefabrication makes use of recent advances in cell biology to induce the transformation of a flap from one tissue type to another. An application of these advancements can be found in bone and joint reconstruction, which is still most commonly performed with less than ideal alloplastic materials and remains a formidable challenge despite advances in free tissue transfer. With the possibility of inducing mesenchymal tissue to differentiate into bone, a simple muscle flap may be molded and transformed into a vascularized bone graft of desired shape and size.

MICROSURGERY COST AND OUTCOMES
CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Since first reported in the mid-1970s, the use of vascularized bone grafts has continued to be refined. Offering rapid bony union, increased stiffness and strength, less resorption, and more rapid hypertrophy than conventional bone grafts, they have distinct advantages in selected cases. They do, however, require specialized microsurgical skills and careful preoperative planning. With sources including the fibula, iliac crest, rib, radial styloid, and indications ranging from nonunion, tumor reconstruction, congenital pseudarthrosis, and radial club hand to traumatic and infectious defects, the opportunities that can be afforded by vascularized bone grafts are vast and varied.

HISTORY

Strauch, Bloomberg, and Lewin performed some of the first experiments on free tissue transposition in dogs in 1971 when they isolated a rib on the internal mammary pedicle and transposed it to the jaw. This was followed, again in the canine, with a free vascularized rib graft in 1973 by McCullough and Fredrickson. With the advent of microvascular techniques and development of microsurgical instruments, anastomosis of vessels as small as 1 mm was successfully accomplished by Buncke in 1965 in a rhesus monkey. Improvement on these techniques opened the door for the transfer of composite tissue. The first free skin flap was reported by Daniel and Taylor in 1973, involving the transfer of an iliofemoral island flap based on the superficial circumflex iliac artery to the right lower extremity. This was followed by a report in 1975 of the first free bone graft by Taylor et al., who transferred a rib to a tibial defect. Buncke et al. (1) successfully transferred the first composite bone flap utilizing a rib to the tibia in 1977 to treat a tibial pseudarthrosis, and this was followed shortly by Taylor's report of the first such graft using groin skin and iliac bone in 1978.

GOALS OF TREATMENT

The basic goals of treatment are:

1. To provide restoration of skeletal continuity
2. To achieve union rapidly, thus avoiding the slow process of creeping substitution as required for conventional grafts
3. To provide viable soft tissue coverage early
4. To restore and maintain the anatomy of the limb
5. To restore limb function including motion and strength

The surgeon should always strive to avoid complications and perform the procedures with the least morbidity and operative time necessary. For three-quarters of a century, conventional corticocancellous bone grafting, which has been shown to involve necrosis of the graft followed by a long process of revascularization, osteogenesis, and remodeling, has been the sole option in treatment of segmental bone defects. The living bone graft circumvents this prolonged process. With these goals in mind, the next step is the assessment of the patient and his or her expectations, the underlying pathology, and what is available to use as graft tissue. All of these points have to be considered in individualizing the treatment plan for each patient. Once this is determined, the surgical team can move to the next step in planning a vascularized bone graft.

INDICATIONS

Several issues regarding patient selection are crucial to planning a vascularized bone graft. Patient age and underlying medical condition play an important role in determining which patients are candidates. Although there is no age limit for vascularized bone grafts, elderly patients with underlying medical problems may present an unacceptably high surgical risk. Carefully weigh the risks of a long surgical procedure and requirement for prolonged limb protection against patient expectations. Those patients with evidence of peripheral vascular disease may also present risks that predispose to failure. Patients with multiple previous attempts at treatment may have altered local anatomy and limited availability for tissue coverage. Patients who smoke have been shown to have delayed bone healing. Those with hypercoagulable conditions or clotting abnormalities may also require special consideration.

DEFECT CHARACTERISTICS

In patients with a history of trauma, irradiation, or infection, the condition of the recipient vessels in the defect must be carefully considered, as they may be at increased risk for failure of the graft because of poor arterial inflow and venous outflow. These procedures are often long and tedious, and the extensive dissection and long operative time required may exacerbate a previously quiescent infection and may increase the risk of graft failure.

DONOR SITE AVAILABILITY

Several factors must be considered when choosing a bone for vascularized transfer. First, the donor bone must be of sufficient size to fill the defect. Free vascularized grafts offer advantages over conventional grafts in cases of defects greater than 6 to 8 cm. Lesser defects may not require as extensive a procedure, and a pedicled vascular graft may suit such a case well. Free vascularized iliac crest grafts are useful for defects no longer than 10 cm because of both the curvature and the structural characteristics of the bone. The nutrient vessels must be of adequate size for successful microvascular anastomoses. Arteriograms may aid in determining...
the availability and status of vessels. Last, donor site morbidity must be minimized.

APPLICATIONS

Current applications for vascularized bone grafts continue to expand. Well established are the uses of such grafts in patients with large defects secondary to trauma or after resection of locally aggressive or malignant bone tumors. Refractory nonunions, resection for osteomyelitis, and congenital pseudarthrosis of the tibia or forearm are other situations in which living grafts can be most useful. More recently, the use of vascularized bone grafts in the treatment of avascular necrosis of the femoral head has been reported with some mixed results. Avascular necrosis of the scaphoid (Priser's disease) and of the lunate (Kienbock's disease) has also been treated with vascularized bone grafts in hopes of arresting the underlying disease process.

TRAUMA

Trauma is the most common cause of segmental bone loss in both upper and lower extremities. Perhaps the most frequent indication for vascularized bone grafts is the posttraumatic and often massive bone loss associated with severe trauma. Autogenous cancellous bone graft methods are not well suited for large defects of bone greater than 6 to 8 cm, as resorption of the graft may occur, and it does not provide structural support. In addition, scarring and relative avascularity of the recipient bed may not be conducive to graft incorporation. Defects in the tibia are most common; however, defects of the femur, ankle, and radius have also been treated with vascular bone grafts. An important concern in this setting is the condition of the recipient site, as often the bed has significant scarring. The arterial inflow to the area may be tenuous as well because of the "zone of injury," which may extend a significant distance from the apparent bony defect. The fibular graft is most often utilized, as it nicely fits the longitudinal defect and is of sufficient length for most reconstructive settings. The rib graft was the first reported graft used clinically, but its usefulness in orthopaedics is somewhat limited because of its curved and malleable nature. It also has the potential for higher donor site morbidity if careful harvesting technique is not followed. The iliac crest is also useful; however, again the curvature of the bone often limits its application for defects less than 10 cm, and donor site morbidity is not insignificant.

TUMOR

Much has been written about the use of vascularized bone grafts in the setting of tumor resection and reconstruction. Patients with locally aggressive or malignant tumors of bone often require en bloc resections that leave a large defect requiring reconstruction. Welland et al. (61,62) have reported on a large series in which they used free fibula graft for the reconstruction of defects after massive tumor resections.

Case Study 1 A 20-year-old college athlete presented with pain, swelling, and increased deformity of his wrist and forearm over several months' duration (Fig. 36.1).

A locally aggressive fibromyxoma was treated by en bloc resection and vascularized fibular grafting.

Case Study 2 A 10-year-old girl presented with pain in her right hip of several months' duration (Fig. 36.2). A low-grade chondrosarcoma was treated by wide local excision, leaving a defect measuring 14 cm in the proximal femur. The defect was reconstructed using a vascularized fibula dowelled into the recipient femur and external fixation to stabilize the graft. The graft healed uneventfully, but the patient later required a valgus intertrochanteric osteotomy to correct a resultant varus deformity of the proximal femur.

Osteomyelitis

A frequent problem faced by the orthopaedic surgeon, osteomyelitis can pose management and treatment problems for many reasons. The resection of soft tissue and bone is often too massive to obtain adequate debridement of the infected area. Often the patient has undergone multiple procedures including several irrigations and debridements. As many as 18 procedures were reported in a recent study (5) to have preceded presentation for the definitive grafting procedure. This leaves a significantly scarred and relatively avascular soft tissue bed to work with. The integrity of the surrounding vessels could also be potentially compromised, leading to high risk of graft failure. Furthermore, the potential of recurrence of the infection leading to almost certain graft failure is a foremost concern.

Case Study 3 A 32-year-old patient sustained a bumper-type injury that resulted in a comminuted open fracture of the proximal tibia complicated by osteomyelitis (Fig. 36.3). Following debridement and application of an external fixator, the patient was left with a 13-cm bone defect, with interval healing after a vascular latissimus dorsi flap. The tibial bone was subsequently fractured at the proximal junction site, however, and later required an open reduction, internal fixation, and plating before complete healing occurred.
Nutrient artery and segmental musculoperiosteal vessels (Studies have shown that the peroneal artery, which is intimately related to the undersurface of the bone, is the predominant blood supply to the fibula, supplying a VASCULARIZED FIBULA.

Interfere with successful microvascular anastomoses. Be aware that a normal arteriogram may not provide a true assessment of the arterial inflow. Scarred blood vessels or those easily prone to spasm may appear normal. Assessed the patient, the defect, and the possible donor sites as described elsewhere in this chapter well before the selected case. The surgeon should first be well trained and well versed in microvascular techniques and be able to perform multiple types of microvascular anastomoses that may be required in scarred or otherwise traumatized tissue. Conventional bone-grafting methods have failed to successfully treat these patients. Refractory nonunions can occur in many locations, but the well-known sites are the tibia and scaphoid. The tibia is often subjected to open injuries, and the blood supply to the area can be easily interrupted. The anatomy of the blood supply to the scaphoid lends itself to compromise, especially with proximal pole fractures. These situations may not often require the massive size grafts as seen in the previously discussed conditions; however, they still require a nutrient blood supply in which osteocytes and osteoblasts can survive, thus facilitating healing of the bone without the usual replacement of the graft with creeping substitution. In the case of scaphoid nonunions, a local pedicled vascularized bone graft will often be adequate to treat a nonunion. Zaidenberg et al. (72) described a vascularized graft to the scaphoid based on the radial styloid that offers promising results. Several other authors have reported on vascularized metacarpal bone grafts based on the branches of the radial and ulnar arteries.

CONGENITAL PSEUDARTHROSIS

Congenital pseudarthrosis remains one of the most challenging problems facing the orthopaedic surgeon today. Conventional bone-grafting methods have failed to successfully treat these patients. Chen, Weltland, Haqan, and Bunke have all reported promising results using vascularized free fibular grafts in the treatment of this difficult problem. Congenital pseudarthrosis of the forearm is uncommon. Sellers (45) reported only 23 cases after a review of the literature. Conventional treatment has been fraught with poor results and recurrent nonunion. Allieu (1) and Sellers (45) both report improved results with the use of free vascularized graft for this condition.

Case Study 4 An 11-year-old boy with von Recklinghausen's disease presented with a congenital pseudarthrosis of the right tibia and fibula that had defied several previous attempts at bone grafting and immobilization (Fig. 36.4). An extraperiosteal dissection and excision of the pseudarthrosis of the tibia and fibula were performed, resulting in an 8-cm tibial defect. A buttress plate was used to secure the graft to the tibia proximally and distally. Six months postoperatively there was good incorporation of the fibula graft proximally as well as distally. The patient subsequently required a contralateral epiphysiodesis to equalize a leg length discrepancy and an osteotomy of the tibia to correct valgus bowing.

AVASCULAR NECROSIS (AVN)

Several recent reports on the treatment of avascular necrosis of the femoral head have been published. This difficult problem often presents in the younger patient as a result of trauma, steroid use, or alcohol use or may be idiopathic. This group of patients is often too young for hip arthroplasty but is severely debilitated secondary to pain and stiffness. A vascularized bone graft may offer them a chance to retain their native hip as long as possible while restoring some of their quality of life. Both iliac crest and fibula have been reported in the literature as possible sites of donor bone graft. Results have been mixed, with some authors reporting good results and others saying that the results are no better than with simple core decompression. Scaphoid and lunate AVN have also been treated with vascularized bone grafts with promising results.

PREOPERATIVE PLANNING

The surgeon should first be well trained and well versed in microvascular techniques and be able to perform multiple types of microvascular anastomoses that may be required in scarred or otherwise traumatized tissue. Assess the patient, the defect, and the possible donor sites as described elsewhere in this chapter well before the procedure. Obtain preoperative arteriograms of both the donor and recipient site to evaluate any vascular abnormalities that could preclude a successful graft transfer. Be aware that a normal arteriogram may not provide a true assessment of the arterial inflow. Scarred blood vessels or those easily prone to spasm may appear normal on an arteriogram. The surgeon will often be required to make intraoperative judgments of vascular viability and should be able to recognize vessel damage that would interfere with successful microvascular anastomoses.

SURGICAL TECHNIQUES

VASCULARIZED FIBULA

Studies have shown that the peroneal artery, which is intimately related to the undersurface of the bone, is the predominant blood supply to the fibula, supplying a nutrient artery and segmental musculoperiosteal vessels (53). Commonly an arteriogram of a normal leg exhibits a proximal anterior tibial artery takeoff followed by a bifurcation of posterior tibial and peroneal arteries. Occasionally, a separate peroneal artery does not exist, which may preclude use of the fibula as a donor. Although not essential, a two-team approach can save considerable operative time. The surgical technique for the donor fibula is rather constant, with the patient supine and the hip and the knee flexed.
Use a lateral approach to the fibula, extending from the neck of the fibula in a distal direction.

Identify the interval between the peroneus longus and the soleus muscles. Incise the deep fascia the entire length of the incision.

Figure 36.5. Cross section of the middle third of the lower extremity, outlining the lateral approach for harvest of the fibula (dotted line). T.A., tibialis anterior; D.P.N., deep peroneal nerve; A.T.V., anterior tibialis vessels; E.D.L., extensor digitorum longus; P.T., peroneus tertius; S.P.N., superficial peroneal nerve; P.B., peroneus brevis; P.L., peroneus longus; P.C.S., posterior crural septum; F.H.L., flexor hallucis longus; P.V., peroneal vessels; G.A., gastrocnemius aponeurosis; P., plantaris; I.S., intermuscular septum; P.T.V., posterior tibial vessels; P.T.N., posterior tibial nerve; F.D.L., flexor digitorum longus; I.M., interosseous membrane. (From Weiland AJ. Vascularized Bone Transfers. In Murray JA, ed. AAOS Instructional Course Lectures, Vol. 33. St. Louis: CV Mosby, 1984:448.)

Expose the lateral border of the fibula. Approach the fibula in a proximal-to-distal direction and elevate, with extraperiosteal dissection, the peroneus longus and brevis off the anterior border of the fibula.

Divide the anterior crural septum along the length of the graft and identify and protect the deep peroneal nerve and anterior tibial artery and vein as the extensor group of muscles is dissected from the interosseous membrane.

Divide the posterior crural septum the entire length of the graft and reflect the soleus as well as flexor hallucis muscles off the posterior border of the fibula.

Preserve the nerve to the flexor hallucis longus while performing this dissection. Continue this dissection until the peroneal vessels are encountered.

The nutrient artery is found in the middle half of the fibula, usually just proximal to the midpoint. The peroneal vessels pass circumferentially around the fibula. Preserve them with extraperiosteal dissection. The venous drainage is via paired venae comitantes of the peroneal artery and closely parallels it.

Measure the length of the fibular graft needed and mark it, taking care to preserve at least the distal 6 cm of fibula to maintain stability of the ankle mortise. In children less than 10 years of age, perform a synostosis between the fibula and tibia to prevent proximal migration of the distal fibula, which can cause valgus ankle deformity.

Perform the proximal and distal osteotomies with a Gigli or power saw, taking care to place a bone retractor between the peroneal vessels and the fibula. Retract the bone graft posteriorly and laterally and divide the interosseous membrane along the entire length of the bone graft.

Retract the graft anteriorly. Dissect the tibialis posterior muscle off the posterior aspect of the middle third of the fibula. At this point, the fibula graft will be isolated on the peroneal neurovascular bundle (Fig. 36.6). Dissect the pedicle proximally until the bifurcation of the posterior tibial artery and peroneal artery is identified.

Before dividing the pedicle, deflate the tourniquet and allow circulation to the fibula for 10 to 15 min.

Figure 36.6. The osteotomized fibula after the interosseous membrane has been divided. The vascular pedicle of the peroneal artery and vein is clearly visible in the proximal extent of the wound.

The structure most at risk proximally is the peroneal nerve and its branches, which must be protected at all times.

The technique for preparing the recipient site varies depending on the clinical condition being treated. In posttraumatic cases, focus initial attention at identification and protection of neurovascular structures. Failure to isolate a healthy level of recipient vessels is the most common cause for failure of free tissue transfer. The zone of injury often far exceeds the limits of the bone defect in posttraumatic and infected cases.

Resect necrotic or nonviable bone ends.

Rigidity fix the fibular graft into the defect. A variety of techniques may be used, including doweling of the end of the fibula inside the tibia, end-to-end apposition, or bayonet-type fixation. Regardless of the position of the fibular graft, rigid fixation is needed with external and/or internal fixation. Do not use medullary fixation through the vascularized fibular graft to avoid disrupting its blood supply. In most instances, pack cancellous bone graft in and around the juncture points of the recipient and donor bone to promote more rapid union.

Perform the microvascular anastomoses. Usually one artery and one vein are anastomosed. Whenever possible, perform end-to-side arterial anastomosis so as not to compromise distal circulation to the extremity. End-to-end vein anastomosis is standard practice. The caliber of the recipient vein must be equal to or larger than that of the peroneal vein so that venous hypertension does not occur. Some authors recommend two venous anastomoses to assure adequate venous drainage. The recipient vein may be from either the superficial venous system or venae comitantes, as long as it is of sufficient caliber and scar-free.

The fibular graft, because it is devoid of larger amounts of soft tissue or muscle, seems particularly tolerant of ischemia lasting up to 6 h. Do not rush attempts at achieving secure bony fixation to limit ischemia time, as secure fixation is of utmost importance.

Adequate circulation is assessed by a patent and functioning anastomosis as well as by bleeding at the edges of the muscle cuff on the fibular graft. Before wound closure, ascertain that the vascular pedicle is not redundant, twisted, or kinked. It is preferable to resect and tailor a functioning anastomosis that is looped or kinked because of the potential danger of thrombosis.

Although there is no universal agreement on the use of anticoagulants, some surgeons find it helpful to give intraoperative heparin before removing the vascular clamps from large lower extremity vessels.

Pack cancellous bone chips harvested from the iliac crest about the proximal and distal juncture sites, insert deep drains, and close the skin.

Close the donor site defect in two layers, the subcutaneous layer and the skin. Do not close the fascia, as this may lead to a compartment syndrome.

At present, there are no 100% reliable techniques for monitoring the vascularity to the bone graft in a noninvasive fashion. Overlying skin islands may be taken with the graft, preserving the iliac crest. Immobilize and protect the grafted bone segment from weight bearing for at least 2.5 months or until incorporation and callus around the juncture sites are seen. In the adult, lower extremity graft incorporation usually occurs in 4 to 6 months, but it may be wise to protect the graft site with an orthosis throughout the first year.

Even experienced microsurgeons, if a novice at vascularized fibular grafting, should perform cadaveric dissections before surgery to refamiliarize themselves with the relationships of neurovascular structures to the interosseous membranes. With attention to meticulous technique, a very low incidence of donor-site morbidity can be expected.

VASCULARIZED ILIAC CREST

First described by Taylor as based on the superficial circumflex iliac artery (SCIA), this graft has undergone changes. In an elegant study combining cadaver dissection, angiography, and clinical trial, Taylor showed that the most reliable pedicle for the osteocutaneous iliac crest graft is the deep circumflex iliac artery, as it supplies a greater portion of the bone as well as an elliptical area of skin over the iliac crest and the iliacus, transversus, and internal oblique muscles as compared to the superficial system (5d). In planning this graft, the incisions, orientation of the bone, and the choice of donor side should be carefully planned in advance. Use the
ipsilateral crest in the tibia if the recipient artery is to be the anterior tibial; however, use the contralateral crest for the recipient posterior tibial artery.

The iliac crest graft, based on the deep circumflex iliac artery (DCIA), can be harvested with or without a skin flap. If a skin graft is taken, place the incision in the long axis along the upper border of the anterior part of the iliac crest. The upper limit of area of skin that can be harvested is not known currently. Areas averaging 18 × 7.7 cm have been described. Skin medially to the anterior superior iliac spine (ASIS) relies more on its blood supply from the anastomoses between the DCIA and the SCIA, and this means there may be temporary sluggish flow to this skin, but expect viability.

- Place the patient supine on the table with a small bump under the donor hip to help elevate the crest and aid in harvesting. If skin is to be harvested with the graft, mark the area on the skin.
- Make an incision from the femoral artery to a point about 10 cm posterior to the anterior superior iliac spine. A transungual approach to the vascular pedicle is preferred.
- Expose the external oblique muscle and incise it in line with its fibers, approximately 3 cm superior to the iliac crest. This edge of the muscle includes perforator branches of the DCIA. Then curve the incision toward the ASIS and parallel to the inguinal ligament to enter the inguinal canal. Next, identify the spermatic cord or round ligament and retract upward and medially. The external iliac artery can be palpated through the transversalis fascia.
- Incise the fascia and identify the DCIA and vein. They are most easily identified where they converge toward each other about 1 to 2 cm lateral to the external iliac artery. Trace the DCIA vessels laterally, dividing the transversalis fascia, internal oblique, and transversus abdominis from the inguinal ligament. As the ASIS is approached, it may become easier to identify the ascending branch lateral to the ASIS and then trace it medially to its origin from the SCIA by incising the internal oblique muscle 3 cm above and behind the ASIS.
- To isolate the bone, incise the transversus muscle parallel to the iliac crest, leaving a minimal rim of muscle on the bone. Incise the transversalis fascia, retract the external oblique fat, and expose the transversalis and the iliacus fascia. Incise the iliacus 1 cm medial to this line, thus exposing the periosteum of the iliac fossa. Bluntly dissect the iliacus muscle away from the remaining bone.
- Incise the lower skin border and cut the attachment of the tensor fasciae latae and gluteus muscles sharply from the bone. Divide the iliacus and lateral part of the ASIS, and reflect the iliacus muscle and sacrotuberous ligament medially.

Microvascular surgery has the same complications as other surgery, such as infection, wound problems, and others. Use good surgical technique to minimize these.

- Regardless of the frame used, it must not block access to the microvascular anastomoses. The pins or wires can be carefully passed through the graft, always protecting the nutrient artery and pedicle. Pack cancellous graft around the junction sites and close the wound over drains.
- Healing of the graft can be expected in 8 to 12 weeks, roughly the same as healing rate for fractures at the same site.

**RIB**

Ostrup, Fredrickson, and Tam showed by injection studies that the posterior intercostal vessels give rise to the principal nutrient vessel of the ribs, whereas the anterior intercostal arteries supply mainly the periosteum of the rib. The graft, therefore, is based on the posterior vessels (10). The graft can survive on the anterior pedicle, but the bone may show some necrosis.

- Measure the pattern of the defect and trace out the pattern on the chest. Make a posterior transverse incision between two ribs (10).
- Identify the intercostal vessels posteriorly at the beginning of the dissection and develop the flap margins of the underlying rib in an anterior direction.
- Expose the rib and cut a segment sized to the bony defect. Dissect the vessels back to the pedicle and carefully ligate them. Then transpose the graft to the defect and secure it. Close the donor defect primarily over drains.

Complete survival of the rib as free living bone occurs only when the intramedullary blood supply is maintained via the nutrient artery, which is a branch of the posterior intercostal artery. The nutrient artery must be isolated at the level of the rib head and closed as previously described (65). Skin medially to the anterior superior iliac spine (ASIS) relies more on its blood supply from the anastomoses between the DCIA and the SCIA, and this means there may be temporary sluggish flow to this skin, but expect viability.

**PITFALLS AND COMPLICATIONS**

Microvascular surgery has the same complications as other surgery, such as infection, wound problems, and others. Use good surgical technique to minimize these.

Loss of function of the flexor hallucis longus (FHL) can occur when a fibula is harvested as a result of dissection of its origin off of the fibula, damage to its nerve, or postoperative scarring. Avoid loss of FHL function and peroneal nerve palsy by identifying and protecting these structures when necessary and avoiding unnecessary dissection into the muscles surrounding the fibula. When the fibula is harvested, a major vessel to the leg is sacrificed, but this rarely leads to any problems.
In harvesting the iliac crest, the lateral femoral cutaneous nerve to the thigh may need to be sacrificed. Advise patients about this ahead of time. Iliac grafts may be bulky. Minimize bulk by placing the grafts in the defect in the coronal plane. Secondary debulking may be necessary.

**AUTHORS’ PERSPECTIVE**

Vascularized bone grafts have expanded treatment options for multiple clinical situations where obtaining bone union has traditionally been difficult. However, the ability to perform such a procedure and the practical nature of doing this are two different situations. It is our opinion that the vascularized fibular graft is most useful for defects of the tibial and for avascular necrosis of the femoral head. The use of iliac crest grafts is somewhat more limited because of the more curved nature of the bone and the morbidity of the donor site. It should be considered only if the fibular graft is not an option for a patient because of trauma or previous harvesting. Rib grafts have very limited use in orthopaedic surgery and are used only as a last resort to the other graft sites. Their curved nature makes them very amenable to use in the mandible. The dorsal/radial graft is useful for nonunions of the scaphoid, but we would recommend its use only for selected proximal pole nonunions and only after failed open reduction, internal fixation, and standard bone grafting, as it is more involved and requires greater dissection on the dorsal aspect of the wrist.

PRINCIPLES OF HAND SURGERY AND SURGICAL APPROACHES TO THE HAND AND WRIST

A. BASIC PRINCIPLES OF HAND SURGERY

Sterling Bunnell (1882 to 1957), the father of modern hand surgery, said, “Next to the brain, the hand is man’s greatest asset and to it is due the development of man’s handwork. The hand begins in the opposite cerebral cortex and extends from there to the tips of the nails” (5,6). He emphasized the importance of a detailed knowledge of structural and functional anatomy of the hand and a basic comprehension of the entire upper extremity (10). He also stressed the importance of atraumatic surgical technique in reconstructive hand surgery. Reconstruction of the hand is often a composite problem, requiring knowledge of orthopaedic, plastic, microvascular, and neurologic surgical techniques. The hand surgeon must be trained to handle all of the tissues in the extremity. Surgical reconstruction of the hand requires careful technique to minimize the formation of adhesions, which tend to bind together the nicely adjusted movable parts. Although cosmesis is important, the primary purpose of surgical reconstruction is to restore enough function to allow the patient to be self-sufficient (6,5,6,7,10,12,13,14,15 and 18).

PREOPERATIVE PLANNING

Even in emergency surgery, the surgeon usually has time to examine the extremity carefully to determine the severity of involvement of the skin, vessels, nerves, tendons, and skeleton. He or she can then plan the anticipated surgical procedure, which, after cleansing and debridement, might call for a skin graft or repair of lacerated radial, ulnar, and digital arteries and nerves. Through clinical examination and radiographs, the physician can evaluate the skeletal structures and plan for reduction and internal fixation of subluxations, dislocations, and fractures.

For severe injuries, paralytic conditions, and some disease entities, staged surgical repair and reconstructive procedures may be indicated. In these cases, a sequence of surgical procedures can be planned and, in most cases, can be discussed with the patient and relatives before surgery.

The primary requirement in hand surgery is the restoration of the position of function, nutrition, sensibility, motion, and good skin cover. The ends of the digits should have noncicatricial touch surfaces. The thumb should oppose the fingers, and the hand should open and close for the functions of pinch, hook, and grasp. The wrist should usually be in an extended position or occasionally in a straight position, and the fingers should be flexed partially at the metacarpophalangeal, proximal interphalangeal, and distal interphalangeal joints. The priorities of reconstruction are, in order of their importance, artery, skin, bone and nerve, and tendon.

For elective surgical procedures, advise patients to discontinue any medications (aspirin, nonsteroidal antiinflammatory drugs) that may increase perioperative bleeding at least 4 days before surgery. Patients on warfarin should be under supervision by an internist, who should be consulted regarding management.

OPERATING ROOM SETUP

Position a standard operating table so that a hand table can be attached to it. The distal end should have a stable, perpendicular appendage that extends to the floor. When fluoroscopy is needed, use a radiolucent table without legs that interfere with positioning of the fluoroscope. Always choose a table supported by legs when using a microscope, otherwise the operative field will drift out of focus as weight is placed on and taken off the table. With the patient in a comfortable supine position, abduct the extremity to 90° and place it on the table. Arrange the overhead lights opposite each other in line with the hand table so that neither surgeons’ nor nurses’ heads obstruct the focused light. The stools on which the surgeon and the assistant sit opposite from each other should be firm and stable, and their height should be adjustable. Both the surgeon and the assistant must be comfortably erect, with their forearms resting on the hand table.

TOURNIQUETS

A tourniquet is mandatory for almost all hand surgery. As Bunnell said, “A jeweler can’t repair a watch in a bottle of ink, and neither can we repair a hand in a pool of blood” (5). A bloodless field allows very small vessels and nerves to be seen and dissected with accuracy and minimal trauma.
Formerly, Esmarch bandages were used as tourniquets, and tourniquet palsy was not uncommon. Likewise, with the use of blood pressure cuffs that were not monitored by a mercury manometer or equipped with protective safety devices, false pressure readings, which sometimes masked extremely high pressures, remained undetected. The tourniquet gauge should, therefore, be checked and calibrated at least daily and the figures recorded (24). The calibration of many newer tourniquets is more stable and reliable. Become familiar with the one you are using and be confident that the pressure readings are accurate. Until a time of 2 hours was established by Wilgis as a safe period for a tourniquet to remain in place, tourniquet palsy was common (25).

UPPER ARM TOURNIQUET

- Properly position the patient and the extremity, then smoothly wrap several layers of sheet padding or Webril-type soft cast padding around the upper arm and into the lower axilla.
- Apply the pneumatic cuff snugly and as high as is comfortably possible over the padding.
- Securely attach the cuff to the tubing that leads from a nitrogen source, and inflate the tourniquet briefly to ensure that the system is operating properly.
- During skin preparation, take care to avoid seepage of solutions onto the cast padding and tourniquet cuff. Accomplish this by placing a vinyl-drape around the tourniquet with an adhesive border sticking to the upper arm. Be careful that this drape is not completely circumferential because when the tourniquet is inflated, a shearing force is applied to the skin that could result in injury.
- After preparation and draping, mark the skin with a methylene blue pen to outline the proposed incisions.
- Elevate and exsanguinate the extremity with a snugly wrapped 4-inch rubber or elastic bandage. In most adults, inflate the tourniquet to a pressure of 250 mm Hg; occasionally, in patients with heavily muscled arms or significant hypertension, inflate the tourniquet to 300 mm Hg.

In children, the pressure generally need not exceed 200 mm Hg. Exsanguination is contraindicated in patients with infections or tumors. However, in these patients, elevate the extremity for a few minutes before inflating the tourniquet.

- In most surgical procedures requiring more than 2 hours of operating time, deflate the tourniquet for 10 to 15 minutes at the end of the first 1 to 1.5 hour. During this period, apply pressure to the wound with a soft pad for the first 5 minutes.
- Then gently remove the pad and secure hemostasis with electrocautery and ligatures. Elevate the extremity again and re inflate the tourniquet.
- Following application of the dressing, splint, or cast (if required), immediately remove the tourniquet and underlying padding to avoid venous congestion.

FOREARM AND FINGER TOURNIQUETS

Forearm tourniquets are safe, effective, and well tolerated for surgery in the distal forearm, wrist, and hand (11). The optimal tourniquet pressure for this technique is 75 to 100 mm Hg above the patient’s systolic pressure (11).

- Wrap several layers of Webril-type soft cast padding circumferentially around the proximal forearm and apply a pneumatic tourniquet approximately 5 cm below the medial epicondyke.
- Protect with a vinyl drape (as described under upper arm tourniquet) to keep the Webril dry.
- Exsanguinate with an Esmarch bandage before tourniquet inflation.

A relatively minor procedure on the digit can be performed using a digital tourniquet.

- Apply an encircling rubber tourniquet (Penrose drain 1.25 mm, or ½ inch, in diameter) at the base of the digit.
- Wrap the drain once around the base of the digit without tension, then mark and clamp with a hemostat the points at which the surfaces meet on the circumference.
- Remove the loop. Shorten the distance between the two marks by 20 mm.
- Reposition the Penrose drain around the base of the digit.
- As the assistant elevates and compresses the finger, stretch the drain around the finger so that the length is shortened by 20 mm. Then clamp the drain with the hemostat.

The pressure thus generated produces a bloodless field; the risk of digital nerve and arterial damage secondary to this pressure is minimal.

As an alternative, Salem described a method of simultaneous exsanguination of the finger and application of a digital tourniquet (21).

- Cut a finger from a sterile rubber glove and roll it onto the finger.
- Cut the tip from it and roll the remaining portion proximally to form a rubber ring at the base of the finger.

This technique is contraindicated in the presence of infection or tumors. There is no good way to standardize or measure pressure beneath a digital tourniquet, and there have been cases of ischemia from the surgeon forgetting to remove the digital tourniquet before applying the dressing. For these reasons, an arm or forearm tourniquet is preferable.

ANESTHESIA

The choice of anesthesia for each procedure, other than a local block, is made by the anesthesiologist (17, 23). Discuss with the anesthesiologist the patient's concerns and wishes, the estimated length of the operation, and the length of time the tourniquet will be in place. For most children, for apprehensive adults, and for extensive procedures and patients requiring surgery elsewhere on the body, general anesthesia is usually preferable. A general anesthetic may also be necessary because infection or neoplasm may contraindicate regional anesthesia.

Regional anesthesia in the form of supraclavicular, axillary, brachial, and peripheral nerve blocks is very satisfactory for many procedures involving the upper extremity. Preoperative and, if necessary, intraoperative sedation may be used to keep the patient from moving and to lessen discomfort from the tourniquet.

Intravenous anesthesia using 1% lidocaine solution and two tourniquets on the arm, when administered by a competent anesthesiologist, is satisfactory for many surgical procedures on the hand that take no longer than 1 ½ hours. The three main problems with this technique are tourniquet pain, oozing at the surgery site, and risk of systemic anesthetic toxicity from cuff failure. Re-exsanguination 15 to 20 minutes after injection of the local anesthetic by firm reaplication of a sterile Esmarch bandage, followed by complete release and immediate reinflation of the double cuff tourniquet provides a better surgical field with improved tourniquet tolerance (18).

With proper preoperative sedation and, if necessary, intravenous sedation, an arm tourniquet is generally well tolerated for half an hour or longer. Many procedures can be performed simply with local anesthesia or a digital block. Some clinical anesthesia is produced almost immediately with a 1% solution of plain lidocaine hydrochloride, but the full effect takes 3 to 7 minutes and lasts about an hour (20). Avoid local anesthetics with epinephrine for procedures on the hand. Injection in or close to an artery can result in ischemic necrosis of digits.

DIGITAL NERVE BLOCK

- Keep the position of the neurovascular bundles in mind.
- Insert a 26-gauge needle dorsally between the metacarpal heads and just proximal to the finger web space.
- Make a small skin wheal and advance the needle to the palmar aspect of the web space.
- Aspirate to make sure that you are not in the digital artery or vein. Then inject 2 to 3 ml of 1% lidocaine.
- Rotate the needle 90° and advance it subcutaneously to the opposite side of the finger and repeat the injection of 2 to 3 ml lidocaine into the other web space.

When active movement of the patient’s fingers is desirable during surgery, a block of the superficial branch of the radial nerve above the styloid process of the radius, as well as of the ulnar and median nerves on the palmar aspect of the wrist, is indicated.

WRIST BLOCK

- Block the median nerve between the palmaris longus and flexor carpi radialis tendon. In this interval at the proximal wrist crease, insert a 22-gauge needle directed 45° distally and 45° dorsally toward the floor of the carpal tunnel. If paresthesias are elicited, withdraw slightly and redirect the needle. Inject 5 ml of 1% lidocaine.

INSTRUMENTS

The hand surgeon requires special instruments that are often more delicate than those required for most other surgical procedures. Small knife blades, such as Bard-Parker #15 and #11; small Adson forceps; pointed, curved, and straight scissors; osteotomes and chisels; rongeurs and small bone cutters; probes; hemostats; curets; gouges; tendon strippers; sharp hook and blade retractors; needles; sutures; and ligatures are indispensable for hand surgery. Other special instruments, various hand holders (including those made of malleable lead), hand and motorized drills, special sutures, and small needles should be available in the operating suite before starting a procedure.

MAGNIFICATION

Many hand surgeons routinely use 2.5 × to 4.5 × magnifying glasses or loupes when dissecting. With magnification, the planes between diseased and normal tissue are more clearly apparent. Likewise, the small branches of the digital nerves and arteries are seen and protected easily. Operating loupes have been designed on one of three basic types of magnification systems: simple, compound (galilean), and prismatic. For discussion of the fundamental optical principles and terminology, and a concise description of various loupes available on the market, the reader is referred to Baker and Meals’ article (1).

Those who perform microvascular surgery need a variety of microsurgical instruments, as well as a double-headed or triple-headed binocular microscope with electric foot controls that allows 6 × to 15 × magnification. Learn, practice, and develop the technical skills of operating with microscopic magnification in the microsurgery laboratory; only after gaining this experience can the skill be applied to patients.

GLOVES, SKIN PREPARATION, AND DRAPPING

Although vaccination against hepatitis B virus is now available, there is no vaccination against either the hepatitis C virus or the human immunodeficiency virus (HIV). Take care to avoid injury to the surgical team by needle sticks (27). Although the incidence of glove puncture varies with the type of surgery, it is suggested that, on average, 5.6 injuries occur per 100 procedures (3). Double surgical gloves significantly protect the surgeon against needle perforations, but they impair comfort, sensitivity, and dexterity (instrument and tissue handling) during operations (28). Each surgeon must individually deliberate whether the price of perceived impairment of sensation and dexterity is worth the benefit of extra protection against injury.

Each hand surgeon and operating facility should establish a standardized routine for preparation of the skin and draping, thereby ensuring that each patient receives the same careful attention to detail that is necessary for successful hand surgery. If the surgical procedure is an elective one, caution the patient at the time of scheduling to avoid scratches and abrasions to the hand and the entire extremity for 2 weeks before surgery. Advise patients who are manual laborers and who are accustomed to having grease and dirt on their hands to scrub their hands with a detergent solution twice daily for several days before surgery.

Formerly, it was customary to shave the entire extremity, but it has been shown that this is unnecessary and, in fact, may do more harm than good. Shaving should be limited to the site of the proposed incisions and is done in the operating room immediately before final skin preparation. The nails should be cleansed and trimmed, and polish should be removed before the patient enters the operating room.

After the patient and the extremity are properly positioned, scrub the hand and forearm for 10 minutes with a sterile povidone-iodine solution from the tips of the nails to the upper arm, where the pneumatic tourniquet is in position. Then dry the extremity with sterile towels and paint it with povidone-iodine. Povidone-iodine stains the nails and obscures the evaluation of capillary flow in patients whom the vascular status must be assessed intraoperatively (e.g., replants, revascularizations). Consider an alternative scrub solution like chlorhexidine or hexachlorophene, particularly in these situations. Next, apply sterile drapes and stockinette to the hand and forearm. Cover the hand table with a waterproof drape to prevent contamination of the drapes should they become wet during the procedure. Then exsanguinate or elevate the upper arm, where the pneumatic tourniquet is in position. Then dry the extremity with sterile towels and paint it with povidone-iodine. Povidone-iodine stains the nails and obscures the evaluation of capillary flow in patients whom the vascular status must be assessed intraoperatively (e.g., replants, revascularizations). Consider an alternative scrub solution like chlorhexidine or hexachlorophene, particularly in these situations. Next, apply sterile drapes and stockinette to the hand and forearm. Cover the hand table with a waterproof drape to prevent contamination of the drapes should they become wet during the procedure. Then exsanguinate or elevate the extremity and request that the tourniquet be inflated. Take a seat, usually on the axillary side of the patient, and cut the stockinette to expose the hand.

BASIC SURGICAL TECHNIQUE

The basic aim of hand surgery is to restore function and cosmesis to the greatest extent possible within the shortest, safest period of time. In acute injuries, this can often be done by thorough cleansing and debridement of the wound, followed by primary repair of nerve, bone, and tendon injuries. However, in some severe and mutilating injuries, the primary object of treatment is to obtain healing of the skin and subcutaneous tissues and skeletal stabilization without intercurrent wound infection. These injuries often mandate delayed wound closure and a further delay in the repair of tendons and nerves. For each injury or reconstructive procedure, formulate a basic plan, which may consist of one or more stages (12,13).

The time required for the induration of tissues that follows each injury and surgical procedure to subside is variable and must be anticipated. It is best to wait until all inflammatory signs have subsided, the danger of infection is past, the tissues are soft and supple, and the joints are flexible. During this waiting period, proper positioning, encouragement of active motion, and the use of corrective splinting help to prevent permanent stiffness.

Make surgical incisions so that they offer the best possible exposure, protection of important structures, and healing with minimal scar. For some conditions, they should parallel the flexion creases in the fingers, palm, and wrist. Zigzag incisions described by Bruner or the traditional Bunnell incision in a midlateral location are often most appropriate (4,5). On the dorsum, curved and S-shaped incisions are often appropriate for the fingers, metacarpal area, and wrist. Transverse incisions are often used at the level of the wrist. See Table 37.1 and Table 37.2 and the approaches described later in this chapter.

Hospitals and outpatient facilities should maintain a supply of commonly used hand splints in several sizes. Various hand splints, fabricated for different purposes, are advertised in orthopaedic periodicals and can be obtained from surgical supply houses or manufacturers.

Extension gradually, as in changing the position from one of nonfunction to that of function. Rubber bands, spring wire, or flat blue spring steel produce tension that is...adequate for preventing contracture.

Splints should not only maintain the position of function but should also allow function of all uninjured parts. Dynamic splinting is used to draw joints into flexion or extension, and, in some cases, to allow tissues to grow until they adapt to the desired position. Joints are gradually pulled into increased flexion or extension to correct deformities, to place the limb in the position of function, or to produce more motion in a joint. Splints should not only maintain the position of function but should also allow function of all uninjured parts. Dynamic splinting is used to draw joints into flexion or extension, and, in some cases, to allow tissues to grow until they adapt to the desired position. Joints are gradually pulled into increased flexion or extension to correct deformities, to place the limb in the position of function, or to produce more motion in a joint.

In most cases, the dressing and splints should be applied with the forearm in slight supination. This is especially important if the splints or cast extend above the elbow. Sometimes, the forearm should be in a midposition, but rarely should it be immobilized in pronation.

GENERAL CARE

On removal of the drapes and tourniquet, evaluate and record the status of circulation in the exposed fingertips. Keep the hand elevated on pillows that are appreciably higher than the shoulder. Evaluate the neurovascular status at regular intervals if the procedure was extensive enough to warrant hospitalization. If there is any question about adequacy of circulation, loosen the bandages and splints, if a cast has been applied, it should be split and spread along its full length.

When the patient becomes ambulatory, the extremity should be held in an elevated position at shoulder level or above. This position is often easiest to maintain if the splints or cast extend above the elbow.

On discharge from the hospital or outpatient facility, patients and their relatives are instructed to check circulation in the fingertips by the blanch test and to observe for any numbness or tingling that was not previously present. Patients are advised to return immediately should there be any concern about changes in sensibility or the adequacy of circulation.

SPLINTING

The correct use of splints is an important aspect of hand surgery. Splinting is used to prevent deformity, immobilize the operated part, protect joints and tendons, change or correct the position of joints, substitute for paralyzed muscles, and move joints passively.

The wrist is the key joint in the mechanics and function of the hand, whereas the metacarpophalangeal joint is of primary importance in the mechanical balance of a finger. Splinting the wrist in extension and the metacarpophalangeal joints in flexion is of fundamental importance unless specifically contraindicated.

Temporary splinting or immobilization is used before and after many surgical procedures. Splints may be made with plaster of Paris, fiberglass, plastic, or malleable metal. They are usually padded with sheet wadding, cotton, or felt, and are fastened to the extremity with web straps and buckles or Velcro fasteners.

Immobilization is used for treating infection, holding fractured bones in place, and facilitating healing after trauma or surgery. A limb is held in a certain position to protect against separation of newly repaired tissues, such as tendons, nerves, ligaments, and arteries; to keep paralyzed muscles in a relaxed position; and in some cases, to allow tissues to grow until they adapt to the desired position. Joints are gradually pulled into increased flexion or extension to correct deformities, to place the limb in the position of function, or to produce more motion in a joint. Splints should not only maintain the position of function but should also allow function of all uninjured parts. Dynamic splinting is used to draw joints into flexion or extension gradually, as in changing the position from one of nonfunction to that of function. Rubber bands, spring wire, or flat blue spring steel produce tension that is controllable yet insufficient to injure the joints or to cause ischemia.

Internal splinting using K-wires, pins, screws, or plates is used to pin and immobilize fractured bones or joints. Special internal removable sutures can be used to pull the proximal ends of severed tendons distally, thereby eliminating or diminishing tension at the site of repair where individual sutures are used.

Various hand splints, fabricated for different purposes, are advertised in orthopaedic periodicals and can be obtained from surgical supply houses or manufacturers. Hospitals and outpatient facilities should maintain a supply of commonly used hand splints in several sizes.

CONCLUSION

The following article, entitled “Who Should Do Surgery of the Hand?” was published as an editorial in 1961 and is as relevant today as it was then (14). It is reprinted by permission of Surgery, Gynecology & Obstetrics.

Approximately one third of all injuries requiring the services of a physician or a surgeon, whether in the emergency department of a metropolitan hospital or the office of a rural practitioner, involve the hand. The physician administering the primary treatment for such injuries has a great responsibility, since his treatment determines, to a large extent, the final outcome.

All physicians must be taught the basic principles that should govern the treatment of an injury to the hand. They must know that it is important to protect wounds from contamination and infection and that adequate help, facilities, and proper instruments must be available before one starts to care for the injured hand. The traumatized hand must be cleansed thoroughly but gently. When compared with injuries of the arm, leg, or abdomen, the involved tissue of the hand should be sparingly debrided. Whereas many wounds of the arms and legs should be treated by delayed closure, almost all wounds of the hand should be closed primarily and this closure must be without tension. In some instances, the use of skin grafts is necessary to avoid tension. When possible, fractures should be reduced and immobilized at the time of the primary treatment. However, if the physician is not trained to care adequately for the bone injury, less harm will be done if the skin is closed, the hand is placed in a position of moderate dorsiflexion of the wrist, moderate flexion of the fingers, and moderate abduction and opposition of the thumb, and a bulky dressing is applied to prevent edema. In such selected instances, the fractures can be dealt with after the cutaneous wound has healed. Even more important is the necessity to realize that severed nerves and tendons do not require primary repair; less harm will be done under unfavorable conditions by secondary repair of nerves and tendons after the initial wound has healed. A surgeon who attempts primary abruption of a flexor tendon in its digital sheath should have had considerable education, training, and experience in reconstructive surgical treatment of the hand and should be capable of performing a tendon graft.

Extensive, reparative, restorative, reconstructive, and rehabilitative surgery of the hand should be carried out in hospitals by surgeons well qualified and dedicated to this field of surgery. The surgeon interested in treatment of the severely injured hand must be educated to work in orthopedic surgery, plastic surgery, and neurosurgery. He should have knowledge of dermatologic, circulatory, paralytic and arthritic diseases which are prone to affect the hand. He must be well versed in the most minute details of the surgical and functional anatomy of the entire upper extremity. He must be versed in rehabilitative procedures and trained in splinting and bracing. He must be capable of teaching the patient how to prevent and overcome stiffness of joints and how to co-ordinate muscles which formerly had one function but after a tendon transfer have another function.

Above all, the surgeon who devotes much of his time to surgery of the hand must teach medical students, interns, and residents how to care properly for injuries which affect the hand. Many of the principles established by such pioneers as Allen Kanavel, Sterling Bunnell, and Sumner Koch are still basic and pertinent. It is important that these principles be learned if clipping of the hand is to be minimized.

Always think and strive to avoid being in the predicament that results in pondering to yourself “if there were only an operation that could undo the results of my last operation!”

B. SURGICAL APPROACHES TO THE HAND AND WRIST
Michelle Gerwin Carlson

There are several factors that are important to consider when choosing the surgical approach to the hand and wrist. An ideally planned incision will give the maximum exposure of the pathology with the minimum necessary length of incision and risk of injury to the surrounding structures. If possible, the incision should fall within Langer’s lines to produce the most cosmetically pleasing scar and avoid hypertrophy (i.e., a transverse incision rather than a longitudinal one for excision of a dorsal ganglion). Injury to surrounding structures includes not only intraoperative injury but postoperative fibrosis that may limit range of motion. For instance, the dorsal approach to a metacarpal fracture avoids the dissection of the neurovascular bundles and flexor tendons necessary in a palmar approach. The dorsal approach is not only more facile but decreases the chance of postoperative fibrosis of the flexor tendons that may hamper rehabilitation and ultimately decrease range of motion. Cutaneous nerves should always be preserved whenever possible to decrease the risk of neuroma formation and painful scars. Loupe magnification is recommended for visualization of all the small structures of the wrist and hand. Microscope magnification is often necessary for repair of nerves and vessels.

APPROACHES TO THE DIGITS

There are essentially three approaches to the digit: the dorsal approach, the midaxial approach, and the palmar approach. The midaxial approach and the midlateral approach are similar, except that the midaxial incision is dorsal to the midlateral. The midaxial incision is made at the anatomic midpoint of the finger. The midaxial incision is made at the connection of the centers of rotation of the respective joints and is slightly dorsal to the midlateral because the joints are dorsal to the rest of the soft tissues in the digit (flexor tendons). The midaxial incision is more often used because it is right over the bone and, on deep dissection, leaves the neurovascular structures safely in the palmar flap.

DORSAL APPROACH

Indications The dorsal approach is effective for the exposure of the extensor mechanism and bone of the proximal and middle phalanx, proximal interphalangeal (PIP) joint and metacarpophalangeal (MP) joints.

Contraindications The dorsal approach does not allow for visualization of palmar articular fractures of the joints, for which a palmar approach is usually more effective. A transverse or H-type incision may be more appropriate for the exposure of the distal interphalangeal (DIP) joint for excision of a mucous cyst or arthrodesis. A longitudinal incision over the DIP joint may extend into the germinal matrix of the nail bed and cause nail deformity with growth.

Technique (Fig. 37.2)

![Figure 37.2. The dorsal approach to the digit. The dorsal sensory branch of the digital nerve and the dorsal veins have been retracted.](image)

- Make a longitudinal incision over the dorsum of the digit in the midline. Take care with deep dissection to protect the dorsal veins when possible and the dorsal sensory branches of the digital nerves.
- The extensor mechanism is well visualized. For exposure of the proximal phalanx, make an incision between the central slip and lateral band, being careful to preserve the insertion of the central slip on the base of the middle phalanx. If an arthrodesis of the PIP joint is to be performed, the central slip is divided longitudinally and is elevated off the base of the middle phalanx, along with subperiosteal dissection of the proximal and middle phalanx. In the thumb, make the exposure on one side of the extensor pollicis longus tendon. Expose the MP joint with proximal extension of the incision. Incise the dorsal hood 2 mm radial or ulnar to the extensor tendon, leaving a rim of hood attached to the extensor tendon for later repair.

MIDAXIAL APPROACH

Indications The midaxial approach is indicated for exposure of the neurovascular bundle, the proximal, middle or distal phalanx, and the flexor sheath. Because the incision lies in the axis of the finger, it heals very well despite early mobilization and is often barely visible when healed. It provides excellent visualization of phalangeal fractures for placement of internal fixation (either screws or plates) on the radial or ulnar aspect of the bone. In this position, they are less likely to interfere with gliding of the adjacent tendon than in the dorsal or palmar position. The radial or ulnar midaxial incision may be favored based on the fracture anatomy, and this decision should be made preoperatively. Visualization of the neurovascular bundles is excellent through this incision, and it is ideal for isolated digital nerve repair. Visualization of the flexor tendons is sufficient to allow for debridement of tenosynovitis, but flexor tendon repair may be difficult.

Contraindications Visualization of the flexor tendons for repair is limited through this approach and is better accomplished through a palmar approach.

Technique (Fig. 37.3)

![Figure 37.3. The midaxial approach to the digit. A: The incision is made by connecting the flexion creases of the digits. B: The phalanges, fibrous sheath, and neurovascular bundles are visualized. The extensor hood is retracted or incised proximally, and the dorsal sensory branch is retracted dorsally. C: Axial schematic demonstrating midaxial approach.](image)

- Make a longitudinal incision over the dorsum of the digit in the midline. Take care with deep dissection to protect the dorsal veins when possible and the dorsal sensory branches of the digital nerves.
- The extensor mechanism is well visualized. For exposure of the proximal phalanx, make an incision between the central slip and lateral band, being careful to preserve the insertion of the central slip on the base of the middle phalanx. If an arthrodesis of the PIP joint is to be performed, the central slip is divided longitudinally and is elevated off the base of the middle phalanx, along with subperiosteal dissection of the proximal and middle phalanx. In the thumb, make the exposure on one side of the extensor pollicis longus tendon. Expose the MP joint with proximal extension of the incision. Incise the dorsal hood 2 mm radial or ulnar to the extensor tendon, leaving a rim of hood attached to the extensor tendon for later repair.

- Flex the digit completely at the MP, PIP, and DIP joints. Mark the dorsal aspect of the flexion creases at these joints. Then extend the digit and connect these marks by a longitudinal line. It can be extended distally along the distal phalanx palmar to the nail. Proximally, it can be extended up dorsally over the MP joint except on the radial aspect of the index and ulnar aspect of the little finger, where it may be extended radially and ulnarily, respectively. Similarly, the incision can be extended palmarly proximal to the MP joint in a zigzag fashion to increase palmar exposure.
Carry the incision down through the deep tissues dorsal to the neurovascular bundles. Divide Cleland's ligaments to expose the neurovascular bundle. With the neurovascular bundle in the palmar flap, the periosteum of the phalanges can be visualized. Palmarly, the flexor tendon sheath can be identified.

Proximal dissection of the proximal phalanx will encounter two structures that limit exposure. The first is the dorsal branch of the digital nerve. This nerve lies dorsal over the middle phalanx but travels palmar to dorsal over the proximal phalanx and needs to be identified and protected. The second is the lateral band. This can be incised longitudinally to allow for excellent exposure of the proximal phalanx. Repair is optional if the contralateral lateral band is intact.

Palmarly, the flexor sheath can be incised between the A2 and A4 pulleys for debridement of the flexor tendons.

**PALMAR APPROACH**

**Indications** The palmar approach is ideal for exposure of the digital flexor tendons for repair, tenosynovectomy, or tumor excision. It is extensile into the hand. It also provides excellent visualization of the neurovascular bundles and is frequently used for the excision of Dupuytren's disease. It is the exposure of choice for a volar plate arthroplasty or the palmar articular fracture (C).

**Contraindications** The palmar approach is not ideal for the repair of phalangeal shaft fractures or the extensor mechanism.

**Technique** ([Fig. 37.4](#))

- Plan a zigzag Brunner incision across the digit, extending from the distal phalanx into the palm. Cross the digital flexion creases at 45° angles to create a flap with a 90° corner. Any portion of this incision can be used.
- Dissect the subcutaneous tissue carefully to expose the flexor sheath and neurovascular bundles by division of Grayson's ligaments.
- Now incise the flexor sheath by creating an L with a radially or ulnarly based flap to allow access to the flexor tendons. This should be done between, proximal, or distal to the A2 and A4 pulleys. Take care to preserve these pulleys to prevent bowstringing of the flexor tendons postoperatively.
- If access to the PIP joint is desired, create a flap in the sheath over the joint, retract the flexor tendons, and expose the volar plate of the joint. Dissect the flexor plate from the middle phalanx to expose the joint.

**APPROACHES TO THE HAND**

There are two approaches to the hand: dorsal and palmar. The dorsal approach exposes the extensor tendons, metacarpals (MP), and carpometacarpal (CMC) joints, and the intrinsic muscle compartments. The palmar approach exposes the flexor tendons and lumbricals, neurovascular bundles, and Dupuytren's disease.

**DORSAL APPROACH**

**Indications** The dorsal approach exposes the extensor tendons, and the metacarpal, MP, and CMC joints.

**Contraindications** The dorsal approach is contraindicated for exposure of palmar articular fractures of the MP joint. It also does not provide visualization of the neurovascular bundles or flexor tendons.

**Technique** ([Fig. 37.5](#))

- Make a longitudinal incision over the desired metacarpal. Extend it proximally or distally to expose the MP or CMC joint. Perform subcutaneous dissection to avoid injury to the cutaneous nerves, which are branches of the radial or ulnar nerve. The extensor tendons are visualized and may consist of multiple slips and multiple juncturae (C, D, 8, 11, 12, and 13).
- If deeper exposure is desired, make an incision in the investing fascia of the extensor tendons and retract the extensor tendons. Occasionally, it will be necessary to divide the juncturae tendinea to provide exposure of the metacarpal or MP joint. These can be later repaired if desired.
- Subperiosteal dissection of the metacarpal is then possible to complete the exposure. The interosseous muscles are evident on either side of the metacarpal. The second is the lateral band. This can be incised longitudinally to allow for excellent exposure of the proximal phalanx. Repair is optional if the contralateral lateral band is intact.
- Distal extension exposes the MP joint. Divide the extensor hood on either the radial or ulnar side, then incise the capsule to expose the MP joint. Proximal extension exposes the capsule of the CMC joint, which can be incised longitudinally and elevated subperiosteally.

**PALMAR APPROACH**

**Indications** The palmar approach to the hand is used for visualization of flexor tendons, neurovascular bundles, lumbricals, or Dupuytren's disease. It is also recommended for palmar articular fractures of the MP joint.
Contraindications The palmar approach is relatively contraindicated in the internal fixation of fractures of the metacarpals because it is more likely to cause adhesions between the flexor tendons and the bone.

Technique (Fig. 37.4)

- Make a zigzag Brunner incision in the palm over the desired area of exposure, usually over the flexor tendon. This can be extended to a Brunner incision of the digit and across the carpal tunnel.
- Incise the palmar fascia longitudinally. Careful dissection reveals the flexor tendon and common digital arteries and nerves on either side.
- The A1 pulley is visualized over the MP joint, and a palmar pulley can be identified proximally. The arteries can be traced proximally to the superficial palmar arch.
- Accomplish visualization of the MP joint with incision of the A1 pulley and detachment of the volar plate from the base of the proximal phalanx.
- In the thumb, care must be taken when dissecting over the flexor tendon because the radial neurovascular bundle originates ulnar to the flexor tendon and crosses to its radial side at the metacarpal level.
- For surgical release of trigger fingers, center a single longitudinal incision over the A1 pulley for the index through little fingers. A transverse incision for the thumb may be used. Alternatively, the incision can be placed in the distal palmar crease transversely for the little, ring and long finger, and the proximal palmar crease for the index finger. If the longitudinal incision is used, do not cross any palmar creases or a scar contracture can form.

Figure 37.6. Planned incision for release of trigger fingers (A1 pulleys).

APPROACHES TO THE WRIST

DORSAL APPROACH

The dorsal approach to the wrist is an extensile longitudinal incision with a few exceptions. It can be extended proximally to include the distal radius and ulna, and it can be extended distally into the hand as already described. Depending on the exposure desired, make the incision in the midline or displaced slightly radially or ulnarly. In certain situations, such as the approach to the scapholunate joint, the approach to the scaphoid, or for a proximal row carpectomy, a transverse incision may be used for a more cosmetic result.

Approach to the Distal Radius and Extensor Tendons

Tendons

Indications This approach is indicated to expose the distal radius for internal fixation of fractures or wrist fusion, or to expose the extensor tendons for tenosynovectomy.

Contraindications The dorsal approach to the distal radius is not effective in exposing the palmar aspect of the radius for fractures with palmar displacement or palmar articular fractures.

Technique (Fig. 37.7)

Figure 37.7. The dorsal approach to the distal radius and extensor tendons. A: The incision is usually placed in the midline. B: Exposure of the extensor tendons. Axial schematic demonstrating incision of the dorsal retinaculum over the second dorsal compartment with radial and ulnar dissection of the extensor retinaculum. C: Exposure of the distal radius. Axial schematic demonstrating incision of the dorsal retinaculum over the third dorsal compartment with subperiosteal radial and ulnar dissection of the extensor tendons.

- Make a longitudinal incision over the digital extensor tendons. It may be midline or displaced slightly radially or ulnarly, depending on the location of the pathology.
- Use blunt dissection through the subcutaneous tissue to prevent injury to cutaneous nerves and the dorsal veins, when possible. Expose the extensor retinaculum and make deep skin flaps just superficial to the retinaculum if an extensor tenosynovectomy is planned. For the approach to the distal radius, skin flaps are not necessary.

Exposure of the Extensor Tendons

- Incise the dorsal retinaculum longitudinally over the index or fifth dorsal compartment. Then dissect radially and ulnarly cutting the intercompartmental septa to expose all six dorsal compartments as desired. Do not dissect the compartments superiosteally and avoid damage to the adjacent extensor tendons. This procedure can be aided by placing a small elevator in the next compartment to be exposed. This method easily identifies the intercompartmental septum for division.
- The retinaculum is particularly difficult to dissect between the second and third compartment. Here, subperiosteal dissection is necessary on Lister's tubercle to maintain continuity of the retinaculum. This approach is easily extensible into the hand and up the forearm.
- Often in closing the retinaculum after tenosynovectomy, it is split transversely, with half placed below the tendons and half above. Repair of the dorsal retinaculum is necessary to prevent bowstringing of the tendons.

Exposure of the Distal Radius
Approach to the Distal Radioulnar Joint

- To include the distal radioulnar joint, continue ulnar dissection using the above-mentioned technique. If only the distal radioulnar joint needs to be approached, then a smaller skin incision can be made directly over the fifth dorsal compartment.
- Incise the extensor retinaculum over the fifth dorsal compartment and retract the extensor digitorum quinti tendon radially. The capsule of the distal radioulnar joint is immediately beneath this compartment and can be incised longitudinally. A synovectomy of the joint can then be performed, the distal ulna excised, or the triangular fibrocartilage complex (TFCC) repaired.
- After synovectomy or TFCC repair, repair the dorsal capsule primarily. After distal ulnar excision, reattach the dorsal capsule of the distal radioulnar joint to the palmar capsule over the end of the distal ulna with several nonabsorbable sutures to prevent subluxation of the distal ulna. Repair the extensor retinaculum with nonabsorbable sutures and close the skin as usual.

Approach to the Radiocarpal Joint

Indications The approach to the radiocarpal joint can be an extension of the previously described approach to the distal radius, with the dissection continued distally to dissect the carpal bones subperiosteally. This approach is useful for radiocarpal fusions. When a limited exposure of the wrist is known to be needed preoperatively, a transverse incision may be used with a more cosmetically appealing result. Often the scar, when healed, is barely visible within Langer's lines. If a later radiocarpal fusion is necessary, a longitudinal incision can be made at a right angle to this incision without complication. It is possible to expose the terminal branch of the posterior interosseous nerve through this transverse incision, if desired. Carry out the dissection proximally with incision of the third dorsal compartment under the proximal skin flap. The terminal branch of the posterior interosseous nerve is then evident between the third and fourth compartments and can be excised.

Contraindications A transverse incision is not extensile and should be avoided when exposure of the hand or distal radius is desired.

Technique Make a transverse incision over the proximal row approximately 1.5 cm distal to Lister's tubercle. The length of the incision is dependent on the pathology to be explored. (*Fig. 37.8*).

![Figure 37.8](image_url)

**Figure 37.8.** The dorsal approach to the radiocarpal joint. A transverse incision is made over the radiocarpal joint distal to Lister's tubercle. After longitudinal incision of the extensor retinaculum and T-incision of the dorsal capsule, the radiocarpal joint is exposed.

Proximal Row Carpectomy The incision will need to be over the entire carpus, approximately 3 to 4 cm in length.

- Carry the incision down through the subcutaneous tissue, taking care to identify and protect the cutaneous branches of the radial and ulnar nerves.
- Incise transversely the capsule overlying the proximal row. Make a T over the lunate. Then expose the scaphoid, lunate, and triquetrum subperiosteally.
- After removal of the carpus, repair the capsule with nonabsorbable suture and close the skin.

Scaphoid and Scapholunate Joint

- Make a dorsal transverse incision 2 to 3 cm in length centered over the scaphoid or scapholunate joint, respectively. The scapholunate joint can be palpated 1 to 1.5 cm directly distal to Lister's tubercle.
- After the cutaneous nerves are dissected free, incise the capsule over the scapholunate joint, and dissect radially and ulnarly along the radiocarpal joint as necessary. Take care to avoid damage to the dorsal vessels entering the wrist of the scaphoid.
- After repair of the scapholunate ligament or fixation of the scaphoid fracture, repair the capsule with nonabsorbable suture and close the wound with a subcuticular suture.

PALMAR APPROACH

The palmar approach to the wrist provides excellent visualization of the distal radius, carpal tunnel, digital flexor tendons, palmar aspect of the carpus, median and ulnar nerve, and the radial and ulnar arteries. One of two incisions can be used. The more radial incision centered over the flexor carpi radialis exposes the distal radius, radial artery, and scaphoid. The more midline incision exposes the carpal tunnel, median and ulnar nerve, ulnar artery, digital flexor tendons, carpus and distal radius, ulna, and palmar distal radioulnar joint. For the isolated exposure of the distal radius, the radial incision is preferred because it does not involve dissection around the digital flexor tendons and thereby decreases the chance of postoperative adhesions.

Approach to the Distal Radius and Scaphoid

Indications The palmar radial approach to the distal radius and scaphoid is indicated when the only structures that are necessary to be exposed are the distal radius, scaphoid, and radial artery. It has the advantage of not dissecting around the flexor tendons, therefore minimizing postoperative adhesions. It can be extended to include exposure of the scaphotrapezial joint distally and the palmar radius proximally.

Contraindications The carpal tunnel is not visualized through this incision but can be visualized through a separate incision. The flexor tendons, median and ulnar nerves, and ulnar artery, as well as the remainder of the carpus, are not visualized either and are better exposed through the midline palmar approach.

Technique

- Make a longitudinal incision over the flexor carpi radialis tendon, extending proximally as far as necessary (*Fig. 37.9*). Distally, end the incision at the proximal palmar wrist flexion crease if only the radius is to be exposed. If exposure of the scaphoid is necessary, the incision begins 2 cm proximal to and then extends just past the distal wrist flexion crease to the scaphoid tubercle. This approach is known as the Russo approach to the scaphoid. Carry the incision down through subcutaneous tissue in line with the flexor carpi radialis. It is important not to deviate ulnar to the flexor carpi radialis because injury to the palmar cutaneous branch of the median nerve can occur. [6].
Incise the sheath overlying the flexor carpi radialis and retract the flexor carpi radialis ulnarily.

Expose the radial artery along the radial border of the sheath and protect it.

Incise the sheath deep to the flexor carpi radialis and retract the flexor tendons ulnarily. Identify the pronator quadratus on the palmar radius and incise it longitudinally on its radial aspect, leaving a small portion radially for reattachment.

Then subperiosteally expose the radius ulnarily to the distal radioulnar joint.

If exposure of the scaphoid is desired, incise the palmar capsule longitudinally to the scaphoid tubercle and expose the scaphoid.

Close with repair of the palmar capsule and reattachment of the pronator, if possible. Then repair the skin with interrupted or running subcuticular sutures as desired.

**Approach to the Carpal Tunnel and Guyon's Canal**

**Indications** This approach is indicated for exposure of the median nerve in the carpal tunnel and ulnar nerve in Guyon's canal. Limited visualization of the flexor tendons and palmar aspect of the carpus is afforded (4,10).

**Contraindications** Exposure of the distal radius, and flexor tendons for rheumatoid flexor tenosynovectomy for rheumatoid arthritis requires proximal extension of this incision.

**Technique (Fig. 37.10)**

![Figure 37.10. Palmar approach to the carpal tunnel and Guyon's canal. A: The skin incision is made in line with the radial aspect of the fourth finger. Care should be taken not to stray radial to this line because injury of the palmar cutaneous branch of the median nerve may result. B: The palmar fascia fibers are noted to run longitudinally and are transected. After transection of the transverse carpal ligament, the median nerve and flexor tendons are identified within the wound and can be retracted for exposure of the palmar carpus. C: The location of Guyon's canal, which can be identified in the ulnar aspect of the wound.](image)

- Make a longitudinal incision in the palm in line with the radial border of the ring finger. The distal extent of the incision intersects Kaplan's cardinal line (a line determined by abducting the thumb and drawing a horizontal line from the first web space parallel to the proximal transverse palmar crease). The proximal extent of the incision is the distal wrist flexion crease. Then incise sharply down through the subcutaneous tissue because the palmar cutaneous nerve is out of potential harm.
- Incise the palmar fascia longitudinally, and identify the ulnar nerve and artery beneath the palmar fascia in the ulnar aspect of the wound. Remember that the ulnar artery can be palmar to the palmaris brevis, and other anomalies have been reported as well (5,9). The ulnar artery and sensory branch of the ulnar nerve continue distally and may cross radial to the hook of the hamate (3).
- Then incise the transverse carpal ligament longitudinally, ensuring that the proximal aspect of the ligament is transected. Often, a tenotomy scissors is necessary to complete the proximal release. For further details, see Chapter 52 on compression neuropathies.

**Approach to the Digital Flexor Tendons, Radiocarpal Joint, and Distal Radius**

**Indications** This exposure provides the best access to the flexor tendons, median and ulnar nerves, and radiocarpal joint. The distal radius can also be exposed through this incision.

**Contraindications** If the distal radius alone is to be exposed, it is better to approach it through the radial palmar incision. This midline approach has an increased incidence of flexor tendon adherence owing to the dissection necessary around the tendons.

**Technique (Fig. 37.11)**

![Figure 37.11. Palmar approach to the digital flexor tendons, radiocarpal joint, and distal radius. Extension radial to the palmaris may produce injury to the palmar cutaneous branch of the median nerve. Deep dissection allows visualization of the digital flexor tendons, which may be retracted radially to expose the palmar distal radius and pronator. Subperiosteal dissection of the pronator exposes the distal radius. The radiocarpal joint is exposed through a longitudinal or T-incision.](image)
• The incision is a proximal extension of the incision made for exposure of the carpal tunnel. Cross the wrist flexion creases at 45° angles. Proximal to the proximal wrist flexion crease, the incision can be a straight line, ulnar to the palmaris tendon.
• Divide the antebrachial fascia, identify the median nerve and flexor tendons, and the ulnar nerve in the ulnar aspect of the wound.
• Retract the flexor tendons and the distal radioulnar joint. To expose the distal radius, incise the pronator along its radial margin, leaving a small cuff of tissue to which to repair it. Expose the radius subperiosteally. The distal radioulnar joint can be visualized by longitudinal incision into the palmar capsule. Take care distally not to incise the triangular fibrocartilage complex (TFCC).
• Close the wound with repair of the pronator and the capsule. Close the skin with interrupted or subcuticular sutures.

**Radial Approach to the Scaphoid**

**Indications** The radial approach to the scaphoid provides excellent visualization of the proximal pole, waist, and distal pole of the scaphoid. It useful in procedures in which a dorsal extensile exposure of the scaphoid is desired, such as for vascularized bone grafting of the scaphoid, and provides excellent exposure of the radial styloid for radial styloidectomy.

**Contraindications** If the palmar aspect of the radius or flexor tendons need to be exposed, then the palmar approach to the scaphoid provides better visualization of the palmar wrist structures.

**Technique** ([Fig. 37.12](#))

![Image](image1.png)

Figure 37.12. The radial approach to the scaphoid. **A:** The curvilinear incision is made over the anatomic snuffbox, between the extensor pollicis longus and extensor pollicis brevis. **B:** A longitudinal incision is made in the radiocarpal joint capsule, and the radial artery is retracted distally. The scaphoid is visualized.

- Make a curvilinear incision over the anatomic snuffbox. Extend it proximally over the dorsal or radial aspect of the wrist as needed. Then proceed between the extensor pollicis longus dorsally and the extensor pollicis brevis palmarly. These tendons are easily identified because traction on the extensor pollicis longus produces extension of the thumb IP joint and traction on the extensor pollicis brevis produces extension and abduction of the thumb ray without extension of the IP joint.
- Take care to avoid injury to the superficial branches of the radial nerve, which may be multiple (1).
- Retraction of the tendons allows visualization of the radial artery and its dorsal branches, which must be preserved to maintain the vascularity of the scaphoid.
- Incise the joint capsule longitudinally and expose the scaphoid with distal and palmar retraction of the radial artery. It is important when exposing the scaphoid not to disrupt the dorsal blood supply to the bone by stripping the vessels that enter the scaphoid through the dorsal waist.

**Ulnar Approach to the Distal Ulna**

**Indications** The ulnar approach to the distal ulna is useful for distal ulnar excision or internal fixation, exposure of the extensor carpi ulnaris tendon, or open visualization of the TFCC.

**Contraindications** This exposure does not provide visualization of the distal radius, or the extensor or flexor tendons.

**Technique** ([Fig. 37.13](#))

![Image](image2.png)

Figure 37.13. The ulnar approach to the distal ulna. **A:** The longitudinal incision is made along the palmar aspect of the extensor carpi ulnaris tendon. **B:** The sheath over the extensor carpi ulnaris tendon is incised, and the extensor carpi ulnaris is retracted dorsally. Care must be taken to avoid injury to the dorsal sensory branch of the ulnar nerve, which travels from palmar to dorsal in this region. Subperiosteal dissection may be performed on the distal ulna and the ulnocarpal joint may be incised longitudinally to expose the TFCC.

- Make a longitudinal straight incision over the ulnar aspect of the distal ulna, just palmar to the extensor carpi ulnaris tendon. Center it over the ulnar head and extend it distally across the ulnocarpal joint and proximally as far as necessary.
- Perform deep dissection in a blunt fashion because the dorsal sensory branch of the ulnar nerve runs from palmar to dorsal across the distal ulna in this region.
- Incise the retinaculum over the extensor carpi ulnaris tendon longitudinally and retract the tendon dorsally.
- Incise the ulnocarpal joint capsule longitudinally along its ulnar aspect to visualize the TFCC. Start the incision distally and do not cut into the TFCC. Proximally, the distal radioulnar joint capsule and ulnar periosteum may similarly be elevated off the distal ulna to allow its exposure.
- Closure of the wound may include repair of the distal radioulnar joint capsule and the retinaculum over the extensor carpi ulnaris tendon if it is noted to sublux palmarly.

FINGERTIP INJURIES

Fingertip injuries are defined as those injuries occurring distal to the insertion of the flexor and extensor tendons. They are the most common injuries of the hand and can lead to a significant functional and cosmetic deficit if they are not treated appropriately. The fingertip is the end organ for touch and is richly supplied with special sensory receptors that enable the hand to relay the shape, temperature, and texture of an object. The glabrous skin of the fingertip is specially adapted for pinch and grasp functions. Its volar surface consists of a fatty pulp covered by highly innervated skin. The skin of the fingertip is firmly anchored to the underlying terminal phalanx by multiple fibrous septa that traverse the fatty pulp.

After a fingertip injury, restoration of sensibility, stable skin coverage, and adequate padding are the goals of reconstruction. There are many treatment options, which range from allowing the wound to heal by secondary intention to flap coverage or revision amputation. No single procedure can be recommended, but each case must be individualized depending on the needs of the patient and the type of injury. Patient-related factors that should be considered include age, occupation, avocation, and general health. Injury-related factors include associated nail bed injuries, angle of injury, bone exposure, digit injured, and concomitant injuries.

This section reviews the common procedures performed for this injury. It discusses the indications, advantages, and disadvantages of each procedure, along with a treatment algorithm.

CLASSIFICATION OF FINGERTIP INJURIES

Allen has classified fingertip injuries into four types based on the level of injury. Type 1 injuries involve only the pulp, and type 2 injuries involve the pulp and nail bed. Type 3 injuries include partial loss of the distal phalanx, whereas type 4 injuries are proximal to the lunula. This classification is useful because it allows the surgeon to help organize treatment options. For example, type 1 injuries may heal quite well by secondary intention. In contrast, types 3 and 4 often require some type of flap coverage. Injuries must also be thought of in terms of whether bone is exposed and the angulation of injury. There are three general terms used to describe the angulation of injury—dorsal oblique, transverse, and volar oblique. In general, dorsal oblique and transverse injuries are more suited to local flaps. Volar oblique flaps often require a regional flap. By considering all of these factors for each patient, a rational treatment plan can be initiated.

Figure 38.1. The classification of injuries is illustrated.

Figure 38.2. The angles of injury are shown.
HEALING BY SECONDARY INTENTION

The simplest treatment of fingertip injuries is to allow the wound to heal by secondary intention. This method relies on reepithelialization and contracture to provide wound closure. It is reserved for small defects (6 to 8 mm) without exposed bone and with minimal loss of pulp tissue. In young children this method provides good results even if bone is exposed:

- Begin treatment with a thorough debridement of the wound, which can be performed under local anesthesia in the emergency room.
- Perform local wound care two to three times daily with dressing changes. Healing is usually completed by 3 to 6 weeks depending on the size of the defect.

Chow and Ho reported good results in their series of patients treated in this manner (7). They noted that very few patients had pain or limited range of motion at 6 months from injury, although there was a 27% incidence of nail deformity. Other complications of this treatment method include delayed healing, pyogenic granuloma, cold intolerance, and stump tenderness. One should realize that the missing tissue is replaced by scar. Owing to the deficient tissue, the tip can become quite sensitive and therefore patients who use their fingertips repetitively during work are poor candidates for this technique.

COMPOSITE GRAFTS

If the amputated part is clean and the tissue is of adequate integrity, use the part for soft-tissue coverage. If there is no exposed bone, defat the skin and suture it into the defect. The defatting is extremely important, because this piece will now act as a free skin graft. Minimize its thickness to enhance its chances of "taking." This skin, however, may necrose and then would serve as a biologic dressing. The chance of success with this treatment is greater when used in children.

In children younger than 3 years old, we consider reattaching the amputated part as a composite graft (29). This is because children of this age have the extraordinary ability to heal these injuries. Elsash reattached amputated fingertips without a microvascular anastomosis in 35 patients; subsequent survival was correlated with the level of injury (11). Tip amputations without nail bed involvement (Allen Type 1) survived in four of five patients. In contrast, only 2 of 10 amputations proximal to the lunula (Allen Type 4) survived. The major complication of this procedure is the necrosis of the composite graft. If the finger is amputated 2 mm proximal to the lunula, then replantation can be considered. Microvascular anastomosis is difficult at this level. This procedure can give better cosmetic and functional results when compared with terminalization and revision amputation.

REVISION AMPUTATION

A simpler course of action involves shortening of the digit or revision amputation. This procedure is indicated in situations in which minimal bone is exposed and the angle of the injury is such that other options are not appropriate. Take care to limit loss of length, particularly in treating the thumb. This procedure can be performed under local anesthesia in the emergency room if minimal bone shortening is required. Develop the flaps to cover the tip of the digit, preferably with volar skin. Use the volar skin rather than the dorsal skin to provide a more padded and durable soft tissue cover for the fingertip. Patients can return to their activities as tolerated when the soft tissues have healed.

SKIN GRAFTS

Skin grafts can be used in injuries where there is skin loss but adequate subcutaneous tissue is present with no exposed bone. The lack of exposed bone is paramount, because skin grafts will not "take" on bone. Use this technique for injuries with skin loss of greater than 1 cm. In cases of smaller skin defects, allow the wound to heal by secondary intention, as previously described. Skin grafts can be divided into split thickness or full thickness. Full-thickness grafts provide better sensibility and durability, as well as a better cosmetic result. On the other hand, split-thickness skin grafts have a greater likelihood of "taking." Idler and Strickland recommend split-thickness grafts because of their ability to contract and draw in normal tissue with a greatly reduced size of the defect (19). Take split-thickness skin grafts of 0.012 to 0.015 inches thick. Harvest smaller split thickness grafts free hand from the glabrous skin of the hypothenar eminence. Take larger grafts from the thigh or buttocks. Harvest full-thickness skin grafts locally from the palmar wrist crease or from the hypothenar area (Fig. 38.3A, Fig. 38.3B). The palmar wrist crease provides an area of approximately 2 × 6 cm, whereas the hypothenar skin provides an area of 2 to 2.5 cm in width by 6 to 8 cm in length. Harvest larger amounts of full-thickness skin grafts from distant sites such as the hairless area of the groin. The donor site in a full-thickness graft is typically closed primarily. Excellent hemostasis of the injury site must be obtained to avoid the postoperative complication of hematoma formation. Secure the graft with a bolus stent type of dressing that is left undisturbed for 5 to 7 days. Start therapy after the dressing is removed.

Skin grafts can be used in injuries where there is skin loss but adequate subcutaneous tissue is present with no exposed bone. The lack of exposed bone is paramount, because skin grafts will not "take" on bone. Use this technique for injuries with skin loss of greater than 1 cm. In cases of smaller skin defects, allow the wound to heal by secondary intention, as previously described. Skin grafts can be divided into split thickness or full thickness. Full-thickness grafts provide better sensibility and durability, as well as a better cosmetic result. On the other hand, split-thickness skin grafts have a greater likelihood of "taking." Idler and Strickland recommend split-thickness grafts because of their ability to contract and draw in normal tissue with a greatly reduced size of the defect (19). Take split-thickness skin grafts of 0.012 to 0.015 inches thick. Harvest smaller split thickness grafts free hand from the glabrous skin of the hypothenar eminence. Take larger grafts from the thigh or buttocks. Harvest full-thickness skin grafts locally from the palmar wrist crease or from the hypothenar area (Fig. 38.3A, Fig. 38.3B). The palmar wrist crease provides an area of approximately 2 × 6 cm, whereas the hypothenar skin provides an area of 2 to 2.5 cm in width by 6 to 8 cm in length. Harvest larger amounts of full-thickness skin grafts from distant sites such as the hairless area of the groin. The donor site in a full-thickness graft is typically closed primarily. Excellent hemostasis of the injury site must be obtained to avoid the postoperative complication of hematoma formation. Secure the graft with a bolus stent type of dressing that is left undisturbed for 5 to 7 days. Start therapy after the dressing is removed.

Complications from this procedure include hematoma, necrosis of the skin graft, and donor site complications.

LOCAL FLAPS

Local flaps use adjacent local skin with its subcutaneous tissue and normal sensory end organs to cover defects. There are two common advancement flaps used for fingertip injuries. Both share similar principles in that a V incision is made adjacent to the defect. Atasoy and colleagues popularized the V-Y advancement flap in which the incision is made palmar, and Kutler described a similar flap in which the incisions are made laterally (2,22). The skin and subcutaneous tissues are advanced forward, and the proximal defect is closed end to end. After closure, the proximal portion of the wound forms the vertical line of the Y. Range of motion therapy is started 7 to 10 days following either local advancement flap as the wound permits. Another local flap is the homodigital triangular flap, which is dissected more proximally and the digital artery is included within the flap. Lanzetta et al. have recently described good results using this technique for volar oblique amputations (23).

V-Y Advancement Flap

The V-Y advancement flap that was popularized by Atasoy et al. is used in fingertip injuries with dorsal angulation (2). It can be used for transverse amputations, although it is more difficult in this setting. The procedure is, however, contraindicated in palmarly angulated injuries.

- Make the incisions with the apex of the V at the midpalmar distal interphalangeal joint and the arms of the V extending to the widest portion of the amputation (Fig. 38.4B).
Figure 38.4. A: A V-Y advancement flap, most useful in patients with a dorsal oblique type of injury, is shown. B: This is the approach for a planned incision. C: An incision to the fibrous septal attachments at the bony phalanx is shown. D: The septae are released; traction is placed distally. E: Tension is released. F,G: The wound is closed.

- Incise the skin, leaving the subcutaneous tissues intact.
- Release the fibrous septa connecting the flap to the underlying bone. This allows maximum mobilization and keeps the flap's blood and nerve supply intact.
- Use gentle traction with skin hooks to advance the flap into the defect.
- Release all tension so that suturing the distal margin of the flap is done without blanching (use small monofilament suture, 6-0 or 7-0). This avoids potential tip necrosis.
- Close the remaining donor defect side to side. This flap provides like tissue with good color and sensory characteristics.

Complications of this procedure include necrosis of the flap, hypesthesias, dysesthesias, impaired sensation, and cold intolerance.

V-Y Kutler Flap

The Kutler V-Y flap is also useful for transverse amputations (13,22,35). The design of this flap is similar to the V-Y advancement flap in that the apex is at the distal interphalangeal (DIP) joint and the base at the amputation site, although in this procedure the flap is placed laterally. The flaps can be elevated on one or both sides of the digit. Care again must be taken to divide the fibrous septa and preserve the neurovascular supply of the flap (Fig. 38.5).

Figure 38.5. Kutler flaps are shown. A: This is the method used for bilateral flaps. B: The incision with traction is illustrated. C,D: The wound is closed.

- Plan bilateral flaps with the apices of the triangles in the midlateral line of the distal interphalangeal flexion crease.
- Make the incisions to the level of the fibrous septal attachments at the bony phalanx, using traction distally with a skin hook to release proximal septa so flaps advance to the midline (Fig. 38.5B).
- Begin tension-free closure with small (6-0 or 7-0) nonabsorbable monofilament suture.
- Complete closure with several interrupted absorbable sutures at the amputated nail bed margin (Fig. 38.5D).

The disadvantage of this flap is the limited advancement and the resultant suture line lies over the pulp. This factor has likely led to the hypersensitivity noted by some patients. The two advancement flaps have similar complications including numbness, cold intolerance, and dysesthesias.

REGIONAL FLAPS

Regional flaps are defined as flaps taken from other parts of the hand that do not use tissue adjacent to the defect. This section discusses the cross-finger and thenar flap, which are considered for injuries not amenable to local flaps. They are well suited for volar oblique type injuries. The cross-finger flap can also be used in treating more proximal soft-tissue injuries of the finger. Owing to the postoperative immobilization required, the procedures are discouraged in patients predisposed to finger stiffness. This includes patients older than 50 years of age, patients with rheumatoid arthritis, and patients with multiple injured digits. These flaps are also not well suited for young children because of lack of compliance and simpler methods are usually adequate.

Cross-Finger Flap

The cross-finger flap is a random pattern flap taken from the dorsum of the adjacent finger to resurface a palmar defect. Do not use this flap in patients with vasospastic disorders including Buerger's disease and Raynaud's phenomenon (6,8,17).

- Create a template for the defect, drawing the pattern on the dorsum of the adjacent digit over the middle phalanx. Base the flap on the lateral aspect of the adjacent finger. The flap may be dissected from the midlateral line of the lateral aspect of the adjacent finger to the midlateral line medially as required to encompass the size of the defect.
- Carry down the dissection through the subcutaneous tissues, taking care not to disturb the paratenon of the extensor mechanism. Leave the paratenon intact to allow skin grafting of the donor site.
- Also leave undisturbed the dorsal veins within the flap.
- Cleland's ligaments, however, may need to be divided to provide full mobility. An innervated flap can be accomplished by including a dorsal cutaneous nerve branch, which is then sutured to the proper digital nerve.
- After the flap is raised, deflate the tourniquet. Obtain hemostasis to prevent hematoma formation.
- Insert the flap and trim appropriately (Fig. 38.6). Suture the flap into the recipient finger defect, using an interrupted half-buried mattress monofilament suture (6-0 or 7-0). Cover the donor site with a full-thickness skin graft that is sutured to the hinged portion of the flap. Secure the skin graft with a bolster dressing and immobilize the digits in a position that places the least tension on the flap. This is usually in the intrinsic plus position. Kirschner wires are rarely needed to maintain this position.
Figure 38.6. A dorsal cross-finger flap is shown. A: This is the method for a planned incision. B: A full-thickness skin graft is sutured and secured. C: The flap is sutured. D: The palmar view of the repair is shown. E: A cross section of the donor finger is shown.

- Divide the flap and inset at 10 to 14 days postoperatively. Begin therapy soon after flap division. Be careful not to divide the flap too close to the recipient side in order to allow the flap to be inset more easily. This is a reliable flap, but there is usually a color mismatch at both the donor and recipient sites. One can expect protective sensation postoperatively, with two-point discrimination often twice normal.

Reverse Cross-Finger Flap

The reverse cross-finger flap is more commonly used for dorsal finger defects.

- Design the flap with its base at the midaxial line of the middle phalanx of the donor finger.
- Elevate the skin of the donor finger as a full-thickness skin graft and separate from the subcutaneous tissues. The base of this skin is opposite to the defect.
- Elevate the subcutaneous tissue on the dorsum of the donor finger as a flap, with its base hinged adjacent to the defect, leaving the paratenon again intact.
- Inset this flap into the defect and sew the skin back over the donor site. Then create a skin graft for the flap of subcutaneous tissue that has been transferred to the recipient finger defect.
- Apply a bolus stent-type dressing.
- Place the skin graft over the transferred subcutaneous tissue (Fig. 38.7).

Figure 38.7. A reverse cross-finger flap is shown. See the text for details. A: Design of the skin flap. B: Elevate the subcutaneous flap. C: Donor skin is sutured. D: The subcutaneous flap is sutured, and the skin is grafted.

To illustrate the use of a cross-finger or reverse cross-finger flap, a defect located on the palmar aspect of the long finger could be treated with a standard cross-finger flap. The donor finger would be the ring finger, and the flap would be hinged radially. The donor site would then be skin grafted. If the defect of the long finger was dorsal, a reverse cross-finger flap would be performed. The donor finger, however, would be the index finger and the flap would be hinged ulnarily. In this procedure, the recipient finger requires skin grafting.

Thenar Flap

The thenar flap has similar indications and contraindications as the cross-finger flap. The procedures are best suited for volar fingertip defects.

- Elevate this random pattern flap from the thenar eminence and hold the involved finger in flexion for insetting of the flap. Placing the flap ulnarily on the thenar eminence has been associated with scar tenderness. Base the flap proximally, distally, or radially dependent on the defect (Fig. 38.8A). The distal border should be parallel and adjacent to the metacarpophalangeal (MP) joint crease. The flap should be 1.5 times the width of the defect. This allows the soft tissue of the finger to assume a more rounded and normal appearance.

Figure 38.8. A thenar flap is shown.

- Once the flap is outlined, dissect the skin and subcutaneous tissues off the thenar musculature.
- Take care not to injure the radial digital nerve or recurrent branch of the median nerve.
- Close the flap donor site primarily in a linear fashion with interrupted monofilament sutures, or cover with a full-thickness skin graft (Fig. 38.8B, Fig. 38.8C). Smith and Albin described an H-type thenar flap (40). In this procedure, fill the donor defect by advancing the remaining half of the H (Fig. 38.9). Approximate the raised flap to the amputation site by palmarly abducting the thumb and flexing the MP joint and the distal interphalangeal joint of the recipient finger. This minimizes the amount of proximal interphalangeal (PIP) flexion required for immobilization to less than 40° to 50° and decreases the risk of a PIP flexion contracture.

Figure 38.9. A: A modification of the technique described by Smith and Albin is to incise two flaps in an H shape with small Burow's triangles cut at the base of the distal flap. B: The proximal flap is turned in a standard fashion to cover the fingertip, while the distal flap is advanced proximally to close the donor defect at one operation. (From Calkins ER, Smith DJ. The Cross Finger Flap. In: Blair WP. Techniques in Hand Surgery. Baltimore: Williams and Wilkins, 1996:58.

- Divide the flap at 10 to 14 days postoperatively. The base of the pedicle on the thenar eminence may be trimmed of excessive tissue, but usually neither the donor site nor the recipient finger requires further insetting.
- Start active flexion and extension exercises immediately.

The major criticism of this flap in the past has been a PIP flexion contracture and tenderness at the donor site. Melone et al. analyzed 150 cases and recommended
designing the flap high on the thenar eminence and not on the palmar aspect of the hand (28). In Melone’s series, the average 2-point discrimination was 7 mm. In addition, the donor site was an infrequent source of pain. Only 4% of patients developed a flexion contracture, none of which were believed to be related to the procedure.

**DISTANT FLAP COVERAGE**

Distant flaps are defined as flaps obtained from areas of the body other than the injured limb. These procedures are considered in hand injuries with large soft-tissue defects and provide thick, fatty coverage with little sensibility. The flaps can be developed from the chest, abdomen, groin, or opposite arm.

**THUMB COVERAGE**

The thumb plays a crucial role in prehension and is involved in 50% of the function of the hand. Preservation of length of the thumb is more important functionally than in any other digit. Procedures used for thumb coverage described in this section include the Moberg advancement flap, cross-finger flap, palmar cross-finger flap, and neurovascular island flaps.

**Moberg Advancement Flap**

The Moberg advancement flap involves advancement of the volar skin with its subcutaneous tissues and neurovascular bundles distally into a thumb tip defect (27,30). The unique anatomy of the thumb makes this flap more suitable for the thumb than the other digits. There is a risk of a flexion contracture postoperatively, but the thumb has only one interphalangeal joint, and a flexion deformity of this joint causes little functional deficit. The fingers, however, have two interphalangeal joints, and a flexion contracture of the proximal interphalangeal joint imparts a significant disability. Other differences between the thumb and fingers include their respective blood supplies. A component of the blood supply to the thumb arises from the first dorsal metacarpal artery. The thumb is less dependent on the volar blood supply. In contrast, the fingers rely more on the volar blood supply and, therefore, risk tip necrosis with this flap. The volar advancement flap has many advantages over other local, regional, and distant flaps. It provides immediate restoration of essentially normal sensation with preservation of length. It can be done in a single stage with low donor site morbidity. The pulp contour is restored, and the rehabilitation time is relatively short. In contrast to a neurovascular island flap, no cerebral cortical programming is needed.

- This flap is well suited to the volar oblique amputation of the thumb that is 1 to 1.5 cm in length. The surgical technique involves skin incisions on both the radial and ulnar midaxial lines. Make these incisions dorsal to the neurovascular bundles. Extend the incision proximally to the MP flexion crease or proximal phalanx (Fig. 38.10A). The incision can be extended further proximally to the thenar eminence for larger defects.

- Elevate the flap from the flexor sheath and flex the thumb at the interphalangeal and MP joints to allow coverage of 1 cm defects (Fig. 38.10). Contour the flap when inserting it. The flap may be sutured to the nail. If the skin blanches, more proximal dissection is needed.

- Make a transverse incision at the base of the flap to allow further advancement to cover defects up to 1.5 cm. The resulting defect on the thenar eminence can then be covered with a skin graft.

- Other variations of the procedure to gain length include a V-Y advancement at the base or bilateral Z-plasties along the longitudinal incisions (10). In addition, Dellon has described a modification that can be made up to 3 cm in length by using rotational flaps proximally (9). Results of the Moberg advancement flap have shown excellent return of sensibility within two-point discrimination with 2 mm of the contralateral fingertips.

**Cross-Finger Flap for Thumb Defects**

Cross-finger flaps for thumb injuries can be performed using a number of variations. This includes a standard cross-finger flap, a cross-finger flap including a branch of the superficial radial nerve with or without neurorrhaphy, and a palmar cross-finger flap. In treating thumb injuries, the index finger is used as the donor site for the standard cross finger flap and the long finger is used for the palmar cross-finger flap (3,18,43,44). The importance of a sensate thumb tip has led to the use of innervated flaps. One option is a cross-finger flap that includes a branch of the superficial radial nerve.

- Raise the flap from the dorsal aspect of the proximal phalanx of the index finger. Dissect the superficial radial nerve branches and protect them proximally.

- Make a V-type incision with one limb along the radial midlateral line of the index finger and extending proximally along the second metacarpal.

- Make the other limb of the incision from the ulnar side of the defect of the thumb. Inset the flap and transfer the sensory nerve branches to the thumb incision.

- Use a full-thickness graft to resurface the donor site.

- Detach the flap at 3 weeks.

Walker et al. found that performing a first web space Z-plasty at the time of division can avoid a first web contracture (44). One can modify this procedure by transecting the dorsal radial sensory nerve branch more proximally and performing a neurorrhaphy with the ulnar digital nerve of the thumb. These procedures have the obvious advantage of bringing an innervated pedicle to the thumb. In Walker’s series, all had cortical adaptation, but when carefully asked three of five patients had sensation referred to the dorsal index finger. They found that most patients had good sensation that may have been a combination of median and radial nerve sensation. They also found that the ulnar aspect of the flap had better sensory recovery than the radial aspect.

**Palmar Cross-Finger Flap**

A palmar cross-finger flap has been described for injuries of the distal thumb. The surgical technique is similar to the standard cross-finger flap except the palmar skin is elevated for the flap. When used for the distal thumb, the long finger is often the donor site.

- Design the flap on the palmar surface of the middle phalanx. Its base should lie along the ulnar border in the midaxial line (Fig. 38.11A).

**Figure 38.10.** A palmar advancement flap is shown. A: This is the method for a planned incision. B: Palmar soft tissue is advanced. C: Suture the flap into place distally, using a small (6-0 or 7-0) monofilament suture without tension. It may be necessary to flex the interphalangeal joints to achieve tension-free closure. Place a full-thickness skin graft over the donor defect.

**Figure 38.11.** A palmar cross-finger flap is shown. A: This is the flap design. B: The flap is elevated. C: The flap is inset, and the donor site skin is grafted. D:
The repair is completed. E: A schematic cross section of the donor finger illustrates the proper plane of dissection.

- Elevate the flap just superficial to the flexor sheath, taking care to preserve the ulnar neurovascular bundle and to not separate the flap from the radial neurovascular bundle (Fig. 38.11B).
- Suture the flap into place with a fine monofilament suture and suture a full-thickness skin graft over the donor middle phalanx. Apply a bolus dressing.
- Complete the repair.

Advantages of this procedure, as advocated by Vlastou et al., include better quality of skin because it is taken from the palmar surface (43). In addition, both digits are positioned in a more comfortable posture, which may decrease PIP joint stiffness. Cosmesis is also improved because the scar is on the palmar surface as compared with the more obvious dorsal surface of the donor digit. The risks of this procedure include exposing the tendon flexor sheath, stiffness, a painful donor site, and the potential for neurovascular injury. These complications have limited its use.

**Neurovascular Island Flaps**

The neurovascular island flap transfers the soft tissue of the border of a finger with its neurovascular bundle to the thumb. This technique sacrifices sensation in a finger of less importance to transfer sensate soft tissue to the thumb. It can be performed as a primary or reconstructive procedure. The donor site is often the ulnar border of the long finger, although one may also use the ulnar or radial aspect of the ring finger (24).

- Preoperatively, it is important to assess the arterial flow of the donor finger and the digit adjacent to the flap because the adjacent vessel is ligated. After the recipient site is prepared, dissect the digital nerves of the thumb to the muscle bellies of the flexor pollicis brevis and transect at this point. The deep location of the nerves helps prevent neuroma formation.
- Outline the donor site flap 3 to 4 mm proximal to the midline of the nail plate. The more distal the flap on the donor finger, the better the sensibility in the recipient thumb. Carry the incision proximally along the midlateral line and palmar aspect of the hand. The distal margin of the flexor retinaculum marks the proximal portion of the incision. If the anatomy is normal, dissect from proximal to distal.
- Confirm that the common digital artery arises from the superficial arch and not the deep arch. Take care not to skeletonize the neurovascular bundle but, rather, take the neurovascular bundle as a unit with the subcutaneous tissue. This minimizes the risk of injury to the vessels.
- Ligate the digital artery branch to the adjacent finger and longitudinally separate the common digital nerve of the web space. Continue to dissect proximally to the superficial palmar arch. Then pass the neurovascular bundle beneath the digital nerve and transfer it to the thumb.
- Make a wide tunnel superficial to the palmar fascia. Then place a penrose drain from the thumb and passing into the palmar defect. Place the flap inside the penrose drain and transfer to the thumb.
- After suturing the flap into place, assess its viability. If flow is not adequate, ensure that there is no kinking of the vascular pedicle.
- Treat the donor site defect with a combination of primary closure and full-thickness skin graft (Fig. 38.12).

**First Dorsal Metacarpal Artery Flap**

The first metacarpal artery flap restores sensate skin to the volar thumb in a one-stage procedure without the need for microvascular repair. Sherif has reviewed the anatomy of the first dorsal metacarpal artery (FDMA) and found the artery present in all cases (38) (Fig. 38.13). The artery originates from the radial artery, just distal to the extensor pollicis longus before the radial artery dips in between the two heads of the first dorsal interosseous muscle. He also found that the FDMA gave off three consistent branches: a radial branch, an ulnar branch, and an intermediate branch. Furthermore, a cutaneous branch was always present and originated from either the radial artery or the first dorsal metacarpal artery. The FDMA is superficial to the dorsal interosseous fascia and is covered by some fibers of this layer. Before making the incision, a Doppler scan may be used to identify the FDMA.

- Elevate the flap from the dorsal aspect at the base of the index finger. It can be extended to the PIP joint distally (14,31,38,39). If additional width of the flap is needed, expand it toward the third metacarpal to avoid a first web space contracture.
- Expose the FDMA distally to proximally and raise the aponeurosis with the perivascular fat as a pedicle (Fig. 38.14). The artery is usually superficial to the fascia, and a branch of the superficial radial nerve is included in the pedicle.
Figure 38.14. The design of various flaps in the first web space is shown. A: Proximally based flaps are based on one of the FDMA branches. The island flap pedicle includes the FDMA and its branches, the first DIO fascia, subcutaneous tissue and veins, as well as the radial nerve branches and the accompanying artery. B: The distally based flap is based on one of the distal perforators (arrows). C: A double flap from the web space: The fascial flap is based on FDMA (marked in the drawing by a hook), and the cutaneous flap is based on the artery accompanying the radial nerve (dotted line).

- Take care to stay superficial to the extensor tendon paratenon. Rotate the proximally based flap around the point of origin of the artery at the base of the first interosseous space. During the dissection, there is often a large perforator near the second metacarpal neck that must be ligated.
- Once the pedicle is raised, tunnel it subcutaneously to the thumb without kinking. The flap can be used to cover thumb defects, either palmarly or dorsally, and can reach from the proximal portion of the thumb almost to its tip.

CONCLUSIONS

Our approach to fingertip injuries is the following: for adults, we assess the injury-related factors as well as patient-related factors such as age, occupation, general medical health, hand dominance, compliance, and associated injuries (Table 38.1). For small defects (less than 8 mm) with no exposed bone, we prefer to let these injuries heal by secondary intention. We have found that the cosmesis and sensitivity are adequate. If the defect is larger or has exposed bone, then we try to use a local flap. The flap required is dependent on the angulation of injury. For transverse or dorsal oblique injuries, we prefer a local V-Y advancement. We also use a lateral V-Y advancement for transverse defects. If the defect is oriented volarly, we perform a cross-finger flap or a thenar flap. Both require patient compliance, a second surgical procedure, and postoperative rehabilitation. For larger defects, we consider distant flaps and revision amputation. If there is a minimal portion of the nail bed remaining or no bone to support the nail bed, than a revision amputation is performed with ablation of the nail germinal matrix.

Table 38.1. Management of Thumb and Fingertip Injuries in Adults

We consider thumb injuries as a separate category. For volar injuries, we prefer the Moberg advancement flap. For larger defects, we use a first dorsal metacarpal or a cross finger flap.

For children younger than 3 years of age, we replace the amputated portion as a composite graft. In the 3- to 8-year-old age group, we de-fat the amputated part and use it as a free skin graft. Patients older than 8 years of age are treated as adults (Table 38.2).

Table 38.2. Children with Distal Amputations

We agree with Louis (25), who believes that the deficit in sensitivity, hypesthesias, dysesthasias, and cold intolerance in distal tip amputations may be primarily related to the injury and not to the treatment.

NAIL BED INJURIES

The anatomy of the fingernail is highly specialized. It has four components: the nail plate, the nail bed, the perinail soft tissues, and the underlying bone and ligamentous support. The nail has multiple functions, including supporting and protecting the fingertip. It also plays a role in sensation of the digit in that if the nail is lost two-point discrimination of the finger decreases (45). Nail growth is dependent on several factors including age of the patient, injury pattern, and seasonal changes. On average, growth is approximately 0.1 mm per day. After loss of a nail, it takes approximately 3 to 6 months for a new nail to grow in completely, and nail growth is not normal for the first 100 days (5).

Optimal treatment of a nail bed injury requires an understanding of the anatomy and physiology of its components (Fig. 38.15). The nail fold is the most proximal portion of the nail complex. It consists of two parts, which include the dorsal roof and germinal matrix. The dorsal roof of the nail fold forms the cells that contribute to the shine of the dorsal nail surface. The nail bed also consists of two components. The most proximal portion is the germinal matrix. It is located along the proximal ventral floor of the nail fold and extends to the lunula. This is the area of the nail bed epithelium where nail plate production begins, and it is critical to nail growth (Fig. 38.16). The sterile matrix is the distal portion of the nail bed and extends from the lunula to the hyponychium. The sterile matrix acts as a road map for growth of the advancing nail and functions to keep the nail adherent to the underlying epithelium (Fig. 38.17). The eponychium is the distal portion of the nail fold that attaches to the dorsal surface of the nail. The lunula is the white arc just distal to the eponychium that parallels the natural distal shape of the nail. Distally, the hyponychium is the area of junction of the nail bed and the fingertip skin. It functions as a protective barrier and prevents bacteria from migrating beneath the nail.
Both Zook et al. and Guy have reviewed the etiology of nail bed injuries and had very similar findings. The majority of these injuries occurred from a closing door, a machine injury, a saw injury, or by being crushed between two objects (Table 38.3) (16, 48).

Table 38.3. Causes of Nail Bed Injuries

The initial treatment of the injured nail bed is of utmost importance to prevent a nail deformity. Treatment of a nail deformity often requires a reconstructive procedure that is technically demanding, and the results are typically less than optimal. One problem facing the surgeon evaluating the injured nail is obscured visualization due to a subungual hematoma. In general, subungual hematomas encompassing greater than 50% of the nail have a higher likelihood of being associated with a displaced nail bed injury. In this situation, one should consider removing the nail and exploring the nail bed. Injuries with a subungual hematoma of less than 50% of the nail are less likely to have a repairable nail bed injury and should be treated nonoperatively. Patients may experience pain from the pressure related to a subungual hematoma. Making a small hole in the nail with a microophthalmic cautery can relieve the pressure. Drain the hematoma while taking care to not injure the underlying nail bed.

CLASSIFICATION OF NAIL BED INJURIES

Injuries of the nail bed can be divided into those that involve the germinal matrix or sterile matrix. In general germinal matrix injuries are more serious. Nail formation starts and is predominantly from the germinal matrix; therefore an injury in this region has a higher likelihood of permanently affecting nail growth. Van Beek et al. have further classified acute fingernail injuries, as outlined below (42).

Germinal Matrix Injury:

GI: Small subungual hematoma proximal nail (25%)

GII: Germinal matrix laceration, large subungual hematoma (50%)

GIII: Germinal matrix laceration and fracture

GIV: Germinal matrix fragmentation
GV: Germinal matrix avulsion

**Sterile Matrix Injury:**

SI: Small nail hematoma (50%)

SII: Sterile matrix laceration, large subungual hematoma (50%)

SIII: Sterile matrix laceration with tuft fracture

SIV: Sterile matrix fragmentation

SV: Sterile matrix avulsion

This classification system provides a framework for determining the appropriate treatment regimen (Table 38.4). Obtain radiographs to evaluate for a displaced distal phalanx fracture. Treat grade I injuries nonoperatively unless they are painful, for which decompression or nail removal can be performed.

**Table 38.4. Treatment of Nail Bed Injuries**

**Repair of Grade II, III, and IV Injuries**

- Treat grade II, III, and IV injuries by first carefully removing the nail. An adherent nail may indicate a grade I injury with limited nail bed involvement.
- Facilitate nail removal with a freer elevator by exploiting the plane between the nail and the nail bed. Be careful when removing the nail so as not to injure the nail bed.
- Clean the nail and debride the nail bed if necessary. There is little advancement possible of the nail bed, so limit debridement to contaminated or devitalized tissues.
- Repair the nail bed under loupe magnification using 6-0 or 7-0 chromic suture.
- If the proximal germinal matrix is injured, visualization may be obscured by the nail fold. Make skin incisions at 90° to the nail fold along the lateral border of the nail. Then elevate the nail fold to evaluate the extent of injury fully.
- Most distal phalanx fractures are treated with a splint. A displaced fracture may cause displacement of the nail bed, and occasionally Kirschner wire fixation is required.
- After repair, replace the nail beneath the nail fold. Replacement of the nail has several important functions: (a) it serves as a template for the new growing nail; (b) it serves as a splint for fractures, (c) it provides a biologic dressing for the nail bed, and (d) it prevents scarring of the nail fold to the nail bed.
- Suture the nail in place with 4-0 or 5-0 nylon sutures. Place two horizontal mattress sutures proximally both radially and ulnarly to prevent injury to the germinal matrix. One or two simple sutures may be placed in the distal aspect of the nail and pulp to further secure the nail.
- If the nail is fragmented or not available, an artificial nail, Silastic sheet, or nonadherent gauze can be used.
- Bandage the finger to protect the digit and restrict motion for 7 to 10 days. Leave the replaced nail in place for 2 weeks.

**NAIL BED AVULSIONS**

The nail bed can avulse from either the germinal or sterile matrix. Similar to nail bed lacerations, the majority of avulsions occur in the distal aspect of the sterile matrix. Nail bed avulsions account for approximately 15% of all traumatic injuries to the nail (36). If the nail bed is allowed to heal by granulation, the resultant scar may cause a nail deformity or nonadherence.

**Avulsed Segment**

Ideally, the avulsed nail bed is sutured in an anatomic position (36). Often, the nail bed is attached to the nail plate. A decision must be made whether to separate the nail bed from the nail plate or suture the nail bed and plate as one unit. If the pieces are small, we tend to suture the nail bed and plate as one segment. If the fragment of the avulsed nail bed is large, it is carefully separated from the nail plate (Fig. 38.18). The nail bed can be sutured directly onto bone, as outlined by both Zook and Shepard (36,47).

**Figure 38.18.** A: A nail bed avulsion is shown. B: The matrix is attached to the plate. C: The avulsed segment is sutured. D: The nail plate is replaced.

- Many times, inspection in these situations reveals that the nail matrix is still attached to the avulsed nail plate. If the segment of nail matrix is large, shave it away for use as a free graft (Fig. 38.18B).
- Properly align the avulsed segment and suture it to the defect with 6-0 or 7-0 chromic suture.
- Replace the avulsed nail to cover the defect (Fig. 38.18D). If the nail plate is badly damaged, the dressing should be fine mesh gauze or other nail substitute.
- Use half-buried horizontal mattress sutures in conjunction with nail root elevation to anchor a displaced nail plate or nail bed, or both, into the proximal nail fold (Fig. 38.19).
Incomplete Avulsions

Incomplete avulsion of the nail bed often occurs at the germinal matrix. A bending force through the distal phalanx is transmitted proximally to avulse the germinal matrix and displace the nail from beneath the nail fold. In the past, the distal nail was left in place and the proximal avulsed nail bed was reapproximated (34). At present, elevation of the entire nail to ascertain the degree of injury and repair is recommended (Fig. 38.19) (36).

If the avulsed segment of nail bed is not available or amenable for repair, alternative treatment methods are necessary. In the past, treatment involved split-thickness skin grafts, dermal grafts, and healing by secondary intention. Zook and Shepard have used split-thickness nail bed grafts with good success (37,47). The preferred donor site is the injured nail, although grafts have been described from the great or second toe. Full-thickness grafts are discouraged due to the associated donor site morbidity.

- Harvest a split-thickness graft from adjacent tissue for coverage. A split-thickness nail matrix graft from a great toe can be used if insufficient tissue is presented on the digit of the avulsion.
- When taking a split-thickness nail graft, keep in mind that the thickness of the nail sterile matrix is only 240 to 990 µm (30 to 40 thousandths of an inch) and that the grafts are 165 to 240 µm (7 to 11 thousandths of an inch) (Fig. 38.20). Use a microscope to facilitate harvesting the graft.

NAIL RECONSTRUCTION

Nail bed injuries can lead to a variety of nail abnormalities. Typical deformities include nonadherence, split nails, linear ridging, crooked nails, and hooked nails. Nonadherence after trauma is the most common nail deformity. Distal nonadherence can be problematic due to dirt becoming lodged underneath the nail. Proximal nonadherence is more troublesome because the nail can become unstable and tear loose when picking up small objects. Nonadherence occurs when the nail does not adhere to the abnormal scar that has formed within the injured nail bed. Scar excision and primary repair has been performed. Although Zook and Russell believe that primary closure of the nail bed leads to excessive tension with resultant increased scar, they have recommended split-thickness nail grafting (25,37,47).

Split nails occur because of a longitudinal scar in the germinal or sterile matrix. The nail, therefore, grows on either side of the scar in the germinal matrix. The scar in the sterile matrix leads to nonadherence, and increased stresses in the nail causes the split or crack. Reconstructing a split nail is similar in principle to treating nonadherence. If the split is in the sterile matrix or distal germinal matrix region, the scar is excised and replaced with a split-thickness matrix graft. A split nail due to an abnormality in the germinal matrix requires a germinal matrix graft, which can be harvested from another finger or toe. Both have the complications of persistent deformity and donor site morbidity (Fig. 38.22).
**Linear Ridging**

Linear ridging is often secondary to a bony protuberance beneath the nail bed. As described by Kleinert, the treatment in this setting involves incising the nail bed over the involved area (20). An ostectomy is performed, and the nail bed reapproximated. Shepard has reported good results in six patients with this technique (Fig. 38.23) (37). If the etiology is due to scar from an injury to the sterile matrix, one can excise the scar and replace it with a split-thickness nail bed graft. For defects in the germinal matrix, one may be forced to use a full-thickness graft with its associated donor site complications. Linear ridging may be related to compression of the germinal matrix from a mucous cyst arising from the DIP. These cysts often arise in association with an osteophyte of the DIP related to degenerative joint disease. The deformity may progress from ridging to a split nail. Aspiration of the cyst often leads to recurrence. The surgical management involves excision of the osteophyte and cyst, including the stalk from the DIP. Gingrass et al. have reported a low rate of cyst recurrence with this technique (15). Progression of the nail deformity is prevented, but the deformity is likely to persist.

**Lateral Deviation**

Lateral deviation of the nail is due to a full-thickness avulsion of the lateral aspect of the nail bed with displacement (20). Rather than rotating a portion of the nail bed into the defect, the recommended management involves elevation of the entire nail bed and placing it in a straight position (Fig. 38.24).

**Hooked Nail**

A hooked nail involves volar displacement of the distal aspect of the nail. It can be due to a malunited fracture or a deficiency of skin of the digital pulp. Atasoy et al. have described an “antenna” procedure for correcting the deformity (Fig. 38-25) (4). The procedure involves freeing the tethered pulp and nail bed, splinting the freed nail bed, and reconstructing the soft-tissue defect of the pulp.
Figure 38.25: A: A hook-nail deformity and normal contour of fingertip (dotted line) are shown. B: This is the procedure for removal of nail plate and skin marking. C: The pulp is reflected, the full-thickness of the nail matrix is elevated, and the nail matrix is splinted with three small Kirschner wires, like antennae. D: Coverage of the defect with a cross-finger flap is shown. E: Appearance after division of flap (2 weeks after surgery). (From Atasoy E, Godfrey A, Kalisman M. The “Antenna” Procedure for the Hook-Nail Deformity. J Hand Surg 1983;8:55.)

- Elevate the curved nail plate from the nail bed along its length and discard the portion of the nail plate distal to the lunula.
- Incise the pulp skin along the hyponychium and extend it on both sides of the pulp. Deepen the incision to reflect the pulp skin in a normal contour. Elevate the full-thickness nail bed to the level where the nail bed is straight.
- Insert two or three 0.028 Kirschner wires into the distal phalanx to splint the nail bed.
- Cover the pulp defect with a cross-finger flap. Shepard has recommended reconstructing the pulp defect with a lateral V-Y advancement flap and skin graft rather than a cross-finger flap (27). Bone grafting of the elevated portion of the distal phalanx has been discouraged by Zook due to the likelihood of bone graft resorption (46).
- An alternative treatment method involves shortening the nail bed, thereby allowing the nail to be supported by bone. A hook nail may be prevented while treating the initial injury by shortening the nail bed 2 mm greater than the distal phalanx (21). Both procedures are simple solutions but leave one with a shortened nail.

TOTAL NAIL LOSS

Total nail loss can be treated by split-thickness skin grafting, nail prosthesis, or total nail reconstruction. Total nail reconstruction involves transfer of the nail bed as a free or vascularized nail graft. The free graft can be taken by elevating the nail plate and harvesting the nail bed and matrix as far as the proximal end of the nail matrix (28,33). In free nail grafts, Shepard notes the importance of taking the proximal nail fold. All patients in his series in which this was not incorporated would have failed. When the proximal nail fold was incorporated, he had a 50% success rate (27). The lateral edge of the great toe is often the donor site. The donor site is covered with a split-thickness skin graft.

Vascularized nail flaps have also been described. These flaps transfer a free nail with the advantage of better biologic adherence and viability. They are technically more difficult and take much longer to perform (12). Three types of vascularized grafts have been described. The first type is a long pedicle vascularized nail flap. This flap entails an 11 cm incision in which the digital artery and vein are used for anastomosis. A venous flap allows for a shorter incision, with the venous anastomosis proximal to the interphalangeal joint. The disadvantage of this flap is the concern of the existence of venous valves. The last flap is the short pedicle vascularized nail flap, which represents a combination of the above two flaps.

AUTHORS’ PERSPECTIVE

Nail bed injuries represent a very common injury in which the severity is often overlooked. It is imperative that these injuries be treated accurately initially to prevent a nail deformity. Nail bed injuries should be repaired anatomically and may require fixation of a displaced distal phalanx fracture. If it is available, the nail or substitute is replaced beneath the nail fold. Limiting a nail deformity may preclude the need for one of the technically demanding reconstructive procedures.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Through a unique combination of sensibility, stability, and mobility, the hand allows us to manipulate our environment. The thumb's mobile carpometacarpal joint and stable metacarpophalangeal (MP) and interphalangeal (IP) joints allow both precision pinch and power movements, including grasp. The stable carpometacarpal joints of the index and long fingers provide for stability along the central longitudinal axis of the hand, whereas the relatively mobile ring and little carpometacarpal joints provide mobility to allow cupping or flattening of the hand. The hingelike MP and especially the IP joints allow the ability to grasp objects of varying size.

Because of the constant exposure of the hand to external forces, dislocations and ligamentous injuries of the digital joints are quite common (396,397). Proximal interphalangeal (PIP) joint injuries are probably the most common joint injuries in the hand (68,128). Fortunately, in the acute phase, most digital dislocations and ligament injuries can be treated by closed or nonoperative means. This chapter discusses these topics by joint. The fingers are covered as one, except where a specific injury to a specific joint in a specific finger requires individual attention. The joints of the thumb are addressed separately. A general treatment algorithm is provided at the beginning of each section.

ANATOMY

All the IP and MP joints of the fingers and thumb are similar in that their stability is provided by a series of ligaments. The major stabilizers of these joints include the volar plate and the collateral ligaments. The volar plate is a fibrocartilaginous structure firmly attached to bone distally, with a filmy proximal recess. On the sides of each joint are the collateral ligaments, which blend palmarly with the accessory collateral ligaments. The shape of these collateral ligaments varies from a slightly fanlike shape at the proximal IP level to very fan-shaped at the MP joint.

INTERPHALANGEAL JOINTS

The proximal and distal interphalangeal joints are similar in configuration. The PIP joint is a hinge or ginglymus joint, consisting of a convex bicondylar proximal phalangeal notch articulates with a corresponding middle phalangeal median ridge (Fig. 39.1). Dorsally, the central slip attaches to a tubercle on the base of the middle phalanx. Palmarly, the volar plate forms the floor of the joint. The volar plate has a thickened distal fibrocartilaginous portion that is thicker along its lateral edges. The volar plate attaches along the volar base of the middle phalanx, blending with the volar periosteum of the middle phalanx centrally and the collateral ligaments laterally (Fig. 39.2) (12,14,15,20,28,38,76,77,82,85,137). The proximal portion of the volar plate tapers along its lateral edges to form two check-rein ligaments (Fig. 39.3) (12,14,15,82). Laterally, the collateral ligaments consist of a thicker dorsal cordlike collateral ligament proper, and a thinner volar accessory component (76,91,137). The collateral ligaments arise from a concavity along the lateral aspect of the proximal phalangeal head. The ligaments pass obliquely and palmarly to attach distally into a volar lateral tubercle on the base of the middle phalanx and along the distal lateral margin of the volar plate. The volar plate provides resistance to hyperextension injuries of the PIP joint. Resistance to lateral stresses are provided mostly by the collateral ligaments and secondarily, if at all, by the volar plate (68,114). Some stability is also afforded by the surrounding tendon and retinacular system (15,85,128). Disruption of at least two portions of the volar plate and two collateral ligaments must occur for displacement of the PIP joint (30).
The distal interphalangeal (DIP) joint, in addition to the stability provided by the collateral ligaments and volar plate, has some dynamic stability provided by the insertions of the flexor digitorum profundus and the terminal tendon of the extensor mechanism on the base of the distal phalanx.

**METACARPOPHALANGEAL JOINT**

The MP joint of the fingers is a condyloid joint, consisting of a relatively ovoid metacarpal head articulating with an elliptical cavity at the base of the proximal phalanx. The metacarpal head is narrower dorsally than palmarly in the sagittal plane, and it has a proportionately larger anteroposterior diameter than that of the phalangeal head (Fig. 39.4). Joint motion is primarily in the sagittal (flexion–extension) plane, but both coronal (abduction–adduction) plane and small circumduction movements also occur (217).

The MP joint capsule extends from the metacarpal neck to the base of the proximal phalanx. Volarly, the joint capsule blends with the volar plate, which consists of a thick fibrocartilaginous distal portion and a thin membranous proximal portion. The volar plate is more securely attached to the proximal phalanx than to the metacarpal neck. The volar plate is also continuous medially and laterally with the deep transverse metacarpal ligament (Fig. 39.5) (162,167,173,192,217). Dorsally, the MP joint capsule is thin, and it is reinforced by a loose insertion of the common extensor tendon. The collateral ligaments extend from the metacarpal head to the base of the proximal phalanx, and they also insert into the volar plate. In addition, the metacarpal origin of the collateral ligament is more dorsal than its counterpart at the PIP joint (207). These factors dictate that the collateral ligaments of the MP joint are at their longest or most taut in full flexion (Fig. 39.6), while those of the PIP are most taut at only a few degrees of flexion. It is important to remember this when testing for collateral ligament stability or when determining the tension appropriate for a repaired ligament, both during the repair and after surgery. Additionally, the sagittal bands and intrinsic muscle tendons provide secondary support to the MP joints (124).
to the uninjured joint in the opposite hand, can be helpful in detecting ligament injuries (digital block or intraarticular injection) is helpful to reap the maximum benefit from a stress view. Similarly, stress views of the injured joint under fluoroscopy, when compared to the uninjured joint in the opposite hand, can be helpful in detecting ligament injuries.

**CARPOMETACARPAL JOINTS**

The carpometacarpal (CMC) joints of the hand consist of a fixed, stable central unit that comprises the index and long CMC joints and the relatively mobile radial (thumb) and ulnar units (ring and little). Together they form the fixed transverse metacarpal arch of the hand (Fig. 39.7). The index and long finger metacarpals articulate with the trapezoid and capitate with strong CMC ligaments, providing relatively little motion (242-244,263,271). Stability of these joints is provided by tight joint articulations, thick dorsal capsular ligaments, volar ligaments, interosseous ligaments, and by some support of the transverse carpal ligament. Additionally, insertions of the flexor carpi radialis and extensor carpi radialis longus into the base of the index metacarpal, and of the extensor carpi radialis brevis into the base of the long metacarpal provide some dynamic stability to the these joints (Fig. 39.8).

![Figure 39.7. The carpometacarpal joints of the index through little fingers form the fixed transverse arch of the hand.](image)

**Figure 39.8.** The carpometacarpal joints with supporting ligaments and tendon insertions. (From Gunther SF. The Carpometacarpal Joints. *Orthop Clin North Am* 1984;15:25, with permission.)

![Figure 39.8. The carpometacarpal joints with supporting ligaments and tendon insertions.](image)

The ulnar ring and little finger metacarpals are relatively mobile, providing approximately 10° to 30° of flexion and extension, respectively, as well as a few degrees of supination (212,244). They articulate with two separate hamate facets. A slightly convex fifth metacarpal base articulates with a slightly concave ulnar hamate facet, whereas a somewhat flatter fourth metacarpal articulates with the radial hamate facet. Stability to these joints is provided by the carpometacarpal and interosseous ligaments. Additionally, the hypothenar muscles and insertions of the extensor carpi ulnaris and flexor carpi ulnaris via the pisometacarpal ligament (a continuation of the flexor carpi ulnaris insertion) provide some dynamic stability to these joints.

**PATHOPHYSIOLOGY**

Injuries to the digits and hand can occur from a variety of external forces. These forces can be direct (crush, burns, lacerations) and/or indirect forces (rotational, bending, axial loading). With indirect forces, the direction of the deforming force determines the type of joint injury, while the amount of force dictates whether the injury is a subluxation or a dislocation. For instance, dorsal PIP joint dislocations are often accompanied by a longitudinal compressive force; the magnitude of compression affects the complexity of the injury. When greater longitudinal compressive forces are combined with a hyperextension deforming force, dorsal PIP fracture-dislocations are produced. The mechanism of injury for a particular joint disorder is further discussed with each specific injury.

Secondary dynamic forces, provided by tendon insertions, frequently accentuate the deformity. For instance, insertion of the abductor pollicis longus on the base of the thumb metacarpal, and of the adductor pollicis on the metacarpal shaft, will accentuate a thumb CMC joint dislocation or fracture-dislocation.

Injuries of the soft tissues, usually through either direct forces or excessive indirect forces, can produce open wounds or neurovascular injuries. These injuries will ultimately affect the course of treatment. The treatment of an open dislocation with neurovascular compromise is different from that of a simple closed injury.

**GENERAL PRINCIPLES OF TREATMENT**

The goal for any treatment of digital dislocations or ligament injuries is to restore functional, pain-free, and stable joint motion. To accomplish this goal requires an early, accurate evaluation and diagnosis of the injury and adequate treatment. The goal of treatment for injuries seen late is usually to provide pain relief.

Obtain a history of the mechanism of the injury (e.g., extension, flexion, lateral deviation force) and timing of the injury (acute versus chronic). Examine for active joint range of motion, neurovascular status, flexor and extensor tendon function, areas of localized tenderness, and, finally, passive joint stability. Most dislocations or ligament injuries that are closed and simple can be treated by nonoperative means. Digital block or nerve block anesthesia can be helpful in evaluating joint stability or reducing dislocations, but this is often unnecessary. Determine and record the neurologic status prior to an anesthetic or treatment of the injury.

Dislocations are usually obvious from clinical examination, but good radiographs in at least two orthogonal planes (perpendicular to one another) are necessary. With a digital injury, radiographs of the digit (not of the hand) before and after treatment are needed to accurately assess any associated fractures, as well as the efficacy of treatment.

Use stress views to evaluate ligament injuries if clinical testing leads to a question about the integrity of a ligament (Fig. 39.9A). If used, anesthesia (usually a digital block or intraarticular injection) is helpful to reap the maximum benefit from a stress view. Similarly, stress views of the injured joint under fluoroscopy, when compared to the uninjured joint in the opposite hand, can be helpful in detecting ligament injuries (Fig. 39.9B).
Other specifically radiographs may also be helpful in evaluating particular joint injuries. An oblique view (Brewerton view) of the metacarpal heads may be helpful in detecting small metacarpal head fractures (171,185,189,206). The Brewerton view is taken as an anteroposterior (AP) view of the hand with MP joints of the hand flexed approximately 65° and the x-ray beam tilted 15° from an ulnar to radial direction (185). Evaluation of the thumb CMC joint requires a true AP view and a lateral view of the joint (Robert view) (403). The AP radiograph is taken with the hand fully pronated and with the dorsum of the thumb lying flat on the x-ray plate. The x-ray beam is then centered over the thumb CMC joint. The lateral radiograph of the joint is taken with the radial side of the thumb lying on the x-ray plate (thumb nail lying perpendicular to the plate) and the x-ray beam centered over the joint. Evaluation of the finger CMC joints will frequently require oblique views of the hand. Occasionally, due to the difficulty in evaluating these joints, tomography or computed tomography (CT) may be needed.

After reduction of the joint, assess both active stability (full active range of motion) and passive stability (passively applied medial–lateral and anterior–posterior stress). If the injury is amenable to closed treatment, use a cast dressing that immobilizes the hand and wrist as well as all the fingers and, if necessary, the thumb. Take care when using a digital splint, as an acutely injured digit can be further harmed by immediately taping it to a digital splint. After surgical intervention, a similar cast dressing is applied.

In most cases with closed treatment, the dressing is changed within 5 days. Begin an appropriate active motion program, modifying for the specific injury. The same is recommended for many postoperative cases. The goal is to provide joint stability and adequate protection against reinjury or disruption of the repair while gaining maximal motion to prevent tendon adherence or joint stiffness.

CLASSIFICATIONS

Dislocations and ligamentous injuries of the interphalangeal, metacarpophalangeal, and carpometacarpal joints can be classified similarly. Classification can be based on the status of the skin (closed versus open), the duration of injury (acute versus chronic), the degree of joint displacement (subluxation versus dislocation), the status of the joint surface (dislocation versus fracture–dislocation), and the ability to reduce the joint dislocation (simple versus complex).

Joint subluxations occur with disruption of some of the joint soft tissue supporting structures, but some contact remains between the articular surfaces. With dislocations, there is a loss of contact between the joint surfaces. Joint dislocations and subluxations can be further subclassified based on the direction of displacement of the distal portion of the injured digit relative to the proximal portion, that is, dorsal, lateral, or palmar (volar) dislocations.

Specific classifications of an injury pertaining to a particular joint will be discussed separately.

FINGERS

DISTAL INTERPHALANGEAL JOINT

Assessment and Indications for Treatment

In addition to an obvious DIP joint dislocation, flexor or extensor tendon avulsion injuries, nail bed injuries, and open injuries are common (Table 39.1). Assess these structures and obtain true AP and lateral radiographs of the digit and particularly of the DIP joint. Open dislocations require adequate debridement and antibiotics.

Table 39.1. Algorithm for Assessment of Distal Interphalangeal (DIP) Joint Injuries

Distal interphalangeal joint dislocations are uncommon. The more common injuries occur secondary to a hyperextension force (dorsal dislocation, dorsal lip fracture or fracture–dislocation), forced extension against resistance (flexor profundus tendon avulsion injury), flexion injury (extensor tendon avulsion injury), hyperflexion force (palmar dislocation), and lateral deviation force (collateral ligament injury). The addition of a longitudinal compression force usually adds some form of an intraarticular fracture.

DIP Joint Dislocations

Dislocations of the DIP joint are almost always dorsal and are rare (42,83). These injuries are usually produced by a longitudinal compression and hyperextension of the joint. Occasionally, a lateral, and even less commonly a palmar, dislocation can occur. Look for flexor (jersey finger) (Chapter 48) or extensor tendon (mallet finger) (Chapter 49) avulsion injuries, which are common. Simultaneous dislocation of the distal and proximal interphalangeal joints has been described and should be detectable by careful clinical examination and adequate radiographs of the injured digit (24,80,83,120,145,252,260,264,217,218,239,242).

- Perform a closed reduction, with or without digital block anesthesia, using longitudinal traction on the distal phalanx.
- Place direct pressure on the dorsal base of the distal phalanx, displacing it distally and palmarly.
- Postreduction radiographs should confirm congruous reduction of the joint.
- After joint reduction, assess joint stability and flexor and extensor tendon function. If joint instability is present after joint reduction, splint the joint for 2 to 3 weeks in 10° to 20° of flexion (for dorsal dislocation).
- With a palmar dislocation, dorsal lip fracture–dislocation, or terminal extensor tendon avulsion (mallet finger) injury, avoid splitting the DIP joint in hyperextension. This prevents dorsal skin wound problems. Splint, generally, for 6 weeks or more to promote healing (see Chapter 49). Fracture–dislocations of the joint can occur (46,51).
- If the flexor digitorum profundus is avulsed with the volar fragment, reattach the tendon.

Figure 39.9. A: AP radiograph with lateral stress applied to the proximal interphalangeal joint. Lateral deviation of more than 20° is indicative of a complete collateral ligament injury. B: Fluoroscopic stress view of the thumb MP joint showing lateral subluxation of the proximal phalanx.
Open dislocations of the DIP joint are frequent and require irrigation, debrideinent, and antibiotics. Repair any associated nail bed injuries or nail plate avulsions. When the dislocation is chronic (greater than 3 weeks) or irreducible, perform an open reduction. Irreducible DIP joint dislocations may be secondary to interposed volar plate, flexor tendon, fracture fragment, or a sesamoid bone. Remove the interposed structure to reduce the joint.

Open Reduction of an Irreducible DIP Joint Dislocation

- Make a straight dorsal midline, transverse, or H-shaped incision and split the extensor tendon longitudinally in the midline. Alternatively, divide the tendon transversely and repair it at the time of closure.
- If the volar plate is interposed between the joint surfaces, incise as much of it as necessary to displace it palmarly.
- Release the collateral ligaments subperiosteally at their insertion into the middle phalanx and continue the dissection until the joint can be reduced. Test the joint for stability.
- If the joint is grossly unstable, transfuse the joint with smooth 0.035–0.045 Kirschner (K-) wire(s) for 3 weeks. If the joint is fairly stable, immobilize it in a splint for a few days for comfort.
- Then apply a dorsal-block splint and allow active flexion. Remove the splint after 3 weeks.
- If the joint surface damage is extensive, perform a primary arthrodesis (see Chapter 72).

Complications

Complications in the treatment of DIP joint injuries will usually occur from a failure in diagnosis, from a delay in treatment, or from undertreatment. Failure to recognize a concomitant injury to soft tissues (e.g., flexor or extensor tendons) will result in a deformity (e.g., jersey finger or mallet finger). Unrecognized dislocations generally require an open reduction and pin fixation, instead of a closed reduction. Delayed reduction of the joint may also result in significant articular damage, necessitating an arthrodesis. Redislocation of a dorsal DIP joint dislocation can occur if hyperextension is not prevented for at least 3 weeks.

DIP Joint Ligament Injuries

Unless they accompany a dislocation, nearly all ligament injuries of the DIP joint are partial tears or sprains at the DIP joint level and thus can be treated nonoperatively. Temporary splinting for a few days for comfort should be followed by an early, vigorous active motion program.

**PROXIMAL INTERPHALANGEAL JOINT**

**Assessment and Indications for Treatment**

Proximal interphalangeal joint dislocations and subluxations are frequently associated with an injury to the volar plate, collateral ligament, extensor tendon (central slip), and joint articular surface (Table 39.2). Assess these structures and take true AP and lateral radiographs of the digit, particularly of the PIP joint. Stress views to assess collateral ligament injuries may be helpful. Open dislocations require adequate debridement and antibiotics.

**Table 39.2. Algorithm for Assessment of Proximal Interphalangeal (PIP) Joint Injuries**

Proximal interphalangeal joint injuries, especially dislocations, are among the most common hand injuries ranging from a simple hyperextension injury, as seen in sporting injuries, to a severely comminuted fracture. The more common injuries occur secondary to a hyperextension force (dorsal subluxation or dislocation, volar plate rupture), longitudinal compression and hyperextension force (dorsal fracture–dislocation), lateral deviation force (collateral ligament injuries), and combined rotatory and longitudinal compression force (rotatory dislocations).

**PIP Joint Dorsal Dislocations**

There are several dorsal PIP joint dislocation classification systems ranging from a simple hyperextension injury to the volar plate, collateral ligament, extensor tendon (central slip), and joint articular surface (Table 39.2). Assess these structures and take true AP and lateral radiographs of the digit, particularly of the PIP joint. Stress views to assess collateral ligament injuries may be helpful. Open dislocations require adequate debridement and antibiotics.

**Table 39.2. Algorithm for Assessment of Proximal Interphalangeal (PIP) Joint Injuries**

Proximal interphalangeal joint injuries, especially dislocations, are among the most common hand injuries ranging from a simple hyperextension injury, as seen in sporting injuries, to a severely comminuted fracture. The more common injuries occur secondary to a hyperextension force (dorsal subluxation or dislocation, volar plate rupture), longitudinal compression and hyperextension force (dorsal fracture–dislocation), lateral deviation force (collateral ligament injuries), and combined rotatory and longitudinal compression force (rotatory dislocations).

**Figure 39.10. Three types of dorsal PIP joint hyperextension injury (see text for description of injuries).**

Figure 39.10. Three types of dorsal PIP joint hyperextension injury (see text for description of injuries).

The acute dorsal injury without fracture can usually be reduced by closed means. A digital block is often unnecessary. The volar plate, by necessity, is ruptured, usually from the middle phalanx, but the collateral ligaments rarely are ruptured completely from their attachments. Perform reduction with longitudinal traction and direct pressure on the dorsal base of the middle phalanx, displacing it distally and palmarly. Confirm congruous reduction of the joint with postreduction radiographs. Assess both active and passive stability of the joint after reduction. With type I and II dorsal dislocations, the joint is usually stable after reduction. Type III injuries are discussed in the following section. Use a resting splint with the finger flexed to 20° to 30° for 7–10 days. Do not splint the digit in flexion for an extended period of time, and begin early active motion with protection against hyperextension. Alternatively, use an orthoplast figure-eight splint, preventing joint hyperextension. Protect the injured digit, especially during sporting activities, by taping it to the adjacent uninjured digit. Reassure the patient that persistent swelling and slow
resolution of stiffness is to be expected.

Treat open PIP joint dislocations with irrigation, debridement, and antibiotics (71,129).

Chronic dorsal dislocations are uncommon, as are irreducible dorsal dislocations (36,43,62,71,101), and require open reduction. An attempt at gentle closed reduction under adequate anesthesia is permissible but is best done in the operating room; if it is unsuccessful, the joint then can be approached surgically.

Open Reduction of a Chronic, Irreducible, Dorsal PIP Joint Dislocation

- Make a straight or slightly curvilinear dorsal longitudinal incision.
- Divide the central slip of the extensor mechanism in the midline but do not dissect distal to the base of the middle phalanx, as the attachments of the central slip to the middle phalanx and triangular ligament must remain intact.
- If the volar plate is interposed, split the interval between it and each accessory collateral ligament. Mobilize the volar plate and perform a trial reduction of the joint.
- If this fails, release the origins of the collateral ligaments from the proximal phalanx by sharp subperiosteal dissection. This should allow reduction if the joint is hyperextended and the volar plate is pushed palmarward.
- After reduction, test the joint for instability. If instability is present, transfix the joint with smooth 0.035–0.045 K-wire for 3 weeks.
- If the joint is fairly stable, close the extensor split and the skin separately with nonabsorbable sutures. Take postreduction radiographs to confirm congruous reduction of the joint.
- Immobilize the hand in a cast dressing with the PIP joints flexed no more than 10°. After 5–7 days, begin active flexion for an additional 2–4 weeks, using a dorsal extension-block splint to prevent hyperextension of the joint.

Complications

The most common complication following a dorsal PIP joint dislocation is stiffness secondary to prolonged splinting (146). Prolonged splinting of the joint in flexion can produce a joint flexion contracture, due to contracture of the volar plate (also referred to as a pseudoboutonnière deformity) (80,91). A significant contracture can be treated with dynamic splinting, serial casting, or, eventually, surgical release of the contracture (25,36,80,86,149).

In contrast to prolonged splinting of the PIP joint, if joint hyperextension is not prevented for at least 3 weeks, either redislocation of the joint or a chronic swan-neck deformity may occur (104). A true lateral radiograph will help guard against persistent subluxation. With a chronic swan-neck deformity, painful snapping of the lateral bands over the phalangeal heads or inability to initiate joint flexion may occur. Treatment includes primary realignment of the volar plate or sublimis tenodesis (see the section below on volar plate ruptures) (17,12,39,72,78,91,109,110,132,136,144,145).

PIP Joint Palmar Dislocations

Palmar PIP dislocations are rare and result from a longitudinal and rotatory force directed on a partially flexed PIP joint (39,127). The injury results in volar displacement of the middle phalanx relative to the proximal phalanx. There is a disruption of the extensor mechanism (central slip), creating a boutonnière injury. One proximal phalangeal condyle may herniate between the central slip and the lateral band, producing a rotatory or irreducible PIP joint dislocation (see Rotatory Dislocations). There may be an injury to a collateral ligament and the volar plate (proximal phalangeal condyle may herniate between the central slip and the lateral band, producing a rotatory or irreducible PIP joint dislocation (see Rotatory Dislocation) (72,93).

Figure 39.11: A: Lateral radiograph of volar proximal interphalangeal dislocation. B: Diagram showing how the boutonnière develops as the head of the proximal phalanx herniates through the extensor mechanism.

Usually, closed treatment will successfully reduce these dislocations:

- Reduce a palmar PIP joint dislocation with gentle traction on the middle phalanx with the MP and PIP joints flexed (34,146). Wrist extension may relax the extensor mechanism. In general, full passive extension of the joint is obtainable and postreduction radiographs should confirm congruous reduction of the joint.
- After reduction, test active PIP joint extension to determine the status of the central slip. With disruption of the central slip, the PIP joint should be splinted in extension for 4–6 weeks, either with smooth K-wire transfixed the joint or simply with an external splint.
- The DIP and MP joints should be permitted to move so that the extensor mechanism is less likely to become adherent. If the dislocation is irreducible or chronic (36,106,115,111), surgery is necessary.

Open Reduction of a Chronic Palmar PIP Joint Dislocation

- Make a straight dorsal or slightly curvilinear incision.
- Mobilize the lateral bands so that the head of the proximal phalanx is no longer caught between them.
- Reduce the joint, and transfixed it in extension with smooth 0.035–0.045 K-wire.
- Reattach the central slip to the base of the middle phalanx with nonabsorbable sutures to remaining periosteum, through bone holes, or with miniature suture anchors. Repair the interval between each lateral band and the central slip with nonabsorbable sutures. Postreduction radiographs should confirm congruous reduction of the joint.
- Remove the pin after 6 weeks, having allowed active motion at the MP and DIP joints during that time.

Complications The results of open reduction of a chronic palmar PIP joint dislocation tend to be poor, emphasizing the need for early recognition of the injury (28,34,38,41,106,110,146). If any or too early PIP flexion is allowed during the immobilization period, a boutonnière deformity will result. Treatment of the boutonnière deformity varies depending on the duration of the deformity (35,89).

PIP Joint Rotary (Irreducible) Dislocations

Irreducible rotary dislocation of the PIP joint, a complex volar-lateral dislocation, is an uncommon injury in which the middle phalanx is displaced laterally and palmarly (6,21,24,30,36,38,59,61,63,65,69,93,98,105,106,110,111,122,127,135,143). The injury occurs secondary to a combined rotatory and compressive force applied to the PIP joint. Clinically, the PIP joint is swollen and tender. The digit may be deviated and flexed. In contrast to the palmar PIP joint dislocation, for which passive extension is possible after reduction, there is resistance to active and passive flexion and especially to passive extension.

On the injured side of the joint, the collateral ligament is ruptured and the condyle of the proximal phalanx usually penetrates through a longitudinal rent between the lateral band and the central slip (Fig. 39.12). The lateral band is looped through the joint around the condyle, preventing reduction.
Figure 39.12. A longitudinal rent in the extensor mechanism produced by the condyle of the proximal phalanx (above probe) splits the central slip (held by forceps) from the lateral band (below probe). The band then loops around the condyle and through the joint, preventing reduction.

Radiographically, the lateral and palmar dislocation can be improved by closed reduction, but there will be a persistent subluxation and widening of the joint space on the side of injury (Fig. 39.13). Due to the rotatory nature of the injury, on a true lateral radiograph of the digit, one phalanx may appear slightly rotated relative to the other. This persistent subluxation of the joint usually must be treated surgically. Attempt closed reduction following digital block anesthesia, with gentle longitudinal traction and finger rotation (26,28,38,134). Flex the MP and PIP joints to relax the lateral bands, and extend the wrist to relax the extensor mechanism. Confirm congruous reduction with radiographs and test for active motion and active and passive stability. With incomplete active PIP joint extension, split the joint in full extension for 3–6 weeks.

Figure 39.13. AP radiograph showing persistent subluxation or widening on one side of the PIP joint.

Open Reduction of a Rotatory (Irreducible) PIP Joint Dislocation

- Make a mid-axial or dorsal curvilinear incision angled toward the injured side of the PIP joint. The condyle protruding between the central slip and the lateral band will be seen at once (Fig. 39.14).

- Remove the lateral band from the joint with a blunt instrument. The joint will promptly reduce.
- Repair the collateral ligament if disruption of the collateral ligament results in persistent joint instability or subluxation. If the lateral band is not badly damaged, repair the longitudinal rent in the interval between the lateral band and the central slip. If the lateral band is severely damaged, excise it.
- The remaining intact central slip and lateral band are sufficient to provide full extension of the finger (106). Intraoperative postreduction radiographs should confirm congruous reduction of the joint.
- After 5–7 days of immobilization in a cast dressing, start active motion, with the finger strapped to the adjacent finger to protect against reinjury. Protect the finger for 4–6 weeks.

Complications Complications from treating rotatory PIP joint dislocations are usually due to failure to diagnose the dislocation, causing a delay in treatment that results in a fixed flexion deformity (146). Incomplete joint reduction results from incomplete removal of the lateral band. Joint instability results from inadequate collateral ligament repair. Failure to adequately reduce the joint will result in a fixed flexion deformity. Late treatment consists of volar plate and collateral ligament release, excision of the lateral band, and reduction of the joint (106).

PIP Joint Fracture–Dislocations

Fracture–dislocation of the PIP joint is probably the most difficult fracture–dislocation to treat in the hand. As the middle phalanx displaces proximally and dorsally, the head of the proximal phalanx is driven into the palmar lip of the base of the middle phalanx. A comminuted depressed fracture usually results and can involve 70% or more of the articular surface. These injuries can be divided into stable and unstable fracture–dislocations (28,38). In stable fracture–dislocations, the volar lip fracture usually involves less than 40% of the articular surface. The dorsal portions of the collateral ligaments remain attached to the middle phalanx. With unstable fracture–dislocations the volar lip fracture involves more than 40% of the articular surface. The collateral ligaments usually remain attached to the volar lip fracture. Dorsal joint subluxation, which is difficult to reduce and to maintain by closed means, tends to occur with PIP joint extension.

Whenever possible, treat this injury closed with the dorsal extension-block splinting technique (26,41,52,131). Dorsal subluxation associated with volar lip middle phalangeal fractures can occasionally be reduced with PIP joint flexion. Always try this technique first, since it yields the best results if applicable (Fig. 39.15). The key to its usefulness is restoration of the joint alignment, not reduction of the fracture. If the fracture reduces also, this is a bonus.
Rubber Band Traction with an External Outrigger Device

Force-Couple Splint

Dynamic Skeletal Traction

Extension-Block Pinning

Dorsal Extension-Block Splinting

Use a padded hand-based aluminum splint or combine an aluminum splint with a short arm cast. With the latter technique, a padded aluminum splint loop is taped to a short arm cast over the top of the finger being tested (Fig. 39.16).

Extension-Block Pinning

Force-Couple Splint

Insert smooth K-wires transversely into the middle phalangeal base (Fig. 39.17B) and into the center of the proximal phalangeal head (Fig. 39.17C), parallel to the PIP joint articular surface.

Place a threaded K-wire in a dorsal to volar direction in the proximal half of the middle phalanx (Fig. 39.17D) and through the dorsal and volar cortices, being careful not to penetrate the flexor tendon.

On both sides of the finger, bend the distal K-wire proximally at 90° and pass it proximal and palmar to the proximal wire (Fig. 39.17E). Make a second 90° bend in the distal wire, 5–10 mm proximal to the proximal wire, and direct the wire dorsally or vertically (Fig. 39.17F). Bend a hook into the ends of the K-wire to retain a rubber band.

Connect the vertically oriented, threaded K-wire and the vertical arms of the distal K-wire with a rubber band, producing linkage, or a force couple (Fig. 39.17G). Bend the proximal wire outside of the distal wire.

Connect the vertically oriented, threaded K-wire and the vertical arms of the distal K-wire with a rubber band, producing linkage, or a force couple (Fig. 39.17H).

Place adhesive tape around the ends of the proximal K-wire to prevent the two ends of the wire from spreading apart (Fig. 39.17I).

Place a transosseous wire horizontally into the distal head of the middle phalanx and bend the wire distally on both sides of the finger at 90° angles.

The U-shaped component is looped over a circular 3- or 6-inch-diameter hand/forearm outrigger hoop splint.

Rubber Band Traction with an External Outrigger Device

Figure 39.15. Fracture–dislocation of the PIP joint. B: Joint reduced by flexion of the finger to 60° or more. The fracture reduction (anatomic here) is a bonus but is not necessary for a good result. C: Healed fracture–dislocation with good joint congruity.

The U-shaped component is looped over a circular 3- or 6-inch-diameter hand/forearm outrigger hoop splint.

Place a loop into the ends of the wire and connect with rubber bands, the ends of the wire to a sliding U-shaped thermoplastic component.

The wire prevents dorsal subluxation of the middle phalanx as seen on a lateral radiograph.

Place a transosseous wire horizontally into the distal head of the middle phalanx and bend the wire distally on both sides of the finger at 90° angles.

A true lateral radiograph of the digit will confirm that the joint subluxation is corrected.

Adjust the splint weekly by reducing the degree of PIP joint flexion by 25%, or approximately 10°. Take radiographs weekly to ensure that dorsal joint subluxation has not recurred.

If joint alignment cannot be restored by closed means, extension-block splinting should be abandoned and an alternative procedure used. These measures include extension-block pinning (135,138), skeletal traction or dynamic skeletal traction (2,3,17,22,55,97,105,115,119,121), dynamic hinged external fixation (48,49,66,74), open reduction and internal fixation (33,40,60,61,66,68,93,122,141,144,147,148 and 149), and volar plate arthroplasty (11,26,31,60,81,87).

Extension-Block Pinning

Figure 39.16. Extension-block splint.

Dynamic Skeletal Traction

Readers are advised to read the original articles for a detailed description of the skeletal traction techniques (2,3,17,55,97,105,119,121).

Force-Couple Splint

Use a small needle to identify the joint line (Fig. 39.17A).

Insert smooth K-wires transversely into the middle phalangeal base (Fig. 39.17B) and into the center of the proximal phalangeal head (Fig. 39.17C), parallel to the PIP joint articular surface.

Place a threaded K-wire in a dorsal to volar direction in the proximal half of the middle phalanx (Fig. 39.17D) and through the dorsal and volar cortices, being careful not to penetrate the flexor tendon.

On both sides of the finger, bend the distal K-wire proximally at 90° and pass it proximal and palmar to the proximal wire (Fig. 39.17E). Make a second 90° bend in the distal wire, 5–10 mm proximal to the proximal wire, and direct the wire dorsally or vertically (Fig. 39.17F). Bend a hook into the ends of the K-wire to retain a rubber band.

On both sides of the finger, bend the proximal K-wire at 90° in a palmar direction (Fig. 39.17G). Bend the proximal wire outside of the distal wire.

Connect the vertically oriented, threaded K-wire and the vertical arms of the distal K-wire with a rubber band, producing linkage, or a force couple (Fig. 39.17H).

Place adhesive tape around the ends of the proximal K-wire to prevent the two ends of the wire from spreading apart (Fig. 39.17I).

The force couple allows joint range of motion and is used to palmarly displace the middle phalanx and dorsally displace the proximal phalanx and thereby reduce dorsal subluxation of the PIP joint fracture–dislocation (2,3) (Fig. 39.17J).
The rubber band provides traction across the PIP joint. Use of the outrigger splint allows active finger flexion and extension (119, 121) (Fig. 39.18).

### Dynamic Hinged External Fixation

- Under fluoroscopic guidance or open visualization, place a K-wire horizontally into the proximal phalangeal head center axis of rotation.
- Place the centering hole of a hinged external fixator [e.g., the Compass PIP Hinge (Smith and Nephew Richards, Memphis, TN)] over the central axis pin (Fig. 39.19).

**Figure 39.19.** Placement of the hinged external fixator. From Jones BF, Stern PJ. Interphalangeal Joint Arthrodesis. *Hand Clinic* 1994;10:267.

- Place smooth K-wires initially through the proximal and then through the distal pin blocks in the mid-axial line of the digit. Hold the middle phalanx reduced during K-wire placement in the distal pin block.
- Apply joint distraction or passive joint motion, as needed, using a built-in distraction screw or worm gear mechanism (Fig. 39.20).

**Figure 39.20.** Application of joint distraction. From Jones BF, Stern PJ. Interphalangeal Joint Arthrodesis. *Hand Clinic* 1994;10:267.

### Volar Plate Arthroplasty

Open reduction and internal fixation of the palmar lip fracture is a demanding and often frustrating technique. If the fragment is sufficiently large and the fracture fairly fresh, however, internal fixation may provide reasonably good joint motion. Methods of fixation include K-wires, screw fixation, and intraosseous wiring.

Volar plate arthroplasty, as described by Eaton and Malerich (31), is an alternative that can be used for acute as well as chronic injuries. Advancement of the volar plate attempts to restore the impacted volar articular surface.

- Make a palmar zigzag incision over the PIP joint.
- Elevate the flexor sheath from the distal edge of the A2 to the proximal edge of the A4 pulley, protecting the digital arteries and nerves at all times.
- Retract the flexor tendons without damaging the vincula.
- Excise the remaining collateral ligaments connecting the proximal and middle phalanges (especially in chronic cases), and then open the joint by hyperextending it (like a shotgun) (Fig. 39.21).

**Figure 39.21.** PIP joint exposed by opening like a shotgun. From the bottom: Fracture fragment with attached volar plate, head of proximal phalanx, base of middle phalanx with defect from compression fracture.

- Debride small or loose fragments. If the fragment attached to the volar plate is large, fix it with fine smooth K-wire(s), screws, or an intraosseous wire to the middle phalanx, being careful to establish a smooth articular surface and a congruous joint reduction.
- Confirm congruous reduction of the joint with postreduction radiographs.
- More commonly, the volar plate fragment cannot be used. Dissect it free subperiosteally from the volar plate, retaining all possible length of the plate. Mobilize the volar plate as much as possible, leaving its proximal attachment intact, by freeing any restraining bands in the recess.
- Create a transverse trough in the middle phalangeal defect at the dorsalmost part of the cancellous defect, near the palmar margin of the remaining dorsal articular cartilage. The trough must be perpendicular to the long axis of the middle phalanx. Place drill holes at the lateral margins of the trough.
- Place a criss-cross, nonabsorbable suture (2-0 or 3-0 Prolene) in the distal volar plate, and pass the ends through the drill holes. To prevent tethering of the distal
extensor mechanism, flex the DIP joint 30° when passing the sutures dorsally.

- Reduce the PIP joint, and pull the volar plate into the trough with the joint flexed no more than 30° (Fig. 39.22). Tie the suture over a protected button dorsally.

Figure 39.22. A: View from palmar side of volar plate arthroplasty as sutures lead the distal edge of the volar plate into the trough at the base of the middle phalanx. B: Lateral view of volar plate arthroplasty, secured with the joint flexed.

- Confirm congruous reduction of the joint with intraoperative postreduction radiographs. Suture any remaining collateral ligament to the lateral margin of the volar plate.
- Transfix the joint with a smooth 0.035–0.045 K-wire with the joint in 20° to 30° of flexion.
- Immobilize the hand in a cast dressing. Remove the wire at 2 weeks, and encourage active flexion with use of an extension-block splint. Begin active extension at 4 weeks and extension splinting at 5 weeks if full extension is lacking. Motion may continue to improve for several months.

Complications Dorsal PIP joint fracture–dislocation complications are usually due to failure to treat the initial injury adequately or secondary to loss of reduction of the joint. Persistent joint dislocation can occur with closed treatment when the joint hinges instead of reducing congruously, or redislocation occurs with too rapid mobilization of the joint into extension. Redislocation can also result from inadequate reduction at surgery, or from failure of the pullout suture or of internal fixation. Angulation of the joint can occur secondary to asymmetrical impactation of the volar lip fragment or with oblique placement of the volar plate bone trough. Flexion contracture occurs with prolonged immobilization. Posttraumatic arthritis results from articular damage.

Treatment of complications includes joint contracture release, repeat open reduction and internal fixation, opening-wedge osteotomy and bone grafting, volar plate arthroplasty, and joint arthrodesis (27,38,64,140,146,149).

PIP Joint Lateral Dislocations—Collateral Ligament Injuries

Acute Collateral Ligament Ruptures Collateral ligament injuries are usually caused by an abduction or adduction force with the PIP joint in extension (91). The radial collateral ligament tends to be more commonly injured than the ulnar collateral ligament (42). Clinically, tenderness occurs over the site of injury, and joint laxity to lateral stress may be present. Most PIP joint collateral ligament injuries are incomplete and need only to be protected by strapping to an adjacent digit for 3–6 weeks (41,96). However, lateral dislocations of the PIP joint can result in complete, but uncommon, rupture of a collateral ligament and at least a portion of the volar plate (28,38). Angulation greater than 20° with lateral stress testing indicates a complete collateral ligament injury (34,68,95) (Fig. 39.94).

Treatment of complete collateral ligament injuries is controversial. After closed reduction, assess stability of the joint by active motion and confirm joint congruency on radiographs. Acutely, use a temporary splint for comfort, followed by strapping to an adjacent digit for 3–4 weeks, encouraging full active motion. Repair of the collateral ligament has been described (4,13,16,60,81 and 62,91,84,113,116), but joint stiffness is a problem. The index radial collateral ligament is probably the only ligament that needs early surgery (41,65,94).

Open Repair of Acute Collateral Ligament Ruptures

- Make a radial mid-axial incision.
- Divide the transverse retinacular ligament, reflect it, and retract the radial lateral band dorsally.
- Identify and repair the torn collateral ligament. The stump usually is still attached at the middle phalanx and is repaired with nonabsorbable sutures.
- If no residual stump is present, roughen the bone and drill parallel holes obliquely across the phalanx. Pass a nonabsorbable suture, using a modified Bunnell suture technique, through the torn edge of the ligament. The two suture ends should be passed through the holes in the bone and out through the skin. Tie the suture over a protected button with the joint reduced and the ligament pulled taut. Miniature suture anchors can be used instead of a transosseous pullout suture technique (Fig. 39.23).

Figure 39.23. Miniature suture anchors can be used instead of a pullout suture technique to repair the collateral ligament.

- Repair the accompanying partial tear of the volar plate as well.
- Repair the retinacular ligament, close the skin, and confirm congruous reduction of the joint with radiographs.
- Splint the digit in no more than 20° of PIP joint flexion for 5–7 days and then start active motion with adjacent finger-strapping for an additional 2–3 weeks.

Chronic Collateral Ligament Ruptures Chronic collateral ligament injuries are rarely sufficiently symptomatic to require reconstruction. Often, there are degenerative changes in the joint, and ligament reconstruction cannot be expected to alleviate symptoms due to arthritis. Once again, if reconstruction of a chronic PIP collateral ligament rupture is necessary, it is on the radial side of the index finger.

Reconstruction of the collateral ligament can be done by shortening or imbricating the remaining ligament or by augmenting the repair, usually with a slip of the superficialis (78,91,104,113).

Open Repair of Chronic Collateral Ligament Ruptures

- Make a surgical approach similar to that made for the acute collateral ligament injury.
- Identify the ligament and dissect it free. Imbricate it in its midportion, or shorten it and suture it with a nonabsorbable suture at the proper length.
- If further reinforcement is needed, separate the radial slip of the superficialis, leaving it attached distally detaching it proximally. Pass the tendon through a drill hole in the head of the proximal phalanx with a pullout suture and tie the suture over a protected button on the ulnar side of the proximal phalanx.
- Alternatively, pass the superficialis through two holes drilled on the proximal aspect of the proximal phalangeal head and suture the tendon to itself. Spread out the tendon dorsally and suture its radial (now dorsal) edge to the remaining fibers of the collateral ligament.
- Close the wound as previously described. After 10 days of immobilization in no more than 20° of flexion, encourage the patient to actively exercise with strapping to the adjacent long finger for an additional 4–5 weeks.

Complications Complications in the treatment of lateral PIP joint dislocations usually occur from inadequate initial treatment, and they are frequently an expected outcome of the injury, even with adequate treatment. Pain, instability, loss of motion, and arthrosis can occur from incomplete joint reduction, lateral translocation, or
uneven forces within the joint secondary to excessive scarring (146).

Late reconstruction cannot be expected to produce a perfectly stable joint. Potential problems of ligament reconstruction include joint stiffness or persistent laxity.

**PIP Joint Volar Plate Ruptures (Swan-Neck or Hyperextension Deformity)**

Volar plate ruptures of the PIP joint can result from a dorsal PIP joint dislocation or hyperextension injury (type 1 dorsal PIP joint dislocation). The volar plate usually detaches distally from the middle phalanx, with or without a piece of bone. If the volar plate ruptures distally with a small fragment of bone (as seen on the lateral radiograph), the joint is inevitably incongruous. This injury must be differentiated from the serious PIP joint fracture–dislocation. Treat the minor volar plate fracture as any other volar plate injury, with protection against hyperextension by either a temporary dorsal-block digital splint or by strapping to an adjacent finger for 3 weeks. Encourage full flexion.

Chronic volar plate ruptures can result in a swan-neck deformity with dorsal subluxation of the lateral bands. Painful flexion of the PIP joint can occur as the lateral bands sublux palmarly over the proximal phalangeal condyles. Distinguish this swan-neck deformity from the type of swan-neck deformity secondary to an extensor terminal tendon disruption (mallet finger). With volar plate insufficiency, the patient will be able to actively extend the DIP joint with the PIP joint held in full extension. Nonoperative treatment includes use of a orthoplast or silver (double-ring) splint to help prevent PIP joint hyperextension (Fig. 39.24). Symptomatic volar plate ruptures (Fig. 39.25) can be helped by surgical correction. Options include late reattachment or shortening of the volar plate, with or without some form of volar reinforcement (1,7,12,22,27,78,91,104,109,132,136,144).

![Figure 39.24. Silver ring (or double-ring) splint used for swan-neck deformity to prevent hyperextension at the PIP joint. The splint can be padded if it irritates the dorsum of the digit.](image)

**Open Repair of Chronic Volar Plate Ruptures**

- Make a palmar zigzag incision and release the flexor sheath between the A2 and A4 pulleys.
- Protect the digital vessels and nerves while retracting the flexor tendons to expose the volar plate. If it has been ruptured in midsubstance and repair is possible, suture the edges directly.
- More often, it will be detached distally (Fig. 39.26A). In that case, roughen the base of the middle phalanx and create a transverse trough. Place a nonabsorbable suture in the distal end of the volar plate with a modified Bunnell suture technique. Place drill holes at the lateral margins of the trough in a distal but somewhat lateral direction so that the extensor mechanism will not be injured or trapped by the passing of the pullout suture. Pass the ends of the suture from the volar plate through the drill holes, and tie them over a protected button. To prevent tethering of the distal extensor mechanism, flex the DIP joint 30° when passing the sutures dorsally. As the suture is tied, flex the PIP joint. Apply gentle traction on the suture so the distal end of the volar plate is pulled snugly into the trough (Fig. 39.26B).

![Figure 39.26. A: Volar plate rupture usually occurs distal from the base of the middle phalanx. B: The distal margin of the volar plate is pulled snugly into a trough in the middle phalanx and secured through drill holes in the bone.](image)

- If there is not enough of the volar plate left to advance or repair, a volar reinforcement procedure can be used. With this technique, isolate either slip of the superficialis. Leave it attached distally and detach it proximally under the A2 pulley.
- Place a drill hole transversely in the neck of the proximal phalanx. Draw the proximal end of the detached superficialis slip into the hole, using a pullout nonabsorbable suture, and tie it over a protected button (Fig. 39.27). Take care to ensure that the superficialis slip is taut when the PIP joint is in 10° to 15° of flexion.
One superficialis slip is fixed to the proximal phalanx, creating a tenodesis of the PIP joint. Temporarily fix the joint with a 0.035–0.045 smooth K-wire for 3 weeks, and then protect it with a dorsal-block splint for an additional 4 weeks.

**Complications**

The complications associated with treating volar plate ruptures are the same as for dorsal PIP joint dislocations. Operative repair for chronic volar plate ruptures, as for any ligament repairs or reconstructions, can lead to some loss of motion and chronic thickening. A flexion deformity is common.

**METACARPOPHALANGEAL JOINT**

**Assessment and Indications for Treatment**

Metacarpophalangeal joint injuries are frequently associated with an injury to the volar plate, collateral ligament, and joint articular surface, which require adequate assessment and AP, lateral, and oblique radiographs of the hand (Table 39.3). A Brewerton view or oblique view of the metacarpal heads may be helpful to identify small fractures (see the section above on General Principles of Treatment) (171,185,198). Open dislocations require adequate debridement and antibiotics.

**Table 39.3. Algorithm for Assessment of Metacarpophalangeal (MP) Joint Injuries**

Injuries to the ligaments and dislocations of the MP joints are uncommon. Most of these occur with the fingers in some extension when the collateral ligaments are more lax. This provides some margin for protection so that complete ligament rupture is unusual. The most common mechanism of injury is hyperextension or ulnar deviation of the joint. The most commonly involved joint is the index finger, followed by the thumb and little finger. Central digit dislocations are usually associated with dislocation of either the adjacent index or little finger (42,151,153,154,156,170,177,186,187,188,195,200,202,211,212,216).

Metacarpophalangeal joint injuries are classified as dislocations or collateral ligament injuries. The dislocations are based on the direction of the dislocation (dorsal versus volar) and whether they are easily reducible (simple) or irreducible without surgical intervention (complex).

**Dorsal MP Joint Dislocations**

With a hyperextension injury to the MP joint, the membranous portion of the volar plate usually ruptures off the metacarpal neck. Dorsal MP dislocations can be classified as simple (subluxation) or complex dislocations (165,172,174). Simple MP joint dislocations are easily treated by closed reduction. Take care not to convert a simple dislocation into a complex dislocation (165,172,176,383). With simple MP joint dislocations, the proximal phalanx is hyperextended on the metacarpal head, but some contact remains between the MP joint articular surfaces. The proximal edge of the volar plate lies palmarward over the metacarpal head. Therefore, the base of the proximal phalanx should be pushed distally and palmarly. If hyperextension with traction is mistakenly used, the volar plate can slip dorsally over the metacarpal head and prevent reduction.

Interposition of the volar plate between the metacarpal head and the base of the proximal phalanx makes this complex dislocation irreducible (153). The lumbral medially and the flexor tendon laterally around the metacarpal neck prevent reduction of the dislocation by longitudinal traction only (Fig. 39.28) (175). With a complex dislocation of the little finger, the structures preventing reduction include the abductor and flexor digiti minimi ulnarily and the lumbral and flexor tendon radially (154).

**Figure 39.28.** The factors producing a complex dorsal MP joint dislocation (see text for details). (From Kaplan EB. Dorsal Dislocation of the Metacarpophalangeal Joint of the Index Finger. J Bone Joint Surg 1957;39A:1081, with permission.)

Clinically, the joint is slightly hyperextended, with the phalanx appearing parallel to the metacarpal with a tendency for the digit to overlap its neighbor (Fig. 39.29). On the palmar surface, the skin is puckered or dimpled. Radiographically, the joint space is widened, the joint surfaces are offset, and the sesamoid appears to lie within the joint (Fig. 39.30) (163,173,201,208).
The phalanx can occur, producing a complex dislocation (from the proximal phalanx, or collateral ligament avulsion, can occur (Palmar MP joint dislocations are rare (inappropriate skin incision. Redislocation can occur if hyperextension is not prevented, and loss of joint motion can occur with prolonged immobilization.

Complications

In treating dorsal MP joint dislocations may result either from a delay in treatment or from overly aggressive treatment. Damage to the articular surfaces can occur with repeated attempts at a closed reduction or secondary to a forceful open reduction. Traction and hyperextension of the digit can possibly convert a simple MP joint dislocation into a complex dislocation.

Loss of joint motion and degenerative arthritis may occur with delayed reduction. A combined volar and dorsal approach and collateral ligament release may be needed to properly reduce a longstanding dislocation. Injury to the neurovascular bundles can occur in the palmar approach with an inappropriate skin incision. Redislocation can occur if hyperextension is not prevented, and loss of joint motion can occur with prolonged immobilization.

Palmar MP Joint Dislocations

Palmar MP joint dislocations are rare. Avulsion of either the dorsal capsule from the metacarpal proximally or the volar plate from the proximal phalanx, or collateral ligament avulsion, can occur . Interposition of these structures between the metacarpal head and proximal phalanx can occur, producing a complex dislocation . If an attempt at a closed reduction under adequate anesthesia is unsuccessful, an open reduction is
These injuries are frequently associated with metacarpal shaft fractures and soft-tissue injuries \((164,181)\). Clinically, tenderness is present over the injured ligament, and stress testing (passive radial/ulnar deviation) with the MP joint flexed produces pain. Obtain radiographs, including oblique and Brewerton views \((171,185,189,206,213)\), to identify avulsion fractures. Stress views with the MP joint in full flexion may help confirm a ligament tear \((215)\). Arthrography has been used to identify the location of the collateral ligament injury \((164,181)\). The collateral ligament is avulsed off the metacarpal head most commonly but can also be torn distally or in midsubstance \((185,196,213)\).

Initial treatment usually consists of immobilization with the MP joints flexed 30° to 50° for 3 weeks, followed by taping the finger to the adjacent digit for an additional 3 weeks \((164,172,174)\). Surgery is advocated for gross instability of the joint \((60,61,164,181,205,217)\), an associated displaced avulsion fracture (displaced 2 or 3 mm), or a displaced or rotated avulsion fracture involving 20% or more of the articular surface \((174)\). With persistent joint instability, late reconstruction has been advocated \((164,196,178)\).

**Operative Repair of MP Joint Collateral Ligament Injuries**

**Acute Collateral Ligament Ruptures**

- Make a longitudinal incision in the dorsum of the web space on the affected side of the digit.
- Incise and retract the transverse fibers of the extensor hood. Incise the joint capsule dorsal to the collateral ligament parallel to its dorsal margin. Dissect and mobilize the ligament.
- If there is an attached avulsion fracture of adequate size attached to the ligament, reduce and fix the bone fragment with one or two smooth 0.035 K-wires \((Fig. 39.32)\).

**Figure 39.32. A: A displaced articular fracture usually is attached to the collateral ligament. B: K-wire fixation of the displaced fracture often must be done by placing the wire in the phalanx first.**

- If the fragment is too small, place a pullout suture around it. Place a drill hole obliquely connecting the cortex on the opposite side of the phalanx to the site of the intended ligament attachment. Place the pullout suture through this hole and over a protected button.
- Close the transverse fibers of the hood and skin in layers and check for congruous reduction of the joint and adequate alignment of the fracture fragment with radiographs.
- Immobilize the hand with the MP joints flexed to 45° for 3 weeks and protected by taping the finger to the adjacent digit for another 3 weeks.

**Complications** Complications in treating MP joint collateral ligament ruptures are usually due to undertreatment of the injury. They include residual pain, joint swelling, instability (index finger with pinch), and deviated digit (abducted little finger) \((166,179,186,213)\).

Repairing or reconstructing the collateral ligament too tightly (i.e., collateral ligament repair with the joint held in extension) will result in a loss of joint motion.

**Carpometacarpal Joint**

**Assessment and Indications for Treatment**

Carpometacarpal joint dislocations are frequently associated with intraarticular fractures, so adequate assessment of the articular surfaces is needed with true AP, lateral, and oblique pronated radiographs of the hand \((Table 39.4)\). Occasionally, tomography or a CT scan may be helpful to identify small fractures. Open dislocations require adequate debridement and antibiotics.

**Table 39.4. Algorithm for Assessment of Carpometacarpal (CMC) Joint Injuries**

**Dislocations and Ligamentous Injuries**

Dislocations and ligamentous injuries of the CMC joints are virtually synonymous and will be considered together. Due to the inherent stability of the CMC joints, which are further strengthened by strong surrounding ligaments, pure CMC joint dislocations are uncommon; fracture-dislocations of the CMC joints are much more common.

The most common site for subluxation or dislocation is at the base of the fifth metacarpal \((221)\). The fifth and fourth metacarpals may dislocate together, or all four may do so \((221)\). Often, an intraarticular fracture is associated with dislocation of the CMC joint \((60,61,221,222,228,230,231,243,251,252\) and \(263,266,269,269,273,274,275\) and \(276,278,279\) and \(280\)).
Evaluation of AP, lateral, and oblique radiographs reveals the injury (240). A 30° pronated lateral view, which places the fourth and fifth CMC joints in profile, will help in diagnosing dislocations or fracture–dislocations of these joints (221,232,233,250). Tomography or CT scan can be used to further delineate the injury or help diagnose occult fractures (250).

For dislocations without fracture, treatment options include a closed reduction, closed reduction and percutaneous K-wire fixation, and open reduction internal fixation of the dislocation (229,236,239,244). Closed reduction is usually possible.

- With adequate analgesia, apply longitudinal traction to the involved digit(s). Apply pressure over the dorsal base of the dislocated metacarpal in a distal and volar direction, then extend the metacarpal to help reduce the dislocated joint. Occasionally, closed reduction will fail because of interposed soft tissues or chondral fragments.
- If the reduction is successful, immobilize the hand with the wrist extended, the MP joints flexed, and the IP joints extended for 3–4 weeks.
- The CMC joint(s) must be frequently evaluated for redislocation. Because of the possibility of redislocation, closed reduction with percutaneous pinning is preferable (227,228) and (229,236,239,247,259,271).
- Transfix the metacarpal to the appropriate carpal or an adjacent stable metacarpal. Small associated fractures with some articulaur incongruity are unimportant (270).

If redislocation occurs, closed reduction fails, or a substantial intraarticular fracture is present and remains significantly displaced after a closed reduction, do an open reduction. Chronic dislocations usually require open reduction and internal fixation. Extensive dissection with excision of scar tissue may be necessary to achieve reduction. If symptomatic posttraumatic arthrosis is present, a resection or resection–interposition arthroplasty is useful, and an arthrodesis remains an option (220,221,222,223,224,225,226,227,228,229,230,231,232,233,234,235,236,237,238,239,240,241,242,243,244,245,246,247,248,249).

Open Reduction of a CMC Dislocation

**Acute CMC Dislocation**

- Make a dorsal longitudinal or oblique incision over the affected joint. Protect the dorsal sensory nerve branches and veins.
- Incise and reflect the scarred ligaments by subperiosteal dissection. Perform an open reduction of the joint if the joint surfaces are preserved. Confirm proper position with radiographs.
- If arthrosis is present, resect the proximal 1 cm of the base of the metacarpal. A tendon anchovy or a portion of the joint capsule may be interposed in the area of the resected metacarpal. Repair the dorsal ligaments and close the skin. Use K-wire fixation if the joint is unstable. Splint the hand for 3–4 weeks, but permit early finger motion.

If a CMC arthrodesis is used instead of arthroplasty, take care to preserve the transverse metacarpal arch by fusing the fourth and fifth metacarpals in some flexion.

**Complications** A delay in diagnosis or treatment of CMC dislocations may result in chronic CMC dislocation and subsequent arthrosis (281). Undertreatment may result in a redislocation of the CMC joint following closed reduction alone or secondary to premature removal of fixation wires.

Injury of sensory nerves is common, so care in protecting them is imperative. Improper pinning of metacarpals to adjacent metacarpals can lead to a “pancake” hand from flattening of the transverse metacarpal arch. Posttraumatic arthritis can occur with poor surgical alignment of the carpometacarpal or intermetacarpal joints.

**THUMB**

**ANATOMY**

The anatomy of the joints of the thumb is somewhat different from that of the other digits. Like the finger MP joint, the thumb MP joint is a condyloid joint allowing for flexion–extension and abduction–adduction. The amount of thumb MP joint flexion varies widely, ranging from 5° to 115° (355). Variable amounts of MP joint hyperextension can also occur, ranging up to 45° (average 8°) (285). The amount of MP joint abduction–adduction is less in the thumb than in the fingers (0° to 20°, average 10°) (285). A slight difference in the shape between the proximal phalangeal condyles produces a slight amount of pronation of the thumb with MP flexion (285,308,373).

Like the finger PIP joint, the thumb MP joint is supported by strong collateral and accessory collateral ligaments as well as a volar plate. The adductor pollicis inserts into the radial sesamoid bone located within the volar plate, as well as the proximal phalanx. The abductor pollicis brevis and flexor pollicis brevis insert into the radial sesamoid, also located within the volar plate. Additionally, the adductor and abductor pollicis brevis tendons have an insertion or expansion into the extensor aponeurosis (328,370,371,376). Further support to the MP joint is provided by extensor pollicis longus and brevis tendons associated with the dorsal MP joint capsule and the flexor pollicis longus tendon, overlying the volar plate and sesamoids, volarly. Stability is therefore provided by both static and dynamic restraints.

The trapeziometacarpal joint consists of two saddle surfaces in apposition (Fig. 39.33) (287,389,391,392,393 and 394,406). The longitudinal axes of each joint surface are oriented perpendicular to one another, allowing flexion–extension, abduction–adduction, and some pronation–supination (389,390,395). An elongated volar lip of the thumb metacarpal provides an attachment site for the volar metacarpal ligament to the tubercle of the trapezium. Although it has a relatively loose capsular support, thickenings in the joint capsule help provide joint stability. Four ligaments have been frequently cited as the main stabilizers of the CMC joint: the volar or anterior oblique (palmar trapeziometacarpal) ligament, the dorsal (posterior) oblique ligament, the dorsoradial ligament, and the intermetacarpal ligament (386–387,389,392,399,402,404,406,408,409,411). Tubercles on both the metacarpal and trapezium serve as attachment sites for these ligaments (Fig. 39.33).

THUMB METACARPOPHALANGEAL JOINT

Assessment and Indications for Treatment

The assessment and indications for treatment are similar to those of the MP joint of the fingers. Thumb MP joint injuries are frequently associated with collateral ligament and volar plate injuries, as well as an occasional intraarticular fracture.

Injuries to the ligaments and dislocations of the thumb MP joint are common and consist of dislocations, collateral ligament injuries, and volar plate ruptures. The dislocations are based on the direction of dislocation of the phalanx (dorsal versus volar) and whether they are easily reducible (simple versus complex).

Thumb MP Joint Dislocations

Dislocations of the MP joint usually are dorsal, resulting from hyperextension, and can be treated closed (296,299,308,309). The dislocation results in a complete tear of the volar plate proximally and usually of a portion of the collateral ligaments (377). Dorsal subluxation of the MP joint can occur with less severe hyperextension injuries (324). Volar MP dislocations are not as common (313,322,344,349,383). Clinically and radiographically, hyperextension of the MP joint is noted. Widening of the joint space is suggestive of soft-tissue interposition. Interposition of the sesamoids between the metacarpal head and the base of the proximal phalanx is highly suggestive of a complex MP joint dislocation.

- Perform closed reduction of the dislocated joint under adequate analgesia with the wrist and IP joint flexed to relax the flexor tendon.
- Avoid longitudinal traction and hyperextension of the thumb MP joint, and push the base of the proximal phalanx distally and palmarly.
- Confirm congruous reduction of the joint on radiographs and test for active and passive joint stability. Test for collateral ligament stability and treat accordingly (see sections below on collateral ligament ruptures).
- Occasionally, dorsal dislocations may prove to be irreducible because of interposition of the volar plate or other structures (e.g., sesamoid, flexor pollicis longus) between the base of the proximal phalanx and the head of the metacarpal (296,301,310,312,323,329,341,343,354). When this situation is present, do an open reduction. Volar (322,341), dorsal (160,301), and lateral (353) approaches to the MP joint have been advocated.

Open Reduction of an Irreducible Thumb MP Joint Dislocation

- Make a chevron-shaped incision on the radial aspect of the joint, bringing the apex of the incision somewhat palmarly. Take care to not injure the digital nerves, especially the radial.
- Partially release the proximal flexor tendon pulley and retract the flexor pollicis longus.
- Make a longitudinal incision between the radial collateral ligament and the edge of the volar plate. Place a stiff-angled probe or a skin hook behind the volar plate, extricate it from the joint, and allow the joint to reduce.
- Repair the ligament, if needed, either directly or using pullout suture technique.
- Close the skin. Confirm congruous reduction of the joint with radiographs. After initial immobilization for comfort for a few days, begin motion using an extension-block splint for 3–4 weeks.

Thumb MP Joint Ulnar Collateral Ligament Ruptures

Ulnar collateral ligament ruptures of the MP joint, also referred to as gamekeeper's thumb and skier's thumb, are common injuries (289,295,296,304,305,329,343,349,381,368,371). The mechanism of injury includes forceful abduction or radial deviation of the thumb proximal phalanx. Other injured structures may include the volar plate, the dorsal MP joint capsule, and the adductor aponeurosis, or there may be an avulsion fracture of the proximal phalanx (289,293,296,304,305 and 306,322,327,329,333,340,343,347,357,362,371,375,378,379).

A Stener lesion (376) occurs when there is interposition of the adductor aponeurosis between a completely avulsed ulnar collateral ligament (avulsed from the proximal phalanx) and the proximal phalanx ligament insertion site, or between two ends of a midsubstance ligament tear (Fig. 39.34). Interposition of the adductor aponeurosis interferes with healing of the ulnar collateral ligament. Complete ligament avulsion is needed to produce a Stener lesion; therefore, differentiating the complete from partial ligament avulsion injury is necessary to diagnose a Stener lesion. The reported incidence of a Stener lesion occurring with an acute ulnar collateral ligament rupture varies with different series, but it ranges from 14% to 83% (311).

![Figure 39.34. The ulnar aspect of the metacarpophalangeal joint of the right thumb. After distal rupture, the ulnar collateral ligament has been folded right over. The torn end sticks out proximal to the adductor aponeurosis (shown divided in the lower picture). (From Stener B. Displacement of the Ruptured Ulnar Collateral Ligament of the Metacarpophalangeal Joint of the Thumb. A Clinical and Anatomic Study. J Bone Joint Surg 1962;44B:869, with permission.)](image)

There is painful swelling of the MP joint with localized tenderness over the region of the ulnar collateral ligament, with instability when gently applying radial stress to the thumb MP joint (289,296,299,304,311,356,371,378). If there is no end point of resistance and angular deformation is more than 30° compared to the uninjured thumb (Fig. 39.35), a complete ulnar collateral ligament rupture is likely (289,304,318,355,356,372). Perform the test with the MP joint in full extension and at 30° of flexion. Palpation of the end of the ruptured collateral ligament is difficult, but it confirms a complete ligament rupture (282). Local or nerve-block anesthesia may be helpful in testing the collateral ligament if there is significant pain or muscle spasm (289,304,311,329,340,347,356,357,358).

![Figure 39.35. Complete instability to radial stress of the MP joint of the thumb. (From Neviaser RJ, Wilson JN, Lievano A. Rupture of the Ulnar Collateral Ligament of the Thumb—Correction by Dynamic Repair. J Bone Joint Surg 1971;53A:1367, with permission.)](image)
Adductor Pollicis Advancement for Chronic Thumb Ulnar Collateral Ligament Injury (Neviaser Technique)

Repair of a Chronic Thumb Ulnar Collateral Ligament Injury (Neviaser Technique)

- Use the approach for the acute collateral ligament injury. Protect the digital nerves dorsally and palmarly (Fig. 39.38).
Isolate and detach the major tendon of insertion of the adductor pollicis. Leave enough tendinous tissue to accept a pullout suture.

- Mobilize a broad, proximally based, U-shaped flap on the metacarpal. Drill a biconical hole in the ulnar midaxial line of the proximal phalanx, 10–12 mm distal to the joint. Enlarge the opening on the ulnar side of the proximal phalanx to accept the adductor tendon.

- With the joint reduced, imbricate or advance the flap of scarred collateral ligament and suture it to the residual soft tissue at the phalangeal base with a nonabsorbable suture.

- Place a nonabsorbable modified Bunnell suture in the adductor tendon and pass it through the proximal phalanx to exit percutaneously on the radial side. With the thumb adducted, tie the suture over a protected button, making sure the adductor tendon is pulled well into the ulnar hole of the phalanx.

- Repair the aponeurosis and skin separately and immobilize the thumb in a spica cast for 4 weeks. Then begin protected motion in a removable custom splint for another 2–3 weeks. Remove the button and pullout suture at 5–6 weeks. Avoid forceful stressing of the ligament reconstruction for 3 months (351).

Free Tendon Graft for Chronic Thumb Ulnar Collateral Ligament Injury (Smith Technique)

- Use the approach for the acute collateral ligament injury (Fig. 39.39).

Drill a hole transversely, in a radial to ulnar direction, along the base of the proximal phalanx just distal to the articular surface.

- Place the hole volar to the axis of joint motion. Place a suture in the end of the free tendon graft and pass it through the proximal phalanx to exit percutaneously on the radial side, pulling the tendon through the ulnar hole. Tie the suture over a protected button.

- Alternatively, create two holes on the ulnar side of the base of the proximal phalanx, one dorsally and one volar to the axis of motion. Connect the holes within the medullary canal and enlarge them so that a free tendon graft (palmaris or long toe extensor) can be placed through them.

- Pull the remaining portion of the free tendon graft to the metacarpal head. Make parallel longitudinal incisions in the remnant of the collateral ligament. Secure the tendon graft, with nonabsorbable sutures, to the metacarpal head by weaving the graft through the ligament.

- Alternatively, place two holes in the ulnar side of the metacarpal head, one dorsal and one volar. Pass the tendon graft between the two holes and through an intramedullary tunnel. Pass the remaining portion of the tendon graft distally back on itself, parallel and volar to the other limb of the tendon graft. Suture the two limbs of the tendon graft to one another. Repair and imbricate, if needed, the adductor aponeurosis to the extensor mechanism and then close the skin (371).

Extensor Pollicis Brevis Tendon Transfer for Chronic Thumb Ulnar Collateral Ligament Injury (Sakellarides Technique)

- Use the approach for the acute collateral ligament injury (Fig. 39.40).

- Transversely incise the scarred collateral ligament and create proximal and distal flaps.

- Dissect and mobilize the extensor pollicis brevis. Detach either half or all of the tendon distal to the MP joint, leaving it proximally based.

- Drill two holes, one dorsally and one medially, in the base of the proximal phalanx. Place a nonabsorbable modified Bunnell suture in the extensor pollicis brevis tendon and pass it through the dorsal hole, exiting medially. Suture the end of the tendon to the remaining proximal stump of collateral ligament. If no proximal metacarpal ligament stump is available, use a pullout suture technique. Repair and imbricate any remaining portion of the collateral ligament.

- Repair the adductor aponeurosis to the extensor mechanism and close the skin. Stabilize the MP joint with a K-wire, if needed (398).

Complications A delay in diagnosis or treatment of thumb MP joint ulnar collateral ligament injuries can result in chronic MP joint instability with pain, loss of pinch strength, and, with time, arthrosis (336,392).

With surgical repair or reconstruction, sensory nerve injury and web space contractures can occur. A loose ligament repair may leave a lax joint. Loss of joint motion is common following ligament repair or reconstruction. Residual pain can persist from unappreciated joint arthritis.

Thumb MP Joint Radial Collateral Ligament Ruptures

Injury to the radial collateral ligament of the MP joint is less common than its ulnar counterpart (294,331,333,346,371) and is usually caused by forceful adduction, ulnar deviation, or torsion of the thumb proximal phalanx. The radial collateral ligament can be avulsed from either the base of the proximal phalanx or the metacarpal head, or it can be attenuated in its midportion (294,300,371). The dorsal joint capsule may also be torn. The thumb often lies in ulnar deviation and slight pronation, a finding confirmed by radiographs (Fig. 39.41). Without a radial collateral ligament to provide stability, the proximal phalanx is deviated ulnarily by the strong pull of the adductor...
Volar Plate Capsulodesis for a Thumb MP Joint Hyperextension Injury

arthrodesis if arthritic changes are present.

For patients with chronic hyperextensibility at the MP joint, pain and weakness can occur with grasping or pinching (294-310). Treat partial radial collateral ligament injuries in a thumb spica cast with the thumb in a reduced position for 4 weeks. Unfortunately, these injuries usually are not recognized until found in the chronic state. As with the ulnar collateral ligament, treatment options include direct ligament repair (304-343,371), reeling or imbrication of the scarred collateral ligament or reattaching a remnant of scarred tissue to the proximal phalanx (294,310), free tendon grafting (291-307,371), or MP fusion. If there is posttraumatic arthritis, do an arthrodesis. If the joint is not arthritic, use the following reconstruction (350,351).

Repair of a Tear of the Thumb Radial Collateral Ligament

Acute Thumb MP Joint Radial Collateral Ligament Injury

- Make a chevron incision on the radial side of the MP joint, protecting the dorsal radial sensory nerve.
- Divide the abductor pollicis brevis aponeurosis just radial to its insertion into the extensor tendon, and reflect it for later repair. Repair the ligament either in midsubstance or to either the proximal phalanx or metacarpal head, depending on the area of injury. If the ends of the torn ligament are identifiable, divide the capsule and ligament transversely and imbricate them. Repair any capsular and extensor mechanism tears.
- Close the skin separately. Stabilize the joint with a K-wire fixation if there is residual joint instability. Postoperative treatment is similar to that for ulnar collateral ligament tears.

Chronic Thumb MP Joint Radial Collateral Ligament Injury

- Use the approach for the acute collateral ligament injury. Detach the tendon of the abductor pollicis brevis with sufficient length to hold a suture.
- Create a proximally based, U-shaped flap of scarred radial collateral ligament mass.
- Drill a bicortical hole about 10–12 mm distal to the joint. Enlarge the radial hole with a curet.
- Imbricate or reef the ligament flap with the joint reduced. Pass a nonabsorbable suture through the abductor pollicis brevis tendon using a modified Bunnell suture technique. Pass both ends of the suture through the drill hole in the proximal phalanx and out through the skin on the ulnar side. Tie the suture over a protected button, making sure the tendon fits snugly in the radial hole (Fig. 39.42).

Complications Complications in treating thumb MP joint radial collateral ligament injuries are the same as those listed under ulnar collateral ligament tears described earlier.

Volar Plate Ruptures

Acute hyperextension injuries of the thumb MP joint are common and can be diagnosed by eliciting tenderness over the volar plate and detecting hyperextension of this joint (with the IP joint flexed) compared to the opposite thumb (311,377). Unlike the finger PIP joints, the volar plate detachment occurs proximally from the metacarpal. Treat with dorsal-block splinting (restricting the last 20° of extension) for 4 weeks.

For patients with chronic hyperextension at the MP joint, pain and weakness can occur with grasping or pinching (311,361,362). For patients failing nonoperative measures, the operative options for chronic MP joint instability include a volar plate capsulodesis (343,384), tenodesis (302,330), dynamic tendon transfer (361), or arthrodesis if arthritic changes are present.

Volar Plate Capsulodesis for a Thumb MP Joint Hyperextension Injury

- Make a palmar zigzag incision and retract the digital arteries and nerves.
- Incise the A1 pulley in its proximal portion and retract the flexor pollicis longus. Incise the intervals between the sides of the volar plate and the accessory collateral ligaments. Release the distally based volar plate proximally and excise the sesamoids subperiosteally.
- Using an osteotome or a dental chisel, create a transverse trough in the metacarpal neck. Drill a hole through each edge of the trough obliquely through the metacarpal. Perform a trial reduction of the proximal edge of the volar plate into the trough. When the plate is properly seated, passive extension of the MP joint should be limited to 15° of flexion. If less flexion is evident, trim a portion of the free edge of the volar plate and recheck the position of the MP joint.
- Weave a nonabsorbable suture through the free proximal edge of the plate, using a modified Bunnell technique. Pass the suture ends through the drill holes and the skin and tie over a protected button, thereby drawing the volar plate securely into the trough.
- An alternative, but more difficult, method includes creating a synostosis between the sesamoids and metacarpal neck to produce a 15° to 20° flexion deformity of the MP joint. Transfix the joint with a smooth K-wire to maintain the joint position.
- Suture the accessory collateral ligaments to the edges of the volar plate with 5-0 nonabsorbable suture and close the skin.
- Use a plaster thumb spica splint for 4 weeks, allowing IP joint flexion at 1 week. Remove the splint and pin at 4 weeks. Begin exercises with an extension-block
Complications Complications in treating thumb MP joint hyperextension injury include joint stiffness with prolonged joint immobilization (278). Chronic instability can occur if hyperextension is not prevented for a sufficient amount of time. Degenerative arthritis can occur after chronic instability has developed (314).

Following surgical correction for chronic instability, a permanent flexion contracture is common. Recurrent hyperextensibility is the result of a loose capsulespersion, insecure fixation of the volar plate to the proximal phalanx, or insufficient immobilization.

Posttraumatic sesamoid arthritis of the MP joint can occur. The radial sesamoid appears to be more frequently involved (380). Acute injuries should be treated with the immobilization of the MP joint, usually in slight flexion (315, 359). Chronic injuries, refractory to nonoperative treatment, are usually successfully treated with sesamoid excision (358, 380). Sesamoid excision is performed through a volar approach to the MP joint volar plate, with enucleation of the sesamoid through a longitudinal incision in the volar plate (389).

TRAPEZIOMETACARPAL (CARPOMETACARPAL) JOINT

Assessment and Indications for Treatment

Thumb CMC joint dislocations are frequently associated with intraarticular fractures. To assess, take true AP and lateral radiographs of the thumb CMC joint (Robert view) (403). Dorsoradial subluxation of the CMC joint may indicate ligament injury. Stress radiographs may be helpful in diagnosing instability of the joint (392, 393, 395).

The most common dislocation or ligament injury at this joint is the Bennett’s fracture–dislocation (see Chapter 40). Trapeziometacarpal dislocation without fracture is far less common but quite difficult to treat because of persistent instability (243).

Acute Trapeziometacarpal Dislocations

Trapeziometacarpal dislocations without a concomitant fracture are rare. Most dislocations occur dorsally. The mechanism of injury is thought to be axial compression with a load on the metacarpal in flexion (405, 411). Disruption of the dorsal ligaments probably occurs to allow the joint to dislocate (388, 410, 411), but the volar ligament is intact and is subperiosteally stripped off the base of the metacarpal (388, 410, 411). Clinically, a prominence is noted dorsoradially at the base of the thumb metacarpal with the thumb held in an adducted position, similar to that seen with a fracture–dislocation at the CMC joint.

Treatment options include a closed reduction or open reduction, with or without K-wire fixation, and thumb spica cast immobilization (252, 400, 401, 410, 412).

- Perform a closed reduction under adequate analgesia using longitudinal traction, abduction, and extension of the thumb. Place direct pressure on the base of the thumb metacarpal base, displacing it distally, volarly, and ulnarily.
- Postreduction radiographs should confirm congruous reduction of the joint.
- Immobilize in a thumb spica cast with the thumb held in abduction and extension and pressure placed on the dorsoradial aspect of the metacarpal base. With joint instability or radiographic signs of persistent subluxation, add percutaneous transarticular K-wire pinning. Remove the wires and cast at 6 weeks and begin exercises.

Despite successful reduction of acute dislocations of the thumb CMC joint, instability and redislocation are common, and early ligament reconstruction may be necessary. It is important to monitor the patient radiographically after K-wire removal at frequent intervals until it is certain that stability has been achieved.

Chronic Trapeziometacarpal Dislocations

For chronic dislocations or for recurrent instability with posttraumatic arthritis, arthroplasty or arthrodesis is preferred (see Chapter 71, Chapter 72). If there is no significant arthritic change, do a ligamentous reconstruction. The most widely accepted technique uses the flexor carpi radialis as described by Eaton (390, 392, 395).

Thumb Trapeziometacarpal Ligamentous Reconstruction (Eaton)

- Make an incision along the dorsoradial margin of the thumb metacarpal and curve it palmarward as it approaches the wrist flexor crease, ending over the flexor carpi radialis. Take care to protect the sensory nerves (Fig. 39.43 and Fig. 39.44).
- Extraperiosteally elevate the thenar muscle origin from the trapezium and metacarpal and retract it distally. Incise the roof of the flexor carpi radialis tunnel and any remaining volar radial CMC joint capsule.
- Use a drill or gouge to create a tunnel in the metacarpal base dorsally between the extensor pollicis longus and brevis and exiting at the palmar beak of the metacarpal. Take care not to enter the trapeziometacarpal joint.
- Longitudinally split half of the flexor carpi radialis for 6 cm, leaving it distally based. Expose the proximal portion of the tendon through transverse incisions over the tendon.
- Pass the tendon through the bone trough, in a volar to dorsal direction, using a suture or wire to guide the tendon through the trough. Reduce and pin the joint with a smooth K-wire, avoiding the tendon slip.
- Pull the tendon slip taut and suture it to the dorsal periosteum of the metacarpal.
- Redirect the tendon slip beneath the extensor pollicis brevis and abductor pollicis longus proximally across the joint and back under the remaining intact portion of the flexor carpi radialis. Turn the tendon slip back to the palmar periosteum of the metacarpal, and suture it there. Place additional sutures wherever the tendon slip changes direction.

Figure 39.43. Stabilization of the trapeziometacarpal joint by half of the flexor carpi radialis (FCR).

Figure 39.44. Using the accessory slip of the abductor pollicis longus (APL) to stabilize the trapeziometacarpal joint.
Close the skin and immobilize the thumb in a thumb spica cast for 4 weeks. Remove the K-wire and protect the thumb for an additional 2 weeks with a removable thumb spica splint. Start active exercises, but do not expect maximal return of motion for up to 4–6 months.

An alternative to using the flexor carpi radialis tendon is to use one of the slips of the abductor pollicis longus. The most common insertion for the commonly present second slip is into the trapezium (40). This natural anchor can be used to secure the ligament to the volar aspect of the metacarpal. If the second slip is not present, use the radial branch of the superficial radial nerve. 

Make a longitudinal incision starting along the dorsal ulnar side of the proximal third of the first metacarpal, curve it palmarward over the trapezium, and continue it along the anterior border of the first dorsal compartment.

Use a drill or gouge to make a dorsal-to-palmar hole in the metacarpal parallel but distal to the trapeziometacarpal joint. Pass the slip of abductor pollicis longus tendon through the hole using a suture attached to the end of the tendon slip.

Reduce the joint and tighten the tendon about the joint. Loop the tendon back on itself and suture to its trapezial insertion.

Reinforce the new "ligament" by spreading it out and suturing it to the capsule on each side of the tendion wherever it crosses the joint.

Pin the joint with a smooth K-wire if necessary. Immobilize the thumb in a thumb spica splint or cast for 6 weeks. When the cast and pin are removed, begin exercises (392).

Complications Complications in treating thumb trapeziometacarpal dislocations are usually the result of failing to identify the injury. Failing to immobilize an incomplete ligament injury can lead to persistent joint instability, requiring ligament reconstruction (391,392). Failing to recognize a complete dislocation will require an open reduction and ligament reconstruction (391,392). Persistent instability may lead to symptomatic joint arthritis requiring arthrodesis or arthroplasty (see Chapter 71, Chapter 72). Persistent subluxation can result if the new ligament is not tightened sufficiently with the joint reduced.

INTERPHALANGEAL JOINTS (FINGERS AND THUMB)

---
METACARPOPHALANGEAL JOINTS (FINGERS)

CARPOMETACARPAL JOINTS (FINGERS)

Fractures involving the tubular bones of the hand are the most common of all skeletal injuries (17). The skeleton of the hand is inherently related to adjacent joints, overlying gliding tendon units, and deforming muscle forces. Although failure to gain union following a metacarpal or phalangeal fracture is rare, concomitant problems present a different story. Preventing angular or rotational deformity, articular stiffness, and tendon adhesion challenges even the most experienced surgeon (54). As Charnley recognized: “The reputation of a surgeon may stand as much in jeopardy from this injury [phalangeal fracture] as from any fracture of the femur” (13).

The vast majority of phalangeal and metacarpal fractures can be successfully treated without surgery. A nonanatomic outcome, however, can jeopardize overall hand function, leading at times to a prolonged and major disability (11). Therefore, it is important to identify the fractures that require operative treatment (Table 40.1), the surgical approaches that minimize soft tissue adhesions, and the postoperative management that best encourages joint mobilization and avoids soft tissue contracture (6).

Table 40.1. Phalangeal and Metacarpal Fractures Often Requiring Internal Fixation

### FUNCTIONAL ANATOMY

The longitudinal and transverse arches of the hand pass through the metacarpals, having a keystone in the metacarpophalangeal joints. The rigid central pillar of the hand passes through the second and third metacarpals, and the mobile carpometacarpal joints of the thumb, ring, and little rays permit mobility at the borders of the hand. The deep transverse metacarpal ligaments connect the four metacarpals of the hand and provide internal support, particularly for the long and ring metacarpals.

The extrinsic flexor tendons exert a flexion and adduction force on the distal metacarpals that is enhanced by the short but powerful intrinsic tendons that pass on the palmar side of the midaxis of the metacarpophalangeal joint.

In contrast to the interconnected metacarpals, the phalanges are isolated skeletal units and are subject to the deforming muscle forces of both the extrinsic flexor and extensor tendons and the intrinsic tendons. The proximal parts of the proximal and middle phalanges are subject to strong flexor forces, whereas the more distal shafts and neck tend to go into hyperextension because of the pull of the extensor mechanism.

The thumb plays a unique role in all forms of prehensile hand function by the complex configuration of the carpometacarpal joint as well as the transmission of power through the numerous tendon insertions. When the integrity of the thumb skeleton has been disrupted or deformed secondary to fracture malunion, the balance of these forces is disturbed, leading to deformity.

### PRINCIPLES OF TREATMENT

Determine the fracture pattern by three radiographic views—anteroposterior, lateral, and oblique. Check rotational and angular alignment by evaluating the relationship of the fingernails to each other in both extension and flexion. It may be necessary, after careful assessment of the neurovascular status, to anesthetize the digit or hand to better assess rotational alignment and fracture stability.

If the fracture proves unstable, internal splintage is required. Kirschner wire fixation, particularly when placed percutaneously, is an excellent method in single or adjacent metacarpal or phalangeal fractures. Use of this technique requires expertise in wire placement and image intensification (4, 24, 37).

Open reduction and internal fixation are performed using various methods, including interosseous wire and tension band wire techniques as well as more stable miniscrews and plates (5, 6) and 3.5 mm and 7.5 mm (19, 23, 26, 27, 28, 35, 36, 40, 43, 46, 50). The greater the severity of the combined skeletal and soft tissue injury, the more important it becomes to achieve stable fixation that allows early mobilization.

The postoperative program is directed toward preserving joint motion and minimizing adhesions of the gliding structures, such as the tendons and joints. Under the supervision of a hand therapist, static and dynamic splints, antiedema measures such as Coban wraps, and active assisted range-of-motion exercises have proved an...
effective means of regaining motion and avoiding joint contracture, even in severe combined skeletal and soft tissue injuries of the hand.

CLASSIFICATION

Like fractures of long bones, phalangeal and metacarpal fractures call for specific methods of treatment depending on the fracture pattern and location. Features used to classify phalangeal and metacarpal fractures include location, fracture configuration, soft tissue integrity, and inherent stability (Table 40.2). These tubular bones are divided into base, shaft, neck, and articular heads (Fig. 40.1). In children, the epiphyseal zones are found at the bases of the phalanges and the head and neck of the metacarpals. The thumb metacarpal differs in that the epiphyseal center is found at the base.

Figure 40.1. Anatomy of the metacarpal and phalanx.

Table 40.2. Functional Fracture Classification

SURGICAL TECHNIQUES

METACARPALS

In general, longitudinal incisions are preferred over transverse or serpentine approaches on the dorsum of the hand, as they limit trauma to the venous and lymphatic systems (Fig. 40.2).

Figure 40.2. Dorsal surgical approaches to the metacarpals.

- Approach the long and ring metacarpals through a longitudinal incision between the bones, using a Y-shaped extension if necessary to provide more proximal or distal exposure. Approach the border metacarpals individually through longitudinal incisions, with curving extensions as needed.
- Facilitate exposure of the distal metacarpal shafts, neck, or head by cutting through the juncruarlae tendinae linking the common extensor tendons. Tag these for later reapproximation with 5-0 nylon suture.
- Next, incise the junction of the sagittal band and extensor tendon to permit access to the metacarpophalangeal joint. Reapproximate it with fine nonabsorbable suture.
- At the shaft level, incise the periosteum carefully, leaving as much attached as possible and preserving the origins of the interosseous muscles. Gently expose the fracture site and remove the hematoma by irrigation with a small-bore needle and use of a dental pick.
- Surgical approaches to the thumb metacarpal are most often required for intraarticular fractures at the base. The palmar approach described by Gedda and Moberg starts proximally at the wrist crease and extends distally along the metacarpal shaft (Fig. 40.3) (22).

Figure 40.3. Surgical approaches to the thumb metacarpal: palmar (A) and dorsal (B).

- Elevate the thenar muscles subperiosteally off the metacarpal shaft to give good exposure to the palmar aspect of the carpometacarpal joint. This approach is
particularly effective for Bennett fractures with small palmar fragments. The radiodorsal approach is preferred for fractures that extend onto the proximal metacarpal shaft.

- Make the incision along the radial edge of the metacarpal. Identify and preserve crossing branches of the radial sensory nerve as well as the insertion of the abductor pollicis longus tendon. Elevate the thenar muscles subperiosteally off the shaft, if necessary, to improve exposure of the base.

**PHALANGES**

- Approach the proximal and middle phalanges through dorsolateral or midaxial incisions (Fig. 40.4).

![Figure 40.4. Surgical approaches to the phalanges.](image)

- Elevate the dorsal skin flap off the paratenon of the extensor tendon. Preserve the dorsal venous arcade whenever possible. Pay careful attention to preserving the paratenon and peristeum to avoid later adhesions between the phalanx and tendon.
- If more distal exposure of the shaft is necessary, incise the transverse retinacular ligament to allow further mobilization of the extensor mechanism. Mark this interval for later reapproximation.
- Approach the proximal interphalangeal joint straight dorsally between the central extensor tendon and the lateral band or between the lateral band and the collateral ligament. Occasionally, additional exposure can be obtained by osteotomizing the insertion of the central slip onto the base of the middle phalanx and reflecting the tendon proximally. The insertion can later be secured with a tension wire or small screw.
- Use a complete or partial H incision to gain access to the head of the middle phalanx or distal interphalangeal joint. Split the extensor tendon longitudinally or in a Z fashion to expose the joint.

**METACARPAL FRACTURES**

**EPIBASAL FRACTURES**

Fractures at the bases of the metacarpals, particularly the mobile ring and little, require a careful assessment of any intraarticular involvement. These fractures are often the result of crushing injuries and are associated with fracture-dislocations at the carpometacarpal joints. Accurate reduction may offset later posttraumatic arthrosis, particularly in the ulnar metacarpals. Achieve reduction with longitudinal traction and Kirschner wire fixation from little to ring metacarpal, metacarpal to hammate or capitate, or both. If comminution is extensive, surgical options are indirect reduction with a mini–external fixator or open reduction with a condylar plate. Approach the treatment of fractures at the base of the little metacarpal in a manner similar to that for fractures of the thumb carpometacarpal joint.

**Postoperative Management**

We recommend immobilization in a removable splint positioned with the wrist slightly extended, metacarpophalangeal joints flexed 80° to 90°, and interphalangeal joints free for movement. Start motion at the metacarpophalangeal and interphalangeal joints within the first week. Remove percutaneous pins after 4 weeks, and begin grip-strengthening exercises.

**PITFALLS AND COMPLICATIONS**

Posttraumatic arthrosis can occur if accurate reduction is not achieved. It can be more symptomatic in the ulnar metacarpals because these carpometacarpal joints are so mobile. Arthrodesis may eventually be necessary.

**SHAFT FRACTURES**

The treatment of metacarpal shaft fractures has progressed considerably since the 1930s, when virtually all metacarpal fractures were treated by bandaging over a roller bandage with little or no attempt to correct displacement. Angulation, shortening, or rotation that cannot be controlled by plaster support requires internal fixation. In addition, fractures associated with soft-tissue crush or open injuries are better managed with internal fixation (Table 40.3).

Table 40.3. Indications for Internal Fixation—Metacarpal Shaft

Percutaneous Kirschner wire fixation may be applicable for some transverse shaft fractures (37). Potential problems are inherent with the placement of the wire through the metacarpophalangeal joint capsule or the extensor tendon mechanism. For multiple transverse fractures or those associated with crushing injuries, we prefer dorsally placed tension band plates (Fig. 40.5), generally using four-hole one-quarter tubular plates with 2.0- or 2.7-mm screws. Some compression can be gained at the fracture line by drilling eccentrically in the farthest holes from the fracture line and placing both screws simultaneously (29). If comminution is noted at the fracture line, use a longer plate and place a small amount of cancellous bone graft—readily obtained from the distal radius—in the zones of comminution.
Figure 40.5. A 24-year-old laborer’s dominant right hand was crushed by a dumpster. There was extensive soft-tissue trauma associated with three metacarpal shaft fractures. A,B: Anteroposterior and oblique views revealed transverse metacarpal shaft fractures. C: Through two longitudinal incisions, one-quarter tubular plates and 2.7-mm screws were applied. D,E: Full flexion and extension were achieved within 6 weeks despite the extensive soft-tissue crush. F,G: Anteroposterior and oblique radiographs 6 months after plate removal.

Spiral and long oblique fractures provide a wide surface amenable to interfragmentary screw fixation (Fig. 40.6). The length of these fractures should be at least three times the diameter of the shaft at the level of the fracture to permit adequate fixation with screws alone. The screws should distribute interfragmentary compression evenly along the entire fracture length. Place one screw perpendicular to the fracture line and one perpendicular to the shaft to ensure distribution of compression and offset shear stresses on the implants. With short oblique fractures, a single screw cannot withstand the rotatory, shear, or bending stresses of normal activity. These stresses must be neutralized by a plate to allow early mobilization (Fig. 40.7).

Figure 40.6. A 27-year-old surgical resident sustained spiral malrotated second and third metacarpal shaft fractures in a sporting event. A: Oblique radiograph shows the rotatory displacement of the metacarpal shaft fractures. B: Clinically, malrotation was readily apparent. C: The large fracture surfaces proved amenable to interfragmentary screw fixation using 2.7-mm and 2.0-mm screws. Note the arrangement of the screws to offset shear and rotational stresses. The patient made a full functional recovery.

Figure 40.7. A 35-year-old laborer sustained a severe crush injury to his left hand. In view of the massive soft-tissue trauma, rigid internal fixation was chosen to rapidly mobilize the hand. An interfragmentary screw was placed through a small T-plate.

The use of external fixation for closed, unstable metacarpal shaft fractures has been shown in recent studies to yield excellent results for union and total arc of hand motion (44,66). Traditionally, external fixation has been used for complex comminuted and open fractures, where the principles of indirect reduction and minimization of soft tissue stripping are advocated.

Postoperative Management

Close incisions over a small vacuum drain, wrap the hand in Dacron batting dressing, and support it in a plaster splint. Begin active assisted range-of-motion exercises 48 to 72 h after surgery. Coban wraps around the digits and hand effectively control postoperative swelling. Take radiographs at 1, 3, and 6 weeks after surgery. The patient should be able to start light manual activities at 3 weeks and unrestricted activities by 6 to 8 weeks.

PITFALLS AND COMPLICATIONS

The surgeon must be confident that the internal fixation is rigid enough to support the fracture during rehabilitation. Leaving the hand immobile until fracture union after an extensive surgical exposure can result in tendon adhesions or joint contracture. Unforeseen comminution or longitudinal fracture lines may cause the unwary surgeon to place the screws in unsound bone. Study the fracture pattern once the hematoma has been cleared and before the actual reduction. When a screw is loose because its threads have been stripped, achieve stable fixation by placing a larger screw, redirecting the screw, or using a longer plate. Converting to Kirschner wire fixation with tension loops of stainless-steel wire is also effective when rigid fixation is inadequate (18).

NECK FRACTURES

Fractures of the metacarpal neck are almost always the result of direct impact. The deformity is generally palmar angulation of the distal fragment; rarely, malrotation may also be present. Excessive flexion of the distal fragment can lead to hyperextension at the metacarpophalangeal joint, interference with grip, and pain over the metacarpal head in the distal palm. Although most would agree that more than 10° of palmar angulation is unacceptable in the index and long metacarpals because of their immobile carpometacarpal joints, some controversy surrounds fractures of the metacarpal necks of the ring and little fingers. Several authors have reported acceptable functional results with flexion deformities of at least 70° in the little finger (16,30,31). We believe that reduction should be considered for angulation beyond 30° to 40° in the little finger and beyond 20° to 30° in the ring finger (49,53).

Treatment

Closed reduction of metacarpal neck fractures is readily accomplished by the 90–90 method introduced by Jahss (33) of flexing the proximal interphalangeal joint and
using the proximal phalanx to push the metacarpal head into position. Reduction by direct pressure on the prominent palmar surface of the head with counterpressure on the dorsum of the shaft works equally well. Immobilization in this position is not acceptable to hold the reduction in place because of the risk of joint contracture or skin necrosis.

Percutaneous Kirschner wire fixation has proved most effective in stabilizing metacarpal neck fractures, particularly of the little and ring metacarpals. The wires, generally 0.035 in., can be introduced transversely, proximal and distal to the fracture and into the adjacent metacarpal, obliquely across the fracture, or longitudinally through the flexed MP joint. Place a 14-gauge hypodermic needle against the metacarpal to function as a pin guide. These methods of treatment carry a risk of permanent metacarpophalangeal joint stiffness when the pins transfixed the extensor mechanism.

- We prefer to introduce the Kirschner wires from the base of the metacarpal. Using image intensification, make a small transverse incision over the dorsoulnar aspect of the base of the metacarpal. Create a small window in the metacarpal base. Bend a 0.045-in. Kirschner wire into a gentle arc and hammer it distally up the shaft while holding the fracture reduced in the 90–90 position. The pin should extend into the subchondral bone of the head (Fig. 40.8).

- Introduce a second pin if motion is felt at the fracture. Cut the pin(s) just beneath the skin and apply an ulnar gutter splint with the metacarpophalangeal joint maintained in flexion. Gentle motion may be initiated 2 weeks after surgery.
- Percutaneous pins, placed sagittally from dorsal to palmar and bonded together by methylmethacrylate, have also been advocated as a reliable means of holding the reduction without opening the fracture site (45). The method, however, carries the risk of the extensor mechanism being transfixed by the pins or pin track sepsis. This technique is perhaps best reserved for fractures associated with soft tissue injury or bone loss.
- Reserve open reduction and internal fixation for grossly displaced fractures, fractures associated with extensive soft tissue trauma, or fractures seen too late for manipulative reduction. Because of the proximity of these fractures to the joint and extensor mechanism, we prefer crossed Kirschner wires looped with a stainless-steel wire as a tension band (Fig. 40.9).

- Place two 0.035-in. or 0.028-in. Kirschner wires, either criss-crossing the fracture or parallel to the fracture, dorsal to the midaxis of the bone. Place a 28-gauge stainless steel wire dorsally over the fracture and just under the points of the wires.
- Initiate motion 48 to 72 h after surgery. The Kirschner wires can be removed under local anesthesia in the office.

**PITFALLS AND COMPLICATIONS**

The major difficulty associated with the treatment of metacarpal neck fractures lies in the potential for stiffness of the metacarpophalangeal joint. Avoid open reduction if possible, percutaneous techniques are preferable. We generally bury the Kirschner wires just under the skin to avoid pin track infections.

**HEAD FRACTURES**

Less common than neck injuries, metacarpal head fractures are intraarticular fractures seen most often in young adults as a result of athletic injury (39). They vary from an osteochondral fracture to two- or three-part fractures in a sagittal or coronal plane to grossly comminuted fractures (28).

**Treatment**

Treatment planning should include anteroposterior and lateral tomography to determine the operability of the fracture as well as the location of the fragments. For nondisplaced as well as very comminuted fractures, splint support and protected motion are preferable.

Open reduction and internal fixation are indicated for the split or three-part fracture (28).

- Through a dorsal approach, open the joint capsule longitudinally. Meticulous handling of the small fracture fragments is imperative to avoid further fragmentation or devascularization. Preserve any soft tissue attachments.
- Provisionally stabilize the fracture with 0.028-in. Kirschner wires, verifying the reduction with anteroposterior, lateral, and oblique radiographs. As a general rule, if the fracture fragment is larger than two to three times the diameter of the screw head, internal fixation with 1.5-mm miniscrews is preferred.
- If secure fixation can be achieved, early mobilization of this joint injury can be started.
- With smaller fragments, Kirschner wire fixation is recommended. With impacted fragments, cautious elevation and support with cancellous bone graft obtained from the end of the radius can restore the anatomic profile of the metacarpal head (Fig. 40.10).

**Figure 40.8.** A: A 21-year-old musician sustained a completely displaced metacarpal neck fracture of his dominant right hand. B,C: Three 0.045-mm Kirschner wires were inserted through a small opening in the base of the metacarpal. D–F: Motion exercises were started after 2 weeks, and full range of motion and healing were observed at 7 weeks. Pins were removed after 10 weeks.

**Figure 40.9.** A 46-year-old woman was thrown from a horse, sustaining multiple injuries. Anteroposterior radiograph shows a fifth metacarpal neck fracture treated by two crossed Kirschner wires and a dorsal stainless-steel loop acting as a tension band.

**Figure 40.10.** A 22-year-old man suffered an open metacarpal head fracture. A: Anteroposterior radiograph shows a displaced split fracture. B: Irrigation,
debridement, open reduction, and internal fixation with two 1.5-mm screws were performed. This patient began early motion after 1 week to allow for wound healing.

Postoperative Management

Postoperative management depends on the stability of the internal fixation. Screw fixation, if rigid, will permit protected motion 48 to 72 h after surgery. Kirschner wire fixation should be held in a splint with the metacarpophalangeal joint flexed 70° for 10 to 14 days before motion is started.

PITFALLS AND COMPLICATIONS

Inability to fix the fracture fragment securely, increased fragmentation, or excessive soft-tissue stripping can lead to avascular necrosis, loss of reduction, metacarpophalangeal joint stiffness, or posttraumatic arthrosis. Proper preoperative assessment, particularly with tomography, may prevent the surgeon from entering into an unduly difficult reconstruction.

THUMB METACARPAL FRACTURES

Most thumb metacarpal fractures occur at or near the base. The distinction between intraarticular and extraarticular fractures is important, particularly in that the thumb metacarpal will tolerate at least 30° angulation without noticeable deformity or altered function (25). The carpometacarpal joint of the thumb is critical for thumb and hand function, however, and inadequate treatment can lead to a substantial hand disability (13). Special radiographic views, including tomography or the Robert anteroposterior view taken with the hand in maximum pronation so that the dorsum of the thumb is against the radiographic plate, are often required to assess the fracture pattern accurately.

Treatment

Several techniques, all with good reported results, have been advocated for treatment of Bennett's fracture-dislocation (8,21,51). The small palmar fragment remains attached to the trapezium and second metacarpal by the stout anterior oblique ligaments, while the shaft of the metacarpal is pulled proximally and radially, allowing the abductor pull to increase the deformity at the base.

Our approach has been directed toward regaining anatomic reduction of the intraarticular fracture.

- With image intensification, attempt closed reduction by longitudinal traction, pronation, and compression on the base of the metacarpal. If an anatomic reduction can be realized, percutaneous Kirschner wire fixation using 0.045 wires will guard against redislocation. The use of a 14-gauge hypodermic needle facilitates the placement of the Kirschner wires into the tubular shaft of the metacarpal.
- Direct one wire into the second metacarpal and a second into the trapezium. Cut the wires just under the skin and apply a thumb spica cast for 6 weeks (Fig. 40.11).

**Figure 40.11.** A displaced Bennett's fracture was treated successfully by a closed reduction and percutaneous Kirschner wire fixation. Image intensification facilitated the pin placement.

- If an anatomic reduction cannot be obtained or maintained, open reduction and internal fixation are required. Through the palmar approach of Gedda and Moberg, reduce the fracture and gently hold it with a bone-reduction clamp while making provisional fixation with Kirschner wires.
- Introduce a 2.0- or 2.7-mm cortical screw from a dorsal direction into the fragment, placing the gliding hole in the metacarpal shaft. Use the half-threaded 4.0-mm cancellous screw only if adequate fixation cannot be achieved, as this type of screw may be difficult to remove.
- If small Kirschner wires are used, support the fixation by an additional Kirschner wire between the thumb metacarpal and second metacarpal as well as by a thumb spica cast for 4 to 6 weeks. With stable screw fixation, protected motion may be initiated 48 to 72 h after surgery.

Rolando (42) described a Y-shaped intraarticular fracture, but significant comminution is far more common. Preoperative tomography is exceedingly important to determine the operability of these fractures. Often they are impacted and require support with a cancellous bone graft. Place a small T or L plate on the dorsal surface of the metacarpal to support the reconstruction (Fig. 40.12) (19).

**Figure 40.12.** A 42-year-old man fell and sustained a closed intraarticular Rolando fracture of the base of his right dominant thumb. A: Anteroposterior radiograph shows the fracture configuration. B: The fracture was openly reduced and internally fixed with a 2.0-mm interfragmentary screw as well as a small L plate. C: The fracture healed, and the functional recovery was excellent.

When the comminution is too extensive to allow screw-and-plate fixation, use Kirschner wire fixation with cancellous bone graft and mini–external fixation stabilizing the thumb metacarpal to the index metacarpal. This technique maintains distraction on the joint while healing occurs (Fig. 40.13) (19).
the dorsal aspect of the shaft in association with transverse or crossed Kirschner wires effectively functions as a tension band (in the midaxis of the shaft; also, the oblique Kirschner wire required to neutralize rotational forces may interfere with gliding of the lateral band. A wire loop placed on the way of instrumentation, and the fixation is less bulky than plates. The disadvantages, however, include the failure to gain a tension band effect if the wire loop is placed near the fracture.

The interosseous wire technique advocated by Lister is most effective for transverse fractures. Longitudinal screws are required for fractures that cannot be well reduced by manipulative reduction, those associated with soft tissue trauma, and those seen late.

Phalangeal fractures are common. The associated complications are significant, and the functional disability can be profound. Certainly many are nondisplaced, stable, and readily treated by splintage or buddy straps, and others are easily reduced and held by external plaster support. Because of the intimate relationship of the tendons and joints to the phalangeal shaft, however, certain unstable phalangeal fractures—including displaced, comminuted, spiral, or short oblique—require internal fixation to ensure anatomic alignment and restore functional mobility.

Treatment

Many unstable phalangeal shaft fractures can be successfully treated by percutaneous wire fixation (Fig. 40.14).

**Figure 40.13.** A 30-year-old tool-and-die worker’s dominant thumb was caught in a lathe, causing extensive skeletal and soft-tissue trauma. **A:** Anteroposterior radiograph shows a comminuted intraarticular fracture at the base of the metacarpal as well as a severe fracture of the proximal phalanx. **B:** Following repair of the flexor pollicis longus and the radial digital nerve and artery, an open reduction and internal fixation of the base of the metacarpal was accomplished. The impacted articular fragments were reduced, held with 0.035-mm Kirschner wires, and supported by distal radius cancellous bone graft. A mini-external fixation unit was placed to prevent settling of the joint reconstruction, to maintain the first webspace, and to maintain reduction of the proximal phalanx fracture. **C:** Rehabilitation of the hand progressed with the fixator in place.

**PITFALLS AND COMPLICATIONS**

Failure to achieve or maintain anatomic reduction may result early in abduction deformity of the thumb metacarpal, leading to posttraumatic arthritis. Miniscrew-and-plate fixation should be used only by a surgeon experienced in these techniques because inadequate fixation can lead to collapse of the articular restoration and to substantial later disability. When approaching this area, avoid prolonged intraoperative traction on the branches of the radial sensory nerve, which can result in a distressing neuritis.

**PHALANGEAL FRACTURES**

**SHAFT FRACTURES**

Stabilize fractures of the base, transverse shaft, and neck by one 0.045-in. or two 0.035-in. Kirschner wires placed longitudinally through the metacarpal head, preferably to one side of the extensor tendon and extended distally into the subchondral bone at the condylar levels. Verify the reduction and wire placement by image intensification, followed by standard radiographs in three views.

Anteroposterior and lateral radiographs revealed a comminuted fracture with angular and rotatory malalignment. **A:** Three weeks after appropriate anesthesia, apply longitudinal traction through the middle phalanx and flex the metacarpophalangeal joint 60° to 70° with the proximal phalanx fixed about 45° (Fig. 40.15). **B:** Make angular and rotatory corrections at this juncture. If swelling is not profound, anatomic landmarks for insertion of Kirschner wires include the flare of the head of the proximal phalanx and the proximal palmar skin crease, which also lies under the flare (Fig. 40.15). The size of the Kirschner wire is determined by the location of the fracture and the size of the bone.

**C:** Set up the base of the proximal phalanx and the base of the proximal palmar skin crease, which also lies under the flare (Fig. 40.15). Therefore, the angle of the base of the proximal phalanx and the base of the proximal palmar skin crease, which also lies under the flare (Fig. 40.15). The size of the Kirschner wire is determined by the location of the fracture and the size of the bone.

**D:** A 37-year-old cardiologist sustained a closed fracture of his ring finger in a basketball game. **A:** Anteroposterior and lateral radiographs revealed a comminuted fracture with angular and rotatory malalignment. **C,D:** Treatment consisted of closed reduction, percutaneous longitudinal Kirschner wire placement, and plaster cast for 3 weeks. **E:** The fracture healed in near-anatomic position, and full function resulted.

- After appropriate anesthesia, apply longitudinal traction through the middle phalanx and flex the metacarpophalangeal joint 60° to 70° with the proximal phalanx flexed about 45° (Fig. 40.15).
- Make angular and rotatory corrections at this juncture. If swelling is not profound, anatomic landmarks for insertion of Kirschner wires include the flare of the head of the proximal phalanx and the proximal palmar skin crease, which also lies under the flare (Fig. 40.15). The size of the Kirschner wire is determined by the location of the fracture and the size of the bone.
- Stabilize fractures of the base, transverse shaft, and neck by one 0.045-in. or two 0.035-in. Kirschner wires placed longitudinally through the metacarpal head, preferably to one side of the extensor tendon and extended distally into the subchondral bone at the condylar levels. Verify the reduction and wire placement by image intensification, followed by standard radiographs in three views.
- Apply either dorsal and palmar splints or a plaster cast. Take care that the plaster does not come into contact with the pins, which are left protruding through the skin for ease of removal.
- Remove the cast at 3 weeks and the pins at that time or at 4 weeks, depending on the radiographic appearance. Initiate active assisted range-of-motion exercises under a therapist’s supervision.

Spiral or short oblique fracture patterns can be satisfactorily stabilized with parallel Kirschner wires placed across the fracture site. For the index and little fingers, introduce the wires from the radial and ulnar sides, respectively, and leave them protruding through the skin for ease of removal. Open reduction and internal fixation are required for fractures that cannot be well reduced by manipulative reduction, those associated with soft tissue trauma, and those seen late.

- Approach the shaft through the interval between the lateral band and common extensor tendon. More distal exposure may require division of the transverse retinacular ligaments, which are marked for later reappraisal. Spiral fractures for the most part are amenable to interfragmentary screw fixation using 1.5-mm screws.
- Directing one screw perpendicular to the phalangeal shaft and a second perpendicular to the fracture line protects the fracture from shear and rotatory stresses. Countersink the holes to keep the screw heads from interfering with the overlying gliding structures. If the fracture is a short oblique pattern, the interfragmentary screw will require a neutralization plate to protect against shear or rotational forces, even though the plate may prove to be bulky.

The interosseous wire technique advocated by Lister is most effective for transverse fractures (Fig. 40.15) (38). Application is straightforward and requires little in the way of instrumentation, and the fixation is less bulky than plates. The disadvantages, however, include the failure to gain a tension band effect if the wire loop is placed in the midaxis of the shaft; also, the oblique Kirschner wire required to neutralize rotational forces may interfere with gliding of the lateral band. A wire loop placed on the dorsal aspect of the shaft in association with transverse or crossed Kirschner wires effectively functions as a tension band (23).
fibrocartilaginous joint surface on the base of the middle phalanx but it also avoids contracture of the soft tissues (force-couple technique described by Agee (1)). Unstable fracture-dislocations of the proximal interphalangeal joints are also difficult to treat and have a high incidence of residual stiffness or joint subluxation. The devascularization of the collateral ligament or fragment by the relatively large screw head.

Fix unicondylar fractures with 1.5-mm lag screws. Small condylar fractures may be held by directing the screw from the opposite cortex, thereby avoiding added exposure by osteotomizing the insertion of the central slip, which is later replaced and secured with a tension band wire.

In condylar fractures, the fracture must be sufficiently exposed to allow the fracture line and the joint to be visualized. Take care to avoid dissection of the soft tissue attachments to the condyles. We recommend either a dorsal or midaxial incision at the proximal interphalangeal joint level; use a modified H incision over the distal attachments to the condyles. We recommend either a dorsal or midaxial incision at the proximal interphalangeal joint level; use a modified H incision over the distal

Bicondylar fractures, often the result of a more severe trauma, have a high risk of residual joint stiffness. For this reason, we try to obtain fixation rigid enough to permit mobility while preventing potential joint contracture. Kirschner wires can usually be removed at 3 to 4 weeks. We prefer to leave interfragmentary screws in place unless they prove bothersome.

ARTICULAR FRACTURES

Nondisplaced fractures may be splinted, but frequent observation is required because of a high rate of displacement (52). Displaced phalangeal articular fractures, particularly basilar avulsion types and the condylar or bicondylar variants, often require open reduction and internal fixation, as the fragments are small and frequently are not only separated but also rotated (3). Obtain three radiographic views to visualize the fracture and degree of displacement adequately.

Stable internal fixation permits the start of active motion 48 to 72 h after surgery. Coban wraps help reduce digital swelling, and static and dynamic splints help restore mobility while preventing potential joint contracture. Kirschner wires can usually be removed at 3 to 4 weeks. We prefer to leave interfragmentary screws in place unless they prove bothersome.

PITFALLS AND COMPLICATIONS

Following external fixation, excessive soft tissue stripping, inadequate or loose internal fixation, and prolonged immobilization can cause loss of position or motion (20,47). Because of the inherent relationships of the tendons to the phalangeal skeleton, screws placed in the anteroposterior plane can risk tendon rupture if they protrude excessively from the bone (19).

Tension band fixation using a 28-gauge stainless-steel wire is effective for avulsion fractures such as bony gamekeeper’s thumb fractures, lateral avulsion injuries, and dorsal avulsions of the middle phalanx (6,38).

In condylar fractures, the fracture must be sufficiently exposed to allow the fracture line and the joint to be visualized. Take care to avoid dissection of the soft tissue attachments to the condyles. We recommend either a dorsal or midaxial incision at the proximal interphalangeal joint level; use a modified H incision over the distal interphalangeal joint. For extremely displaced bicondylar fractures or those with associated impaction of the base of the middle phalanx, we have on occasion obtained added exposure by osteotomizing the insertion of the central slip, which is later replaced and secured with a tension band wire.

Fix unicondylar fractures with 1.5-mm lag screws. Small condylar fractures may be held by directing the screw from the opposite cortex, thereby avoiding devascularization of the collateral ligament or fragment by the relatively large screw head.

Bicondylar fractures, often the result of a more severe trauma, have a high risk of residual joint stiffness. For this reason, we try to obtain fixation rigid enough to permit early postoperative joint mobilization. Securely fix both condyles with a lag screw placed through a mini–condylar plate along the side of the shaft. This plate is designed to sit on the side of the shaft, thus avoiding interference with the glide of the extensor mechanism.

Unstable fracture-dislocations of the proximal interphalangeal joints are also difficult to treat and have a high incidence of residual stiffness or joint subluxation. The force-couple technique described by Agee (1) has the advantage of maintaining joint reduction while encouraging joint mobility. Not only does it help mold a new fibrocartilaginous joint surface on the base of the middle phalanx but it also avoids contracture of the soft tissues (Fig. 40.16) (1).
PITFALLS AND COMPLICATIONS

Phalangeal articular fractures are among the most difficult hand injuries to treat because of their small size, precarious vascular supply, and propensity for associated soft-tissue contracture. Excessive exposure and soft tissue stripping, inadequate skeletal fixation, or fragmentation of the condylar fragments results in loss of joint mobility, arthritis, or avascular necrosis. Careful preoperative planning is essential for proper operative management.

AUTHORS’ PERSPECTIVE

The proper treatment of fractures of the metacarpals and phalanges is a challenge because of the constant struggle between the achievement of skeletal union and the maintenance of soft tissue integrity and function. The techniques outlined seek to accomplish both goals. An underlying tenet is that the greater the soft tissue injury, the greater the need for stable fracture fixation to allow early motion. For best results, pay careful attention to edema control as well as the proper positioning and therapy of the uninjured portion of the hand.

CHAPTER 41
DISLOCATIONS OF THE CARPUS

James H. Dobyns and Richard A. Berger

Normal Anatomy of the Wrist

In the normal wrist, there are eight carpal bones, anatomically divided into two rows. From radial to ulnar, the proximal carpal row is composed of the scaphoid, lunate, triquetrum, and pisiform (sometimes not classified as a carpal bone because it is a sesamoid bone within the tendon of the flexor carpi ulnaris). From radial to ulnar, the distal carpal row is composed of the trapezium, trapezoid, capitate, and hamate. Each bone has a unique shape, but each bone may be considered schematically to be cuboid. For the central bones—the capitate, trapezoid, and lunate—only the dorsal and palmar surfaces are available for capsular attachments. The remaining four sides are covered with articular cartilage. In contrast, the marginal carpal bones have an additional surface available for capsular attachments: the lateral (radial) surfaces of the trapezium and scaphoid and the medial (ulnar) surfaces of the hamate and triquetrum.

There are no predictable tendinous attachments to the carpal bones, with the exception of the pisiform. Occasionally, one of the multiple slips of the abductor pollicis longus inserts into the scaphoid or trapezium, and the tendon of the extensor carpi ulnaris may insert into the hamate. Only a few areas on the surfaces of the carpal bones are not covered by articular cartilage or capsular attachments, such as the neck of the capitate and the palmar surface of the proximal pole of the scaphoid. These areas are covered by the synovial layer of the joint capsule.

By Taleisinik’s definition, the carpal ligaments may be divided into extrinsic and intrinsic groups. Extrinsic ligaments are those with an attachment proximal or distal to the carpal bones, and intrinsic ligaments attach entirely to carpal bones. The carpal ligaments may also be classified anatomically as capsular or intraarticular. As a rule, intraarticular ligaments are intrinsic, but capsular ligaments may be intrinsic or extrinsic. Capsular ligaments are well-organized structures that are thickenings of the joint capsule. They are composed of dense fascicles of collagen surrounded by loosely organized areolar tissue called the perifascicular space. This space transmits blood vessels supplying the carpal bones, the ligaments, and a surprising amount of nerve tissue. The nerve tissue in the ligaments may play a role in joint proprioception. Groups of fascicles, aligned in a roughly parallel fashion, form the thickening that is called a capsular ligament. It is covered on the joint surface by a continuous layer of synovial cells, the synovial stratum; on the superficial surface, it is covered by nonparallel fibrous elements called the fibrous stratum. The synovial and fibrous strata are direct extensions of the synovial and fibrous strata composing the joint capsule in regions where no ligamentous thickening is present. Morphologically, intraarticular ligaments are similar to capsular ligaments, but they are surrounded by synovial strata alone.

Ligaments insert into bone in much the same fashion that tendons do. The internal organization of the collagen fascicles is lost to form a zone of fibrocartilage. A “blue line” separates the fibrocartilage into mineralized and demineralized zones. The mineralized zone blends into the cortical bone in a fashion analogous to the formation of Sharpey’s fibers of tendon insertion.

The palmar wrist joint capsule completely covers the carpal bones and joint spaces. After dissection of the synovial lining of the carpal tunnel, the remaining fibers appear to originate proximally from the radial and ulnar margins of the wrist and course obliquely distally toward the midline lunate and capitate. The individual ligaments can be more clearly defined when viewed from within the wrist. Beginning radially, four distinct extrinsic palmar radiocarpal ligaments have been defined (Fig. 41.1). Originating from the radial styloid process and the radialmost palmar lip of the radius is the radioscaphocapitate (RSC) ligament. It courses distally as a single ligament to insert into the radial aspect of the wrist of the scaphoid and hemicircumferentially around the proximal half of the distal pole of the scaphoid. Palmar to the head of the capitate, it merges with fibers from the triangular fibrocartilage (TFC) complex and the triquetrum to form a supporting sling for the head of the capitate, sometimes referred to as the arcuate ligament. Only a small percentage of fibers from the RSC ligament join fibers from the scaphocapitate ligament, which is contiguous and distal to the RSC ligament, to insert into the body of the capitate. There is no discrete radial collateral ligament, but the fibers of the RSC ligament that insert into the wrist of the scaphoid form a radial “wall” in the radiocarpal joint capsule and anatomically are well suited to behave as a radial collateral ligament.

This chapter discusses many types of carpal instabilities and fracture–dislocations of the carpus. Chapter 42 reviews carpal bone fractures.
Just ulnar to the origin of the RSC ligament, with a small amount of palmar overlap, the long radiolunate ligament takes origin (6). It is separated from the RSC ligament throughout its course by the intraligamentous sulcus. The long radiolunate ligament does not attach directly to the scaphoid but passes palmar to the proximal pole of the scaphoid and the palmar portion of the scapholunate interosseous ligament to insert entirely into the palmar margin of the lunate. Just ulnar to the origin of the long radiolunate ligament, the radioscapopholunate (RSL) ligament enters the radiocarpal joint space through a defect in the palmar radiocarpal joint capsule. This structure is not a true ligament; it is a neurovascular bundle supplied by branches from the palmar carpal branch of the radial artery, the anterior interosseous artery, and the anterior interosseous nerve (6). It is covered by a thick synovial lining, readily appreciated with an arthroscope. The RSL ligament is continuous with the membranous proximal portion of the scapholunate interosseous ligament and attaches to the interfacet prominence, a fibrocartilaginous ridge separating the scaphoid and lunate fossae on the distal articular surface of the radius (4,8).

Ulnar to the penetration of the RSL ligament through the radiocarpal joint capsule, the short radiolunate ligament originates and courses distally to insert into the palmar horn of the lunate at the distal limit of the proximal articular surface of the lunate (8). The fibers of the short radiolunate ligament blend imperceptibly with fibers originating from the TFC complex, the ulnolunate ligament complex. The radialmost aspect of this complex is the ulnolunate ligament, which attaches to the palmar horn of the lunate just ulnar to and in continuity with the short radiolunate ligament. More ulnarly, fibers course distally, deep to the palmar portion of the lunotriquetral ligament, where they curve radially to merge with fibers from the RSL ligament palmar to the head of the capitate. Forming the ulnar “wall” of the radiocarpal joint, the ulnolunate ligament inserts into the ulnar surface of the triquetrum, anatomically behaving as an ulnar collateral ligament, and continues distally to insert into the ulnar surface of the hamate. In 60% to 70% of normal adults, a small defect filled with synovial villi is found between the ulnolunate and ulnolunotriquetral ligaments. This defect marks the entrance to the pisotriquetral joint and is uniformly lined by tufts of synovial villi. A second defect in the TFC complex—ulnar collateral ligament complex is found more proximally and in the ulnar wall, which is also lined by synovial villi. This is the prestyloid recess, which sometimes communicates with the ulnar styloid process.

Dorsally, the radiocarpal joint capsule has only one thickened region, the dorsal radiocarpal ligament (Fig. 41.3). It originates from the dorsal margin of the distal radius, centered just distal to Lister’s tubercle, and courses obliquely distally and ulnarly to insert partially into the dorsal horn of the lunate and more substantially into the dorsal surface of the triquetrum. It is separate from the dorsal portion of the lunotriquetral interosseous ligament. It is sent and supports the fourth and fifth extensor tendon compartments at the level of the radiocarpal joint. Overlapping with the insertion of the dorsal radiocarpal ligament on the triquetrum, the dorsal intercarpal ligament originates to course distally and radially, passing just distal to the dorsal horn of the lunate to insert onto the dorsal surface of the waist and distal pole of the scaphoid.

A few fibers also insert into the dorsal surface of the trapezoid. The dorsal intercarpal ligament also forms the floor of the fourth and fifth extensor tendon compartments as they cross the wrist region.

Few ligaments span the midcarpal joint—an expected anatomic feature considering the relatively high range of motion between the proximal and distal carpal rows. However, stability of the midcarpal joint depends in part on the following intrinsic ligaments (Fig. 41.1 and Fig. 41.2). On the palmar surface of the carpus, beginning radially, the first midcarpal ligament is the palmar scaphotrapeziotrapezoidal (STT) ligament. These fibers originate from the distal half of the palmar surface of the distal pole of the scaphoid and diverge in a V pattern to insert onto the proximal surface of the palmar tubercles of the trapezium and the proximal palmar surface of the trapezoid. Ulnar to the origin of the STT ligament, the scaphocapitate ligament originates from the distal pole of the scaphoid (6). The proximal limit of the scaphocapitate ligament is continuous with the distal limit of the RSL ligament. The scaphocapitate ligament is a thick ligament that courses obliquely distally and ulnarly to insert onto the radial half of the palmar surface of the body of the capitate, carrying with it some of the distalmost fibers of the RSL ligament.

Ulnarily, the trapeziotrapezoidal ligament originates from the distal margin of the palmar surface of the triquetrum, just radial to the pisotriquetral joint capsule, to course distally and radially onto the palmar surface of the body of the hamate. A group of fibers from the origin of the pisotriquetral ligament diverge radially with fibers from the ulnar collateral ligament to insert into the ulnar half of the palmar surface of the body of the capitate as the trapeziocapitate ligament. Dorsally, there is a paucity of ligaments spanning the midcarpal joint. The distalmost fibers of the dorsal intercarpal ligament diverge to insert onto the dorsal surfaces of the trapezium and trapezoid, but there are no significant capsular ligaments connecting the proximal carpal row to the capitale or hamate dorsally.

Maintaining the integrity of each carpal row is a function of the intrinsic carpal ligaments. Within the proximal carpal row, there are two intrinsic ligament systems. The scapholunate ligament is composed of thick ligaments dorsally and palmarly, with a proximal and intermediate membranous region, which is continuous with the RSL ligament (2,4,8,23). The proximal region of the scapholunate ligament is longer than the dorsal row and has a more oblique orientation, perhaps allowing more rotation between the two bones. The dorsal region is a true capsular ligament, but the palmar region is entirely intraarticular, because the palmar surface of the scapholunate ligament is covered by, but is separate from, the long radiolunate ligament. Both the dorsal and palmar ligaments of the lunotriquetral ligament are capsular, connected proximally and distally by a membranous region (32). Both regions of the lunotriquetral ligament are quite thick and roughly equivalent in length. When intact, the membranous regions of the scapholunate and lunotriquetral ligaments isolate the midcarpal joint from the radiocarpal joint. In the distal carpal row, the intrinsic carpal ligaments form a nearly continuous sheet of fibers, spanning almost the entire palmar and dorsal surfaces of the trapezium and trapezoid and the bodies of the capitale and hamate (33).

Unlike the intrinsic ligaments of the proximal carpal row, there are no membranous components to the intrinsic ligaments of the distal carpal row (Fig. 41.4). The individual regions, although difficult to separate anatomically, are called the trapeziotrapezoidal, capitotrapezoidal, and capitolunate ligaments. There are two deep intrinsic ligaments in the distal carpal row that are not appreciated until the respective joints are opened. The deep capitolunate ligament is found in a nearly square recess in the contiguous articular surfaces of the capitale and hamate, near the palmar and distal extent of the surfaces. This ligament is thick and has an average...
cross-sectional area of 25 mm². The deep capitotrapezoid ligament is situated in the mutual articular surfaces of the trapezoid and capitate, angling obliquely and dorsally toward the capitate. It is unclear what specific function these deep ligaments serve, but in addition to being mechanical constraints, they have an extremely high nerve content, suggesting some proprioceptive function.

**Figure 41.4.** These drawings of the forearm, carpus, and central metacarpal area show the alignment of (B) the balanced carpus and (A,C) the two common collapse positions—volar intercalated segment instability (VISI) and dorsal intercalated segment instability (DISI)—as they would be seen on a sagittal radiograph. A: Collapse in the VISI pattern is signified by a capitohamate angle of −30° or more. B: In the stable, normally balanced wrist, the radius, lunate, capitate, and third metacarpal form an almost colinear alignment. C: In the DISI pattern, a scapholunate angle of 80° or greater and lunate extension are typical.

**KINETICS OF THE CARPUS**

Until 1982, the understanding of carpal kinematics had remained essentially unchanged from the time of the original radiographic visualization of the carpus in 1895 (12). It was thought that the two carpal rows behaved as separate units, with the scaphoid serving as a link between the rows. Navarro challenged the row concept by introducing a columnar concept, which is supported by Taleisnik (35). This view, however, has generally been accepted in terms of kinetic loading rather than kinematic behavior. With the development of sophisticated measurement techniques and the employment of rigid-body mechanical principles, such as instantaneous screw displacement axes and Eulerian angles, a new and still evolving understanding of the interrelationships of carpal bone kinematics began to unfold (5).

The carpus is capable of motion with six degrees of freedom:

<table>
<thead>
<tr>
<th>Motion</th>
<th>Range</th>
</tr>
</thead>
<tbody>
<tr>
<td>Palmar flexion</td>
<td>60° to 80°</td>
</tr>
<tr>
<td>Dorsiflexion</td>
<td>60° to 80°</td>
</tr>
<tr>
<td>Radial deviation</td>
<td>15° to 25°</td>

<tr>
<td>Ulnar deviation</td>
<td>25° to 35°</td>
</tr>
<tr>
<td>Pronation</td>
<td>5°</td>
</tr>
<tr>
<td>Supination</td>
<td>5°</td>
</tr>
</tbody>
</table>

Combinations of these planar motions result in circumduction. There is a functional direction of motion referred to as the “dart throw” axis, which moves the wrist from dorsiflexion and radial deviation to ulnar deviation and palmar flexion. The radiocarpal and midcarpal joints are thought to contribute equally to palmar flexion and dorsiflexion. The midcarpal joint contributes approximately 50% more motion than the radiocarpal joint to radial and ulnar deviation. The overall center of rotation of the wrist is in the head of the capitate for both major planes of motion (43).

Individual carpal bone motion studies support the row concept of integrated motion (5,15,33). Negligible translation of the carpal bones has been detected, compared with the magnitude of rotation. The bones of the distal carpal row behave very much as a single integrated unit, with minimal intercarpal motion. They move in the same plane as the metacarpals, mostly because of the strong ligamentous attachments between the bones of the distal carpal row. The bones of the proximal carpal row, although overall behaving as a functional unit, show significant differences of motion within the row. As the wrist is dorsiflexed, the scaphoid, triquetrum, and lunate show decreasing magnitudes of rotation in that order. Overall, the major direction of rotation is similar to that of the distal carpal row, but as dorsiflexion is achieved, the scaphoid supinates and the lunate pronates, resulting in a palmar separation of the two bones (23). The scaphoid also rotates through a greater arc relative to the lunate, further separating the palmar aspects of the two bones. The reverse phenomenon occurs in palmar flexion. There is little difference in the pronation or supination angles between the lunate and triquetrum. From ulnar deviation to radial deviation, the major axis of proximal row bone motion is palmar flexion. The relative pronation and supination tendencies of the scaphoid and lunate are similar to those found in palmar flexion of the wrist. The reverse phenomenon occurs in ulnar deviation, with relative separation of the palmar aspects of the scaphoid and lunate, as in dorsiflexion of the wrist. The additional degrees of freedom found in proximal row bone kinematics is probably due to the relative paucity of interosseous ligaments compared with those of the distal carpal row. This may explain the predisposition of the proximal carpal row to mechanical dissociation relative to the distal carpal row.

**TERMINOLOGY AND CLASSIFICATION**

The term instability has been used for years in many different forms, and this has led to substantial confusion and misuse of the term. Recently, the Anatomy and Biomechanics Committee of the International Federation of Societies for Surgery of the Hand published a position statement dedicated to refining the definition of carpal instability (15). In the strictest terms, carpal instability is defined as a condition in which the wrist is unable to bear loads and does not exhibit normal kinematics throughout its arc of motion. This may include malalignment, but malalignment per se does not imply instability. Instability may be purely mechanical, or it may be clinical, as in a patient who has symptoms related to the instability. There are three categories of instability. A grade I or grade II (see Chapter 98) sprain of the soft-tissue restraint mechanisms of the carpus caused by a subluxation alters the natural relationships, but less than with a dislocation. A more severe sprain, perhaps a grade III with complete rupture, is usually caused by a dislocation (luxation). There is sufficient disruption of the soft-tissue restraints to cause two or more normally congruent joint surfaces to lose contact and congruency. A fracture–dislocation is similar to a dislocation, except that one or more major fracture fragments (i.e., at least 3–5 mm in greatest dimension) are produced by the force.

The most common carpal disruption is the perilunate dislocation pattern, which is a combination of radiocarpal and midcarpal disruption. The possible patterns, in proximal to distal progression, are radiocarpal, perilunate, midcarpal, axial, or combinations of these. Various degrees of sprain, dislocation, and fracture–dislocation can occur at any of the anatomic sites (Table 41.1). Fractures of a single or multiple carpal bones are often unstable and are therefore suitable for inclusion under the fracture–dislocation or subluxation categories, but they are discussed in Chapter 42 on fractures of the carpal bones.

**Table 41.1. Carpal Instability Categories**

Diagnosis and treatment are aided by classifying these complex injuries into certain patterns characterized by the mechanism of injury and resultant instability pattern.
The Scaphoid Shift Test (Watson’s Test) does not specifically identify an injury. Compress the proximal carpal row by simultaneously applying convergent pressure to the scaphoid and triquetrum. A positive test is simply a complaint of pain and is identical to or different from the usual symptoms. When conducting any of these tests, particularly provocative maneuvers, ask the patient about pain production and whether the symptoms produced are similar or different from the expected pain. Several tests are useful, including the following:

- Localize the tenderness.
- Test for the presence, power, and excursion of the regional musculotendon units.
- Test for grip power, grip endurance, pinch power, and pinch endurance.
- Examine all neurovascular structures in the hand and wrist.
- Use various provocative maneuvers, which may be active or passive (see following sections). Include any maneuvers known by the patient to elicit symptoms.

The most common provocative maneuvers employed in examining the wrist are those directed at detecting disruptions in the interosseous ligaments between the scaphoid and lunate, as visualized on a lateral radiographic view, whether facing dorsally or palmarly is the clue as to whether it is a DISI or VISI pattern. It is important to know whether the lunate is still bonded or linked with none, one, or both of its proximal carpal row neighbors, the scaphoid and triquetrum. If it is linked, it is termed nondissociated, and, if unlinked, dissociated. DISI or VISI may therefore be coupled with the following acronyms: CID, CIND, and CIC.

The term dissociative has been used for 20 years and was originally coined to describe the abnormal relationships occurring after injury at the scapholunate and triquetrolunate joints. Because the most obvious damage in scapholunate dissociation is to the intrinsic scapholunate and lunotriquetral ligaments in triquetrolunate dissociation, it seemed reasonable to use the term nondissociative for instabilities in which the initial damage appears to be to the extrinsic ligaments of the carpus. Another way of describing the difference is that dissociative lesions begin with damage to the intercarpal ligaments; nondissociative lesions begin with damage to the intracarpal or forearm–carpal ligaments. It is appropriate to refer to a standard midcarpal instability as a CIND-VISI or CIND-DISI, depending on whether the collapse position is in flexion or extension. Because the proximal carpal row is deforming as a unit, this deformity is entirely different from the VISI deformity often seen with triquetrolunate dissociation, in which the deformity takes place within the proximal carpal row. If the intrinsic and extrinsic ligaments are damaged or if ligamentous elements at the radiocarpal and midcarpal levels are damaged, the carpal instability is combined or complex, and the abbreviation CIC is appropriate. This is often unnecessary because most instabilities eventually involve both intrinsic and extrinsic stabilizing structures. Staging of the condition implies various levels of damage to support structures. This theme is developed further as the specific instabilities are discussed.

The terms dynamic and static are also embedded in the literature and still serve a useful purpose, but they are susceptible to misunderstanding. Dynamic may mean progressive, and it is widely interpreted in that way in Europe. Applied to carpal instabilities, it was and is used to describe instabilities that do not appear obvious on the standard posteroanterior (PA) and lateral radiographs but require some stress or loading with the use of a provocative maneuver or a special imaging technique to display the instability. In this sense, dynamic has two different meanings. Static implies that the instability is obvious on standard radiographs taken without special loading maneuvers or techniques. There is a progression of destabilization in carpal instability diagnoses. The spectrum of possibilities in a given instability varies from a barely noticeable sprain or contusion to a severe and seemingly fixed deformity, often with arthritic changes.

### DIAGNOSIS AND PATIENT EVALUATION

The current spectrum of clinically discrete, named pathologic entities includes those listed in Table 41.2.

#### HISTORY

Determine the nature of the trauma, the forces involved, and the position of the wrist and hand at impact. If it is possible, determine whether the injury was a single episode (with or without a particularly dramatic incident), multiple episodes, or not related to a memorable episode. Obtain any information relevant to a prior incident, diagnosis, or treatment involving the same area.

#### PHYSICAL EXAMINATION

Deformity, swelling, abnormal positioning of the wrist, and difficulty in controlling wrist motions are the more common visible signs. There are many soft-tissue problems, particularly tendon entrapments, that may result in audible or palpable crepitus at the wrist, but joint problems also produce noises. These are generally described as clicks, snaps, clunks, thuds, or creaks. Localize these, if possible, and relate them to the movement or stress that produces them. Try to reproduce the patient's pain and relate it to a particular sign or maneuver.

Several tests are useful, including the following:

- Localize the tenderness.
- Test for grip power, grip endurance, pinch power, and pinch endurance.
- Examine all neurovascular structures in the hand and wrist.
- Use various provocative maneuvers, which may be active or passive (see following sections). Include any maneuvers known by the patient to elicit symptoms.

The most common provocative maneuvers employed in examining the wrist are those directed at detecting disruptions in the interosseous ligaments between the scaphoid, lunate, and triquetrum. Many more maneuvers have been described in one form or another, but these form a core of examinations that can be built upon. When conducting any of these tests, particularly provocative maneuvers, ask the patient about pain production and whether the symptoms produced are similar or identical to or different from the usual symptoms.

#### Carpal Compression Test

Compress the proximal carpal row by simultaneously applying convergent pressure to the scaphoid and triquetrum. A positive test is simply a complaint of pain and does not specifically identify an injury.

#### Scaphoid Shift Test (Watson’s Test)
Place the thumb on the palmar skin over the distal pole of the scaphoid and the index finger on the dorsal skin over the scapholunate joint, and palpate the distal pole of the scaphoid at the point where the tendon of the flexor carpi radialis is no longer palpable. The scapholunate joint can be located just distal to the dorsal rim of the radius in line with Lister’s tubercle. Beginning with the patient’s wrist in ulnar deviation, apply a dorsally directed force to the distal pole of the scaphoid while passively deviating the wrist radially. Use the index finger to detect a dorsal shift of the proximal pole of the scaphoid. A positive test is one in which a subluxation is palpated or the patient complains of pain in the region of the dorsal scapholunate joint; it is relatively specific for scapholunate dissociation (38).

Lunotriquetral Shuck Test (Kleinman’s Test)

Place one finger dorsally over the lunate and another palmar to the pisiform, and apply oppositely directed forces through the fingers while the patient’s wrist is passively radially and ulnarly deviated. A positive test is a sense of subluxation through the lunotriquetral joint and pain with the maneuver (26).

Lunotriquetral Ballottement Test (Reagan’s Test)

Stabilize the lunate with one hand and the pisiform–triquetrum column with the other hand. The pisiform–triquetrum column is passively shifted dorsally and palmarly. A positive test is one in which there is an excessive degree of motion compared to that in the contralateral wrist, and the patient complains of pain (30).

IMAGING

The examination should start with high-quality, unambiguous, standard-position PA and lateral radiographs of the wrist (Fig. 41.5) (19). In our practice, these are most often supplemented by stress views (usually grip-compression or arm-weight-traction views), motion studies (lateral extension–flexion or PA deviation views), or special projections, such as carpal tunnel views. If the diagnosis remains unclear, a technician scan, fine-cut computed tomography (CT) with reconstructions, or arthrography of the three carpal spaces may be helpful. Occasionally, ultrasound, magnetic resonance imaging (MRI) with and without gadolinium, or three-dimensional reconstruction may be indicated.

![Figure 41.5. Posteroanterior (A) and lateral (B) radiographs of a normal wrist. From the posteroanterior radiograph, one can easily assess the congruency of the carpal bone alignment using Gilula’s lines (I,II,III) as well as assess ulnar variance. From the lateral radiograph, the scaphoid (dashed line) and lunate (solid line) are easily identified.](image)

ARTHROSCOPY AND SURGICAL EXPLORATION OF THE WRIST

In skilled hands, arthroscopy yields information equivalent to and sometimes better than the combined imaging techniques. However, a thorough understanding of normal arthroscopic anatomy of the wrist is fundamental to making an accurate diagnosis and formulating a treatment plan (1).

An often overlooked value of arthroscopic surgery is that it provides the opportunity to examine the range-of-motion and perform provocative maneuvers before, during, and after surgical access to the wrist. It is fairly common that the information gained about the wrist in this way alters the treatment plan.

An improved surgical approach through the dorsal wrist joint capsule offers many theoretical and practical benefits (Fig. 41.6) (3) This approach is based on the anatomy of the dorsal radiocarpal and dorsal intercarpal ligaments. The dorsal radiocarpal ligament attaches to the dorsal rim of the radius between Lister’s tubercle and the dorsal edge of the sigmoid notch, and distally to the dorsal lobe of the triquetrum. At this same level, the dorsal intercarpal ligament attaches to the triquetrum and spans the midcarpal joint to insert into the dorsal surface of the waist of the scaphoid, the lateral surface of the distal pole of the scaphoid, and the dorsal surface of the trapezoid.

![Figure 41.6. A: The dorsal surface of the carpus defining the anatomy of the dorsal radiocarpal ligament (DRC) and the dorsal intercarpal ligament (DIC). (S, scaphoid; L, lunate; T, triquetrum; Td, trapezoid; DRU, distal radioulnar ligament; R, radius; U, ulna; LT, Lister’s tubercle). B: The dorsal surface of the carpus outlining the landmarks used to create a fiber-splitting capsulotomy. The DRC attaches proximally along the dorsal rim of the radius between LT and the sigmoid notch and distally onto the dorsal lobe of the triquetrum. The DIC attaches ulnarly onto the dorsal lobe of the triquetrum and radially onto the scaphoid and trapezoid. The DRC is split by dividing the distance between LT and the sigmoid notch and connecting this point to the dorsal lobe of the triquetrum. The DIC is split by connecting the dorsal lobe of the triquetrum to the sulcus between the scaphoid and trapezoid. The capsulotomy can be reflected radially by incising the remaining attachment of the capsule along the dorsal rim of the radius to the tip of the radial styloid process. C: The completed fiber-splitting capsulotomy showing the reflected joint capsule. Exposed are the scaphoid, lunate, hamate, and capitate, as well as the radial two-thirds of the radiocarpal joint and the entire midcarpal joint. (From Berger RA, Bishop AT. A Fiber-splitting Capsulotomy Technique for Dorsal Exposure of the Wrist. Tech Hand Upper Extremity Surg 1997;1:2, with permission.)](image)

- After performing a dorsal approach to the wrist capsule using the incision of your preference, identify the following landmarks by palpation: Lister’s tubercle, sigmoid notch, dorsal lobe of the triquetrum, and sulcus of the STT joint.
- Make an incision from the central aspect of the dorsal lobe of the triquetrum proximally to the midpoint between Lister’s tubercle and the sigmoid notch (splitting the dorsal radiocarpal ligament) and radially to the sulcus of the STT joint (splitting the dorsal intercarpal ligament).
- Release the dorsal radiocarpal joint capsule from the dorsal rim of the radius radially, until reaching the tip of the styloid process.
- Tangential to the dorsal cortices of the proximal carpal row, sharply elevate the radially based flap of capsule, exposing the entire midcarpal joint and the radial two-thirds of the radiocarpal joint.

This technique spares half of the normal course of the dorsal capsular ligaments, offers excellent exposure, and provides flexibility in performing capsular modifications, such as capsulodesis, without compromising exposure or stability.
PRESENTATION OF CARPAL INSTABILITY

A survey of the diagnostic methods applied to carpal instability is incomplete without emphasizing that the condition has many presentations, which can be grouped roughly as follows:

1. Symptoms are present, but there is no or questionable deformity, even with imaging and provocative testing.
2. A condition, often referred to as a dynamic instability, may exist; this means that with appropriate stress—sometimes no more than wrist movement—a deformity occurs, but it spontaneously disappears after the stress is discontinued.
3. When a deformity is present on standard radiographs, even at rest, it is often referred to as a static deformity, for which there are three subdivisions: easily reducible, only reducible with difficulty, or not reducible at all by nonsurgical means.
4. The final stage of carpal instability is that of an almost fixed deformity with arthritic changes. The location and degree of the arthritic change are important.

CLINICAL SYNDROMES AND OTHER CARPAL INSTABILITIES

RADIOCARPAL LEVEL

Barton's fracture–dislocation is the most common carpal instability at the radiocarpal level and is usually discussed in the same manner as components of distal radial fractures (14,25,34,36,39) (see Chapter 44). Ulnar translation is the second most common instability at the radiocarpal level (29). It may occur as the residual of a full radiocarpal or perilunate dislocation, or it may develop after lesser degrees of trauma. Its manifestations may be subtle, or there may be a clinically visible ulnar displacement of the carpus and hand. Radiographs may show a gross ulnar displacement on the PA view, with the lunate directly distal to the TFC, or the displacement may be so mild that the lunate overlaps half on the radius and half over the TFC (a 50:50 lunate), rather than the usual 60% or more overlap on the radius. If there is a perilunate (i.e., scapholunate) disruption as well, the scaphoid may remain anatomic, permitting the lunate with the central and ulnar carpus to translate ulnarily (Fig. 41.7). Ulnar translation is a common end point of many carpal instabilities from either the initial injury itself or from chronic stress due to loading at the radiocarpal level, even after various reconstructions. If there is any evidence of ulnar translation instability, reconstructions that increase radiocarpal loading should be avoided.

Figure 41.7. PA view of a combined ulnar translation and perilunate disruption, demonstrating the ulnar shift of the lunate (black arrows), the increased scapholunate gap, and the 40:60 ratio (radial support to TFC support) position of the lunate.

For primary treatment, repair of freshly damaged ligaments dorsally and palmarly may be worthwhile, if done during the first 4–6 weeks and protected with percutaneous internal fixation for approximately 3 months. Even under these circumstances, the tendency toward ulnar slide is so great that many attempts fail. Decreasing the radial-to-ulnar angle by a closing wedge osteotomy of the radius added to the ligament repair or reconstruction has been considered, but experience with this approach is limited. The only procedure proven to halt ulnar translation is a limited radiolunate or RSL carpal fusion.

PERILUNATE LEVEL

The greatest number of wrist instabilities occurs at the perilunate level (Fig. 41.8), reflecting a combination of radiocarpal and midcarpal disruption patterns (28). The disruption probably occurs in this manner because the lunate is strongly bound to the distal radius and weakly bound to the distal carpus; combined with the strut-like interference of the radially stabilizing scaphoid, which often fractures, this produces the most common of the full dislocations of the carpus: transscaphoid perilunate fracture–dislocation. This and other transosseous perilunate dislocations are often referred to as greater arc injuries, and the purely ligamentous perilunate dislocations are called lesser arc injuries (Fig. 41.9) (28).

Figure 41.8. The most common dislocations involving the carpus. Group I, perilunate and lunate dislocations, are usually only different stages of the same disruption pattern. Groups II and III are variations of the transosseous perilunate dislocations plus dislocations of single or paired carpal bones. Group IV includes the radiocarpal dislocations, both ligamentous and transosseous (i.e., fragments of the radius, ulna, or both bones).

Figure 41.9. Coronal-plane sketches of the wrist showing simplified versions of one of the disruption pathways for a lesser arc injury (left) and a greater arc injury (right). Several additional versions of the greater arc injuries are seen in groups II and III of Figure 41.7.
Most perilunate level injuries result from the application of a body-weight force on an outstretched hand, such as during a fall, a sports-related impact, or a motor vehicle accident. Certainly, injuries to the perilunate ligaments can occur with less impact under certain circumstances. Mayfield et al. (23) recreated a pattern of progressive perilunate instability by applying excessive axially directed loads to cadaver specimens positioned in maximum ulnar deviation, dorsiflexion, and supination. Ulnar-sided instability patterns are felt to result from similarly directed force in a radially deviated wrist, although this has not been reproduced in a laboratory environment. It is also conceivable that ligamentous injuries can occur with the wrist positioned in palmar flexion.

These fracture-dislocations and dislocations are fairly obvious clinically, resulting in a painful, tender, short, broad, and thick wrist. On radiographs, overlap of the carpal rows, an empty-cup lunate, and a displaced capitate are usually obvious (Fig. 41.10 and Fig. 41.11), but there is a remarkably high incidence of failure to diagnose this injury. There are many variants of this injury that do not reflect the full disruption pattern or that spontaneously reduce and therefore may be very difficult to diagnose. If the suspicion exists that a carpal injury may be greater than is obvious, one should investigate further with movement, traction, compression, and translational provocative maneuvers, as well as arthrography or arthroscopy. High-resolution tomography or CT will demonstrate the fracture details.

![Figure 41.10. PA (A) and lateral (B) radiographs show details of a complicated transosseous perilunate type of fracture-dislocation. It can be described as a transscaphoid, transunlar styloidy, perilunotriquetral dislocation with an associated subluxation of the pisiform. The lunate and triquetrum are still in a relatively normal alignment with the forearm, and all physicians would be willing to call this a perilunate type of dislocation.](image)

![Figure 41.11. PA (A) and lateral (B) radiographs of the same wrist show the lunate displaced palmarward and ulnarward, permitting the distal carpal row elements, particularly the capitate and hamate, to intrude toward the radius, displacing the scaphoid into flexion and the triquetrum ulnarward. Most physicians would call this a lunate dislocation because the carpal bones, other than the lunate, are fairly well aligned with the forearm. Nevertheless, the lunate is still in contact with a portion of its articular surface with the radius and still has intact ligament connections by its palmar radiolunate ligaments; therefore it is a stage of perilunate dislocation.](image)

Treat early with closed reduction to minimize the risk of neurovascular or musculotendinous compromise (14,27,28,34,36). Longitudinal traction with the fingers in Chinese finger traps combined with manipulation usually results in reduction, especially if anesthesia is used. Sometimes, closed reduction can be maintained with the help of three-point molding in a thumb spica cast or splint (see Chapter 10). Apply dorsally directed pressure with pads and careful cast molding at the palmar projections of the scaphoid tuberosity and the pisiform, and palmarly directed pressure with pads and careful cast molding at the neck and dorsal sulcus of the capitate and Lister's tubercle. Monitor the patient closely after reduction to manage pain and swelling, assess sensory and motor functions, and ensure that the reduction is maintained. If the reduction is lost, open reduction and internal fixation, sometimes with a bone graft, is indicated. During open reduction and fixation, accomplish the following:

- Inspect and decompress the median and ulnar nerves, if compromised, and repair any extraarticular soft-tissue damage.
- Inspect and repair extrinsic and intrinsic ligament damage.
- Remove intraarticular debris and any interposed material.
- Survey and record the areas of joint cartilage damage and treat, if appropriate.
- Identify and treat fractures, restoring bone substance, position, and shape.
- Anatomically realign the carpal elements to each other and to the forearm.
- Internal fixation, percutaneous fixation, external fixation, or combinations of these are usually required to maintain position.

The postoperative routine depends on the specifics of the injury. Incorporate the hand and forearm in a well padded thumb spica splint, and elevate the hand. Start immediate motion of the fingers. Do not remove Kirschner wires (K-wires) for 8 weeks, unless they are loose or symptomatic. Splint the wrist and do not start range-of-motion exercises before 3 months.

SCAPHOLUNATE DISSOCIATION

Scapholunate dissociation and rotary subluxation of the scaphoid are the same disorder, but the terms focus on differing aspects of the pathology. One directs attention to the linkage between the scaphoid and the rest of the proximal carpal row, and the other focuses on the scaphoid itself; both terms have been expanded to include the entire spectrum of injuries that disrupt the normal relationships of the scaphoid to the rest of the carpus. The pathomechanics of this condition are variable, but the classic mechanism is the same as that for perilunate dislocation. It is obvious that scapholunate dissociation as a residuum of perilunate dislocation is a more unstable variety than scapholunate dissociation as a solo entity.

It is entirely possible for scapholunate dissociation to occur independently of clinically significant perilunate injuries, although the entire spectrum of perilunate injuries must be considered with regard to treatment options. It has been hypothesized that even partial injuries of the scapholunate ligament may progress with cyclic loading to complete dissociation over time. In our experience, the palmar region of the scapholunate ligament is the most commonly disrupted site. This is probably related to the combined limited strength of the palmar region of the ligament and the phenomenon of mutual separation of the palmar regions of the scaphoid and lunate during wrist dorsiflexion and ulnar deviation.

Scapholunate dissociation tends to progress (27). Although some wrists are so inherently stable that a tear of the scapholunate interosseous membrane alone may have little clinical consequence, gradual attenuation of the regional extrinsic support system leads to increasing dissociation. This, plus the fact that none of the current treatments predictably restores normal stability and mobility, explains the continuing confusion about treatment.

**Indications for Treatment**

Acute scapholunate dissociation requires treatment. Consider reconstruction of a large or chronic scapholunate dissociation that shows any of the following:

- Scapholunate gap of greater than 3 mm (Fig. 41.12)
Scapholunate angle of greater than 60°

A positive arthrogram or arthroscopic examination confirming a scapholunate ligament tear with increasing symptoms and minimal joint arthritis

The hope is to avoid the classic pattern of arthritic deterioration in progressive scapholunate dissociation.

**Principles of Treatment**

Several principles apply to the treatment of a scapholunate dissociation (13,14,34,36,40):

- Direct initial treatment of the fresh injury at protecting or repairing all the damaged ligaments and capsular structures.
- If repair is not possible or provides only questionable stability, reconstruction of or substitution for the damaged ligaments is appropriate. Bony stabilization by limited intercarpal fusion is one method of substituting for the damaged ligaments.
- Combinations of repair and reconstruction may be used.

**Surgical Techniques**

Although there are many operative procedures for treating scapholunate dissociation, only two are described here, in addition to the recommended management for the acute, reducible injury. Both surgical methods are best applied if the deformity is easily reducible. If the deformity is very difficult to reduce or if unexpectedly severe cartilage damage is found, a salvage procedure, such as a proximal row carpectomy or a more extensive fusion, may be indicated.

Treatment algorithms seem confusing and variable for scapholunate dissociation. These include cast immobilization, percutaneous pinning, direct ligament repair, capsulodesis, tenodesis, ligament reconstruction, and intercarpal arthrodesis.

A true scapholunate dissociation should not be treated closed because of the following paradox of reduction. In the normal wrist, the scaphoid and lunate will tend to separate at their anterior surfaces during dorsiflexion, while at the same time becoming more rotationally aligned to one another. In scapholunate dissociation, a diastasis develops between the scaphoid and lunate, and rotational displacement between the two bones increases. An attempt to close the scapholunate angle by dorsiflexing the wrist produces an increase in the diastasis, and an attempt to decrease the diastasis by palmar-flexing the wrist increases the scapholunate angle.

A grading scheme for dissociative carpal instability, based on the level of instability as defined by midcarpal arthroscopy, has been developed by Geissler and Freeland (18) (Table 41.3). On the basis of this scheme, we adopted the following treatment algorithm: If the injury is acute and the scapholunate relationship can easily be restored to normal, the scapholunate ligament should be allowed to heal primarily in accordance with the options listed in Table 41.4. For soft-tissue repairs alone to be successful, the reduction must easily be achieved and maintained, and the security of the soft-tissue repair must be high.

Table 41.3. Arthroscopically Based Grading of Dissociative Carpal Instability (Geissler and Freeland, 1996)

Table 41.4. Recommended Treatment for Scapholunate Dissociation Based on Arthroscopic Grades, Chronicity, and Ease of Reduction

- Perform a dorsal fiber-splitting capsulotomy as described above. A palmar approach is occasionally indicated, which necessitates entering the carpal tunnel.

**Palmar Approach**

- Make a standard carpal tunnel incision with a curvilinear proximal extension, preserving the palmar cutaneous branches of the median nerve. Retract the flexor tendons after blunt dissection through the mesotenon radially or ulnarily. Take great care to protect the median nerve, which must be retracted radially, from excessive compression or tension.

- After visualizing the floor of the carpal tunnel, perform a synovectomy, using rongeurs; this reveals the fibrous lining of the palmar carpal ligaments. At this point, verify your orientation to the carpal anatomy; ligamentous tissue is seen converging on both the lunate and the capitate. It is easy to become confused about
which bone is which. If there is any question about a specific level, place a metallic instrument on the bone in question, and obtain a radiograph.

**Acute Scapholunate Dissociation**

Closed reduction and prolonged support are appropriate if ideal alignment is obtained. However, ideal alignment is difficult to achieve in a true, complete scapholunate dissociation, for the reasons cited above. Therefore, closed management is best reserved for the treatment of incomplete scapholunate dissociation, or scapholunate "sprains," where the scapholunate rotational and diastatic relationships are normal.

- Cast support is similar to that described for perilunate dislocation. It may be necessary to percutaneously place temporary multiple K-wires across the scapholunate, radioscaphoid, or scaphocapitate joint intervals. If satisfactory anatomic alignment cannot be achieved, perform a dorsal approach to the carpus as described above.

- After the scaphoid and lunate are exposed, assess the damage to the scapholunate ligament. If the injury is acute, there is usually sufficient tissue to perform a direct repair. Place 0.047 mm K-wires, to be used as joysticks, into the dorsal aspects of the scaphoid and the lunate; these greatly enhance the ease of exposure and reduction.

- Reduce the scapholunate joint anatomically, stabilize it with two K-wires, and then remove the joysticks. Fully reflect the dorsal radiocarpal joint capsule to the level of the waist of the scaphoid. Do not completely strip the capsule from the scaphoid because it is the major source of blood supply to the bone.

- With the wrist maximally flexed toward the palm, use a small burr to "freshen" the attachment line of the scapholunate ligament that has been disrupted, usually along the ulnar margin of the scaphoid.

- With a 1/2 inch (0.8 mm) drill point, drill four to six holes from this freshened margin distally and radially to exit just distal to the proximal articulating surface near the ridged waist of the scaphoid. Using Keith needles, pass a nonabsorbable suture (2-0 or 3-0 Mersilene) through the remnant of the scapholunate ligament and distally through the drill holes to exit at the waist of the scaphoid, where the sutures are tied securely (Fig. 41.13). Bring the radiocarpal joint to a neutral position, and take intraoperative radiographs to confirm the reduction.

**Persistent Scapholunate Dissociation**

Subacute and chronic scapholunate ligament tears are more difficult to treat than injuries. It may be difficult to anatomically reduce the subacutely or chronically disrupted scapholunate joint and obtain a repair that will withstand the demands that the patient will place on the wrist afterward. Degenerative changes will influence the choice of procedure. Two operative approaches are available: soft-tissue repair and augmentation or limited arthrodeses.

Proponents of limited arthrodeses to stabilize the malrotated scaphoid advocate STT fusion or scaphocapitate fusion. Radiocarpal or midcarpal degenerative changes detected radiographically are strong indications for intercarpal fusion. Important objectives with the STT or scaphocapitate fusion include reduction of the malrotated vertically displaced scaphoid, achieving parallelism and congruity of the proximal scaphoid and scaphoid sulcus, closure of the scapholunate interval, and maintenance of carpial height.

**Scaphotrapeziotrapezoidal Fusion**

- Approach the STT joint region through a transverse incision centered over the STT joint or through the longitudinal approach described previously, with a distal extension. If there is any question about the integrity of the articular surfaces of the midcarpal or radiocarpal joints, conduct a preliminary arthroscopic evaluation.

- With dorsal exposure of the STT joint region, adequately decorticate the distal articular surface of the scaphoid and the proximal articular surfaces of the trapezium and trapezoid.

- Position the scaphoid, with radiographic confirmation, so that the radioscaphoid angle is 40° to 45° and the carpal height is restored. Stabilize the three bones in this position with multiple K-wires, Herbert screws or AO screws, or staples, and pack autogenous bone graft from the iliac crest or ipsilateral radial metaphysis into the decorticated region.

- If scaphocapitate fusion is preferred, expose the radiocarpal joint interval through the dorsal longitudinal approach. Decorticate the radial articulating surface of the capitale and the ulnar articulating surface of the distal one-half of the scaphoid. Mobilize, reduce, and bone-graft, as with the STT arthrodesis. Some surgeons advocate carrying out a radial styloidectomy to preserve the origins of the palmar radiocarpal ligaments. Great care must be taken in performing a radial styloidectomy to preserve the origins of the palmar radiocarpal ligaments.

- After an STT or scaphocapitate fusion, we recommend postoperative immobilization with a thumb spica short-arm cast followed by a supporting splint for 4–6 weeks. Use radiographic evaluation on a regular basis to estimate consolidation of the fusion mass. This evaluation may be enhanced with the use of trispiral tomography.

**Soft-tissue Repair and Augmentation**

If there is a subacute or chronic scapholunate dissociation with an essentially fixed deformity, which is difficult to reduce and tends to recur, or if there are periscaphoid degenerative changes or other special situations such as coexisting Kienböck’s disease, the arthrodesis techniques described previously, including STT and scaphocapitate limited fusions, are preferable. If the deformity is relatively easy to reduce and there are no obvious signs of periscaphoid degenerative changes, soft-tissue repair and augmentation may be preferred. The basic prerequisite for soft-tissue repair and augmentation is the ability to reduce and maintain all relationships of the carpus, particularly the abnormally aligned scaphoid, radiocarpal, scapholunate, capitate, and STT joints. Restoration of these relationships is achieved if the scapholunate gap is reduced to 3 mm or less, the scapholunate angle is about 40°, and the capitolunate angle is less than +15°. The soft-tissue procedures center on repair of the remnant of the scapholunate ligament, as described in the section on acute scapholunate injury, supplemented by a capsular flap or a tendon graft flap. The augmentation can be carried out with superficial capsulodesis techniques or by passing an extrinsic tendon graft through the scaphoid and lunate to enhance stability. The capsulodesis described by Blatt (10) uses the dorsal radiocapitate joint capsule with a proximal base; the distal edge of the flap is tethered to the dorsal aspect of the distal scaphoid. The tissue used for this procedure is relatively isotropic, and the resistance to chronic linear shear in tension is suspect.

A technique developed by Dobyns and Linscheid employing a capsuloligamentous flap theoretically promises greater resistance to deforming forces. This flap is based distally over the STT region and incorporates essentially the proximal one-half of the dorsal intercarpal ligament (Fig. 41.14).
forces that must be resisted by damaged and other questionable tissues. Because of these problems, partial or complete recurrence of deformity was common in the system over a prolonged period. There is not sufficient experience with these methods to respond to this concern. The virtue of the soft-tissue techniques is that, at styloidectomy of the radius be performed at the time of the fusion. The long-term concern with radial column fusions is the effect of increased loading on one joint deterioration may occur. After STT fusions, impingement between the distal scaphoid and the radial styloid may occur, and it has been suggested that a small channel and across the scapholunate articulation through the mutual articular channels to exit through the dorsal channel of the lunate. (Fig. 41.15)

Using extrinsic wrist extensor or flexor tendons to augment intrinsic repair is technically demanding. This procedure requires a dorsal and palmar approach and uses a split, distally based strip of extensor carpi radialis longus or flexor carpi radialis, which is passed through drill holes in the scaphoid and lunate in a closed-loop fashion. The blood supply to the proximal pole of the scaphoid and lunate is fragile, and the drill holes do place these bones at risk for avascular necrosis; however, proponents of this technique think that it provides strong static control of the scaphoid.

A modification of this technique proposed by Brunelli and Brunelli (11) is a tenodesis procedure utilizing a distally based strip of flexor carpi radialis. A drill hole is created in a dorsopalmar orientation through the distal pole of the scaphoid, through which the tendon strip is passed. It is then passed proximally and secured to the dorsal rim of the radius. The rationale behind this procedure is the author’s theory that advanced rotational subluxation of the scaphoid requires not only compromise of the scapholunate ligament but also instability at the STT joint. The tendon strip of the flexor carpi radialis stabilizes the STT joint and prevents excessive palmar flexion of the scaphoid.

Recently, interest has developed in substituting bone–ligament–bone autografts for the scapholunate ligament in patients with prearthritic scapholunate dissociation in whom inadequate ligament is present for direct repair. A recent laboratory study evaluating the strength and constraint properties of the subregions of the scapholunate ligament identified the dorsal region of the ligament as the strongest and the major constraint to translation and distraction (7). Proposed substitutes have included bone–ligament–bone complexes based on extensor retinaculum, interscalars, intercarpal ligaments, and carpometacarpal ligaments. These carry significant promise, but clinical experience is very preliminary at this point. One should be cautioned that the strength of the transplanted tissue should approach that of the native scapholunate ligament but also instability at the STT joint. The tendon strip of the flexor carpi radialis stabilizes the STT joint and prevents excessive palmar flexion of the scaphoid.

Postoperative Care and Rehabilitation Postoperative care and rehabilitation are similar for both bony and soft-tissue repair techniques. Support the wrist in the neutral position for 8 weeks or more, removing K-wires between 8 and 12 weeks (sooner if required). Immediately initiate shoulder, elbow, and digit range-of-motion exercises; introduce forearm motion gradually if there is no associated ulnocarpal or forearm problem. Begin wrist motion between 8 and 12 weeks. Keep the exercise limited, light, and isokinetic until 20 weeks. Begin grip strengthening at 6 months. Wrist stress loading may begin at 1 year, contingent on comfort and a benign examination. Earlier rehabilitation may succeed, but the risk of overstressing the wrist is great and it pays to be cautious.

PITFALLS AND COMPLICATIONS

The virtue of the limited fusion techniques is their relative simplicity. It is important to know that the radioscapophoid joint, which takes most of the loading for the carpus, is in good condition; it is vital that this joint be reduced and maintained at its most congruent fit. If these two conditions are not met, rapid radioscapophoid joint deterioration may occur. After STT fusions, impingement between the distal scaphoid and the radial styloid may occur, and it has been suggested that a small styloectectomy of the radius be performed at the time of the fusion. The long-term concern with radial column fusions is the effect of increased loading on one joint system over a prolonged period. There is not sufficient experience with these methods to respond to this concern. The virtue of the soft-tissue techniques is that, at their best, they restore a more normal distribution of stress across the carpal joints. The problems are the relative complexity of the repair techniques and the large forces that must be resisted by damaged and other questionable tissues. Because of these problems, partial or complete recurrence of deformity was common in the

**Figure 41.14.** Dobyns and Linscheid's capsulodesis for augmenting scapholunate ligament repair. The exposed carpal region is seen from a proximal, dorsal, and radial perspective, and the dorsal radiocarpal ligament (DRC) and dorsal intercarpal (DIC) ligaments are also exposed. (S, scaphoid; R, radius; U, ulna; T, triquetrum; L, Lister's tubercle.)

**Figure 41.15.** Dorsal scapholunate ligament reconstruction and capsulodesis technique. A: The exposed carpus is seen from a proximal, dorsal, and radial perspective. The dorsal radiocarpal (DRC) and dorsal intercarpal (DIC) ligaments are also exposed. (S, scaphoid; R, radius; U, ulna; T, triquetrum; L, Lister's tubercle.) In the same fashion by which the DRC flap was elevated in Dobyns and Linscheid's technique (Fig. 41.14), the radial half of the DRC is elevated by detaching its insertion onto the dorsal triquetrum, with the proximal flap left attached to the dorsal rim of the radius. B: Using a high-speed drill or burr, make channels in the dorsal cortices of the scaphoid and lunate adjacent to the scapholunate articulation. These vertical channels are connected to horizontal channels passing just on the dorsal margin of the mutual articular surfaces of the scaphoid and lunate within the joint cleft. C: Pass the proximally based DRC flap into the dorsal opening of the scaphoid channel and across the scapholunate articulation through the mutual articular channels to exit through the dorsal channel of the lunate. D: Draw the DRC flap over the dorsal aspect of the scapholunate ligament and suture it onto itself, after adjusting the tension. Before final suturing, provisionally reduce the scapholunate dissociation and repair the scapholunate ligament, if possible.
early days of soft-tissue repair and reconstruction. The current techniques appear to be giving improved short-term results, but they must pass the test of time (24).

The problems described are the major pitfalls of these techniques, but as in all musculoskeletal procedures, other complications are seen, including pain dysfunction syndromes, neurovascular and compartment compromise, and infection. The last two are infrequent but serious and must be identified early and treated vigorously. Pain is so common that it should be assumed to be a likely occurrence. Plan on good pain control with particular attention to the control of swelling, autonomic dysfunction, and an early start of rehabilitation. Support with transcutaneous nerve stimulators, nerve blocks, and other measures.

OTHER CARPAL INSTABILITIES

Space does not permit a full discussion of the less common types of carpal instability listed in “Terminology and Classification” above and in Table 41.1 and Table 41.2. See the references listed for triquetrolunate dissociation, CIND of the midcarpal and radiocarpal joints, combined types, and axial instabilities (17,25,30,37,42). The most salient features of each of these are discussed in the following sections.

Lunotriquetral Dissociation

Triquetrolunate dissociation (i.e., lunotriquetral dissociation) may occur as an isolated injury, but it more commonly occurs as part of the spectrum of perilunate dislocations. Due to the extensive ligamentous insertion into the triquetrum on the dorsal, ulnar, and palmar surfaces, this injury is generally more stable than its counterpart in the scapholunate joint. Lunotriquetral dissociation is often associated with other wrist problems, including ulnocarpal impingement, TFC-complex tears, and distal radioulnar joint instabilities. Patients complain of pain localized to the ulnar half of the wrist that is often accompanied by a sensation of weakness. Examination reveals tenderness specific to the lunotriquetral articulation and exacerbation of discomfort with ballottement of the unstable triquetrum. Unless there is a significant static deformity resulting in a VISI pattern on lateral radiographs of the wrist, radiographic documentation of lunotriquetral dissociation may be difficult. Arthrography and MRI can demonstrate a defect in the lunotriquetral membrane suggesting triquetrolunate dissociation.

Treatment of triquetrolunate dissociation may not be necessary if symptoms are relieved after correction of the associated conditions. If an acute triquetrolunate dissociation with minimal deformity is discovered, external support with a cast or splint may be all that is necessary. Percutaneous K-wire fixation may be useful, particularly when the arthroscopic grading noted in Table 41.3 is followed.

In the more advanced or chronic stages, in which there is angular deformity, open surgical intervention may be indicated. Several options are available. Direct repair of the interosseous ligament in a fashion similar to that described for the scapholunate ligament may be carried out and augmented with capsular flaps similar to those described for scapholunate dissociation. If the direct repair cannot satisfactorily correct the deformity, two other options are available: augmentation of the ligament repair with a strip of distally based flexor carpi ulnaris passed through drill holes in the triquetrum and lunate, or a lunotriquetral arthrodesis, which is more successful in achieving union than scapholunate arthrodesis. Complications of lunotriquetral arthrodesis, including nonunion, persistent VISI deformity, and persistent subjective complaints, occur in 33% of patients undergoing this procedure. In patients with a fixed VISI deformity, a radiolunate arthrodesis may be necessary to counter the tendency for a VISI deformity to recur after appropriate treatment of lunotriquetral dissociation.

Direct Repair of the Lunotriquetral Ligament

The technique of direct repair of the ligament is similar in sequence to that for the scapholunate ligament direct repair (Fig. 41.16).

Figure 41.16. Direct repair of the lunotriquetral ligament. The lunotriquetral complex is shown in an isolated fashion from a proximal and ulnar perspective. The lunotriquetral interosseous ligament (LT) has been traumatically disrupted, and strong suture (2-0 or 3-0 Mersilene) has been passed through the remnant of the ligament and into channels drilled through the substance of the triquetrum to exit ulnarly. After provisional reduction is achieved, these sutures are drawn tight and tied (L, lunate; T, triquetrum; P, pisiform; FCU, flexor carpi ulnaris tendon).

- After exposing the lunotriquetral joint dorsally by entering the radiocarpal joint through the interval between the fourth and fifth extensor compartments, freshen the triquetral insertion of the lunotriquetral ligament with a burr, and drill paired holes distally and ulnarily. It may be necessary to subperiosteally elevate the triquetral insertion of the TFC complex ulnarily to visualize the exit point of the drill holes. Do not perform this procedure without direct visualization because the extracapsular sutures may accidentally incorporate isolated cutaneous branches of the ulnar nerve.
- Pass the sutures through the remnant of the lunotriquetral ligament, which is usually attached to the lunate, and then through the drill holes, and tie them.
  Transarticular K-wire fixation is recommended. Postoperative care is similar to that outlined for reconstructions of the scapholunate ligament.

Palmar and Dorsal Exposures

Palmar and dorsal exposures are required for augmentation of the lunotriquetral joint with a distally based slip of flexor carpi ulnaris. Refer patients requiring this procedure to surgeons who are experienced in this technique (Fig. 41.17). Through these incisions, test the supporting extrinsic ligaments (i.e., lunotriquetral portion of the dorsal radiolunotriquetral ligament and the overlapping portions of the palmar ulnolunate and ulnotriquetral ligaments), and tighten them, if needed. Lunotriquetral arthrodesis, carried out through a dorsal incision, consists of exposure of subchondral bone on both sides of the lunotriquetral articulation, insertion of a corticoc cancellous wedge of distal radius or iliac crest bone graft across the lunotriquetral joint, and fixation with K-wires or a transarticular compression screw (Fig. 41.18).

Figure 41.17. Reconstruction of the lunotriquetral ligament using the flexor carpi ulnaris tendon (FCU). At least 6–8 mm of the dorsal half of the FCU tendon is elevated from a hemiresection proximally and delivered distally, with maintenance of its attachment onto the pisiform. Preserve the ulnar artery and ulnar nerve, just lateral to this tendon. Vertically oriented drill holes, just larger than the diameter of the free tendon slip, are made through the triquetrum, exiting palmarly just proximal to the pisotriquetral articulation, and through the lunate. The distally based free slip of FCU is delivered dorsally through the triquetrum and across the lunotriquetral articulation. After provisional reduction is achieved, tension is adjusted in the slip, and it is sutured to itself near its attachment to the pisiform.
CARPAL INSTABILITY NONDISSOCIATIVE (CIND)

CIND conditions are manifested by the same intercalated instability patterns (i.e., DISI and VISI) that indicate scapholunate dissociation and triquetralunate dissociation, but no clear disruption of the connections between the bones of the proximal row and between the bones of the distal row is evident. In this condition, the instability is generated through an alteration in the restraints of the radiocarpal joint, the midcarpal joint, or both, although this condition is most often referred to as midcarpal instability in the literature. Common clinical presentations include a "loose jointed" individual, presentation with a snap or a click, a normal arthrogram, and an abnormal motion pattern of the entire proximal row on cineradiography or videotaped fluoroscopy. Radiocarpal and midcarpal arthroscopy can help determine the cause of the problem.

No universal procedure is available for the treatment of CIND because there are many causes. Treatment is directed at the abnormalities that are thought to generate the instability. Often, palmar and dorsal approaches are necessary if capsular repairs are anticipated. Each of the techniques described previously for the nondissociative type of carpal instabilities, including direct capsular repair of the space of Poirier, limited intercarpal fusions (e.g., STT, scaphocapitate, and other midcarpal arthrodesis and capsulodesis procedures to control proximal carpal row instability), and proximal row carpectomy are all viable options. In some circumstances, radiocarpal arthrodesis may provide a reasonable option. Clinical experience with this problem is limited. It is recommended that treatment be done by a surgeon who has accumulated experience with this condition.

In addition to the soft-tissue causes of CIND, there are also extraarticular abnormalities that generate similar conditions termed carpal instability adaptive. For example, a malunion of a distal radial fracture, with resultant dorsal angulation of the distal articular surface, can initiate a zigzag type of collapse that can simulate a DISI deformity. In this situation, treatment involves corrective osteotomy of the radius with an opening wedge osteotomy employing bone graft and plate fixation (see Chapter 44). Although not strictly a CIND, malunion of the scaphoid may also result in a DISI deformity. In this situation, operative treatment is an opening wedge osteotomy of the scaphoid with bone grafting and K-wire or screw fixation across the fracture site.

AXIAL INSTABILITIES

Axial instabilities are disruptions in a columnar or longitudinal direction of the carpus, generally resulting from high-energy impact of the hand (17). They are often accompanied by tearing or avulsion of the individual components of the transverse carpal ligament system, frequently with separation of the metacarpal bases. A history of a high-energy impact with the involved hand raises suspicion of this injury. A high index of suspicion is required to diagnose this condition. Standard radiographs generally enable the diagnosis to be made, but because of the superimposition of the carpal bones, particularly on the lateral view, the findings may be subtle. If there are questions about the possibility of this injury and the standard radiographs do not resolve them, take stress radiographs or perform tomography, CT, or MRI. Coexisting soft-tissue injuries, such as stretching or tearing of contiguous vessels, nerves, or musculotendinous structures, often present a greater problem than the skeletal injury itself.

Direct initial treatment at preservation of the neurovascular and musculotendinous integrity of the affected extremity. Simple reduction of the dislocation may restore blood flow or nerve supply. Look for and decompress a compartment syndrome if it occurs. Repair of injured neurovascular and other soft tissues is often needed. Treatment is directed at the abnormalities that are thought to generate the problem.
Fractures of the carpal bones comprise a significant percentage of traumatic injuries to the upper extremity. Frequently, they are initially dismissed as being trivial, and medical attention is delayed. Their seriousness is often not recognized until months or even years later, when secondary arthritic changes appear. The diagnosis and treatment of carpal fractures require an understanding of the anatomy and mechanics of one of the most complex joints in the body.

ANATOMY AND KINEMATICS

Our knowledge of the wrist dates back to the middle of the 16th century, when Versalius identified and numbered the carpal bones (29). For the next several centuries, the precise shape and articulation of each bone was known in detail, but little attention was paid to its ligaments and even less to its movements. Sir Charles Bell's description of the wrist in his classic treatise, The Hand: Its Mechanism and Vital Endowments as Evincing Design, published in 1813, was simply: “In the human hand, bones of the wrist are eight in number, and they are so closely connected that they form a sort of ball which moves on the end of the radius” (Fig. 42.1). It was not until the discovery of x-rays in 1895 that the study of wrist mechanics began. The following year, Bryce observed that the physiologic axis of the wrist was not fixed but shifted as the joint moved from flexion to extension (4). These studies were later enlarged by other investigators, who recognized the complex and synchronous movements of the carpal bones, movements that impart to the wrist both fluidity of motion and strength (65,61).

![Figure 42.1. Bones of the hand and wrist, from a 19th-century anatomy book by Charles Bell.](image)

In 1919, Navarro introduced the concept of the vertical or columnar carpus (3). He described a central column for flexion and extension comprising the lunate, capitate, and hamate; and two side columns, a medial column and a lateral column. The medial column was for mobility and included the scaphoid, trapezium, and trapezoid. In 1943, Gifford described wrist mechanics differently (37). He likened the wrist to a triple-link system with the radius, lunate, and capitate as the central link. The mechanical advantage of the system is that its two main joints, the radiolunate and lunate-capitate, move only half the excursion of the entire joint. The disadvantage of the system is instability of the central, intercalated mobile segment (i.e., lunate), which is dependent on its anatomic configurations and ligament attachments for stability. More than 50 years after Navarro published his initial account, Taleisnik modified his concept of the columnar carpus by including the entire distal carpal row with the lunate in the central column (92). Taleisnik also limited the medial (rotational) and lateral (mobile) columns to one bone each, the triquetrum and scaphoid respectively. In both the columnar and triple-link concepts of wrist mechanics, the scaphoid is the key bone for carpal stability. Although the scaphoid is anatomically located within the proximal carpal row, it functionally bridges both carpal rows.

DIAGNOSTIC WORKUP

The evaluation of any carpal injury requires a careful physical examination, including the neurovascular status of the hand. Determining precise areas of tenderness aids in localizing the site of injury. Conventional radiographs are always necessary, and generally four views are obtained: posteroanterior (PA), anteroposterior (AP), lateral, and oblique (Fig. 42.2). The PA view in ulnar deviation visualizes the scaphoid, whereas the AP view (palm up or supinated view), usually taken with the fingers clenched and wrist ulnarily deviated, is useful for visualizing rotatory subluxation of the scaphoid. The lateral radiograph should be a true lateral view with the wrist in neutral position in order to evaluate carpal bone alignment (Fig. 42.3). Oblique views can be taken with the hand slightly pronated (posterior oblique) or slightly supinated (anterior oblique). The posterior-oblique view visualizes the carpal bones on the radial side of the wrist, particularly the scaphoid, and the anterior-oblique view visualizes the plafond and, to a lesser extent, the hamate. Additional imaging techniques are sometimes required, including: carpal tunnel views; tomography, either computer assisted (CT) or polyaxial; arthrography; and magnetic resonance imaging (MRI). The CT is the most frequently used special imaging study for detecting carpal fractures and is obtained in at least two planes, using 2-mm slices. It has generally replaced polyaxial tomography (i.e., trispiral tomography) because of its wider availability and superior images. In addition to detecting occult fractures, CT is useful for assessing fracture healing and healing of bone grafts used for the treatment of nonunions. It also permits visualization of precise bony detail that aids in the evaluation of other conditions such as intraosseous tumors or cysts.
SCAPHOID

ACUTE FRACTURES

Fractures of the scaphoid are the most common of carpal fractures. They usually occur in young adult men following falls on their outstretched palms. Experimental studies have shown that the force must be applied to the radial side of the palm, with the wrist extended a minimum of 95°. In that position, the scaphoid is the only carpal bone in contact with the radius. The proximal part of the scaphoid assumes a wedge-shaped configuration between the radius and capitate, where it is supported by the radial collateral and radiocapitate ligaments. The distal pole of the scaphoid, however, is unsupported and capsular structures in the area are lax. It is the distal pole that receives most of the applied force and the bone fractures at its most vulnerable area, its waist.

Suspect a scaphoid fracture when there is tenderness over the dorsal surface of the bone in the anatomic snuff box or over its tubercle on the palmar surface. Confirm the diagnosis with radiographs. The profile of the bone is best seen on PA and posterior-oblique views with the wrist in ulnar deviation. Although radiographs taken immediately after the injury may be negative, the scaphoid should still be considered fractured until proven otherwise. Immobilize the wrist in a thumb spica splint or cast and repeat radiographs in 1 to 2 weeks. If there is a fracture, it should then be evident by the appearance of bone resorption at the fracture site. Occasionally, bone resorption does not appear until 3 weeks after the fracture, and even then radiographs may remain inconclusive. In these cases, radionuclide imaging with technetium-99m can be helpful. Although bone scans are highly sensitive and are generally positive within 24 h of a fracture, they are nonspecific. Therefore, although a fracture can be ruled out with a negative scan, a positive scan requires more specific imaging studies. Vibratory testing, using audible “intrasound” frequencies between 20 and 20,000 Hz (infrasound less than 20 Hz and ultrasound greater than 20,000 Hz are inaudible), has been shown to be effective in diagnosing occult scaphoid fractures. The test is considered positive when pain is sufficient to cause an immediate “positive retraction response.” The definitive test is a CT scan.

Fractures of the scaphoid have been classified using a variety of methods. The two most common are the relationship of the fracture to the longitudinal axis of the scaphoid (Russe's classification) and the site of fracture. Russe's classification comprises three types of fractures. Type I is a transverse-oblique fracture that is horizontal to the wrist joint and oblique to the longitudinal axis of the scaphoid. These fractures comprise approximately 35% of scaphoid fractures. Type II is a transverse fracture at right angles to the longitudinal axis of the scaphoid. It is the most common type of scaphoid fracture (60%). Type III is a vertical-oblique fracture that is vertical to the wrist joint and oblique to the scaphoid. Although vertical-oblique fractures are the rarest and occur in only 5% of scaphoid fractures, they are the most problematic with respect to healing because they are subject to high shear forces and tend to be unstable.
Operative fixation of a nondisplaced scaphoid fracture may occasionally be indicated in patients (e.g., surgeons, dentists) who cannot work with their wrist in a cast and would face serious financial hardship if disabled for months. Bone screws are now available that provide stable fixation and compression of scaphoid fractures such as the scaphotrapezial joint. Fractures of the scaphoid tubercle usually result from direct trauma (Fig. 42.6). Treatment is directed primarily at relieving pain; this can be achieved by wearing a wrist splint for several weeks. There are few consequences of a tubercle fracture failing to heal because the bony prominence is extraarticular. Persistent pain is uncommon, but if it does occur the tubercle can be excised without compromising wrist function.

Scaphoid fractures are also classified according to the time interval between injury and diagnosis. A scaphoid fracture is acute when diagnosed within 3 to 4 weeks of the injury. Healing can be expected in more than 95% of cases with thumb spica cast immobilization, provided the fracture is nondisplaced. When diagnosis is delayed more than 4 weeks, the prognosis is much worse, and failure to heal ranges from 40% to as high as 88% (49). The time period for what constitutes delayed union or nonunion is controversial because both terms have been applied to scaphoid fractures that have not healed after 4 to 6 months of immobilization (75,91). This is an arbitrary time period because it is impossible to state with certainty when delayed union begins. Although it is not unreasonable to label a scaphoid fracture that has not united in 4 to 6 months a “delayed union,” it is often premature to refer to a similar problem within that same time period as a “nonunion.” Unlike nonunions, delayed unions still have the capacity to heal with continued immobilization, which can sometimes take longer than 6 months. A nonunion is essentially a radiographic diagnosis that comprises specific criteria that are usually more obvious when the nonunion is hypertrophic rather than atrophic. Hypertrophic nonunions are characterized by sclerosis at the fracture site, which gives the appearance of a pseudarthrosis. Changes in atrophic nonunions tend to be less obvious; the fragments are osteoporotic, and the fracture margins irregular and cystic. The radiographic changes in both types of nonunions are most clearly seen with CT imaging.

The importance of fracture alignment was first recognized in 1943 by Gilford (37), who observed that when a scaphoid fracture is displaced, the proximal fragment flexes together with the adjacent lunate. This pattern results in a zig-zag deformity at the midcarpal joint, which has been likened to the bellows of a concertina and referred to as a “concertina collapse deformity” (9). Reducing the proximal fracture fragment restores normal tension to the palmar ligaments and corrects the abnormal rotation of the lunate (66). Carpil collapse associated with a displaced scaphoid fracture is generally described as dorsal intercalated segment instability or DISI (53). Unacceptable fracture displacement has been defined as 1 mm or more step-off on PA and/or oblique radiographs, greater than 15° angulation between lunate and capitate, and scapholunate angulation greater than 45° (8). In summary, the factors that have a negative impact on healing are obliquity of the fracture line, a fracture in the proximal pole of the scaphoid, displacement and/or angulation of the fracture, and a delay in diagnosis.

Treatment for nondisplaced scaphoid fractures is a well-molded thumb spica cast extending just distal to the interphalangeal joint, permitting only slight flexion of that joint. Because tension of the radial collateral ligament of the wrist can cause displacement at the fracture site, immobilize the wrist in slight flexion and radial deviation. Avoid forearm rotation by applying a Muenster cast, which permits elbow flexion and extension. After 8 weeks, use a below-elbow thumb spica cast until there is radiographic evidence of healing. It is critically important to document that radiographic healing is complete before immobilization is discontinued.

Conventional radiographs are usually sufficient to determine healing, but, if inconclusive, CT or tomography is necessary (Fig. 42.7), particularly when conventional radiographs appear to show a healed fracture but tenderness persists at the fracture site. If healing is incomplete, continue cast immobilization and obtain new radiographs in 6 to 8 weeks.

Operative fixation of a nondisplaced scaphoid fracture may occasionally be indicated in patients (e.g., surgeons, dentists) who cannot work with their wrist in a cast and would face serious financial hardship if disabled for months. Bone screws are now available that provide stable fixation and compression of scaphoid fractures such as a cannulated AO/ASIF screw (Synthes, Paoli, PA) or Acutrak headless screw (Acumed, Beaverton, OR). Intraoperative radiographic imaging is essential to ensure...
Inlay Bone Graft—Operative Technique

Scaphoid fractures treated soon after the injury that have not healed after months of immobilization are different from fractures that were unrecognized until months after the injury. In the first situation, union is delayed but can still occur with continued immobilization, provided the fracture is stable and there are no radiographic signs of nonunion (i.e., sclerosis and/or cyst formation). Radiographic evidence of avascular necrosis is not an indication that the fracture will not heal, although it may take longer to heal. For scaphoid fractures unrecognized until months after the injury, the likelihood for healing with cast immobilization is poor.

Postoperatively, apply a short-arm thumb spica splint for a week or two until there is soft-tissue healing and then convert to a well-molded thermoplastic thumb spica splint. The patient can then return to light work activities that do not require heavy lifting, pushing, or pulling. For surgeons, the splint can be removed while operating.

CHRONIC FRACTURES

Scaphoid nonunions require surgery, except in elderly or debilitated individuals. It is one of a few orthopaedic problems in which the indication for surgery depends on the radiographic appearance of the bone and not on the severity of patient’s symptoms. Surgery is usually required even in patients who are asymptomatic and have excellent wrist mobility. Prospective studies have shown that without surgery, scaphoid nonunions are likely to lead to traumatic arthritis accompanied by pain, loss of wrist mobility, and weakness (54,57,78).

A wide variety of operative procedures have been recommended for scaphoid nonunions, including drilling the bone, excising the proximal fragment or even both fragments, excising the proximal carpal row, intercarpal and total wrist arthrodeses, prosthetic replacement of the scaphoid, radial styloidectomy, interposition of soft tissue into the nonunion site, and autogenous bone grafting (58). Drilling the bone is only of historic interest and has little relevance to contemporary hand surgery. Excising the proximal fragment is a useful procedure provided the fragment is small, not exceeding 25% of the length of the bone (Fig. 42.9). The fragment can sometimes be removed arthroscopically. Avoid excising larger fragments because it can lead to abnormal shift of the other carpal bones, particularly the capitate. A coiled tendon graft can be inserted into the void as a plug, although it is not essential. Proximal row carpectomies and arthrodeses, whether they are partial or complete, are salvage procedures and are indicated when secondary arthritic changes have developed. Replacing the scaphoid with a silicone prosthesis is another salvage procedure that was popular until the mid-1980s. Since then, the procedure has been abandoned because of its high complication rate, including dislocation, breakage, and, most important, silicone synovitis (58). Titanium carpal implants are available, but they have not gained wide acceptance because they are inherently unstable and frequently cause bone erosion. Interposing a soft tissue flap between the fracture fragments was a procedure first recommended by Bentzon in 1940. It is still recommended by some when bone grafting is unsuccessful.

Bone grafting is the procedure of choice for scaphoid nonunion when there are no arthritic changes (1,58,65). The concept of an inlay bone graft was introduced in 1937 by Matti, who used a dorsal surgical approach (58). Russe modified this to a palmar approach because it was less likely to damage the extrinsic blood supply to the scaphoid (66). A modification of his inlay bone graft remains the treatment of choice (64).

Inlay Bone Graft—Operative Technique

- Make a 3.0- to 4.0-cm longitudinal incision along the radial border of the flexor carpi radialis (FCR) tendon (Fig. 42.10). Curving the distal portion of the incision into the wrist flexion crease facilitates exposure.
Dissect the interval between the FCR and radial artery, and incise the joint capsule longitudinally.

Identify the nonunion. The radial styloid serves as a guide to its location.

Using a power burr, make a deep trough across the nonunion site (Fig. 42.10C). Curve the trough slightly to follow the contour of the scaphoid. Undercut its periphery to enhance stability of the bone graft.

Harvest a corticocancellous graft from the outer surface of the ilium, just below the crest. Some prefer to harvest a graft from the distal radius; however, cancellous bone at this site is not as dense as in the ilium. Shape the graft using a small bone cutter to be slightly larger than the trough so that it will fit snugly.

Insert the graft with its thin cortical surface facing outward to be the covering of the trough. Only cancellous bone is in contact with the nonunion site (Fig. 42.10D). Fill any remaining defects with cancellous chips. With stable nonunions, the graft can be totally cancellous. Internal fixation with Kirschner wires is necessary only when there is movement at the nonunion site after the graft is inserted.

Suture the joint capsule and skin, and apply an above-elbow cast for 6 to 8 weeks. After that period, continue immobilization with a below-thumb spica cast until healing occurs.

Green (38) recommends that power instruments not be used when excavating the trough because of the risk of bone overheating. He uses two corticocancellous struts inserted into the trough with their cancellous surfaces together and cortical surfaces facing outward against the inner walls of the nonunion site to provide better stability.

Green also reported that bone grafting is contraindicated in the presence of avascular necrosis of the proximal fragment, which is evident by the absence of punctate bleeding points in the bone.

His recommendations differ from the experiences of most surgeons. A power burr facilitates preparation of the trough, which is the most important technical part of the operation, and the risk of bone damage is avoided by using irrigation.

Cancellous bone rather than cortical bone should be positioned against the nonunion site.

Other Techniques In 1984, Herbert (41) introduced a double-threaded compression screw for the treatment of scaphoid nonunion. The procedure is technically demanding, and its benefits remain unproven. Newer and more effective screws are now available that are cannulated and provide greater compression (e.g., AO/ASIF screw, Acutrak tapered headless screw) (91).

Malpositioned Nonunions—Operative Technique

The scaphoid nonunion that is angulated is a difficult problem because it is frequently associated with subluxation of the lunate. The lunate, which is attached to the scaphoid by a strong ligamentous ligament, follows the malpositioned proximal fragment, resulting in a “concertina” deformity or DISI deformity at the midcarpal joint. The nonunion site is flexed with apex dorsal angulation, and the bone has a “humpback” deformity. The degree of deformity may not be obvious on conventional radiographs, but it is clearly demonstrated on lateral CT.

- Measure the intrascaphoid angle that is formed by the intersection of lines drawn perpendicular to the proximal and distal articular surfaces of the scaphoid. The normal angle is 30° to 40°. An intrascaphoid angle greater than 45° generally should be corrected.

- Use a palmar operative approach. When lunate tilt is severe, a dorsal operative approach is preferable because it provides better visualization. Care must be taken with a dorsal approach to avoid damage to the radial artery and its dorsal branches to the scaphoid.

- Correct lunate alignment by flexing and ulnar deviating the wrist, and then stabilize the lunate with one or two Kirschner wires.

- Confirm normal midcarpal and midcarpal alignment using intraoperative radiographic imaging.

- Bridge the defect in the scaphoid with an inlay wedge or trapezoidal-shaped bone graft harvested from the ilium. Stabilize the graft with Kirschner wires or a screw.

Complications

When bone grafting is unsuccessful, perform the criteria present when the first operation was performed still exist. The scaphoid should not be fragmented, and there should be no significant arthritic changes. Pulsed electromagnetic fields (PEMP) should also be considered (11). Although double-blind studies have not been performed to prove its efficacy, my experience is that it improves the chances for healing. Another surgical option is a vascularized bone graft. Several donor areas have been suggested, and probably the most effective is one suggested by Zaidenberg et al. (105). They recommended a graft harvested from the dorsoral aspect of the distal radius, a site supplied by an ascending branch of the radial artery. Vascularized bone grafts have also been recommended for avascular necrosis of the scaphoid. The advantages of these procedures over conventional bone grafting have yet to be established by clinical studies.

MALUNIONS

Treatment of a malunited scaphoid is controversial because of the risk that a corrective osteotomy may fail to unite and lead to an even greater problem, a nonunion. Surgery is not a difficult decision for the patient who has a significant disability from wrist pain, tenderness, and diminished grip strength. The decision is more difficult when there are a paucity of symptoms. However, malalignment of the midcarpal joint results in altered wrist kinematics that are likely to lead eventually to arthritic changes. Therefore, surgery is generally recommended for young patients. Careful preoperative planning is critically important and requires CT imaging.

- Use a dorsal operative approach.

- If the position of the lunate can not be corrected by wrist flexion and ulnar deviation, drill a Kirschner wire into the bone to serve as a joystick.

HINTS AND TRICKS

- A radial styloidectomy should not be routinely performed as an adjunct to bone grafting. It is indicated for those rare cases of symptomatic arthritis confined to the area between the styloid process and the scaphoid.

- Use interoperative imaging to insure that carpal alignment has been restored.

- Osteotomize the scaphoid using a thin osteome or a power saw.

- Insert a bone graft similar to the method used for grafting a malpositioned nonunion.

IDIOPATHIC AVASCULAR NECROSIS

Idiopathic avascular necrosis of the scaphoid is a rare condition commonly referred to as “Preiser disease.” Actually, this is a misnomer because the patients Preiser described in his paper published in 1910 all had sustained prior injuries (25). When there are no apparent causes, it is more appropriate to refer to the condition as “idiopathic avascular necrosis of the scaphoid.” It may be similar to avascular necrosis of the lunate (Kienböck’s disease) in that variations in the blood supply to the bone may predispose certain individuals to the condition. Trauma may be the main factor in disrupting the blood supply to the bone, but it may be so trivial that patients are unable to recall the episode(s) (97). Treatment depends on the condition of the scaphoid. In the absence of arthritic changes, a vascularized bone graft should be considered. When disease is chronic and pain is disabling, a salvage procedure would be required such as proximal row carpectomy, scaphoid excision combined with midcarpal arthrodesis, or total wrist arthrodesis.

FRACTURES IN CHILDREN

The scaphoid begins to ossify at age 5 to 6 years, and ossification is completed by age 13 to 15 (89). Before ossification or in the early stages of ossification, scaphoid fractures are exceedingly rare because the bone is almost entirely cartilaginous, which cushions the effects of trauma. Even in the later stages of ossification, a considerable portion of the bone remains cartilaginous, and fractures are less likely to occur than when the bone is fully mature. Scaphoid fractures do occur in children, however; these fractures generally occur after the age of 9, unless there is precocious ossification. Most fractures involve the distal third of the bone or its tubercle (39). The incidence of fractures through the middle third of the bone is only 10% as compared to a 70% incidence in adults (87). Scaphoid fractures in children usually heal within 8 weeks. Nonunions are rare, but when they occur bone grafting is necessary (Fig. 42.11).
A fracture through the wrist of the scaphoid in a child can pose a diagnostic dilemma, especially when there is separation of the fragments. Radiographs may show an actual fracture or what some believe is a developmental variation, a bipartite scaphoid arising from two ossification centers (101). Absence of a history of trauma, equal size and density of both bones with a clear space between them, and contiguous surfaces that are smooth have been cited as indications that a bipartite scaphoid is a developmental variation. If there is a fracture, it is usually incomplete and difficult to reproduce experimentally (21). They probably result from sudden hyperextension-abduction of the thumb that forces the wrist into a position of maximum radial deviation. The triquetrum is wedged between the first metacarpal and styloid process of the radius, and the styloid, functioning as an anvil, fractures the triquetrum. Vertical fractures through the body of the bone are rare (45).

TRAPEZIUM

Fractures of the trapezium account for 3% to 5% of all carpal fractures (76). These fractures are significant injuries when displaced because they affect the important trapeziometacarpal joint of the thumb. If not reduced, they may lead to pain, limitation of the thumb mobility, and weakness. Trapezial fractures fall into two categories: fractures involving the palmar ridge of the bone, and vertical fractures through the body of the bone.

Palmar ridge fractures account for 80% of trapezial fractures and result from falls on the outstretched palm. The ridge fractures either by direct contact or indirectly. An indirect fracture is an avulsion injury caused by a sudden tension force applied to the transverse carpal ligament as the thenar and hypothenar eminences diverge. Trapezial ridge fractures are subdivided into type I fractures, located at the base of the ridge, and type II fractures, located at the tip of the ridge (71). Both types of fractures are associated with local tenderness. Pain with resisted wrist flexion is common because of the close proximity of the FCR tendon to the fracture site.

Vertical fractures through the body of the bone account for the other 20% of trapezial fractures (Fig. 42.12). The mechanism of injury is unclear because they are difficult to reproduce experimentally (21). They probably result from sudden hyperextension-abduction of the thumb that forces the wrist into a position of maximum radial deviation. The trapezium is wedged between the first metacarpal and styloid process of the radius, and the styloid, functioning as an anvil, fractures the trapezium (39,46). The fracture is usually located in the middle of the bone. The lateral fragment remains tethered to the first metacarpal and is often displaced radially and proximally by the pull of the abductor pollicis longus, similar to the mechanism that contributes to a displaced Bennett's fracture. Horizontal fractures through the trapezium are rare (45).

Figure 42.12. Radiograph shows a vertical fracture through the body of the trapezium (arrow).

Trapezial fractures, regardless of location, are frequently overlooked because of inadequate radiographs. Posteroanterior and lateral views fail to show the entire body of the bone: the PA view because of superimposition by the trapezoid and base of the second metacarpal, and the lateral view because of superimposition by the hook of the hamate. In order to visualize the entire body of the trapezium, an oblique radiographic view is necessary. One such view is the Bell's view, which is obtained by placing the ulnar border of the hand on the cassette and directing the x-ray beam at the scaphoid–trapezium–trapezoid joints with the thumb abducted and extended (93). Visualizing the palmar ridge requires a carpinal view.

Treat palmar ridge fractures with a thumb spica cast or splint for 6 to 8 weeks. Type I fractures through the base of the ridge tend to heal faster than type II fractures at the tip of the ridge. Occasionally, a type II fracture fails to unite and causes persistent pain and tenderness. Excision of the bony fragment is warranted in such cases. Treatment for nondisplaced fractures through the body is similar to that for type I and type II fractures of the palmar ridge. However, displaced fractures resulting in joint incongruity require operative reduction and internal fixation with Kirschner wires or a screw.

CAPITATE

Fractures of the capitate are rare and account for only 1.3% of all carpal fractures (75). They occur as isolated injuries or in conjunction with other injuries, particularly fractures of the scaphoid. The combination of a scaphoid and capitate fracture was first reported by Fenton, who named the injury “naviculocapitate syndrome” (26). This is a complex injury that usually occurs following a fall on the outstretched hand with the wrist extended. Fenton believed that the scaphoid, buttressed medially by the capitohamate ligament, was fractured by the styloid process of the radius, which functioned as a chisel. When the force was sufficiently violent, the capitohamate ligament was avulsed. The scaphoid can also fracture by striking the dorsal rim of the radius. When this occurs, the lunate extends, and the capitate migrates even further dorsally and fractures.
as it impinges against the dorsal rim of the radius or against the dorsal rim of the lunate. Similar fractures have been reported following a blow to the dorsum of the flexed wrist, which causes the capitale to strike the volar lip of the radius (98). Regardless of mechanism of injury, the capitale usually fractures at its neck, and the proximal fragment rotates through an arc of 180° (89).

The blood supply to the capitale enters the distal, palmar aspect of the bone. Intracortical circulation then proceeds in a distal-to-proximal direction, similar to the scaphoid (40). Therefore, a fracture through the neck of the capitale jeopardizes the blood supply to the proximal portion of the bone and can lead to avascular necrosis. Displaced capitale fractures require operative reduction and internal fixation (59). Nonunions, with or without avascular necrosis of the proximal fragment, require an illay bone graft (31, 60).

INLAY BONE GRAFT—OPERATIVE TECHNIQUE

- Make a transverse incision over the dorsal aspect of the wrist. Curve the radial end of the incision distally for 1 to 2 cm. If additional exposure is required, curve the ulnar end of the incision proximally for the same distance. Mobilize the skin flaps taking care to protect the sensory branches of the radial nerve and the dorsal sensory branches of the ulnar nerve.
- Incise the extensor retinaculum longitudinally over the fourth tendon compartment and reflect it radially, exposing the second and third compartments. Retract the tendons in the fourth compartment ulnarily, and the tendons in the second and third compartments radially.
- Incise the underlying joint capsule transversely and reflect it proximally and distally. This surgical approach permits excellent visualization of the underlying carpal bones and is useful for a variety of other operations, including intercarpal arthrodeses.
- Make a deep trough across the nonunion site and pack it with a corticocancellous bone from the ilium.
- Close the joint capsule and extensor retinaculum. Immobilize the wrist in slight flexion to minimize the capsulodesis effect that follows any dorsal surgical approach to the wrist joint. Initially, apply volar and dorsal plaster spalnts; when soft tissue healing is complete, usually within 2 weeks, replace the spalnts with a circular cast or a well-molded plastic splint.

LUNATE

The lunate has proportionally the largest surface area of cartilage (approximately 80%) of any carpal bone. Periosteum is confined to two small areas on the volar and dorsal surfaces of the bone through which nutrient vessels pass (95). Injection studies have shown that in more than 90% of specimens, the vessels form three distinct patterns of intracortical circulation that resemble the letters Y, I, and X (Fig. 42.19) (65). The Y pattern is the most common (59%), followed by the I pattern (31%) and the X pattern (10%). Fewer than 10% of specimens had only volar nutrient vessels.

![Figure 42.13. The intracortical vascular patterns in lunates.](image)

ACUTE FRACTURES

The incidence of acute fractures is generally reported to be less than 1.5% of carpal fractures (17, 95). This low figure may reflect a failure to diagnose many lunate fractures. Fractures in bones that have a high proportion of cartilage and cancellous bone, such as the lunate, often go unrecognized because cancellous bone has a higher pain threshold than periosteum (12). Acute lunate fractures have been classified into five types (Fig. 42.14) (95).

![Figure 42.14. Classification of lunate fractures. Type I, fracture of the volar pole; type II, chip fracture away from the nutrient vessels; type III, fracture of the dorsal pole; type IV, sagittal fracture through the bone; type V, transverse fracture through the waist of the bone](image)

- I. Volar pole fractures at the entrance of the nutrient vessel.
- II. Chip fractures not in areas of nutrient vessels.
- III. Fractures of the dorsal pole at the entrance of the nutrient vessel.
- IV. Sagittal fractures through the bone.
- V. Transverse fractures through the waist of the bone.

Although acute lunate fractures almost always heal and there are no reports of late avascular necrosis (24), a type IV fracture proximal to any of the three vascular patterns could theoretically deprive the proximal portion of the bone of its blood supply (46). Compromise to the dorsal circulation could also occur following a type V fracture in a lunate having only a volar nutrient vessel.

KIENBÖCK’S DISEASE

Kienböck’s classic description of lunatomalacia in 1910 resulting from avascular necrosis remains valid to the present day, but the cause of the condition and the most effective treatment remain unresolved (49). In 1928, Hulten observed a correlation between Kienböck’s disease and short ulnas and introduced the term “ulna minus variance” (43). The role that this anatomic variance plays in this condition remains unclear because its incidence varies in different races. Compared to the 87% incidence in Hulten’s series, the average incidence in Japan is only 22% (94). In the United States, ulna variance is normally more positive in black than white Americans (+0.70 mm vs. +0.27 mm) (34). Accurate measurements are important because forearm rotation and grip affect ulna variance. Radiographs must be carried out with the wrist in neutral position, the forearm in neutral rotation (elbow flexed 90° and shoulder abducted 90°), and the fingers extended. Although ulna minus variance is not the primary etiologic factor in Kienböck’s disease, it may increase the vulnerability of a lunate subjected to repetitive compressive forces. Kienböck’s disease may therefore result from unrecognized and untreated minor fractures that disrupt the blood supply to the bone.

Since Kienböck’s description of the condition, there has been general agreement about the radiographic appearance of the lunate in the later stages of the disease. For more than 30 years, however, opinions differed concerning the early radiographic appearance of the bone and the timing and sequence of subsequent changes. In
1947, Stahl attempted to bring order to a controversial subject by classifying changes he observed in wrist radiographs in a large series of patients with the condition (87). His classification system comprised five groups:

- **Group I.** A radiodense line that represented an acute compressive fracture of the lunate. This group of patients was the smallest of his five groups, comprising only 2% of the total number of cases.
- **Group II.** A line of rarefaction secondary to resorption at the fracture site. Stahl thought this occurred about 1 month after the original injury. The number of patients in this group was also small (5%).
- **Group III.** Sclerotic changes in close proximity to the fracture line or in the proximal portion of the bone. These changes occurred about 3 months after the injury. This was the largest group of patients in the series (47%).
- **Group IV.** Fragmentation and collapse of the lunate, the result of one or more vertical fractures through the area of rarefaction. This condition took at least 6 months to develop and was seen in 32% of the patients.
- **Group V.** End-stage disease with secondary arthritis. These patients were considerably older than those in the other groups, and the duration of their disease was the longest. They comprised 14% of the cases.

In 1977, Lichtman modified and improved Stahl's classification by correlating the radiographic appearance of the lunate with the clinical picture. Lichtman classified Kienböck's disease into four stages (52):

- **Stage I.** The earliest manifestation of the disease characterized by a linear compression fracture on conventional radiographs or CT. Since the introduction of MRI, it is now possible to diagnose early vascular injury to the bone. Clinically, patients complain of mild wrist pain.
- **Stage II.** Radiographically, the lunate becomes more dense. Initially, the size and shape of the bone remain the same, but later in this stage there is a decrease in the vertical height of the bone on its radial aspect. This is an ominous radiographic finding that usually indicates that further collapse can be anticipated. Patients typically complain of focal pain and tenderness over the lunate. The wrist is sometimes swollen as a result of joint synovitis.
- **Stage III.** The entire lunate bone is collapsed in the frontal plane and elongated in the sagittal plane. Bony deformation is commonly associated with alterations in the architecture of other parts of the carpus; the capitate is shifted proximally, there is scapholunate dissociation with rotary subluxation of the scaphoid, and the triquetrum is ulnarily deviated. Lichtman later subdivided this stage into III-A and III-B. In stage III-A, the rotatory subluxation of the scaphoid is not fixed, whereas in III-B it is fixed. The extent of lunate collapse can be quantified by the carpal height ratio. The ratio is the distance between the distal articular surface of the radius and the base of the third metacarpal, divided by the height of the third metacarpal. The normal ratio is 0.54 ± 0.03 (61). Conventional radiographs often fail to show the extent of bone damage, and tomography is required (Fig. 42.15). Patients' symptoms in this stage are similar to those with stage II disease, although they usually have greater wrist stiffness.

![Figure 42.15](image)

**Figure 42.15.** A,B: Conventional lateral and posteroanterior views of the wrist in a patient with Kienböck's disease and an ulna minus deformity. The integrity of the lunate could not be determined by conventional radiographs. C: Lateral tomography clearly shows that the lunate had fragmented. This view also demonstrates the usefulness of tomography for visualizing the hamate bone and its hook (arrow).

- **Stage IV** is end-stage Kienböck's disease with generalized arthritic changes in the wrist. Clinical findings can range from mild discomfort to severe incapacitating pain, exacerbated by physical activities. There is usually a significant loss of wrist mobility.

Treatment of Kienböck's disease is variable, depending on the stage of the disease. Although opinions differ regarding the efficacy of a particular procedure, most agree that the objective of treatment for the early stages of the disease is to prevent further deterioration of the lunate and, if possible, reverse any changes that have already occurred. Immobilizing the wrist is a treatment option, but it is impractical because it must be prolonged, up to 1 year, and there is no assurance that it will be successful. Generally, surgery is the preferred treatment, and the procedures indicated for stages I and II can be divided into two groups: decompression of the lunate, and restoration of circulation to the bone.

Reducing compressive forces on the lunate can be achieved by a variety of techniques (72,98), including the following:

- Leveling the distal articular surfaces of the radius with the ulna when there is an ulna minus variance.
- Shortening both radius and ulna when they are of equal length to decrease muscle forces across the wrist.
- Changing the inclination of the articular surface of the radius by a lateral closing wedge osteotomy.
- Intercarpal arthrodesis to transfer some of the load to adjacent carpal bones (e.g., scaphoid–trapezial–trapezoid arthrodesis or scaphoid–capitate arthrodesis) (63,100).
- Captate shortening to decrease the load on the central column (3,4).

Joint leveling is generally recommended and can be accomplished either by lengthening the ulna or by shortening the radius. Each method has its advantages and disadvantages. Ulna lengthening is less complicated but requires an iliac bone graft, which adds donor site morbidity to the procedure. A more serious potential problem is delay or even nonunion at the interfaces of the ulna with the intercalated graft. In addition, the plate necessary for fixation of the graft is in a subcutaneous position and often must be removed later. Another disadvantage of the procedure is that the lengthened ulna may impinge against the sigmoid notch of the radius and cause pain with forearm rotation. With radial shortening, the primary disadvantage is that it requires a more extensive surgical exposure than ulna lengthening. Bone healing is more assured with radial shortening, however, and removal of the plate is usually unnecessary when it is placed on the volar aspect. Another advantage of radial shortening is that it produces relatively higher forces in the extrinsic tendons, which results in additional reduction of force transmission across the wrist (103). Most surgeons recommend radial shortening using a volar operative approach.

Revascularization of the lunate was first proposed by Hori in 1979. He recommended curetting and bone grafting the lunate followed by implantation of the second or third dorsal metacarpal artery and vein. Inserting a pronator quadratus pedicle bone graft from the volar surface of the radius has also been suggested (47) as well as simple curettage and cancellous bone grafting combined with external skeletal traction (106).

**AUTHOR'S PERSPECTIVE**

The lunate can also be revascularized with an autogenous cancellous inlay bone graft inserted into a trough fashioned between the lunate and triquetrum (Fig. 42.16). The triquetrum with its intact blood supply nourishes the bone graft, which serves as a scaffold for revascularization of the lunate. The technique for preparing the trough across the lunotriquetral joint is similar to preparing a trough across a scaphoid nonunion. The procedure is applicable for early stage I and stage II disease. It can occasionally be used for stage III-A disease, provided there is only a linear fracture line in the lunate and the bone has not fragmented. This can best be determined by CT imaging.
Unfortunately, most patients with Kienböck's disease are not seen until the later stages of the condition, when the bone has fragmented and collapsed (stage III) and secondary arthritic changes have developed (stage IV). Unlike treatment for stage I and stage II disease, which is prophylactic and aims to prevent further deterioration for stage III and stage IV disease is palliative. The indication for surgery in patients with stage III and stage IV disease is determined not by the severity of the radiographic changes but rather by the magnitude of their symptoms. For stage III disease, lunate excision and replacement with a silicone prosthesis was a popular procedure before the mid-1980s. It is no longer recommended because of the high incidence of particulate synovitis. A more effective procedure with far fewer hazards is excision of the fragmented lunate and intercarpal fusion. Scaphoid–trapezium–trapezoid and scaphoid–capitate fusions used for reducing compressive forces on the lunate in the early stages of Kienböck's disease can also be used as salvage procedures for stage III disease when combined with lunate excision. With either type of intercarpal fusion, it is important to insure that after the lunate is excised, the normal width of the space previously occupied by the bone is maintained. An abnormally wide space between scaphoid and triquetrum indicates that the scaphoid has rotated, and if the scaphoid is arthrodesed in malposition it will result in later arthritis at the radioscapohoid joint. Normal congruency between scaphoid and capitae and between scaphoid and articular surface of the radius must be preserved.

In stage IV disease, when generalized arthritic changes have developed, proximal row carpectomy and total wrist arthrodesis are the most commonly performed salvage operations. Pain relief following proximal row carpectomy is usually effective, probably on the basis of denervation and decompression of the wrist joint (44). Wrist motions are limited, but generally they are in a functional arc. Grip strength is also reduced, but weakness can be minimized by postoperative exercises. Total arthrodesis is the most predictable operative procedure to provide a stable, pain-free wrist.

HAMATE

FRACTURES OF THE BODY

Fractures of the hamate involve the body of the bone or its hook (hamulus) with about equal frequency. Fractures through the body are either in the sagittal plane or in the coronal plane (55,69,77). Sagittal fractures can be divided according to which side of the hook they lie on. Coronal fractures, when located near the dorsal surface of the bone, are often associated with subluxations of the bases of the fourth and fifth metacarpals (Fig. 42.17). Regardless of direction, fractures through the body of the bone are intraarticular, and it is important to determine if articular congruity has been disrupted. Frequently, CT imaging is necessary. Displaced fractures require open reduction and internal fixation.

Figure 42.17. A,B: Oblique and lateral radiographs show a coronal fracture through the dorsal aspect of the hamate (arrows) associated with dorsal subluxations of the bases of the fourth and fifth metacarpals.

FRACTURES OF THE HOOK (HAMULUS)

The diagnosis and treatment of fractures of the hook of the hamate require a knowledge of the local anatomy. The hook serves as attachment for the transverse carpal and pisohamate ligaments and is the origin for two intrinsic muscles in the hypothenar eminence, the opponens digiti quinti and the flexor digiti quinti. The motor branch of the ulnar nerve passes close to the base of the hook on its ulnar side. Fractures may therefore injure this nerve branch and cause weakness of the ulnar innervated intrinsic muscles. Fractures may also produce a sensory defect on the palmar surfaces of the ring and little fingers. Hook fractures are caused by direct or indirect trauma. Direct trauma is probably the more common mechanism of injury and is often associated with sports activities, such as baseball and tennis. When athletes grip a baseball bat or tennis racquet with the butt end of the handle resting on the hypothenar eminence, the force of the swing is transmitted to the bone, which causes it to fracture. Frequently, the athlete reports a painful “snap” or “crack” (8,88). Indirect trauma to the hook occurs as a result of a fall on the palm with the force transmitted to the bone through muscular and ligament attachments.

Symptoms include dull pain on the ulnar side of the wrist or in the hypothenar area of the palm. Tenderness directly over the hook should be considered a fracture until proven otherwise. Frequently, diagnosis is delayed because of inadequate radiographs. The profile of the hook can not be visualized on routine views, although on the PA view it can be seen as an oval density or “eye sign,” which represents its junction with the body of the bone (Fig. 42.18) (67). Absence of an “eye sign” should arouse suspicion of a fracture at the base of the hook. If the sign is present, however, it does not exclude a fracture through the middle of the hook or at its tip. Although carpal tunnel views show the hook in profile, they often fail to show its base, which is the usual location for most fractures. This is frequently the situation following acute fractures because pain prevents patients from extending their wrists sufficiently for the radiograph to profile the entire hook. For a carpal tunnel view to be diagnostic, it must visualize the flare at the base of the hook where it joins the body of the hamate. Incomplete carpal tunnel views are sometimes interpreted as “negative,” and only later is the correct diagnosis made. The radiographic technique that is most effective for visualizing the hook is CT in the lateral projection (Fig. 42.19).
Figure 42.18. Posteroanterior radiograph of both hands. The oval density or “eye sign” representing the hook of the hamate (small arrows) is seen in the view of the left hand, but it is absent (large arrow) in the view of the right hand because it was fractured.

Figure 42.19. A: Routine carpal tunnel view in a patient who complained of tenderness over the area of the hook of the hamate. Although there appears to be a disruption in the cortical outline of the hook of the hamate (arrow), the radiograph is not conclusive and was interpreted as negative. B: A lateral trispiral tomograph clearly demonstrates a fracture of the hook (arrow). C: The fracture was also evident on a carpal tunnel tomogram (arrow), but not with the same degree of clarity as was demonstrated on lateral tomography. Lateral tomography is the preferred imaging technique to visualize fractures of the hook of the hamate.

Acute fractures heal with immobilization, provided there is no displacement. When the parts are displaced, nonunion is likely because the blood supply to the fragment has been disrupted (73). Although bone grafting has been suggested as a method of treatment for nonunion (89), excision of the fragment is the preferred treatment (16,84).

Fragment Excision—Operative Technique

- Make an incision along the radial border of the hypothenar eminence and curve ulnarly into the wrist flexion crease (Fig. 42.20). This incision avoids a tender scar over the eminence, which is an important contact area for grasp.
- Identify the ulnar neurovascular bundle and carefully retract it.
- Excise the hook by sharply dividing its ligament and intrinsic muscle attachments.
- Repair the fibrous origin of the intrinsic muscles to preserve their power.
- Postoperatively, immobilize the wrist in slight flexion for 2 weeks. Patients can usually resume sports activities within 8 weeks, although there will usually be some discomfort with firm grasp for several months. Residual weakness is generally not a problem, even in professional athletes.

PISIFORM

The pisiform is a sesamoid and is the only carpal bone into which a tendon, the flexor carpi ulnaris (FCU), inserts. The pisiform also serves as origin for the pisohamate and pisometacarpal ligaments, which secure it to the hamate and bases of the fourth and fifth metacarpals. The capsule between the pisiform and underlying triquetrum is tough but lax (70).

Pisiform fractures usually result from direct trauma following a fall on the palm. They also occur in individuals who use the heel of their hand as a hammer for striking objects. These fractures are best visualized by anterior-oblique and carpal tunnel radiographs (Fig. 42.21).

Figure 42.21. A: A fracture of the pisiform was not evident on these three conventional radiographic views because of superimposition of other carpal bones. B: The fracture was obvious on a carpal tunnel view (arrow).

Most pisiform fractures are nondisplaced and heal with conservative splinting. However, fragmentation can occur, which requires excision of the bone. Chronic problems at the pisotriquetral joint can also occur as a consequence of damage to the articular cartilage resulting in chondromalacia. Occasionally, pain and local tenderness are so severe that excision of the pisiform is warranted (Fig. 42.22). Excise it subperiosteally, preserving the fibrous attachments of the ligaments and FCU, which are then resutured. Postoperatively, apply a dorsal splint with the wrist in slight flexion for 2 to 3 weeks.
TRAPEZOID

The trapezoid is the least likely carpal bone to be fractured, with a reported incidence of 0.2% (76). The low incidence is related to the anatomic position of the bone, which is surrounded and securely fixed to the trapezium, base of the second metacarpal, capitale, and scaphoid. Dislocations are more likely to occur than fractures, but they are also very rare.

The distal radioulnar joint (DRUJ) is a complex and important part of the wrist joint, providing several key functions to the articulation between the forearm and hand. Most important, the DRUJ acts in concert with the proximal radioulnar joint to allow the wrist and hand to rotate from pronation to supination and back again. The radioulnar joint appeared in evolution 36 million years ago, and the unique ability to transfer rotational force to the grasping hand is considered to have played a decisive role in human evolution. A forearm that can rotate while the hand grasps is a necessity in using spears, axes, and knives and in carrying infants and baskets, activities that allowed hominids to evolve from food gatherers to food producers.

The diagnosis of problems affecting the distal radioulnar joint can be difficult, and their management challenging. Although a wide variety of surgical procedures have been described to address DRUJ pathology, the best approach to these disorders remains controversial. This chapter summarizes current knowledge about the distal radioulnar joint and suggests treatment strategies for specific conditions. Before one considers the pathologic conditions that affect the DRUJ and options for their treatment, however, it is necessary to understand the anatomy and biomechanics of the joint.

ANATOMY

The bony anatomy of the DRUJ has been well defined. The sigmoid notch of the distal radius is concave and hemicylindrical with three distinct margins: a sharp dorsal margin, a smoother palmar margin, and a distal margin, which is the junction between the lunate facet and the sigmoid notch (Fig. 43.1). The opposed ulnar head is also hemicylindrical but has a smaller radius of curvature than the sigmoid notch. Because of the mismatch in radii, there is some inherent laxity in the normal joint, and translatory motion parallel to the plane of the articular surfaces normally occurs during rotation of the hand. When the forearm is in neutral rotation, it is possible to translate the ulnar head passively approximately 3 mm dorsal and 5 mm palmar against the stabilized radius. In the extremes of forearm rotation, less than 10% of the ulnar head may be in contact with the notch. This relationship is important to consider when the normal shape and relative lengths of the radius and ulna are changed, either surgically, developmentally, or traumatically.

The ulnar styloid is another important element of the bony anatomy of the DRUJ. It is a continuation of the subcutaneous ridge of the ulnar shaft and stands as a strut on the end of the ulna to stabilize the ulnar soft tissues of the wrist. The sheath of the extensor carpi ulnaris, the ulnocarpal ligaments, and the triangular fibrocartilage all attach to the distal ulna and help maintain the congruency of the DRUJ; most of these attachments are at the base of the ulnar styloid.

The soft tissues and supporting structures around the DRUJ have been the focus of many studies. One of the most important structures is the triangular fibrocartilage complex (TFCC), a term coined by Palmer and Werner. It arises from the ulnar aspect of the lunate fossa of the radius and courses ulnarward to insert into the base of the ulnar styloid. It also flows distally, where it is joined by fibers arising from the ulnar aspect of the ulnar styloid and inserts distally into the triquetrum, hamate, and base of the fifth metacarpal. The prestyloid recess is a constant perforation found just distal to the level of the ulnar styloid and should not be confused with a traumatic disruption.
The radioulnar ligament is sectioned, the DRUJ dislocates in pronation. The opposite is true in supination. dorsal radioulnar ligament tightens and tends to displace the ulna dorsally (of the disc. In supination, strain increased dorsally; in pronation, strain increased palmarly. This apparent paradox can be rectified if one realizes that, in pronation, the dorsal RUL becomes maximally tightened and stabilizes the DRUJ in forearm pronation whereas the dorsal RUL becomes maximally tightened and stabilizes the DRUJ in forearm pronation. Other investigators have shown that the stabilizing effects of the dorsal and palmar radioulnar ligaments are dependent on forearm rotation. Schuind et al. (17,78,108) and Taleisnik et al. (98) demonstrated how the ECU is maintained in its position over the dorsal distal ulna by a separate fibroosseous tunnel deep to and separate from the extensor retinaculum. The pronator quadratus actively stabilizes the joint by coapting the ulnar head in the sigmoid notch, particularly in pronation, and passively stabilizes the joint by viscoelastic forces in supination (17,50,78).

The ECU musculotendinous unit has unique features that lend additional stability to the DRUJ complex. Spinner and Kaplan (81) and Taleisnik et al. (98) demonstrated how the ECU is maintained in its position over the dorsal distal ulna by a separate fibroosseous tunnel deep to and separate from the extensor retinaculum (Fig. 43.3). The extensor retinaculum swings around and over the medial border of the ulna to insert primarily on the pisiform and triquetrum. This separate arrangement allows unrestricted rotation of the radius and ulna. Studies based on cadaver dissections have shown that an intact ECU and fibroosseous tunnel partially stabilize the DRUJ even after the TFC and other ligaments are sectioned (91).

In the center of the complex is the triangular fibrocartilage (TFC) proper. The periphery of the TFC is thickest, usually measuring 5 mm, and is the portion best suited to bear tensile loads. The TFC is also well vascularized and therefore has good healing potential (82). Tearing of the TFC along its peripheral margin allows DRUJ displacement and instability. In contrast, the central portion of the TFC is thin (usually only 1–2 mm thick) and has a disorganized, random collagen arrangement and little vascularity. This portion is better suited for force transmission and compressive loading.

Authors disagree about whether or not there may be congenital perforations of the TFC. That has implications for treatment because it would be important to know if a lesion discovered during evaluation of a patient's wrist were congenital or traumatic. Weigl and Spira (108) examined the TFC of 84 cadaver wrists with ages ranging from 1 day to 91 years and found that a congenital fenestration was sometimes present on the border between the radial and middle third of the disc. The frequency of the congenital lesions was not listed, but the authors found that 42% of specimens of all ages had fenestrations, usually without degenerative changes. Tan et al. (59) studied 120 fetal and infant wrists and found perforations in 27 (23%). Mikić found no perforations in traumatized wrists younger than 20 years of age, including 38 fetal hands. Palmer and Werner found that 53% of their specimens had TFC perforations, but all had associated erosions of the cartilage of the lunate and distal ulna.

In most cases, the history and physical exam help clarify the etiology of the lesion.

The ulnotriquetral and ulnolate ligaments also are considered part of the TFCC. They share a common origin from the region of the ulnar styloid base and fan out past the triangular fibrocartilage to insert on the triquetrum and lunate, respectively. The ligaments are important stabilizers of the ulnar corner of the wrist and resist palmar–ulnar displacement of the carpus, particularly in power grip. In rheumatoid arthritis the ligaments may become attenuated and allow such displacement (108), a problem that must be considered in planning treatment of DRUJ problems in patients with rheumatoid arthritis, as discussed below.

The other static stabilizers of the DRUJ are the joint capsule and the dorsal and palmar radioulnar ligaments. The DRUJ capsule is uniformly thin and contributes little in the way of stability. The characteristics and function of the dorsal and palmar radioulnar ligaments have been the subject of debate. Some authors (17,78,108) consider them nothing more than thickenings of the periphery of the TFCC. Other investigators (53) have studied them in cadaver models and have tried to assign specific biomechanical roles to them. The roles the ligaments may play in DRUJ biomechanics are discussed in the next session. Two dynamic stabilizers of the distal ulna are the pronator quadratus and the extensor carpi ulnaris. The pronator quadratus has a superficial head, which is a prime mover for forearm pronation, and a deep head, which helps stabilize the DRUJ (92). The pronator quadratus actively stabilizes the joint by coapting the ulnar head in the sigmoid notch, particularly in pronation, and passively stabilizes the joint by viscoelastic forces in supination (17,50,78).

BIOMECHANICS

Anatomically, the ulna is the stable axis of rotation of the forearm around which the radius moves. If there is a dislocation, it is technically the radius that is displaced dorsally or palmarly with respect to the ulna. In the orthopaedic literature and common usage, however, it is the convention to describe the position of the distal ulna with respect to the radius in describing DRUJ dislocations and instability. The conventional nomenclature is used in this chapter.

The distal radioulnar joint has both rotational and translational components of motion and does not have a single center of rotation. Many laboratory studies have been done to study the forces and structures that normally stabilize the joint as well as pathologic changes that occur after DRUJ injuries. In a recent study, Khara et al. (53) used a cadaver model to assess the roles four structures play in stabilizing the DRUJ in different positions of forearm rotation: (a) the dorsal radioulnar ligaments; (b) the palmar radioulnar ligaments of the TFCC; (c) the pronator quadratus and the distal portion of the interosseous membrane underlying the muscle; and (d) the entire interosseous membrane. The authors showed that all four structures contribute to the stability of the DRUJ. Dislocation, and often diastasis, could occur only if all four structures were divided. It was not possible to define the roles of the dorsal radioulnar ligaments or palmar radioulnar ligaments while the interosseous membrane was intact.

Other investigators have shown that the stabilizing effects of the dorsal and palmar radioulnar ligaments are dependent on forearm rotation. Schuind et al. (88) and others (32,108) have demonstrated that the palmar radioulnar ligaments (RUL) become maximally tightened and thus stabilize the DRUJ in forearm supination, whereas the dorsal RUL becomes maximally tightened and stabilizes the DRUJ in forearm pronation (Fig. 43.4). Paradoxically, at Ekenstam and Hagert (5) concluded the opposite: sectioning studies on five cadavers showed that stability in supination was maintained by the dorsal fibers, and stability in pronation was maintained by the palmar fibers. A study by Adams and Holley (2) measured strain on the surface of the TFC articular disc and calculated the strain at the dorsal and palmar margins of the disc. In supination, strain increased dorsally; in pronation, strain increased palmarly. This apparent paradox can be rectified if one realizes that, in pronation, the dorsal radioulnar ligament lightens and tends to displace the ulna dorsally (Fig. 43.5). Left unchecked, this dynamic tensioning ultimately would lead to subluxation and dislocation of the joint. It is the palmar radioulnar ligaments that check that force and keep the joint reduced. If the interosseous membrane is disrupted and the palmar radioulnar ligament is sectioned, the DRUJ dislocates in pronation. The opposite is true in supination.
Figure 43.4. When the wrist is pronated, as on the left, the dorsal radioulnar ligament is taut, seating the ulnar head against the dorsal rim of the sigmoid notch. In supination, on the right, the palmar radioulnar ligament displaces the ulnar head against the palmar radial rim. Reprinted with permission (59).

Figure 43.5. Cross section through the DRUJ in a cadaver specimen. The central portion of the triangular fibrocartilage has been removed to expose the ulnar head. When the forearm is pronated, as shown here, the dorsal radioulnar ligament (DRUL) is tighter than the palmar radioulnar ligament (PRUL).

Fractures involving the distal radioulnar joint and the distal radius change the biomechanics of the TFC complex. In another study by Kihara et al. (52), dorsally angulated fractures of the distal radius were simulated in a cadaver model. The authors found that incongruency of the DRUJ occurred with increasing dorsal tilt of the distal radius, most pronounced with a change of more than 20° from the initial anatomic alignment. Also, with dorsal angulation, the intact interosseous membrane tightened and thus limited forearm rotation. The authors confirmed that DRUJ dislocation occurred only if both the TFCC and the interosseous membrane were sectioned.

The biomechanics and load bearing of the different components of the DRUJ also have been characterized. Compression and axial loading across the wrist are primarily transmitted to the distal radius, but the force is partially transmitted through the TFC to the ulnar head. Palmer et al. (78) showed that in a forearm with ulnar neutral variance, 80% of the static load is borne by the radius and 20% by the ulna. As ulnar length increases from -2.5 mm to + 2.5 mm, the load borne by the ulna increases from 4% to 42%. Removal of the TFCC decreased the load borne by the distal ulna by approximately 12%.

Biomechanical properties of the collagen arrangement and regional structural differences within the triangular fibrocartilage may explain the quality and location of the TFCC tears seen clinically. Chidgey et al. (24, 25) found that the central disc of the TFC has undulating sheets of crisscrossed, poorly vascularized collagen fibers and that the origin of this disc from the radius is reinforced by collagen bundles projecting out from the radius for 1 to 2 mm. This corresponded with the clinical observation that central disc tears identified arthroscopically in 48 patients usually were oriented parallel to and 1 to 2 mm away from the radial origin of the TFCC at the junction between the short, radially oriented fibers and the remainder of the disc. It is postulated that high shear forces occur in this transition zone and account for the tear patterns seen. Tears were notably absent from the ulnar side of the central disc.

PATHOPHYSIOLOGY

A complex scheme for categorizing and cataloguing the injuries and pathologies about the DRUJ has been proposed (17), but most conditions affecting the DRUJ fall into one of three categories: impingement, instability, or incongruity (Table 43.1).

Table 43.1. Classification of Distal Radioulnar Joint Disorders

<table>
<thead>
<tr>
<th>Impingement</th>
<th>Instability</th>
</tr>
</thead>
<tbody>
<tr>
<td>Impingement disorders are characterized by ulnar-sided wrist pain made worse with ulnar wrist deviation. In ulnar impaction syndrome, ulnar deviation causes the lunate and triquetrum to abut against the ulnar head and TFCC. Radiographs show a long ulna relative to the radius and occasionally sclerotic or cystic changes in the ulnar head, lunate, or triquetrum. Tears of the lunotriquetral ligament and TFCC are common in this condition. Ulnar impingement syndrome is a special variant of impingement disorder. In that case, the distal ulnar shaft contacts the distal radius abnormally (usually the result of prior surgery) to cause pain, made worse with medial-lateral compression of the distal forearm and ulnar wrist deviation. A number of conditions may predispose a patient to an impingement syndrome (Table 43.1).</td>
<td></td>
</tr>
<tr>
<td>Instability of the DRUJ may be acute or chronic and may relate to bony changes or soft tissue injuries or both. Fractures of the distal radius or distal ulna can alter the bony alignment of the DRUJ (52). Nonunion or malunion of these fractures may result in pain, weakness, and lost motion in addition to instability. Ulnar styloid fractures have received renewed interest recently because of the importance of TFCC stability. Ulnar styloid fractures commonly occur together with fractures of the distal radius and are often overlooked while emphasis is placed on treating the radius fracture. Ulnar styloid fractures can be troublesome and painful, however, and can be a mark of TFCC instability. Symptomatic nonunions of the styloid do occur. Hauck et al. (44) recently classified these as type 1 with a stable DRUJ and type 2 with an unstable DRUJ. Type 1 fractures occur through the tip of the styloid and do not cause TFCC instability in and of themselves. Should nonunions of this type occur, they can be treated successfully by excision of the styloid fragment. Type 2 nonunions occur through the base of the styloid, are much</td>

</tr>
</tbody>
</table>
larger fragments, and imply TFCC instability if displaced.

Triangular fibrocartilage injuries can be seen alone or in association with instability of the DRUJ. The most common tear occurs within the articular disc of the TFC near its attachment to the radius. This tear does not seem to cause joint instability; however, the tear itself may be unstable and symptomatic (1,3,25,73,83). Despite the recognition of specific types of TFC lesions (Table 43.2), the exact mechanisms of injury remain unclear. Adams et al. postulated that TFCC tears result from a distraction force during a violent axial load of the forearm; however, their cadaver study did not demonstrate the types of TFCC tears often seen clinically (3). Tears probably result from a combination of compression across the wrist, which traps the disc in the ulnocarpal joint, together with DRUJ distraction or twisting, which creates enough shear force to tear the disc. The regional differences in collagen arrangement also may play a role.

Table 43.2. Palmer’s Classification of TFCC Lesions

INCONGRUITY

Incongruity of the DRUJ may result from a variety of conditions. Osteoarthritis is usually posttraumatic but is occasionally primary. In either case, the DRUJ becomes painful, and there is progressive loss of motion of the wrist and forearm and decreased grip strength (65). Rheumatoid arthritis also commonly affects the DRUJ (8,109). Incongruity may result from trauma such as radius fractures that extend into the DRUJ. Whatever the cause, when the distal ulna and sigmoid notch of the radius have incongruous surfaces, the result may be similar; symptoms include pain, swelling, lost motion, and catching or clicking at the DRUJ with forearm rotation.

PRINCIPLES OF TREATMENT

The distal radioulnar joint provides several key functions to the articulation between the forearm and hand-wrist unit. The goal in treating any derangement of the DRUJ is to restore a pain-free, stable junction between the forearm and the rest of the wrist. Treatment options chosen for individual patients should be based on an understanding of the underlying pathology and specific pathoanatomic disorders (Table 43.3, Table 43.4 and Table 43.5). Three critical questions should be addressed and answered before any treatment is selected: (a) What is the duration of the disorder (acute or chronic)? (b) What is the principal cause of the disorder: ligamentous, cartilaginous, bony, or a combination thereof? And (c) what is the condition of the DRUJ articular surfaces: normal, incongruous, or arthritic?

Table 43.3. DRUJ Pathology General Treatment Algorithm

Table 43.5. Instability Lesions Treatment Algorithm
**DIAGNOSTIC EVALUATIONS**

**HISTORY AND PHYSICAL EXAMINATION**

Begin clinical evaluation of any of the disorders affecting the DRUJ with a detailed, accurate history. Knowing the mechanism of injury or symptom production can be helpful. For example, pain with ulnar wrist deviation that began insidiously or with chronic overuse suggests an impingement problem. Patients with traumatic lesions of the TFCC generally give a history of falling on the outstretched hand, which causes hyperextension of the wrist, or a history of the onset of ulnar-sided wrist pain after lifting a heavy object (69). A torque injury with axial load can also cause DRUJ instability. Specific activities that load the wrist during pronation and supination such as using a screwdriver or using a key may exacerbate the pain from a TFCC lesion. Patients often describe a sensation of catching or snapping in the wrist when there are problems in the DRUJ.

During the physical examination, measure the patient's wrist and forearm ranges of motion, both active and passive. A rigid endpoint with loss of motion suggests a bony problem such as fracture malunion, whereas a soft endpoint with limited motion implies scarring or soft tissue contractures. Look for subluxation of the ECU by watching the tendon while the patient actively supinates and pronates the forearm. Provocative maneuvers and applied stresses can be helpful. Pain with ulnar wrist deviation suggests an ulnar impaction syndrome. A TFCC tear should be suspected if the patient's pain is reproduced when torque is applied to the hand while axial load is applied across the wrist and the forearm is stabilized. Inflammatory changes of the DRUJ usually are associated with generalized conditions such as rheumatoid arthritis (18). Note the presence of any obvious deformity and unilateral grip weakness.

**PLAIN RADIOGRAPHS**

Evaluate all patients' wrists radiographically. If there is a history of a specific traumatic event, include two views that show both the elbow and wrist because a dislocation of either the proximal or distal radioulnar joints may accompany any forearm fracture (Fig. 43.6). In the multiply traumatized patient, this is especially critical because other injuries may mask physical findings that would indicate injuries of the proximal or distal forearm joints. Standard posteroanterior (PA) and lateral views of the wrist can be used to rule out bony problems separate from the DRUJ; however, obtain ulnar variance view radiographs before any procedure on the DRUJ. The ulnar variance lateral view (Fig. 43.7A) is taken with the arm at the side (0° shoulder abduction), the elbow flexed 90°, the forearm in neutral rotation, and the wrist in neutral alignment (30). The ulnar variance PA view (Fig. 43.7B) is obtained with the patient's shoulder abducted 90°, the elbow flexed 90°, and the forearm in neutral rotation. For this view, there is disagreement about whether the wrist should be in ulnar deviation (30) to show the lunate centered over the lunate fossa of the radius or neutral deviation to show the lunate centered over the DRUJ (73). However, it should be evident that wrist position will not affect the relative lengths of the ulna and radius, and most patients are more relaxed with their wrist in neutral rather than extreme ulnar deviation. I prefer that patients keep their wrists in neutral for this x-ray.

**OTHER IMAGING STUDIES**

Computed tomography (CT) scans can be useful for evaluating the DRUJ, particularly when there is a deformity related to the joint with associated pain and lost motion (22,25,54,66,67,69,108). Take three sets of scans, one each with the forearm in pronation, supination, and neutral rotation (Fig. 43.8), and compare to the uninjured wrist to assess joint instability accurately. The scan with the forearm in pronation is most sensitive for detecting palmar subluxation, whereas the neutral image is best for detecting dorsal subluxation and DRUJ diastasis. The supination view is best for confirming the degree of reduction or subluxation of the DRUJ (20). On any single CT image, one can gain clues about the position of the ulna relative to the radius by drawing a line through the dorsal radial and ulnar borders of the radius and a second line through the palmar radial and ulnar corners of the radius. An ulna that is adequately reduced must lie between those lines (66,67).

---

**Figure 43.6.** Illustration of lateral radiographs of the wrist in neutral rotation with dorsal dislocation (a), dorsal subluxation (b), palmar subluxation (c), and palmar dislocation (d) of the ulna (U) on the radiocarpal mass. Complete superimposition of the proximal pole of the scaphoid (S) and the lunate (L) is seen. The radial styloid process is centered over the proximal part of the carpus. C, capitate. Redrawn from an illustration by Elizabeth Roselius © 1993, with permission.

**Figure 43.7.** Forearm positioning for ulnar variance view x-rays: lateral view (A) and PA view (B).

**Figure 43.8.** Illustration of CT scans of a transverse section through the distal radioulnar joint. The sigmoid notch and Lister's tubercle of the radius are seen. The positions of the ulna (U) with (a) dorsal dislocation, (b) dorsal subluxation, (c) palmar subluxation, and (d) palmar dislocation are demonstrated. A line drawn through the dorsal ulnar and radial borders of the radius (R) shows the limit of dorsal congruity of the DRUJ, and a line drawn through the palmar ulnar and radial borders of the radius shows the limit of palmar congruity. Redrawn from an illustration by Elizabeth Roselius © 1993, with permission.
The Darrach procedure is best performed as described by Nolan and Eaton (Darrach Procedure—Nolan and Eaton Technique). Regrowth of the distal ulna occurred had no effect on clinical outcome. Posttraumatic DRUJ pathology. All patients improved. The authors found that the amount of ulna resected and whether or not the dissection was subperiosteal or regeneration occurred also had better results. Hartz and Beckenbaugh (ulnar styloid process was left alone. The patient improved significantly and was pain-free at last follow-up.

Resection of the distal end of the ulna is another option for treating impingement disorders. This procedure is often credited to Darrach, who popularized it, although he was not the first to describe it (30). In a review of 24 cases of distal ulna resection, Dingman (31) discovered the best results were seen in those patients in whom the ulnar styloid process was left in situ to keep the TFCC intact, and he suggested that the resection should be subperiosteal because those patients in whom some bony regeneration occurred also had better results. Hartz and Beckenbaugh (43) reported the long-term results of the Darrach procedure in a group of 62 patients with posttraumatic DRUJ pathology. All patients improved. The authors found that the amount of ulna resected and whether or not the dissection was subperiosteal or regrowth of the distal ulna occurred had no effect on clinical outcome.

**Darrach Procedure—Nolan and Eaton Technique**

The Darrach procedure is best performed as described by Nolan and Eaton (Fig. 43.11) (72).
Figure 43.11. The Darrach procedure. A: The skin incision; take care to avoid the dorsal cutaneous branch of the ulnar nerve. B: The DRUJ and TFCC are shown from a dorsal view. The distal ulna is resected at the radioulnar articulation just proximal to the sigmoid notch. The osteotomy angles obliquely proximalward to avoid a dorsal ulnar prominence. ECU, extensor carpi ulnaris. Redrawn from an illustration by Elizabeth Roselius © 1993, with permission.

- Make a dorsal ulnar incision over the distal ulna. Identify the dorsal cutaneous branch of the ulnar nerve and protect it throughout the case.
- Develop the interval between the extensor digiti quinti and the superficial extensor retinaculum and divide the retinaculum longitudinally, preserving it for subsequent closure. Expose the distal ulna through a longitudinal subperiosteal dissection. Leave the interosseous membrane and pronator quadratus undisturbed.
- The site of distal ulnar resection should be at the level of the radioulnar articulation; angle it 30° obliquely and proximally to avoid leaving a sharp dorsoulnar corner. The resected segment should be 4 to 6 mm on the radial border and 8 mm on the ulnar border.
- Dissect out and remove the distal segment, leaving the ligaments and triangular fibrocartilage intact.
- Close the periosteum meticulously and plicate the dorsal retinaculum. Drains are unnecessary.
- For the first 10 days postoperatively, use an above-elbow bulky dressing reinforced with plaster splints with the forearm maintained in neutral rotation. For the following 2 weeks, the patient should splint the wrist intermittently as symptoms allow and then begin progressive range-of-motion exercises.

Good results can be obtained with careful technique; however, several publications have pointed out many problems with the procedure. Failures have been attributed to excessive bony resection, distal ulnar instability with insufficient soft-tissue structures to tether the remaining ulna, extensor tendon rupture, ulnar deviation of the wrist, weakness, and wrist pain (10,11,13,33,38,45,60,70,71,103,105).

Another type of impingement lesion may result from a shortened distal ulna. The most common cause of that is a prior resection, but it may result from a growth disturbance of the distal ulnar physis (10). In such cases, the shortened ulna may impinge on the distal radius, causing a painful, disabling pseudarticulation. Bell et al. (10) first reported the condition in a series of 11 cases, 10 of which resulted from excision of the distal ulna after injury to the wrist. Further resection of the ulna is contraindicated in ulnar impingement syndrome. Instead, the ulnar stump should be stabilized by some means. Bell et al. recommended creation of a tenodesis using the ECU in the method of Goldiner and Hayes (see below).

INSTABILITY

Many techniques have been described to restore radioulnar stability via soft-tissue reconstructions using a sling of fascia lata or a slip of the overlying ECU and retinaculum (17). No large or long-term studies demonstrate any one specific technique to be superior over another. The techniques commonly used are described below.

Soft-Tissue Stabilization Using the FCU—Hui and Linscheid Technique

Hui and Linscheid (47) described how to re-create a portion of the TFCC using the flexor carpi ulnaris (FCU) (Fig. 43.12).

Figure 43.12. The technique of ulnotriquetral augmentation tenodesis for stabilization of the DRUJ, as described by Hui and Linscheid. A: Starting pathologic position (ulnar head sits dorsal). B: Harvested strip of FCU. C: Drill hole in ulnar head. D: FCU strip passed through drill hole. E: K-wire to reduce DRUJ. F: FCU pulled taut and sutured (see text for details). FCU, flexor carpi ulnaris. TFC, triangular fibrocartilage. Redrawn from an illustration by Elizabeth Roselius © 1993, with permission.

- Make a slightly curving incision from the ulnar border of the small finger metacarpal to the middorsal forearm. Expose the extensor retinaculum and reflect it to its insertion into the pisiform.
- Incise the capsule radial to the ECU tendon and reflect it medially. Make a drill hole through the ulnar head angled from proximal-dorsal to distal-palmar (Fig. 43.12A, Fig. 43.12B).
- Expose the FCU through a separate longitudinal incision on the palmar aspect of the wrist. Split it longitudinally as far proximally as possible and then divide it proximally, leaving the medial half of the insertion intact distally (Fig. 43.12C).
- Make a hole in the pisotriquetral capsule and pass the tendon slip intracapsularly, through the drill hole in the distal ulna and through an enlargement of the prestyloid recess of the TFC (Fig. 43.12D).
- Supinate the forearm to reduce the ulnar head and transfix it to the distal radius with a K-wire. Pull the FCU tendon slip taught, double it back to the radioulnar capsule, and suture it securely to the pisotriquetral ligament (Fig. 43.12E).
- Imbricate the dorsal radioulnar ligament, replace the ECU in its sheath, and imbricate the extensor retinaculum (Fig. 43.12F).
- Postoperatively, immobilize the patient’s wrist and forearm in a splint extending above the elbow for 6 weeks and then remove the K-wire and splint and institute physical therapy. After 3 months, the patient should begin vigorous exercises to regain pronation.

Alternative Soft-Tissue Stabilization Using the FCU—Tsai and Stilwell Technique

The procedure described by Tsai and Stilwell (153) also uses the FCU tendon but relies on the interosseous membrane and ECU to aid in stabilization of the ulna (Fig. 43.13). The authors state that their operation is applicable both to the patient with an intact ulnar head and to the one with continuing instability of the ulnar stump after ulnar head excision.
used for patients with an intact ulnar head as well as those who have had a previous Darrach procedure.

Transfer of the Pronator Quadratus Origin—Johnson Technique

Postoperatively, immobilize the forearm in supination for 2 weeks and then begin gradual forearm rotation exercises. Protect the wrist for 3 months with a removable splint at night and intermittent splinting during the day. Goldner noted that snapping and popping of the soft tissues occasionally persist for 4 to 6 months postoperatively. Maximum improvement may take 1 year.

Transfer of the Pronator Quadratus Origin—Johnson Technique

Johnson (49,50) described a technique of advancing the pronator quadratus so that it becomes a dynamic stabilizer of the DRUJ (Fig. 43.15). The procedure can be used for patients with an intact ulnar head as well as those who have had a previous Darrach procedure.
Make a dorsoulnar incision over the distal forearm. Identify and protect the dorsal cutaneous branch of the ulnar nerve.

Identify the pronator quadratus muscle distally and remove its origin from the ulna, working distally to proximally and including as much periosteum as possible with the tendon. By passively pronating the forearm, the muscle can be relaxed enough to allow for easy advancement dorsally.

Advance the muscle 6 to 9 mm dorsally and secure it to the tendon sheath of the ECU with interrupted, nonabsorbable sutures.

Rotate the forearm back to neutral position and cross-pin the radius and ulna with two 0.062-in. Kirschner wires (K-wires). Maintain the forearm in neutral for 4 weeks and then remove the pins and let the patient begin a supervised exercise program, including gentle range of motion and strengthening.

Treatment of a Failed Darrach Procedure

A failed Darrach procedure with a painful, unstable distal ulnar shaft can be a difficult problem to treat. Ruby et al. (85) described a technique for transferring the pronator quadratus dorsally through the interosseous space to stabilize the distal ulna (Fig. 43.16). They suggested that this be used in combination with the Darrach procedure at the time of the original surgery or to treat Darrach procedure failures.

Stabilization of the Ulna after Failed Darrach—Kleinman and Greenberg Technique

Kleinman and Greenberg (56) described a procedure (Fig. 43.17) designed to solve the problem that combines the principles of stabilizing the ulnar stump with a strip of the ECU (as in the Goldner and Hayes procedure) with transfer of the pronator quadratus origin [as in the transfer described by Ruby et al. (85)]. Their original report described use of the procedure in six patients, and it was successful in all.

The Sauvé-Kapandji Procedure

None of the soft tissue procedures fully achieves the dual goals of restoring radioulnar stability while still allowing forearm rotation. Chronic instability that is deemed too
severe for a soft-tissue reconstruction or instability that persists despite other attempts at management is an indication for a salvage operation using a bony procedure. Arthrodesis of the distal radioulnar joint combined with a surgically created pseudarthrosis site proximally in the ulna is now commonly referred to as the Sauvé-Kapandji procedure. In many cases of painful instability of the DRUJ, it may be the most predictable treatment option.

Sauvé and Kapandji (87) described their procedure for the DRUJ in an article that was published in French in 1936. They were not the first to describe such a procedure (6,7,57) but have often been credited with its inception, and the association between their names and the procedure as it is now performed is deeply entrenched in the literature. In their description, Sauvé and Kapandji recommended resection of a 3-cm segment of distal ulna (just proximal to the DRUJ), followed by decortication of the opposing joint surfaces and fixation with a single screw. They also advocated interposition of the pronator quadratus into the gap in the ulna to prevent reossification of the pseudarthrosis site.

Over the years, the technique has changed, and it continues to evolve. For example, the use of a single screw across the arthrodesis site as suggested by Sauvé and Kapandji has been supported by some authors (64,84,111), but a single screw does not provide rotational control of the distal ulnar segment. Therefore, other authors recommended the use of two screws (91) or two K-wires (96) to stabilize the distal fragment. Various uses have been proposed for the bone resected from the ulna. Goncalves (42) used it as a cortical strut wedged between the radius and ulna. Blanco and Blanco (14) used a 20 mm × 6 mm peg fashioned from the excised ulnar segment together with two K-wires to stabilize the arthrodesis construct.

Throughout its evolution the salient features of the Sauvé-Kapandji procedure have remained unchanged: one must stabilize the DRUJ, restore forearm rotation, prevent reformation of bone across the resected segment, and avoid painful instability of the residual ulnar shaft.

- Make a straight longitudinal incision, 6 to 8 cm long, along the ulnar border of the distal forearm (Fig. 43.18). Bluntly dissect and identify the dorsal cutaneous branch of the ulnar nerve; isolate and protect this nerve throughout the procedure. An alternative incision may be used for selected patients in whom additional procedures are planned at the same sitting. For example, in patients with rheumatoid arthritis, the Sauvé-Kapandji procedure may be combined with another soft-tissue procedure such as a dorsal wrist synovectomy, tenosynovectomy, or tendon transfer to treat extensor tendon ruptures that result from the caput ulnae syndrome. In such cases, start the incision more dorsally to facilitate exposure for the additional procedure, and then extended it proximally and obliquely to expose the distal ulna. Again, identify and protect the dorsal cutaneous branch of the ulnar nerve, which usually crosses the operative field.

- Expose the distal 4 to 6 cm of the ulna extraperiosteally through the interval between the ECU and FCU. Next, select the appropriate level for an osteotomy of the ulnar diaphysis (Fig. 43.19).

- Cut the bone just proximal to the flare of the ulnar head, which will leave enough of a distal ulnar segment to accommodate two fixation screws. It is helpful to use fluoroscopy to confirm that the proposed osteotomy site is appropriate. Make a second cut proximal and parallel to the first and remove a 10- to 12-mm segment of ulna. Save the removed bone for subsequent grafting into the DRUJ arthrodesis site.

- Next, expose the distal radioulnar joint. Make a dorsoulnar capsulotomy just radial to the ECU tendon. Alternatively, stay palmar to the ECU tendon and expose the joint by grasping the distal ulnar segment with a towel clip and reflecting it distally and medially, using the TFCC as a hinge (Fig. 43.20). Denude both the ulnar head and sigmoid fossa of the radius of all remaining cartilage and subchondral bone to create flush surfaces of cancellous bone on each side of the arthrodesis site.

- Cannulated screws are ideal for fixation of the arthrodesis site and offer several advantages over K-wires and solid screws. Using cannulated screws over guide wires allows accurate screw placement and facilitates the alignment of the cortices of the distal ulna and radius. There is no need to remove hardware. Rehabilitation can begin sooner because of secure fixation. K-wires can be problematic because buried pins can irritate cutaneous nerves, and percutaneous pins can cause wound problems; both are avoided if screws are used.

- After selecting the desired fixation device and preparing the joint surfaces for fusion, the next step is to establish ulnar neutral variance. Move the ulnar head proximally or distally as required to bring its distal surface parallel with the distal radius surface (Fig. 43.21). Confirm correct position fluoroscopically.
Figure 43.21. The Sauvé-Kapandji procedure. Establish ulnar neutral variance by moving the distal ulnar segment proximally or distally as necessary to align the articular surface of the ulnar head even with the articular surface of the distal radius. Fluoroscopy is helpful for this step. (Illustration by Birk Cox. Reprinted with permission from Slater RR, Szabo RM. The Sauvé-Kapandji Procedure. Tech Hand Upper Extremity Surg 1998;3:148.)

Select two appropriate guide wires from the chosen screw set and drill them into place to stabilize the ulnar head in proper position. Pass one wire through the radioulnar joint a few millimeters proximal to the subchondral bone, place the second wire proximal enough to allow room for seating of both screw heads without impingement on each other (Fig. 43.22). Confirm correct placement of the guide wires with fluoroscopy. It is important to do this while holding the forearm in neutral rotation. This is best accomplished with the patient's elbow resting on the operating table while the forearm is supported perpendicular to the table in neutral rotation. Avoid the tendency to rest the forearm in pronation on the operating table.

Figure 43.22. The Sauvé-Kapandji procedure. Drill two guide wires for the selected cannulated screws parallel across the distal ulnar segment into the distal radius and across to the far cortex of the radius, and use a cannulated measuring guide to determine the appropriate screw lengths. After the screw lengths have been determined, advance the guide wires through the skin and hold them with a clamp to prevent displacement while the guide wires are overdrilled and the screws placed. (Illustration by Birk Cox. Reprinted with permission from Slater RR, Szabo RM. The Sauvé-Kapandji Procedure. Tech Hand Upper Extremity Surg 1998;3:148.)

Advance the distal wire to the far (radial) cortex of the radius and measure for screw length. The proximal screw provides rotational control and needs only tricortical fixation; therefore, it should be 5 mm shorter than the distal screw. It also can be smaller in diameter if desired, which helps minimize the risk of fracturing the narrow ulnar diaphysis. After the guide wires are in proper alignment and the screw lengths have been measured, advance the wires through the skin to the radial side of the forearm with a mallet and grasp them with a clamp to avoid loss of position during the next steps (Fig. 43.22). Using a mallet minimizes the chance of wrapping up a radial sensory nerve branch with the power drive.

Next, overdrill the guide wires with a cannulated drill bit. A tap is not usually necessary, but use it if the cortical bone is particularly dense. Before insertion of the screws, pack the cancellous bone harvested previously from the excised ulnar segment into the arthrodesis site as a graft (Fig. 43.23). In cases with severe bone loss, insert the resected ulnar piece as a corticocancellous bone graft into the DRUJ space. Then insert the selected screws over the guide wires while manually compressing the ulnar head against the radius. Tighten the distal screw first to avoid compressing the radial and ulnar shafts together and levering the ulnar head out of position.

Figure 43.23. The Sauvé-Kapandji procedure. Cancellous bone from the excised ulnar segment can be packed into the arthrodesis site before the screws are fully seated. The final position of the screws is illustrated. (Illustration by Birk Cox. Reprinted with permission from Slater RR, Szabo RM. The Sauvé-Kapandji Procedure. Tech Hand Upper Extremity Surg 1998;3:148.)

Make a final adjustment of the proximal ulnar shaft length with another osteotomy (if necessary) so that there is a gap of 10 to 12 mm between the proximal and distal ulnar segments. Suture the fascia of the underlying pronator quadratus into the resultant gap to prevent reossification across the pseudarthrosis site (Fig. 43.24). This also helps stabilize the stump of the ulnar shaft. Repair the extensor compartments if they were disrupted, for example, to perform tenosynovectomies. Close the skin in routine fashion and obtain final radiographs.

Figure 43.24. The Sauvé-Kapandji procedure. Suture the pronator quadratus in place in the gap where the ulnar segment was excised (left). The final appearance of the construct is illustrated (right). (Illustration by Birk Cox. Reprinted with permission from Slater RR, Szabo RM. The Sauvé-Kapandji Procedure. Tech Hand Upper Extremity Surg 1998;3:148.)

### Triangular Fibrocartilage Complex Instability

Injury to the triangular fibrocartilage complex is diagnosed with increasing frequency as a cause of ulnar-sided wrist pain. Disruption of the TFC may be associated with instability of the distal radioulnar joint, or the lesions themselves may be unstable and symptomatic without causing instability of the entire joint. Treatment depends on location and characteristics of the injury. (Table 43.6) Tears at the periphery of the TFC, along the well-vascularized medial insertion, are amenable to repair.
Increasingly, surgeons are making the repairs arthroscopically, as described in Chapter 75, but the procedure also may be done by open technique, as originally described.

### Table 43.6. Treatment of TFCC Tears

**TFCC Repair—Open Technique**

Hermansdorfer and Kleinman (46) described the following method of repairing the TFCC under direct visualization (Fig. 43.25).

**Figure 43.25.** Open repair of peripheral TFCC tears. A: Chronic granulation tissue is debrided from the site of injury, a cancellous bony trough is made at the base of the fovea, and drill holes are made across the ulnar cortex into the trough. B: 3-0 nonabsorbable sutures are placed through the prepared edge of the TFCC and passed through the drill holes. C: The distal ulna is percutaneously pinned to the radius with K-wires, and then the sutures are tied securely to reconstitute normal tension in the TFCC. Reprinted with permission (46).

- Make a dorsal skin incision paralleling the distal 3 cm of ulna and extending 3 cm distally and radially. Raise a radially based long retinacular flap to later support the ECU tendon dorsal to the flexion-extension axis of rotation. Retract the ECU tendon ulnarily and enter the ulnocarpal joint via a capsulotomy between the fifth and sixth dorsal compartments. Carefully avoid any further injury to the TFCC.
- Identify the traumatically separated TFCC and debride any granulation tissue from the fovea. Create a trough at the base of the fovea by curettage to cancellous bone.
- Place the forearm in neutral rotation and percutaneously pin the distal ulna and radius with two parallel 0.062-in. K-wires to maintain this alignment. Drill parallel small holes through the distal ulna, exiting at the base of fovea.
- Place 3-0 nonabsorbable sutures through the prepared edge of the TFCC and pass them through the drill holes. Tighten the sutures to bring the torn edge of the TFCC back to the fovea and tie them securely while trying to reconstitute the normal tension in the cartilage disc.
- Repair the dorsal capsule with inverted sutures and pass the previously designed flap of extensor retinaculum deep to the ECU and secure it distally to prevent ulnar subluxation of the tendon. That further enhances DRUJ stability as well.
- Postoperatively, immobilize the extremity in a plaster-reinforced bulky dressing extending above the elbow for 10 to 14 days, followed by an above-elbow cast for 4 weeks. Remove the K-wires after 4 weeks and immobilize the wrist in a below-elbow cast for an additional 6 weeks. Begin vigorous rehabilitation of the forearm and wrist at 12 weeks.

In their original series, Hermansdorfer and Kleinman (46) reported that 8 of 11 patients with follow-up greater than 1 year after this procedure returned to normal activities without pain. Measured grip strength averaged 87% of that of the uninjured hand, and measured wrist and forearm motion averaged between 96% and 99% of the contralateral side. Similar results have been reported by other authors after open and arthroscopic TFCC repairs (27,102).

Little attention in the literature has been given to palmar instability of the DRUJ. It has been my experience that the usual cause of this problem is a malunion of one or both forearm bones, and treatment with soft-tissue procedures is ineffective. If palmar instability is found (usually aggravated by supination), conduct a careful radiographic assessment of the forearm with comparative views of the normal extremity. Corrective osteotomy (angular, rotational, or both) is required to eliminate the instability.

### INCONGRUITY LESIONS

Incongruity of the DRUJ usually results in arthritis. A variety of surgical options have been proposed for treatment. Swanson recommended resection of the distal ulna and replacement with a silicone cap (94). Complications from silicone synovitis, particulate debris, and prosthesis failure led to the abandonment of this procedure and development of different techniques. Other forms of resection arthroplasty have gained more popularity.

**Hemiresection Interposition Technique Arthroplasty—Bowers Technique**

The basic premise of the hemiresection interposition technique (HIT) arthroplasty operation described by Bowers (17) is that the portion of the distal ulna that articulates with the sigmoid notch of the distal radius is excised while the distal ulnar shaft and styloid process are preserved (Fig. 43.26). This preserves the triangular fibrocartilage complex, removes the damaged portion of the ulnar head, and maintains stability of the distal ulna.

**Figure 43.26.** Bowers’ hemiresection interposition technique (HIT) of DRUJ arthroplasty. A: Incision, emphasizing the location of the dorsal cutaneous branch of the ulnar nerve. B: Outline of the dorsal retinacular flaps, proximal (1) and distal (2). C: The proximal flap has been reflected showing the proposed flap in the DRUJ.
 While retaining forearm rotation.

Rheumatoid patients may help prevent more distal joint deformity (In view of the limited success of total wrist arthroplasties and the alternative of wrist arthrodesis, the Sauvé-Kapandji procedure is an excellent choice for patients with other cases developed spontaneous radiocarpal ankylosis that stabilized the wrist and prevented the ulnar-palmar drift of the carpus.

The inflammatory changes and deforming forces acting on the hand and wrist in RA tend to cause palmar and ulnar displacement of the wrist, resulting in decreased mobility, strength, and function. Commonly, resection of the distal end of the ulna, the Darrach procedure, has been recommended for patients with RA and ulnar-sided wrist pain. As Watson describes it, the operation should be performed as follows.

With the forearm in full pronation, open the interval between the extensor digiti quinti and ECU. Identify and protect the dorsal cutaneous branch of the ulnar nerve (Fig. 43.26A).

Develop two flaps of the extensor retinaculum. The proximal flap, about one half the width of the retinaculum, is based radially; the distal flap is based ulnarily. The first retinacular flap (Fig. 43.26B) is used to expose the DRUJ, and the second retinacular flap (Fig. 43.26C) is used to expose the DRUJ. The distal ulna is shaped to resemble a finger (inset) facing ulnarward and contoured so there is no impingement against the radius throughout the arc of forearm pronation and supination as Watson describes it, the operation should be performed as follows.

Place the patient on the operating table with the affected extremity fully pronated on a hand table. The surgeon sits cephalad to the arm. Under tourniquet control, make a longitudinal incision dorsally over the distal ulna. Open the proximal edge of the extensor retinaculum over the ulnar head. Reconstruct or resect the extensor digiti quinti flap at this level places the surgeon immediately dorsal to the sigmoid notch of the radius (Fig. 43.26B, Fig. 43.26C).

Open the capsule of the DRUJ close to the radius, allowing enough tissue to repair. The entire triangular fibrocartilage can be seen through this interval. Remove the convexity of the ulnar head. The resection should preserve the shaft and ulnar styloid relationship (Fig. 43.26D).

Suture the ulnarily based capsular flap over the raw bone of the distal ulna, with the sutures entering the palmar wrist capsule. Rotate the forearm to verify that there is no bony contact between the radius and ulna (Fig. 43.26E).

Figure 43.27. Illustration of the matched ulna resection arthroplasty of the DRUJ. The distal ulna is shaped to resemble a finger (inset) facing ulnarward and contoured so there is no impingement against the radius throughout the arc of forearm pronation and supination. As Watson describes it, the operation should be performed as follows.

If there is inadequate tissue to prevent radioulnar contact, place an "anchovy" of tendon from the palmaris longus tendon in the defect previously occupied by the ulnar head. If there is ulnar positive variance and impaction of the remaining ulnar styloid with the carpus on ulnar deviation of the wrist, the HIT may need to be combined with ulnar shortening to prevent translation and impingement of the residual ulna and ulnar styloid.

After proper bony alignment is obtained, suture the distal, ulnarily based retinacular flap to the dorsal capsular structure remaining on the sigmoid notch. Pass the proximal, radially based flap around the ECU and suture it to the distal aspect of the retinaculum of the fourth compartment.

Postoperatively, immobilize the forearm in neutral rotation for 3 weeks and then begin rehabilitation.

**Matched Ulna Procedure—Watson Technique**

Watson et al. (196) proposed that the distal ulna resection be performed with the intention of sculpting the distal ulna to carefully "match" the slope and shape of the distal radius throughout the arc of forearm pronation and supination. As Watson describes it, the operation should be performed as follows.

After removal of the ulnar head, the ulnar styloid will migrate radially and may impinge on the carpals. Check an x-ray and be sure the distalmost ulna lies at the level of the articular surface of the radius. Resection of the ulnar styloid is almost always necessary to achieve this. Then palpate between the radius and ulna to assure there are matching surfaces throughout the arc of forearm rotation. No interposition of soft tissue is necessary. The deep fascia of the ECU sheath may remain attached to the periosteum of the ulna, but this is not necessary. The raw bone of the distal ulna will become securely adherent to the ulnar sling mechanism without sutures or fixation.

Occasionally the slope of the sulcus of the radius is reversed. When seen on a PA radiograph, the proximal portion of the radius ulnar joint protudes more ulnarward than the distal portion; that is, the slope of the radius sulcus joint may be from proximal ulnar to distal radial. When the joint is shaped in this fashion, the proximal portion of the sulcus should be removed with a rongeur so that the radius and ulnar surfaces are again parallel to one another.

Close the skin in routine fashion, and apply a bulky hand dressing with a plaster splint that extends to the elbow but not above. The below-elbow dressing allows mobilization out of the splint.

Uniform results and consistent pain relief do not follow the Bowers and Watson procedures. In a series in patients with posttraumatic DRUJ disorders reported by Saffar et al. (86), pain relief, wrist motion, and grip strength improved more after the Sauvé-Kapandji procedure than after the Bowers or Watson procedures. My own experience and observations are similar, and therefore I prefer the Sauvé-Kapandji procedure. It provides more predictable results in a variety of settings, including osteoarthritis. A recent study by Mentnar et al. (195) reported 15 patients with osteoarthritis of the DRUJ treated in this fashion, and all achieved good results. They suggested that this should not be done if the TFCC is intact or repairable but gave no supporting data for this statement. I do not consider an intact TFCC a contraindication to the Sauvé-Kapandji procedure. In fact, it seems logical to leave the distal ulna as a buttress for the intact TFCC. Taleisnik (97) considers retention of the distal ulna to help stabilize the TFCC, an advantage of the procedure.

**SPECIAL CONDITIONS**

**Rheumatoid Arthritis**

In evaluating patients with rheumatoid arthritis (RA), make an effort to distinguish the pain and instability of the DRUJ from radiocarpal and midcarpal joint symptoms. This is done by careful palpation, halterment, and compression of the specific areas and a comparison of the degree of symptoms elicited by forearm rotation versus wrist flexion and extension. Despite advanced radiographic findings of radiocarpal and/or midcarpal arthritis, many arthritis patients’ complaints of “wrist pain” can be satisfactorily addressed by the DRUJ pathology.

The inflammatory changes and deforming forces acting on the hand and wrist in RA tend to cause palmar and ulnar displacement of the wrist, resulting in decreased mobility, strength, and function. Commonly, resection of the distal end of the ulna, the Darrach procedure, has been recommended for patients with RA and ulnar-sided wrist pain (48,89,81). However, removal of the distal ulna accelerates further palmar and ulnar translocation and ultimately dislocation of the carpus. This complication has been seen in patients with rheumatoid arthritis treated with the Darrach procedure (13,104). Black et al. (13) showed this to occur in 5 of 34 cases reviewed. Six other cases developed spontaneous radiocarpal ankylosis that stabilized the wrist and prevented the ulnar-palmar drift of the carpus.

In view of the limited success of total wrist arthroplasties and the alternative of wrist arthrodesis, the Sauvé-Kapandji procedure is an excellent choice for patients with rheumatoid arthritis and may obviate the need for further surgery on the radiocarpal joint (Fig. 43.28). With the Sauvé-Kapandji procedure, retention of the distal ulna provides a bony support for the ulnar side of the wrist and preserves the soft-tissue attachments of the ulnocarpal complex. The resulting stability at the wrist in rheumatoid arthritis may help prevent more distal joint deformity (104). The ulnar osteotomy allows as much shortening as necessary to match the length of the radius while retaining forearm rotation.

**Figure 43.26.**

**Figure 43.27.**

Illustration of the matched ulna resection arthroplasty of the DRUJ. The distal ulna is shaped to resemble a finger (inset) facing ulnarward and contoured so there is no impingement against the radius throughout the arc of forearm pronation and supination as Watson describes it, the operation should be performed as follows.
Results of the Sauvé-Kapandji procedure used to treat patients with rheumatoid arthritis have been generally good. In one series, 21 wrists in 17 patients were followed for an average of 39 months following the Sauvé-Kapandji procedure (105). All patients reported an increased ability to use their wrists in the functions of daily living after surgery when compared to before surgery and were pleased with the results. At an average of 39 months' follow-up, forearm pronation averaged 78°, and supination 86°. X-rays showed that ulnar and palmar translocations of the carpus were prevented.

In some cases of rheumatoid arthritis, wrist involvement is so severe that no radiocarpal motion is left, or the wrist is already dislocated. In that setting, a wrist arthrodesis or replacement arthroplasty is indicated. Then there is no benefit to the Sauvé-Kapandji procedure, and the Darrach procedure can be used to treat the DRUJ.

Essex-Lopresti Lesions

In 1951, Essex-Lopresti (37) described two cases of comminuted fractures of the radial head associated with dislocations of the DRUJ. He speculated that the mechanism of injury was a violent longitudinal compression force along the long axis of the forearm that resulted in disruption of the DRUJ and the interosseous membrane and fracture of the radial head. Recognizing the extent of the injury to the forearm, Essex-Lopresti recommended not excising the radial head, or, if that were necessary, implanting a prosthesis in place of the radial head to hold the radius out to length while the interosseous membrane healed.

Since the original report, other authors (20,35) have shown that injuries of the Essex-Lopresti type can occur in conjunction with a variety of forearm fractures. The essential features of the injury are a disrupted DRUJ, a radial head fracture, and an associated forearm fracture. It is important to recognize this injury pattern so that it can be treated appropriately. Every effort should be made to preserve the radial head and perform open reduction with internal fixation of the fracture if a stable closed reduction is not obtainable. If the radial head must be excised for some reason, a prosthesis may be put in its place temporarily. A definitive procedure may be done later. One option for the symptomatic, established Essex-Lopresti lesion is replacement of the fragmented radial head or prosthesis with an alglo graft radial head. A preliminary report of that procedure in five patients followed for 2 to 7 years described good or excellent results in all patients (89).

Galeazzi Fracture-Dislocations

A fracture of the shaft of the radius associated with dislocation of the DRUJ was reported by Cooper in the mid-19th century (28). Nearly 100 years later, in 1935, Galeazzi (40) described his experience with 18 cases. Since then, Galeazzi's name has come to be associated with a fracture of the distal radius in combination with a dislocated DRUJ. It is estimated (63) that these injuries account for nearly 7% of all fractures of the forearm in adults. The mechanism of injury is usually a fall on the outstretched hand with the forearm pronated. With the hand fixed to the ground, continued rotation of the patient's body causes hyperpronation, and the resultant forces cause the radial shaft to fracture. The radius then shortens, producing a disruption of the TFCC or an avulsion fracture of the ulnar styloid, which destabilizes the DRUJ.

Nonsurgical treatment of Galeazzi fracture-dislocations generally results in persistent symptoms, including recurrent or persistent dislocations of the DRUJ (63). Therefore, Galeazzi fracture-dislocations should be treated operatively whenever possible to maximize the chance for a good outcome. The fracture should be fixed rigidly, generally by open reduction and plating. The DRUJ should then be reduced. It should snap into place with a solid endpoint and is usually most stable in supination.

If the DRUJ can not be reduced or tends to spring back into subluxation or dislocation, it suggests soft tissue interposed in the joint. Most often, the ECU is the offending tissue. It may displace around the ulnar border of the dorsally dislocated ulna (6). Other structures that have been reported to block reduction include the extensor digitorum tendons, the extensor digit minimi, the flexor pollicis longus, and the median nerve (12,93). In those cases where the joint cannot be reduced, make an incision over the dorsal aspect of the DRUJ, reflect the displaced soft tissues out of the way, and repair the sheath of the ECU to keep it centered over the distal ulna. Postoperatively, immobilize the forearm in approximately 20° to 30° supination for the first 4 weeks, followed by rehabilitation to gradually restore forearm rotation.

Capsular Release for Rotational Contracture

Fixed pronation or supination contractions of the forearm may be the result of prior trauma to the forearm, interosseus membrane, or DRUJ. In selected cases, capsulotomy of the DRUJ may improve forearm rotation. This is particularly true in those patients who had a previous fracture of the distal radius with involvement of the DRUJ and are left with the sequelae of a contracted joint capsule. In a report of 18 patients, af Eckenstam noted 15 patients had improved forearm rotation following DRUJ capsulotomy (4). Other authors have made similar observations (17). A dorsal approach and capsulotomy should be used for patients with loss of pronation, and a palmar approach and release should be used for patients with loss of supination (5,55).

A WORD ON ARTHROSCOPY

Arthroscopy of the wrist and DRUJ has become a useful way to diagnose and treat lesions of those joints, particularly the triangular fibrocartilage complex. Indications for this surgery are becoming better established. It is beyond the scope of this chapter, however, to address this in detail, and the reader is referred to Chapter 75.

SUMMARY

In conclusion, in order to develop a satisfactory and successful treatment strategy for the multiple disorders of the distal radioulnar joint, one must first localize the pathology and be able to categorize it based on a good understanding of the anatomy and biomechanics of the region. For impingement problems, particularly ulnocarpal impingement, restoration of the length relationships between ulna and radius is required, frequently in the form of ulnar shortening. Instability often can be treated with an appropriate soft-tissue procedure. When the quality and condition of the soft tissues are inadequate, arthrodesis of the DRUJ in the form of the Sauvé-Kapandji procedure solves the instability problem. Injuries to the TFCC are an important source of problems related to the DRUJ. They should be assessed and treated either openly or arthroscopically, as the surgeon's capabilities allow. Incongruity of the DRUJ requires a bony procedure in the form of a resection arthroplasty or distal ulnar excision (rarely), or the Sauvé-Kapandji procedure.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; †, review article; ‡, basic research article; and ‡*, clinical results/outcome study.

Unfortunately, the result of the treatment of distal radius fractures often leaves much to be desired. The fracture that Abraham Colles described in 1814 was nonarticular and occurred during a fall on the outstretched hand in a somewhat osteoporotic patient. All distal radius fractures with dorsal displacement are commonly referred to as “Colles’ fractures” regardless of the fracture configuration, degree of comminution, age of the patient, or mechanism of the injury. Because of their frequency, Colles’ fractures are often regarded and treated casually. Controversy and confusion are found throughout the medical literature about the best way to treat a fracture of the distal radius. The fundamental principle of treatment is the restoration of anatomy with the hope of producing full, painless motion of the wrist. The method selected to achieve this objective can be determined only after careful study of the individual fracture pattern.

### ANATOMY

The distal radius is biconcave, triangular, and covered with hyaline cartilage. A smooth anteroposterior ridge divides the articular surface into two facets: a triangular lateral facet, which articulates with the scaphoid, and a quadrilateral medial facet, which articulates with the lunate. The medial surface of the distal radius forms a semicircular notch covered with hyaline cartilage, which articulates with the ulna head. This articulation enables the radius to swing around the ulna. The lateral surface elongates into a prominent styloid process, which gives attachment to the brachioradialis muscle.  

![Figure 44.1](image1)

The cortical bone in the area of the distal radial metaphysis is quite thin. There is normally an average of 23° of radial angulation in the anteroposterior plane. Average radial length from the tip of the radial styloid to the ulna head is 12 mm, although the variance can be considerable.  

![Figure 44.2](image2)

**Figure 44.2.** Measurement of normal average radial angulation, radial length, and palmar angulation. (From Szabo RM, Weber SC. Comminuted Intra-Articular Fractures of the Distal Radius. Clin Orthop 1988;230:40. Reprinted with permission.)
DEFINITIONS

Given an eponym, one may be sure (1) that the man so honored was not the first to describe the disease, the operation, or the instrument, or (2) that he misunderstood the situation, or (3) that he is generally misquoted, or (4) that (1), (2), and (3) are all simultaneously true (79).

A Colles' fracture is defined as a complete fracture within the distal 2 cm of the radius with dorsal displacement of the distal fragment (80).

A Smith's fracture is a complete fracture within the distal 2 cm of the radius with palmar and proximal displacement of the distal fragment.

Confusion arises in trying to define a Barton's fracture. Barton, in his original article, describes a "subluxation of the wrist consequent to a fracture through the articulating surface of the carpal extremity of the radius" (10). The controversy in his day was that this injury was frequently not recognized but instead was diagnosed and treated as a wrist "sprain." Barton describes the mechanism of injury as a force met by the palm of the hand that drives the carpal bones against the dorsal edge of the articulating surface of the radius, creating a dorsal fracture and subluxation of the carpus. He said: "Rarely a fracture of similar character occurs on the palmar side of the radius from the application of force on the back of the hand" (10). It is therefore better to describe a dorsal Barton's fracture or a palmar Barton's fracture than to inaccurately use the term a "reverse" Barton's fracture. Until we drop eponyms from the scientific language, we need at least to agree on what we are describing with these terms.

PATHOMECHANICS

The injury produced depends on the position of the wrist, the magnitude and direction of force, and the physical properties of the bone. A fall on the outstretched hand with the wrist in 40° to 90° of dorsiflexion produces a distal radius fracture with dorsal displacement (57). The radius probably first fractures in tension on its palmar surface, followed by compression on the dorsal surface, resulting in dorsal comminution. The lunate in particular can exert a compressive force on the distal radius, producing a so-called die-punch fracture (88). The ulnar styloid fracture component of the Colles' fracture results from a force transmitted through an intact triangular fibrocartilage complex.

Fractures of the distal radius with palmar displacement are attributed to more than one mechanism of injury. Smith claimed that this injury results from a fall on the back of the flexed hand (92). This mechanism of injury is not always implicated, and many of these fractures result from a fall on the outstretched extended hand. A fall with the forearm in supination followed by pronation around a fixed extended wrist may be the more common mechanism of injury (29-106).

Radial styloid fractures result from an avulsion (tensile) force generated through the palmar radiocarpal ligaments. Careful evaluation of other ligamentous injuries (e.g., perilunate dislocations with or without spontaneous reduction) should be given to the patient with a radial styloid fracture.

CLASSIFICATIONS

Several classifications exist for distal radius fractures (26,37,39,51,72,74,86,109). Because there is such a great variation in the fracture types, however, no simple classification can be relied on to guide optimal treatment or be of prognostic value. Andersen et al. reported a low degree of interobserver and intraobserver agreement for the Frykman, Melone, Mayo, and AO classification systems for distal radius in a clinical setting using initial plain radiographs (5). Given the limitations of fracture classifications based solely on plain radiographs, their use as the sole means for determining the direction of treatment or for the direct comparison of results among different studies is not warranted (5).

FRYKMAN CLASSIFICATION OF COLLES' FRACTURES

In 1967, Frykman introduced a comprehensive classification of Colles' fractures based on the extent of involvement of the articular surface of the radiocarpal and distal radioulnar joints (37).

Type Fracture
I Extraarticular radial fracture
II Extraarticular radial fracture with an ulna fracture
III Intraarticular fracture of the radiocarpal joint without an ulna fracture
IV Intraarticular fracture with an ulna fracture
V Fracture of the radioulnar joint
VI Fracture into the radioulnar joint with an ulna fracture
VII Intraarticular fracture involving radiocarpal and radioulnar joints
VIII Intraarticular fracture involving radiocarpal and radioulnar joints with an ulna fracture

Frykman's classification fails to identify the direction and extent of fracture displacement (51).

UNIVERSAL CLASSIFICATION OF DISTAL RADIUS FRACTURES

A symposium conference in 1990 led to a treatment-related "Universal Classification" based on the concept and principle of extraarticular versus intraarticular fractures and stable versus unstable fractures. This scheme is modeled after the classifications of Gartland and Werley and of Sarmiento (Table 44.1) (26,39,86).

FERNANDEZ AND JUPITER CLASSIFICATION OF DISTAL RADIUS FRACTURES

This is the most recent classification scheme developed to identify stable versus unstable patterns, to identify children's equivalent injuries, to include associated lesions, and to provide general recommendations for treatment (Table 44.2) (34,51).
Table 44.2. A Practical, Treatment Oriented Classification of Fractures of the Distal Radius and Associated Distal Radioulnar Joint Lessons. By Diego L. Fernandez, M.D. PD

Many other classification systems exist that warrant consideration. The Melone (72,73) and Mayo (26,74) classifications draw attention to the intraarticular fracture components and fit into subdivisions of the Universal Classification type IV. The Comprehensive Classification of Fractures (AO/ASIF) (75) divides fractures into three types based on the presence or absence of articular involvement, with subdivisions into three groups that are further subdivided into three more groups, creating 27 categories.

THOMAS CLASSIFICATION OF SMITH'S FRACTURES

Thomas further classified Smith's fractures (190).

Type Fracture
I Transverse distal radial fracture with palmar and proximal displacement
II Palmar-lip fracture of the distal radius with dislocation of the carpus (palmar Barton's fracture)
III Oblique fracture of the distal radius, tilted palmarly

In evaluating results and recommendations for treatment, it is important to analyze which types of fractures are being discussed in any given series.

TREATMENT

Treatment begins after careful examination of the patient. Sensibility is monitored in the alert patient, with particular attention given to the status of the median nerve. If decreased median nerve function is found in a patient with a swollen wrist, carpal canal pressures are measured and used to differentiate median nerve conduction from an acute compressive neuropathy. The patient with a median nerve conduction may be observed, but immediate operative decompression is recommended for acute carpal tunnel syndrome (42,95). The radiographs are analyzed, and the direction of displacement, degree of shortening and comminution, articular involvement, and ipsilateral carpal injuries are determined.

Because the best results are achieved with anatomic restoration and healing of the fracture, the goal of treatment is to obtain and maintain anatomic position. This goal must be met without compromising nerve function or digital motion.

Assessing stability of the initial fracture is critical in choosing treatment paths (Table 44.3) (96). What constitutes stability? Many distal radius fractures redisclocate in a plaster cast. Despite early radiographic assessment followed by remanipulation within the first 2 weeks of treatment, malunion remains a common problem. Early redisplacement accounts for a small proportion of final displacements (about 5%) and is caused by movement at the fracture as a consequence of acute instability (50). The remaining displacements represent late deterioration in the fracture's position as a result of chronic instability (50). Intraarticular involvement and comminution are cited as the most sensitive indicators of stability (25,44,57). Both Jenkins (50) and Abbaszadegan (1) have found that malunion may be predicted by radial shortening and loss of radial angle on initial presentation independent of articular involvement. Shortening indicates initial metaphyseal comminution. Based on a study of 267 consecutively treated Colles' fractures, Abbaszadegan et al. (2) demonstrated that the probability of an acceptable anatomic result by closed treatment, if initial radial axial shortening is 5 mm or greater, was 20%.

Table 44.3. Treatment of Distal Radius Fractures

SPLINT APPLICATION

Most minimally displaced, noncomminuted distal radius fractures are correctly managed with closed reduction and immobilization in mild flexion (10° to 20°) and ulnar deviation (15°), followed by early mobilization. This group includes Frykman type I and II and Smith's type I and III fractures. Immobilization in pronation and supination for Colles-type fractures has been advocated empirically, but no significance in results has been demonstrated in prospective trials comparing the two (18,31,69,86,87,102,104). Because the hand is more functional in a neutral or slightly pronated position, this is probably the preferred position for immobilization; however, careful examination of the distal radioulnar joint is warranted. Its injury should be considered in choosing a position of forearm immobilization. Smith fractures are more stable in supination. Reduction is performed by traction to the hand manually or with Chinese finger traps and countertraction to the humerus with the elbow flexed. The displacement is reduced gently after disimpaction of the fracture. Initial immobilization is maintained with above-elbow dorsal and palmar plaster slabs in the position previously mentioned.

Sarmiento et al. (86,87) reported improved early results with cast bracing for Colles' fractures, but others demonstrated no anatomic or functional advantage for this form of treatment (94). I have used plaster because it is readily available and easy to work with.

Mold the plaster splints so that three-point pressure is applied to maintain reduction.
Trim the plaster just proximal to the proximal palmar wrist crease and around the base of the thumb to allow full finger flexion and thumb opposition.
Take radiographs after reduction and at frequent intervals over the next few weeks.
After swelling decreases, the slints may become loose and need to be replaced.
After 3 to 4 weeks, set the elbow free, and continue immobilization of the wrist for a total of 6 weeks.
Begin gentle wrist exercises and have the patient wear a removable palmar splint for an additional few weeks.

See Chapter 10 for more technical details as well as a description of the cast technique.

The comminuted displaced distal radius fracture offers a greater treatment challenge. Most orthopaedic surgeons agree that the results of treatment correlate directly
with restoration of normal anatomy (4, 6, 8, 9, 22, 25, 32, 37, 39, 43, 44, 45 and 46, 48, 77, 88, 97, 98). Three techniques have been advocated to manage these injuries: percutaneous pinning, traction maintained by transfixing pins incorporated in plaster or with an external fixation device, and open reduction with internal fixation. For elderly patients (>75 years old) with an unstable extraarticular distal radius fracture, Kyoshoighe has advocated open reduction and the use of bone cement to fill the void caused by osteoporotic bone loss (59). This technique has been used more often in Europe than in the United States but may be replaced by the introduction of newer materials such as injectable calcium phosphate.

**SURGICAL TECHNIQUES**

**PERCUTANEOUS PINNING**

Percutaneous pinning has been tried in many ways with a variety of implants (Fig. 44.3) (16, 21, 28, 38, 54, 68, 79, 83, 85, 88, 97, 98). This technique is limited to the fractures in which anatomic reduction can be obtained by traction and in which there are no more than two intraarticular fragments. I prefer a technique similar to that described by Clancy (21).

![Figure 44.3](image)

**Figure 44.3.** Different techniques of percutaneous pinning. A: Pins placed through the radial styloid. B: Crossed pins. C: Kapandji intrafocal technique. D: Ulna-to-radius pinning without transfixation of the distal radioulnar joint. E: A radial styloid pin and transfixation of the distal radioulnar joint. F: Multiple pins from the ulna to the radius including transfixation of the distal radioulnar joint (Rahyack technique). (From Fernandez D, Jupiter J. Fractures of the Distal Radius. A Practical Approach to Management. New York: Springer-Verlag, 1995:129.)

- Obtain fracture reduction and check with a C-arm recorder
- Insert two crossed 0.062-in. smooth Kirschner wires percutaneously with a wire driver. Introduce the first wire at the radial styloid between the first and second dorsal wrist extensor compartments at a 45° angle with the long axis of the radius and 10° dorsally (Fig. 44.4).

![Figure 44.4](image)

**Figure 44.4.** Technique for percutaneous Kirschner wire fixation of Colles’ fractures. A: Schematic cross section of the distal parts of the radius and ulna, demonstrating the extensor canals (numbered) and the starting points for both Kirschner wires. B: Dorsal view of the wrist, showing correct placement and orientation of both Kirschner wires for insertion into the distal part of the radius while avoiding the extensor tendons. C,D: Anteroposterior and lateral radiographs of distal radius fracture suitable for percutaneous pinning. E,F: Postoperative radiographs demonstrating anatomic reduction and proper fixation. (A,B from Clancy GJ. Percutaneous Kirschner Wire Fixation of Colles’ Fractures. J Bone Joint Surg1984;66-A:1008. Reprinted with permission.)

- Engage the Kirschner wire into the ulnar cortex of the proximal radius and go no farther. Palpate the radial artery in the anatomic snuff box and avoid it.
- Introduce the second Kirschner wire between the fourth and fifth dorsal wrist extensor compartments, starting at the ulnar corner of the distal radius, avoiding the semicircular notch. Direct this wire 45° to the long axis of the radius and 30° palmarly and insert it into the radial cortex of the proximal radius, but go no farther.
- Under fluoroscopy, check the stability of the fracture, quality of reduction, and position of the Kirschner wires.
- Cut both Kirschner wires below the skin or bend the wires and leave them superficial to the skin.
- Fix the extremity in well-padded, long-arm dorsal and palmar plaster splints with the forearm in slight supination.
- Four weeks after surgery, convert this form of immobilization into a below-elbow cast, maintaining the wrist in neutral position.
- Remove the pins at 6 to 8 weeks, and continue immobilization with a below-elbow cast for an additional 2 weeks.

Sometimes this technique produces distraction of the fracture fragments, and union is delayed. Late recurrence of deformity may be produced by early mobilization. Therefore, continue protection of the wrist until the fracture is clinically and radiographically healed.

**INTRAFOCAL (KAPANDJI) PINNING**

This technique differs from percutaneous pinning in that the Kirschner wires are used to buttress the fracture fragments by being inserted into the fracture site dorsally, parallel to the fracture line. The indications for this technique are unstable extraarticular distal radius fractures in young patients (54, 55).

- Insert a 0.062-in. smooth Kirschner wire percutaneously between the first and second extensor compartments parallel to the fracture line (use a small incision and blunt spreading to avoid placing any wires in tendons).
- Insert a second wire between the third and fourth dorsal extensor compartments, also parallel to the fracture line.
- Next, advance both wires with a power wire driver obliquely at a 45° angle to the long axis of the radius to engage the intact proximal cortex.
- Apply a plaster cast (my preference is to go above the elbow). Split the cast when dry.
- Remove pins and cast at 6 weeks.
- Start mobilization of the wrist when clinically and radiographically healed.

**EXTERNAL FIXATION**

If the articular surface of the radius is comminuted into more than two fragments, I have adopted the use of external fixation (4, 25, 43, 44, 64, 70, 90, 105). Although pins and plaster have been used successfully in the treatment of fractures that cannot be held reduced by plaster alone, external fixation has the advantage of being adjustable if fracture displacement occurs and avoids the complications of circumferential plaster (16, 22, 46, 47, 52, 68). External fixation relies on the principle of “ligamentotaxis,” in which a distraction force applied to the caprus aligns the fracture fragments by means of intact ligaments. DePalma has shown in a Colles’ fracture created in the laboratory that disruption to the carpal ligaments is rare. As investigators have gained experience with arthroscopy and open reduction of distal radius fractures, however, injury to these soft tissues has been reported (14, 95, 99). Distraction with external fixation frequently improves length and alignment, but intraarticular displacement may be increased and palmar tilt is often not restored (11). In selected cases in which traction restores length and intraarticular alignment, I use external fixation as the definitive treatment (Fig. 44.5).
If intraarticular fragments do not reduce with traction alone, I prefer to perform open reduction and internal fixation of the main fragments, most commonly through a dorsal approach to obtain restoration of the articular surface. The previously applied external fixator then functions as a neutralization device (Fig. 44.6). If a fracture results in radial shortening, it usually requires supramalleolar osteotomy or bone grafting. Autogenous cancellous bone can fill the gaps created by reducing the articular fragments. Leung demonstrated that bone grafting hastens healing of comminuted fractures of the distal radius and allows early removal of the external fixator without subsequent collapse (65). Many commercially available bone substitutes are being promoted that are made from allograft or synthetic materials. They have the advantage of avoiding donor site morbidity, but they are expensive. One product that stands out from the rest is injectable calcium phosphate; it is being evaluated in clinical trials (61). Calcium phosphate is attractive because it is osteoconductive, has high compressive strength, and is gradually replaced by bone (66).

Several commercially available external fixation frames are available, each with small advantages over the others. In general, two threaded 3-mm half-pins are inserted distally and proximally.

- Make a longitudinal skin incision over the proximal half of the index metacarpal along its radial aspect. Dissect the subcutaneous tissues bluntly, and retract to avoid the small branches of the radial nerve.
- Elevate the portion of the first dorsal interosseous muscle over the metacarpal flare.
- Use a 2-mm drill to penetrate the proximal cortex of the index metacarpal at its metaphyseal flare.
- Insert the first pin with a power driver through this hole in the index metacarpal, and go into the base of the long finger metacarpal but not beyond this point.
- Insert a second pin parallel to the first in a similar fashion with the aid of a guide or the distal portion of the external fixation frame (the technique varies, depending on which external fixation frame is chosen). The depth of penetration of the second pin should be no farther than the ulnar cortex of the index metacarpal.
- Make a 3-cm longitudinal skin incision along the midlateral aspect of the radius, beginning about 10 cm from the distal wrist crease. Dissect the subcutaneous tissues bluntly, and protect the sensory branch of the radial nerve. Retract the wrist tendons dorsally and the brachioradialis and sensory radial nerve palmarly.
- Use a 2-mm drill to penetrate the radial cortex of the radius at the level of the insertion of the pronator teres. Drill a 3-mm threaded half-pin into this hole while aiming at the ulnar shaft until it penetrates the ulna cortex of the radius.
- Insert a second pin distal and parallel to the first with the aid of a guide or the proximal portion of the external fixation frame.
- Close skin incisions loosely and apply sterile dressings to the wounds. Apply the external fixation frame.
- Perform fracture reduction with usual techniques or with the assistance of the fixator.
- Obtain anteroposterior and lateral radiographs to confirm proper positioning of the fixation pins and alignment of the fracture.

Final adjustments can be made with the fixator. If alignment cannot be obtained, however, open reduction and additional internal fixation should be considered. Additional incisions and pin placement are dictated by the fracture fragments that do not align with distraction alone.

Do not forget the distal radioulnar joint. If the distal radioulnar joint is severely comminuted, or the distal ulna is dorsally subluxed, a long-arm plaster splint maintaining the wrist in supination may be needed for additional immobilization. I routinely use this long-arm plaster immobilization postoperatively for the initial 4 weeks.

I now prefer to use an external fixation device called the WristJack (developed by Dr. John M. Agee, Sacramento, CA). Its mechanics permit independent adjustment of length, fracture alignment in the lateral and anteroposterior planes, and the position of the wrist in the flexion-extension plane. Distraction and flexion have a detrimental effect on the functional position of the hand, creating excess tension forces on the extensor tendons and resulting in a “clawing” of the hand (extrinsic extensor plus position). Clawing of the fingers is associated with hand stiffness. This observation and the difficulty in rehabilitating the hand when the wrist is in the flexed position led to the development of the WristJack, which allows for Colles’ fracture fixation with the wrist in the extended position.

In a prospective study of 20 consecutive severely comminuted distal radius fractures, my colleagues and I demonstrated that anatomic reduction could be maintained despite a wrist neutral or extended position during external fixation. Most patients were receiving active digital motion on the day of surgery, and 95% maintained functional finger motion during treatment (64). Dynamic external fixators have been used to allow for early motion of the wrist joint, but one study demonstrated a statistically significant loss of radial length compared with that in the static-fixator group (4 mm compared with 1 mm), with more frequent complications in the dynamic-fixator group (93). Another study showed increasing recurrent dorsal angulation with dynamic external fixation (58).

INTERNAL FIXATION

The technique of open reduction and plate fixation is necessary for managing the displaced intraarticular distal radius fracture with palmar dislocation of the carpus (Smith’s fracture, type II) (Fig. 44.7). Early experience has shown that this fracture seldom is stable. Although acceptable reduction can often be obtained by closed means, redisplacement of the fracture is common. Two surgical approaches to the distal radius are useful to apply a plate palmarly. They are described here as techniques A...
surgical approach is similar except for the Forte plate, which requires a more elaborate exposure. Attempts to treat unstable intraarticular distal radius fractures with plates and screws have led to many problems, including nonrigid fixation, lack or loss of operative displacement of articular fragments, what amount of displacement of articular fragments is compatible with a good outcome?

Tomography significantly underestimated or overestimated displacement. The authors concluded that computed tomography using an arc method of measurement that they describe, is more reliable for quantifying articular surface incongruities of the distal radius. Several authors have advocated open reduction and internal fixation of distal radius fractures when articular incongruities exceed 1 mm. PLATE FIXATION OF THE DISTAL RADIUS—DORSAL APPROACH

Technique A: Palmar Radial Approach

- Make an anterior incision, starting at the distal wrist crease along the radial border of the flexor carpi radialis tendon and extend it to 6 cm proximally.
- Identify the flexor carpi radialis tendon and the radial artery. Incise the deep fascia between the flexor carpi radialis and radial artery. Divide the pronator quadratus at its radial insertion.
- Insert retractors on the ulnar and radial aspects of the radius and analyze the fracture pattern.
- Select a small fragment T-plate that will fit the width of the distal radius. Determine the length of the plate with respect to the proximal extension of the fracture so that the final result will provide stable internal fixation.
- Fix the plate first to the proximal fragment. The fracture is reduced by the buttress effect of the plate. If the distal fragments are large, obtain additional fixation with cancellous screws through the horizontal holes in the plate.
- Obtain radiographs to confirm the fracture reduction and the position of the internal fixation device.
- Reattach the pronator quadratus and close the tissues in layers.

Technique B: Modified Carpal Tunnel Approach

- Technique B uses a modified carpal tunnel incision. This incision allows extension into the carpal tunnel if release is necessary and avoids the palmar cutaneous branch of the median nerve and radial artery, which are vulnerable in technique A.
- Make an incision paralleling the ulnar crease, cross the distal wrist crease in an ulnar direction, and then curve back to the midline. Extend the incision 6 to 8 cm proximally from the distal wrist crease.
- Split the fascia proximal to the flexor retinaculum medial to the tendon of the palmaris longus.
- Identify and tag the median nerve. Incise the fascia and, if necessary, the flexor retinaculum (transverse carpal ligament) along the ulnar border of the median nerve.
- Retract the median nerve, palmaris longus, flexor pollicis longus, and flexor carpi radialis radially, and retract the flexor digitorum superficialis and flexor digitorum profundus ulnarily.
- Insert the T-plate and complete the procedure as described in technique A.
- After surgery, place the extremity in a bulky plaster-reinforced compression dressing until suture removal. Continue immobilization for a total of 5 to 6 weeks in a short-arm cast. Place the wrist in neutral to 15° of dorsiflexion, not in palmar flexion, particularly if the carpal tunnel is opened.

PLATE FIXATION OF THE DISTAL RADIUS—DORSAL APPROACH

Several authors have advocated open reduction and internal fixation of distal radius fractures when articular incongruities exceed 1 mm (33, 101) to 2 mm (15, 60). One of the problems in evaluating this approach is the unreliability of measuring displacement accurately. Cole et al. found a poor correlation between measurements made on images and plain radiographs with a gap or step displacement over 2 mm (23). Thirty percent of measurements from plain radiographs compared to computed tomography significantly underestimated or overestimated displacement. The authors concluded that computed tomography using an arc method of measurement that they describe, is more reliable for quantifying articular surface incongruities of the distal radius (23). They followed this study with an outcome study (20) (see below) that raised the question: Despite the well-established correlation between the development of posttraumatic osteoarthrosis of the radiocarpal joint and residual displacement of articular fragments, what amount of displacement of articular fragments is compatible with a good outcome?

Attempts to treat unstable intraarticular distal radius fractures with plates and screws have led to many problems, including nonrigid fixation, lack or loss of operative reduction, and tendon irritation or rupture, to mention a few (35). This has led surgeons to develop new implants to try to solve these problems (17, 19, 82). The surgical approach is similar except for the Forte plate, which requires a more elaborate exposure (17, 19); the choice of implant is the surgeon’s preference.

- Apply traction longitudinally either with temporary external fixation or finger trap traction. Apply a pneumatic tourniquet.
- Make a 10-cm dorsoradial incision parallel to the radius between the second and third dorsal extensor compartments in line with Lister’s tubercle. Plan the incision so that the articular surface can be exposed through a dorsal capsulotomy and there is enough proximal exposure for the plate. Open the extensor retinaculum between the second and third dorsal extensor compartments and mobilize the extensor pollicis longus tendon after tagging it with an umbilical tape.
- Expose the radius subperiosteally between the extensor carpi radialis brevis and extensor digitorum communis tendons by elevating the fourth compartment. Do not enter the fourth dorsal compartment.
- Insert small Hohman retractors along the radial and ulnar cortices of the radius for retraction of the extensor tendons.
- Incise the dorsal wrist capsule and visualize the joint surface.
- Disimpact and manipulate the articular fragments into anatomic position. Accomplish this by inserting small elevators or curets into the metaphyseal fracture and pushing the fragments into place.
- Fill residual defects with autogenous cancellous bone graft from the iliac crest.
- Obtain provisional fixation with one or two 0.062-in. Kirschner wires but avoid interference with placement of the plate.
- Contour the plate and apply it to the distal radius. Lister’s tubercle can be removed to accommodate the plate.
- Drill, tap, and insert the screws according to the implant chosen.
- Confirm reduction and fixation device placement with radiographs in two planes.
- Close the extensor retinaculum and obtain complete coverage of the implant. Leave the extensor pollicis longus above the retinaculum.
- Close the skin and use a drain if deemed necessary.
- Immobilize the wrist in a long-arm bulky plaster-reinforced dressing for 2 weeks. At 2 weeks, remove the sutures and apply a cast (consider above-elbow immobilization) for an additional 4 weeks or until the fracture is clinically and radiographically healed (Fig. 44.8).

Figure 44.7. A,B: Comminuted Smith type II distal radius fracture, anteroposterior and lateral preoperative radiographs. C,D: Anteroposterior and lateral radiographs demonstrate postoperative reduction and fixation with a palmar T-plate.

Figure 44.8. Treatment of a severe comminuted distal radius fracture with massive soft tissue loss from a close-range shotgun injury. Initial management was irrigation and debridement followed by external fixation with limited Kirschner wire fixation. Definitive treatment consisted of obtaining soft tissue coverage with a microvascular free tissue transfer using a scapular flap. The articular surface was reconstructed with a p-plate and iliac crest bone graft at the same time as soft
tissue coverage. The distal ulna was allowed to form a pseudarthrosis. Preoperative (A) anteroposterior and (B) lateral radiograph. C: After initial incision and debridement and external fixation. D: Anteroposterior radiograph after external fixation. E: Anteroposterior radiograph after internal fixation. F: Lateral radiograph after internal fixation. G: Seven months postoperative wrist flexion. H: Seven months postoperative wrist extension. I: Seven months postoperative pronation with finger extension. J: Seven months postoperative supination with finger flexion.

ARTHROSCOPICALLY ASSISTED REDUCTION

An alternative method to open reduction and internal fixation that allows for visualization of the articular surface is arthroscopically assisted reduction combined with either external or internal fixation (1,27,40,41,66,67,80,196). In one study, 49 of 50 patients had concomitant ligament injuries, and one third had chondral injuries (87). These additional injuries may explain different outcomes unrelated to radiographic findings, as no correlation could be established between x-ray findings and ligamentous injuries (85).

- Wait 2 to 4 days after the acute injury to avoid extravasation of fluid into the soft tissues.
- Wrap the forearm with an elastic bandage or Coban (3M, Minneapolis, MN) to prevent further extravasation. Apply 4 to 7 kg of traction to the index and long fingers and attempt a closed manipulative reduction.
- Use a traction tower, 2.7 mm 30° angle arthroscopic, and standard arthrosopic techniques as described in Chapter 75.
- Place the arthroscope in the 3-4 portal and an outflow cannula in the 6-R portal.
- Lavage the joint thoroughly. Use a small-radius shaver to remove synovium and cartilage debris until the fracture is well visualized.
- Disimpact the fragments by pryng between fracture lines with a hook or small osteotome inserted through the 4-5 portal.
- Insert 0.045-in. Kirschner wires percutaneously into the fracture fragments or into the fracture line (as described in the Kapandji technique) and use these wires as joysticks to manipulate the fragments into anatomic positions.
- Advance the wires across the fracture into intact cortex to maintain reduction.
- Check reduction and position of pins under fluoroscopy.
- Apply a plaster cast (my preference is to go above the elbow). Split the cast when dry. Alternatively, use an external fixator as a neutralization device.
- Remove pins and cast at 6 weeks.
- Start mobilization of the wrist when clinically and radiographically healed.
- Combined internal and external fixation is often needed for the treatment of severe distal radius fractures (12). With open fractures, this approach may be staged as illustrated.

REHABILITATION

All patients regardless of treatment method are encouraged to move their fingers immediately. Patients are instructed to elevate the hand for the first week after treatment. Fractures are immobilized until clinically and radiographically healed. A recent study suggests that ultrasound signal may accelerate the healing of fractures of the distal radial metaphysis and decrease the loss of reduction during fracture healing (62). Further study of this technique is warranted before its value is assessed. When healed, patients are referred for supervised hand therapy to regain wrist motion and strength. Therapy is individually tailored for each patient, depending on severity of the fracture, age of the patient, functional demands, and postfracture problems.

OUTCOMES

Does a poor anatomic result equate with an unacceptable functional result? Aro studied 146 patients with distal radial fractures (7). Ninety-six percent of the patients with radial shortening of less than 3 mm had a good functional result. Twenty-five percent of patients with radial shortening of 3 to 5 mm and 31% of patients with greater than 5 mm radial shortening had an unsatisfactory result, regardless of displacement or angular malalignment of the radial fragment. Even minor shortening of the radius significantly alters the load pattern across the wrist joint, causing functional limitation.

Midradial deviation with loss of palmar tilt alters the wrist mechanics, creating an alignment that permits the carpus to collapse dorsally, leading to dorsal midcarpal instability (88). Midradial deviation with loss of angulation toward the ulna leads to radial deviation of the hand and tends to palmar flex the scaphoid, which leads to increases in the scapholunate angle. Shortening, alone or in combination with angulation, disrupts the congruence of the distal radioulnar joint (DRUJ). This may cause pain in the distal radioulnar joint, interference with pronation/supination, and, because it results in an ulnar plus hand, may interfere with radial and ulnar deviation of the carpus from ulnar impingement and/or impaction.

Of 34 extraarticular Colles’ fractures treated with plaster immobilization, Roth found that 27 remained symptomatic, and 16 had marked functional limitations at the end of treatment (84). Poor end results were associated with loss of radial angle, palmar tilt, and radial length.

Catalano et al. studied the long-term functional and radiographic outcomes in a series of young adults in whom an acute displaced intraarticular fracture of the distal aspect of the radius had been treated with operative reduction and stabilization (20). They found that at an average of 7.1 years, osteoarthritis of the radiocarpal joint was evident on the plain radiographs and computerized tomography scans of 16 of 21 wrists (76%), and there was a strong association between the development of osteoarthrosis of the radiocarpal joint and residual displacement of articular fragments at the time of osseous union. The functional results, however, as determined by physical examinations and responses to questionnaires, did not correlate with the extent of the residual displacement at the time of fracture healing. Furthermore, all patients had a good or excellent functional outcome irrespective of radiographic evidence of osteoarthrosis of the radiocarpal or the distal radioulnar joint or nonunion of the ulnar styloid process (20).

PITFALLS AND COMPLICATIONS

Failure to obtain anatomic reduction can result in secondary deformity of the distal radius, midcarpal instability, and arthritis (60,85). Median nerve damage may occur in the form of acute and late carpal tunnel syndrome, confusion, or stretch. Ulnar nerve damage has also been reported. Radial nerve damage occurs with the placement of external fixation pins percutaneously and can be avoided by a skin incision and proper identification of the sensory branch. A painful, stiff hand and reflex sympathetic dystrophy (80) are best prevented by minimizing swelling, starting digital motion immediately, not immobilizing in extreme positions, and avoiding constrictive dressings. The rate of complications related to fixation pins is as high as 60% in some series (45).

Distal radioulnar joint dissociation or capsular contractures, TFCC tears, and arthritis may require further reconstructive surgery to restore wrist motion (pronation–supination) and eliminate pain. Flexor tendon adhesions and tendon ruptures (particularly extensor pollicis longus ruptures) are known complications (13,30,107). The use of titanium distal radius plates has raised concern over increased tendon ruptures, with the use of internal fixation becoming more popular (63). Nonunion of the distal radius is extremely rare. Segalman and Clark recommend that if 12 mm of subchondral bone remains, union should be attempted with bone grafting and internal or external fixation (89).

Surgical Techniques—Reconstructive Surgery After Fractures of the Distal Radius

Reconstructive surgery after fractures of the distal radius, including operations directed at correcting the distal radioulnar joint problem (Chapter 43), carpal tunnel release (Chapter 56), radiocarpal or limited intercarpal arthrodesis (Chapter 72), and tendon transfers or reconstructions (Chapter 48, Chapter 49 and Chapter 50), are described elsewhere in this book. Corrective osteotomy of the distal radius is the subject of this discussion.

Radial osteotomy is considered if the dorsal angulation of the distal radius is 25° greater than that in the normal wrist and if there is significant shortening (6 mm) of the radius. This amount of deformity usually results in a symptomatic patient. Besides restoring normal anatomy, a dorsal opening wedge reduces the traction and decreases the median nerve, often making carpal tunnel release unnecessary in symptomatic patients with a distal radius malunion (63). Contraindications to osteotomy include advanced degenerative changes in the wrist, significant intrarticular incongruency, fixed carpal malalignment, or a stiff hand. The surgical technique used is that described by D. L. Fernandez (Fig. 44.9) (32). Viegas has described this procedure with minimal internal fixation combined with external fixation across the
Careful preoperative planning includes examination of the radiographs of the affected and the normal wrist. Particular attention is directed at the ulnar variance to restore the normal anatomic relationship with the distal radioulnar joint. The osteotomy must correct the palmar tilt in the sagittal plane, the ulnar tilt in the frontal plane, and rotational deformities in the horizontal plane.

- Make a 10-cm dorsoradial incision parallel to the radius beginning 2 cm distal to Lister's tubercle.
- Expose the radius subperiosteally between the extensor carpi radialis brevis and extensor digitorum communis tendons. Do not enter the fourth dorsal compartment.
- Mark the osteotomy site with an osteotome (about 2.5 cm proximal to the wrist joint).
- Insert a 0.045-in. Kirschner wire perpendicular to the radius 4 cm proximal to the osteotomy site. Insert a second 0.045-in. Kirschner wire into the distal radius so that it subtends an angle with the first Kirschner wire that is 5° more than the amount of deformity (Fig. 44.8).
- Make the osteotomy parallel to the joint surface while protecting the soft tissues with subperiosteal retractors. This is facilitated by placing a fine Kirschner wire along the articular surface of the radius to act as a guide.
- Open the osteotomy dorsally until the two Kirschner wires are parallel to each other (a small Lamina spreader is useful for this maneuver).
- Open the osteotomy on the radial side to correct radial shortening. Rotate the distal fragment to correct any pronation or supination deformity.
- Shape a corticocancellous iliac crest graft into a trapezoid to fill the gap created by the osteotomy. Pack the area with cancellous graft material.
- Maintain the reduction with oblique, crossed Kirschner wires, and obtain anteroposterior and lateral radiographs.
- Obtain rigid fixation by applying a contoured T-plate to the dorsum of the radius. (I have preferred the 2.7-mm ASIF blade plate, which is easiest to cover with soft tissues.) An optional next step is to remove the Kirschner wires; it is acceptable to use only the Kirschner wires for fixation, but postoperative immobilization until union must be maintained. Lister's tubercle may be removed for better fit of the plate.
- Examine the distal radioulnar joint clinically and radiographically. If needed, perform a Sauvé-Kapandji or Darrach procedure (see Chapter 43).
- Close the tissues in layers, making certain that there is good coverage of the plate.
- After surgery, immobilize the wrist in a long-arm bulky plaster-reinforced dressing for 2 weeks. At 2 weeks, remove the sutures and begin protective active range-of-motion exercises.
- The osteotomy usually is healed in 8 to 12 weeks, at which time unrestricted activity is allowed.
- For correction of distal radius fractures with palmar tilt (Smith's fractures), a palmar opening wedge osteotomy is performed by an approach identical to that described for the acute care of Smith's type II fractures (technique B) (91).

CHAPTER 45

GUNSHOT, CRUSH, INJECTION, AND FROSTBITE INJURIES OF THE HAND

Beth A. Purdy and Robert Lee Wilson

Historically, gunshot wounds have been classified on the basis of the velocity of the bullet, with the difference between low and high velocity ranging from 1,100 to 3,000 ft/s (18-32). Velocity increases only the potential for increased tissue disruption; other factors determine the reality of that potential (fragmentation, yaw, missile shape, and deformation). Another popular reference is to the kinetic energy of the bullet, an immeasurable concept that reveals nothing of the magnitude, type, or location of tissue damage or the forces that cause tissue disruption and distracts from these crucial elements. Tissue damage from bullet projectiles occurs through two mechanisms: first, tissue crush by the projectile and any resultant secondary projectiles; and second, tissue stretch from temporary cavitation, which occurs in a radial fashion along the course of the bullet (19,20 and 21,32). Direct tissue damage from the projectile is increased by deformation of the bullet, fragmentation, and bullet yaw and tumble.

The final determination of wound severity is the tissue itself. Tissues such as skeletal muscle have a high level of elasticity and are therefore less affected by temporary cavity displacement pressure (4 atm) than less elastic tissue such as brain, liver, or spleen. Indeed, most injury to extremities is the result of structures directly hit by the intact bullet, bullet fragments, or secondary missiles (19,32,33). Since the Hague Conferences of 1899 and 1907, full metal jacketed bullets were adopted by the military of all major countries to limit unnecessary suffering of war (63). These standards are obviously not applied to civilian weapons. If a full metal jacketed bullet and a soft or hollow point bullet are fired from the same rifle, the latter will result in a much more dramatic wound from both increased yaw and deformation.

Shotgun wounds are classified on the basis of range (Table 45.1) (61). Round projectiles have poor ballistic properties, losing much of their energy in flight through the air. Their wounds are then reflective of the increased mass of the projectiles, not their high velocity. The greater the choke of the barrel, the less spread of pellets at

Severe hand injuries, although rarely life threatening, are frequently life changing. Our hands define our vocations, avocations, pleasures, and even expression. Treatment of these injuries, then, must take into account the person whom the tragedy has struck and use all measures necessary to maximize the return toward normalcy.

The elegant anatomy of the hand has placed many different structures in efficient juxtaposition. Planning the treatment of injuries must take into account the rehabilitation of each structure. For example, a crushing injury at the metacarpal level with dorsal skin loss, extensor tendon injury, and fractures may require stable bony fixation for early mobilization, possible free tissue transfer for skin coverage and tendon gliding, and even possible combination flaps such as the dorsalis pedis flap to include extensor tendons. Isolated treatment of the bony injury may result in a favorable radiograph but would certainly compromise hand function. Treatment of the soft tissue defect without stable bony fixation would be equally disastrous.

Orthopaedic surgery has moved away from such principles as “go to the bone and stay there” to better appreciate the importance of soft tissue treatment and healing. Levin coined the term orthoplastic to emphasize the interplay between soft tissue management and bone reconstruction. Reconstruction of the soft tissue envelope demands definition of the layers deficient as well as the size of the defect before outlining a plan that will treat both the bone and soft tissue to the best advantage (38).

Godina, in a large study from Yugoslavia, reviewed 532 microsurgical reconstructions following extremity trauma (24). These were divided into three groups based on the timing of the free-flap transfer, ranging from less than 72 h to greater than 3 months. He showed that early coverage resulted in a lower rate of infection, fewer hospital days and operations, and earlier bone healing. Drawbacks of the study include the wide range of the middle group (72 h to 3 months). The study did emphasize the supreme importance of adequate initial debridement, which often will obviate later debridement and in some cases allow soft tissue coverage at the initial operation (24).

Hand injury treatment as it applies to gunshot, crush, paint injection, and frostbite is reviewed in this chapter, beginning with emergency room evaluation and treatment, surgical planning, staging, options, and, finally, postoperative rehabilitation.

GUNSHOT WOUNDS

The penetrating trauma over the course of history has made its greatest advances in wartime. More than half of war wounds involve the extremities, and a fifth of these are hand wounds (11). Regrettably, injuries once commonplace only in times of war are now regular and expected occurrences in emergency rooms around the country. Specific injuries of the hands are seldom themselves life threatening but are frequently associated with other wounds and, as a result, are often complicated by delay in treatment. Maximal function and minimal long-term disability will be achieved only with thoughtful treatment, couched in a basic knowledge of ballistics and wound personality, appropriate emergency care, and reconstruction options.

BALLISTICS AND WOUND PERSONALITY

Historically, gunshot wounds have been classified on the basis of the velocity of the bullet, with the difference between low and high velocity ranging from 1,100 to 3,000 ft/s (18-32). Velocity increases only the potential for increased tissue disruption; other factors determine the reality of that potential (fragmentation, yaw, missile shape, and deformation). Another popular reference is to the kinetic energy of the bullet, an immeasurable concept that reveals nothing of the magnitude, type, or location of tissue damage or the forces that cause tissue disruption and distracts from these crucial elements. Tissue damage from bullet projectiles occurs through two mechanisms: first, tissue crush by the projectile and any resultant secondary projectiles; and second, tissue stretch from temporary cavitation, which occurs in a radial fashion along the course of the bullet (19,20 and 21,32). Direct tissue damage from the projectile is increased by deformation of the bullet, fragmentation, and bullet yaw and tumble.

The final determination of wound severity is the tissue itself. Tissues such as skeletal muscle have a high level of elasticity and are therefore less affected by temporary cavity displacement pressure (4 atm) than less elastic tissue such as brain, liver, or spleen. Indeed, most injury to extremities is the result of structures directly hit by the intact bullet, bullet fragments, or secondary missiles (19,32,33). Since the Hague Conferences of 1899 and 1907, full metal jacketed bullets were adopted by the military of all major countries to limit unnecessary suffering of war (63). These standards are obviously not applied to civilian weapons. If a full metal jacketed bullet and a soft or hollow point bullet are fired from the same rifle, the latter will result in a much more dramatic wound from both increased yaw and deformation.

Shotgun wounds are classified on the basis of range (Table 45.1) (61). Round projectiles have poor ballistic properties, losing much of their energy in flight through the air. Their wounds are then reflective of the increased mass of the projectiles, not their high velocity. The greater the choke of the barrel, the less spread of pellets at
any given distance. Decreasing the choke (“sawed-off shotgun”) increases both the ability to conceal the weapon and the ability to hit multiple targets with one shot as a result of increased dispersion of the pellets.

EMERGENCY ROOM MANAGEMENT

- Adhere to the principles of advanced trauma life support. More than half of gunshot wounds to the hand are associated with multiple gunshot injuries (54). In Ogden's study of extremity gunshot wounds, 6% of through-and-through extremity wounds were associated with missile penetration of another "major" body area. Do not allow the obvious hand injury to distract from diagnosing a possibly life-threatening occult wound. Disrobe the patient and inspect all surfaces, including the back.
- Begin specific examination of the wounded upper extremity with assessment of entrance and exit wounds, their size and character, swelling and deformity in the region between, and a mental note of vital structures potentially involved in the path of the bullet.
- Check pulses and circulation by Allen's test. With the high collateral flow in the distal upper extremity, the mere presence of pulses does not rule out a significant vascular injury proximally. Avoid tourniquets for control of brisk bleeding; rather, apply direct pressure. Resist the urge to clamp or coagulate blindly, as future vascular and nerve repair will likely be compromised by inadvertent injury to underlying structures. If an extremity wound is ever fatal, it is most likely related to vascular injury proximally. Avoid tourniquets for control of brisk bleeding; rather, apply direct pressure. Resist the urge to clamp or coagulate blindly, as future vascular and nerve repair will likely be compromised by inadvertent injury to underlying structures. If an extremity wound is ever fatal, it is most likely related to vascular injury proximally.
- Perform a neurologic examination documenting the function in the radial, median, and ulnar nerves. Document profundus and superficialis tendon function as well as the bony architecture of the hand.
- Following examination, gently rinse with saline solution and apply a moist saline dressing and splint as appropriate.
- Administer intravenous first-generation cephalosporin or ceftriaxone.
- Give a tetanus booster in patients with known active immunity and tetanus toxoid plus human recombinant antitoxin to the nonimmunized, according to the guidelines of the Committee on Trauma of the American College of Surgeons.
- Bullet sterilization from the heat of firing was disapproved in 1882 (18). The bullet will carry bacteria from the body surface and any other tissue through which it passes (such as colon). The most important cause of death from missile wounds on the battlefield in the preantibiotic era was streptococcal bacteremia, not clostridial myositis (19).
- Treatment of low-velocity gunshot wounds following emergency room treatment is controversial, with recommendations ranging from a minimum of 24 to 48 h coverage with IV cephalosporin to oral antibiotics given to outpatients only after manifestation of signs and symptoms of infection (29,34,50,70). Marcus advises that "the judgment of the physician performing the initial examination is the most important factor determining the appropriate treatment of a gunshot wound"(52).
- See the discussion that follows on surgical indications.
- Radiographically image the entire involved extremity and do a chest radiograph as well. Complex associated fractures may then be further imaged using CT, especially with involvement of the carpus.
Do not overlook compartment syndrome, other associated gunshot wounds, and missile emboli. Suspect compartment syndrome of the hand when the hand is swollen. This presentation may be confused by associated skeletal and nerve injury. The hand will almost invariably be held in an intrinsics minus position. Naidu and Heppenstall find that excruciating pain with passive motion of the MCP joint of the involved digit is the most sensitive clinical indicator (49).

Measure intracompartamental pressures. Recommendations for fasciotomy vary, ranging from intracompartamental pressures of over 30 mm Hg up to pressures within 30 mm Hg of the diastolic systemic pressure (26,52). There are 10 separate compartments in the hand (Table 45.3). Most frequently, release is necessary of one or two dorsal compartments, the hypothenar, and the thenar, with release of the transverse carpal ligament. The finger is enclosed in a tight investing fascia supported by unyielding volar skin. Occasionally midaxial finger incisions are also required to avoid tissue loss (48,52). The reader is referred to Chapter 13 and Chapter 65 for further discussion of compartment syndromes in the upper extremity.

- Extensor pollicis brevis

Indications for formal vascular imaging are controversial. Ordog proposed a classification to aid in decision making (Table 45.4) (50). In addition, multiple wounds in the same extremity and potential arterial compromise may merit arteriography if the condition of the patient allows, to better plan the surgical approach and intervention.

Table 45.4. Ordog’s Indications for Vascular Imaging

SURGICAL INDICATIONS

The need for formal debridement in the operating room is determined by the severity of the injury. Very often, little information is available regarding the type of weapon, the range at which the injury occurred, or the specific ammunition used. The treating physician must base a reasonable decision not on conjecture as to the velocity of the bullet but on the characteristics of the wound under examination. As previously mentioned, it is possible to have small entrance and exit wounds in the presence of massive underlying soft tissue and bony destruction. This is evidenced by massive swelling, loss of bone stability, and neurologic and vascular deficits, which require emergent surgery. Small entrance and exit wounds in the absence of these clinical signs may, in contrast, be treated with simple wound cleansing and dressing on an outpatient basis. Hampton’s review of 368 bullet wounds of the extremities, more than half of which had associated fracture, showed that over 300 did not require debridement, and no sepsis resulted (28).

Marcus retrospectively reviewed low-velocity gunshot wounds of the extremities and grouped them on the basis of both debridement technique and presence or absence of fracture. Nonoperative treatment was defined as excision of wound margins under local anesthesia in the emergency room and wound irrigation with saline, with or without antibiotics. He found no difference in outcomes between those treated with surgical debridement and antibiotics and those without aggressive treatment (42).

Retained bullet fragments present a further dilemma. When they are lodged in the hand, their mere size may necessitate removal. When retained around joints or joint areas where exposure to synovial fluid and abrasion is possible, excision is also recommended to avoid mechanical damage as well as lead arthropathy (23). When they are lodged in the physi of a child, removal is mandatory. Washington and Lee reviewed their experience with gunshot wounds in children and reported that all physeal arrests were easily predicted on the admission radiographs (70). It was previously thought that the physis was highly susceptible to high-velocity injury if the track of the bullet was nearby.

Neurologic deficit is not sufficient reason for surgical exploration in and of itself, as many are neurapraxias. Phillips recommends no exploration before 3 months, then electrical studies to establish the need for repair or grafting (54).

PRINCIPLES OF OPERATIVE TECHNIQUE

- Acute debridement serves two purposes: to remove nonviable tissue and foreign debris, and to decompress the wounded hand. With the close juxtaposition of many crucial structures in the hand, when there is any doubt about the viability of an important structure, delay excision until the second debridement.
- Bony fragments may be retained, even if detached, unless grossly contaminated.
- There is rarely a good argument to be made for primary closure of wounds following the initial debridement. Sherman studied gunshot wounds and their complications and found that 31% of wounds primarily closed following debridement required further operative care for infection (81).
- Manage wounds open with moist dressings and splints.
- Carry out a second debridement 48 to 72 h following the first. Debridement is a learned art, as emphasized by Brown, who recommends: "Don't get wounded in the first 2 months of the war" (11).
- Complete or near amputations of the hand or digits rarely are appropriate for replantation. Salvage of skin, tendons, bone, nerve tissue, and even digits themselves may be valuable in reconstruction of the remainder of the injured limb. The viable skin covering near-amputations may be valuable in skin coverage.
- Skeletal stability is crucial for soft tissue healing as well as for mobilization of the hand to hasten rehabilitation. Restore both the longitudinal and transverse arches of the hand, even at the time of the initial debridement. In cases of bony loss, use Kirschner wire bayonet spacers, cross-pinning of metacarpals, or external fixation to achieve stability pending secondary bony reconstruction.
- Nerve repair in the hand may be carried out at the time of initial or secondary debridement, or the nerve ends may be marked for later repair or grafting. Stein and Strauss recommend primary repair only in cases of clean transection, whereas Hennessy advocates primary repair whenever possible, using nerves from nonviable parts of the injured hand when available (31,64).
- When vascular repair is necessary, gain control of the injured vessel both proximally and distally with adequate exposure. In the repair of the radial or ulnar artery in the distal forearm following a close-range shotgun wound, use caution to avoid peripheral embolization of pellets. Vascular repair almost always will require segmental resection, as the zone of injury often extends beyond the area visibly damaged. Vein grafting is usually necessary (5,26,32,50,61,64,73).
Skin coverage options after the final debridement include delayed primary closure, healing by secondary intent, local flaps, or distant flaps. Postoperatively, support the wounded tissues with a dressing firm enough to eliminate dead spaces without inhibiting venous return. The dressing absorbs blood and exudates, provides a barrier to further contamination, increases patient comfort, and facilitates mobilization of uninjured parts. Place the hand in an intrinsic-plus position unless that compromises the repairs. Elevate the limb and begin early range-of-motion exercise for the shoulder and elbow to avoid stiffness.

REHABILITATION

The success of rehabilitation requires a patient's understanding of his role and responsibility as an active member of the rehabilitation team. Begin patient education after application of the first postoperative dressing or in the emergency room for those treated nonoperatively. Mobilization of all parts possible, edema control, wound care, and splinting in functional positions are all elements of success in returning the injured limb to useful function.

PITFALLS AND COMPLICATIONS

Pitfalls include compartment syndrome, overlooked associated gunshot wounds, underestimated vascular injury, and peri- or intraarticular lead particles. Lead near or in joints will be dissolved over time by acidic synovial fluid and incite a proliferative synovitis, which may result in focal articular cartilage erosion and degenerative arthritis. Radiographically, lead may resemble chondrocalcinosis, with metallic not calcific deposits. Remove intraarticular lead particles soon after injury. If lead arthropathy is suspected, measure serum lead levels. Delay surgical procedures until levels have been reduced with chelating agents such as D-penicillamine (23).

Duncan and Kettelkamp showed that the primary functional impairment following low-velocity gunshot wounds to the hand was loss of motion secondary to fractures and joint disruption, and this surpassed the disability from infection and tendon, nerve, or vascular injury. Most marked losses involved the proximal interphalangeal (PIP) joint. They strongly recommend stable internal fixation with early mobilization (19).

AUTHORS' PERSPECTIVE

The key concept in the treatment of gunshot wounds to the hand is to treat individually each wound rather than mindlessly following protocols established for high-versus low-velocity weapons. Often there is tremendous social and psychological impact associated with these injuries. Sensitivity to these issues and cooperation with counselors, social workers, and others can strongly influence the final outcome.

CRUSH INJURIES

MECHANISM OF INJURY AND PRINCIPLES OF TREATMENT AND EVALUATION

Compression of the hand and forearm between motor-driven rollers will produce a true crush injury. Such trauma usually occurs in the workplace from a printing press or with a home laundry machine—the classic “wringing arm” (43). The nature of the damage and the severity of the wound produced by these wringers or rollers are determined by a number of factors (17,60). Important ones include clearance between the rollers, the type of surface (steel or rubber), and the temperature of the crushing device. The speed of the roller partially determines the force applied; skin avulsion occurs at higher speeds.

Three forces are involved in roller or wringer injuries (1). A compression force is created when the large extremity is propelled into the small gap between the rollers. Compression results in tissue contusion. A friction abrasion force characteristically produces a distally based flap and often tears the skin. Last, a shearing force moves the soft tissues over deeper fixed structures, resulting in lacerations, subcutaneous hematomas, and disruption of musculotendinous junctions. The degree of injury is related to the roller size, clearance, duration of compression, and the method of extraction. The severity and depth of injury produced by the compression and shearing forces may not be readily evident. Skin that has been completely removed from its blood supply will undergo necrosis (67). Hemorrhage may further separate the subcutaneous tissues from the deep fascia and require drainage. Swelling or bleeding beneath the forearm fascia can produce increased pressure (see Chapter 13 and Chapter 65) and muscle ischemia and result in Volkmann's contracture. Although this is often described in the forearm, ischemic contracture involving the intrinsic muscles can occur in the hand (51). When examining the severely crushed, edematous hand, if pain is produced by the intrinsic stretch test and compartment pressures are significantly elevated, perform decompression of the interossei. If peripheral circulation is impaired and/or distal pulses are not palpable, evaluate further with a Doppler device and do an arteriogram if necessary. Test sensitivity: two-point discrimination values greater than 10 mm are suggestive of nerve compression but do not use a tourniquet.

Crushing injuries of the upper extremity produced by a household laundry wringer were once common occurrences; fortunately, this device has almost disappeared. Crushing device. The speed of the roller partially determines the force applied; skin avulsion occurs at higher speeds.

Figure 45.1. Roller or crush injuries extending to the level of the wrist (A) can dislocate the basal (trapezial–metacarpal) joint and (B) are similar to breaking the binding of a book.
Nerve injuries are difficult to assess, as loss of function most commonly results from a neuropraxia, but direct crushing and traction injury may be present (66). If the nerves are visible in wounds or fasciotomy incisions, inspect them; otherwise, simply observe them as they recover without surgical intervention.

Stabilize fractures, as this enhances tissue management and facilitates rehabilitation.

Repair tendon lacerations or avulsions.

Leave all wounds open at the time of initial debridement. A common injury is a palmar laceration with a distally based skin flap and crush of the thenar and hypothenar muscles. Further necrosis may occur, requiring serial debridements.

Cover the wounds with moist dressings and splint the extremity with the wrist in extension, the MP joints flexed, and the interphalangeal joints extended.

Return to the operating room at 36- to 72-h intervals or as often as necessary to complete debridement of nonviable tissue.

Skin loss will require resurfacing with either grafts or flaps (9,36,39).

Crush injuries involving the dorsum of the hand usually have damage to skin, extensor tendons, and bone and joints. Conventional treatment of these injuries has been with staged reconstruction, first obtaining soft-tissue coverage and then performing bone repair and tendon grafts. Recent studies have suggested that immediate reconstruction with primary tendon and bone grafting along with skin closure results in faster return of motion and fewer surgical procedures.

Injuries that involve both surfaces of the hand frequently result in amputation of some portion.

**POSTOPERATIVE CARE**

Begin rehabilitation of these complex injuries immediately following surgery. While the surgical dressing immobilizes the injured tissues in the appropriate position, move the uninjured portions of the hand. After the wound has stabilized, direct a more vigorous mobilization program at overcoming the most common problems of chronic edema and stiff joints (72).

The best way to limit or decrease edema is through elevation and active motion. Retrograde massage may prove helpful, and thermoelectric gloves can provide continual compression and warmth. To prevent joint stiffness and contractures, promptly mobilize all joints within the limits of pain tolerance. Try to move each joint through as great an arc of motion as possible at least three times a day, and preferably once each hour. With further healing, and when the patient has less pain, dynamic splinting may be added to the exercise program. Although splitting of the hand in metacarpophalangeal joint flexion and interphalangeal joint extension (safe position) prevents the most serious joint contractures, this attitude of the fingers increases the chance of developing contracture of the intrinsic muscles. Persistent dorsal edema of the hand predisposes to intrinsic muscle contracture even if these muscles have not been compromised initially. An intrinsic stretching exercise program can prevent contracture.

An active exercise program not only mobilizes joints but also restores the gliding of tendons and increases both tendon strength and wound healing. Motion begun too early may sometimes compromise soft-tissue healing; therefore, carefully monitor the patient. Persistent drainage from a wound indicates inadequate debridement with the presence of necrotic tissue or retained foreign material.

**PITFALLS AND COMPLICATIONS**

After crush injuries, other problems that occur include scar contractures, tendon adherence, nerve compression, and chronic pain (73). The blood supply to skin flaps that have been markedly contused is usually poor and often distally based. Excise all obviously nonviable skin primarily. Suture borderline tissue flaps without tension and carefully observe them. By 3 to 5 days after injury, tissue viability should be clarified, and the wound can be debrided of all necrotic material.

Treat wounds with skin and soft-tissue loss with the simplest techniques that will provide a satisfactory result, such as a skin graft, either split thickness or full thickness. A local flap can be used to cover a small full-thickness defect resulting in exposed bone or tendon that requires vascularized tissue. More proximal flaps from the arm (posterior interosseous artery or radial forearm) can be employed for coverage of larger defects. More distant flaps (abdominal or groin) and free tissue transfers should be considered.

The latter may be composed of skin, muscle, fascia, or composite tissues. Although detached skin may be debrided and used as a full-thickness skin graft, if it is severely traumatized it will fail to heal. The decision as to which coverage is most appropriate depends on the requirements of future reconstructive surgery.

A scar contracture may be associated with an area of skin grafting or with a surgical incision required for a fasciotomy. Prevention of the latter can be achieved by application of the principles for incision placement (45). Contracted skin grafts can be resected and the defect-treated with local soft-tissue mobilization or tissue expansion if the graft may be released. This is important if the location is one that will receive considerable pressure with use or that will be subject to tissue breakdown. For example, split-thickness skin grafting on the palm may not withstand normal shearing forces, and primary closure of a wound involving a flexion crease ultimately worsens the contracture. Occasionally contractures can be released with a Z-plasty or a local flap.

Although a compartment syndrome should always be considered after a crush injury, direct muscle trauma with necrosis and fibrosis is more common. Selective muscle debridement is part of treating an open injury. Although adherence of injured muscles or tendons is common, prompt remobilization can limit the loss of motion in the hand. However, fractures and joint injuries will compound the problem. Tenolysis should be considered only after all the tissues in the extremity are well healed and the patient obtains full passive motion in the fingers. Adherence proximal to the musculotendinous junction will not respond to a lysis and should not be attempted, as it will not improve distal motion.

Nerve-related complaints may persist after a crush injury. External compression can occur at the site where a nerve passes adjacent to traumatized muscle or injured fixed tissues, that is, ligaments or bone. Crushing trauma is even more likely to produce an intraneural injury. The question is whether there is external compression or internal fibrosis of the nerve. The production of paresthesias on percussion over a nerve may localize the injury but will not clarify the diagnosis. Electromyelograms and nerve conduction studies may help differentiate external or internal compression from traction.

The development of chronic pain after major trauma, particularly crushing injuries, is not rare (19). Several weeks after the initial trauma, the patient should be able to control pain with a nonnarcotic medication. If the patient still has considerable pain after this, a chronic problem must be acknowledged and will require the combined efforts of several specialties. If the patient is to participate actively in an exercise program, pain must be controlled. Supportive splinting and a variety of modalities including transcutaneous electrical nerve stimulator are indicated. The possibility of the patient developing a chronic pain syndrome must be recognized from the onset. Successful treatment requires early recognition and a rapid response.

**AUTHOR’S PERSPECTIVE**

Although this section has dealt with crush injuries of the hand alone, they need to be considered in light of the broader classification of mutilating hand injuries. This is a topic too large to be included in this chapter, but a few principles need to be understood. Reconstructive surgery after a mutilating wound will be more effective if the primary closure reduces the amount of scar tissue. Soft-tissue coverage is critical. The preservation or sacrifice of tissue must be designed to gain the greatest function at the least risk. When the hand has been mutilated, normal function may be an unrealistic expectation in the setting of anatomic loss, but useful function may be created with what remains. Microsurgical techniques have expanded the repertoire of the reconstructive surgeon.

The major pitfall in a mutilating injury is failure to recognize the depth and significance of the original injury. The most critical element after such an injury is the correct immediate reconstruction with primary tendon and bone grafting along with skin closure results in faster return of motion and fewer surgical procedures.

**INJECTION INJURIES**

**PRINCIPLES OF TREATMENT**

High-pressure injection injuries of the hand (HPIIH) caused by grease, paint, or paint thinner occur frequently. Although the wound may initially appear innocuous, these injuries are surgical emergencies that require prompt exploration, decompression, and debridement (41).

Injection guns put out a fine stream of material under pressure that ranges from 600 to 4,000 lb/in². The substance fired at such velocity through a small nozzle enters the skin and spreads along fascial planes, tendon sheaths, or neurovascular bundles—trapping at least fascial planes (55). Tissue within the hand may be mechanically damaged by pressure and rendered ischemic. In addition, the material injected produces an acute chemical inflammation, which may be associated with additional soft tissue and vascular damage (13).

If the wound is not treated, or if the foreign material is not completely removed, chronic inflammation, fibrosis, foreign body granuloma (oleomas), and sinus formation with chronic tissue breakdown may occur. Paint produces an acute inflammatory response, whereas grease causes a delayed chemical reaction resulting in fibrosis and stiffness. The volume of material that enters the hand is directly proportional to the pressure produced by the gun. The greater the volume of material that has
been injected, the greater is the amount of soft tissue damage that occurs.

Following injection, symptoms are often initially minimal, with only a burning discomfort at the injection site. Within a short time, the finger usually becomes distended, pale, and numb with throbbing pain. Subsequently, greater pain and motling of the skin appear. The pain may be related to ischemia, the injection having created a compartment syndrome of the digit. If a considerable volume of material has been injected, enlargement of the finger is immediate. The left hand is involved more frequently than the right, and the patients are usually men. Common injection sites include the distal segment of the index finger, thumb, or middle finger, which are usually used to check a presumed “plugged” injection tip. The palm and other digits are damaged less frequently.

Obtain radiographs of the hand and finger, which may demonstrate how deeply the grease or paint has extended. Many greases are radiopaque because of the lead that has been added as a lubricating agent. If routine x-rays do not yield enough information, xeroradiographs may provide useful information. Patients can develop systemic effects, which include fever, lymphangitis, and an elevated leukocyte count. These signs usually appear within 2 days after the injury and may last 4 to 5 days (43).

OPERATIVE TECHNIQUE

- High-pressure injection injuries require immediate surgery.
- Local anesthetic blocks in the palm are usually contraindicated, and the extremities should obviously not be wrapped with a pressure bandage before application of the tourniquet (35).
- Use a modified midlateral incision to explore the finger. A zig-zag approach, although providing better exposure, is more likely to result in skin slough and may lead to further tissue compromise in wounds left open for subsequent debridement. If necessary, continue the incision into the palm in a curvilinear fashion, extending it past the wrist and into the forearm if needed.
- After surgical exposure, remove all the abnormal material such as grease or paint. Excise any fat or fascia that is involved. Resect tendon sheaths in part if they are involved, taking care to leave essential portions of the fibro-osseous sheath system. A small curet or rongeur may be helpful in removing the material.
- Nerves and arteries that are functional but have the foreign substance embedded in them should be left intact and not resected.
- Even after a meticulous dissection, some foreign material may remain. Solvents for grease or paint are inefficient and are not employed for fear of causing more tissue damage. Pack open the wounds with the intention of performing a secondary exploration and closure in 2 to 3 days.
- An alternative choice is to close the wounds loosely over drains.
- A third choice is to leave the wound completely open, allowing it to heal by secondary intention. Skin grafts may be required to close wounds if critical structures are exposed.
- Perform wound cultures at the time of all surgeries, as infections are not infrequent. Many surgeons recommend antibiotic coverage for 2 weeks, but the use of prophylactic antimicrobial drugs is not clearly indicated unless there is an active infection (41).
- Immobilize the hand in a safe position (MP flexion and interphalangeal joint extension).

POSTOPERATIVE CARE

Treat wounds that are left open with the intent of healing by secondary intention with early motion and whirlpools as well as an intensive active exercise program. Patients whose wounds have been packed open should be considered for the same treatment or have their wounds reevaluated in the operating room for redebridement in 2 to 3 days. When it has been determined that all the foreign material has been removed, involve the patient promptly in the remobilization program as mentioned above. Make no attempt to close small defects with skin grafts. Except during exercise, place the patient’s hand at rest in a position to prevent contractures, particularly flexion contractures at the PIP joint. Eventual impairment is related to the amount of tissue destroyed by foreign material. Paint gun injuries generally inflict greater damage than do grease guns, and injections into the palm have a better prognosis than injury to the digits.

PITFALLS AND COMPLICATIONS

The most frequent complications from injection injuries result from failure to debride the wound sufficiently and premature wound closure. Although much has been written about the toxicity of both grease and paint, injected paint thinner is the most difficult to detect and completely remove (63). Injuries from paint thinner should never be closed primarily; multiple debridements and reexplorations can be anticipated.

Delay in initiating treatment leading to an adverse result often occurs because the patient or physician initially evaluating the injury is unaware of its significance (22). In one recent series, the only patients requiring amputation were those initially evaluated 3 to 8 days following injury. Although prompt surgery is recommended, this alone does not always ensure a good result. It is also possible to obtain a satisfactory result when surgical treatment has been delayed, particularly with grease gun injuries (62).

The question of amputation should be discussed with the patient initially and remain under consideration should delayed healing or complications arise. Retention of the tip of a digit that has required extensive soft-tissue and skin resection is not beneficial. The patient will be left with a painful atrophic finger with little function. The period of disability can be extensive, and it averaged 7 months in one study (22). In a more recent study where patients were treated with open wound management (wide debridement, drainage, open packing, and delayed closure), all the patients returned to work, 92% to their previous job (65). Because of the possible prolonged morbidity, several authors have recommended early amputation, especially after a paint gun injury (35, 57). Prompt amputation often allows the patient to return to work within 6 to 8 weeks of the injury.

Late complications after injection injuries include skin breakdown, ulceration, and sinus formation with discharge of foreign material. Delayed infection rarely occurs if one can obtain wound healing within 2 weeks of the original injury. However, retention of foreign material, necrotic tissue, and chronically open wounds can produce sepsis.

FROSTBITE INJURIES

EPIDEMIOLOGY

Throughout history, frostbite has been closely associated with winter military campaigns. For example, 10% of all casualties in the 1982 Falkland Islands conflict were related to frostbite. Unfortunately, frostbite is also a civilian concern, even in urban, populated areas today. The human body is equipped with many mechanisms for the dissipation of heat but must rely on largely conscious measures for heat conservation. The strongest human defense against frostbite is the conscious decision to wear protective clothing, systemic and vascular disease, previous cold injury, and ability to seek adequate shelter and treatment.

Table 45.5. Differentiation of Cold Injuries
Valnicek, in a 12-year retrospective review of inpatient frostbite injuries in Saskatoon, Saskatchewan, concluded, “Fit, well-prepared people without cerebral impairment rarely present with significant frostbite injury” (66). In this series, 78% of victims were male and 46% associated with alcohol consumption, 17% with psychiatric illness, and 19% with trauma. The distribution of injury was 19% upper extremity, 31% upper and lower, and 47% lower extremity. Of the 63 patients with upper extremity frostbite, 13 required major amputation and 18 minor (66).

In a large review, 843 inpatient and 194 outpatient frostbite cases at Cook County Hospital in urban Chicago were reported over 10 winters. The mean age of the patients was 43 years, with over 76% between the ages of 30 and 60. Upper extremity involvement (47%) was slightly less than lower extremity (53%). Children showed almost exclusively upper extremity involvement, many with bilateral “glove-like” lesions. Hand amputations, when required, were most common at the finger MCP joint and the thumb IP joint (7).

Another review, from Edmonton, Alberta, sought predictors of poor outcome such as major tissue loss. Strong association was found with impaired cerebral function (alcohol, psychiatric illness), lower extremity involvement, infection on presentation, and delay in seeking medical attention (68). Inadequate protective clothing and exposure to metal or wetness was also correlated with severity of injury by Knize in a Denver, Colorado study (67).

PHYSIOLOGY

The human body demonstrates predictable responses to a cold environment. The spinal cord signals the hypothalamus, resulting in increased muscle tone (shivering) and release of catecholamines and thyroxine. Increase in basal metabolic rate, vasoconstriction, and decreased sweating result. The most important organ in temperature regulation is the skin, specifically that of the extremities, which represents more than 50% of total body surface area. Blood flow to the skin during cold stress can virtually cease or can increase as much as 200-fold for heat loss (69). The “hunting reaction,” described by Sir Thomas Lewis in 1830, preserves both core temperature and extremity viability during cold exposure by cyclically alternating vasoconstriction and vasodilation to the limbs (68,69). This regulatory mechanism ceases when the core temperature drops, prioritizing preservation of core temperature over extremity viability.

Frostbite may occur with either slow or rapid freezing of tissue. Slow freezing results in extracellular ice crystal formation, which increases the osmotic pressure of the interstitium, pulling out intracellular water. Intracellular fluid does not crystallize, as it is continuously lost with a corresponding reduction of freezing point (48). Cell membrane damage, most marked in endothelium, occurs by mechanical damage from crystals and dramatic osmotic changes. Endothelial cell injury is seen microscopically with separation from the internal elastic lamina of the arterial wall. Ice crystal formation in plasma resulting in red cell sludging further compromises circulation. Cartilage cells, especially in epiphyseal cartilagel, are very susceptible to even brief freezing. Muscle, blood vessels, and nerves are damaged more quickly than bone and connective tissue (68,69).

Rapid freezing is defined as cooling by more than 10°C/min. This results in immediate cell death by intra- and extracellular crystal formation. Exposure to cold metal or volatile liquids is the most common mechanism.

With rewarming, plasma and extracellular crystals melt, and damaged endothelial-lined capillaries dilate and leak fluid and protein into the interstitium. Intracellular swelling occurs in any viable cells, as they were previously dehydrated and regain water lost. Red and white blood cells and platelets aggregate, contributing to microcirculatory failure, a significant cause of tissue loss (48). Continued tissue injury following reperfusion may also be related to prostanoid-induced vasoconstriction (PGF$_2$$\alpha$, thromboxane A$_2$), similar to factors found in burn injury. These factors have been found in significant concentration in clear blisters associated with frostbite, leading some to recommend their debridement to limit further loss of viable tissue. Aloe vera is an inhibitor of thromboxane A$_2$ and aspirin or ibuprofen controls prostanoid production (90,94).

CLASSIFICATION

The classification of frostbite injury parallels that of burn injury and indicates level of tissue loss. The prediction of level is often less than accurate, leading some to recommend a simplified version indicating only superficial and deep. Table 45.6 demonstrates both systems. Table 45.7 coordinates clinical presentation with degree of injury.

### ACUTE MANAGEMENT

In the prehospital setting, the primary concern is protection of the injured part from mechanical trauma, avoiding pressure, rubbing, or exercise. If there exists any possibility of further cold exposure, rewarming is strongly contraindicated. Refreezing results in much greater tissue necrosis than the persistence of freezing until definitive and controlled rewarming can occur. Salini, in a rabbit model, demonstrated that rapid rewarming was effective in limiting necrosis only when performed immediately after freezing. He recommends it only if it is performed immediately following removal from freezing (69). Unfortunately, most patients’ injuries have already spontaneously thawed on presentation, 88% in the large Chicago Cook County Study (7).

Perform rewarming in a rapid, controlled fashion with 40°C to 42°C water containing a mild antibacterial agent until a flushed appearance to the part indicates reperfusion. Continuous monitoring of water temperature is imperative. Dry rewarming is contraindicated to avoid risk of burn injury. Narcotic analgesics will be required during rewarming. Give tetanus booster and antitoxin if not up to date. Obviously, if hypothermia exists, systemic treatment and measures take priority over rapid rewarming, although they often may be instituted simultaneously. Antibiotic prophylaxis is controversial and likely appropriate only in severe cases with delayed presentation.
Following rewarming, elevate involved limbs and control edema. Debride clear blisters but leave hemorrhagic blisters undisturbed. The goals of wound care are to preserve viable tissue and to prevent infection. Whirlpool treatment is recommended for open wounds. Escharotomy and fasciotomy may occasionally be required. Dressing wounds with topical agents such as aloe vera may be helpful in counteracting the vasoconstrictive effects of thromboxane A₂, and oral aspirin or ibuprofen counteracts the effects of prostanoids (30,44). Systemic vasoconstrictive agents such as nicotine are obviously prohibited. Multiple other treatments have been studied, but their usefulness has not been established; these include dextran, heparin, pluronic F-68, hyperbaric oxygen, phenformin ethylestrenol, streptokinase, urokinase, and reserpine. Hyperbaric oxygen is not helpful and may cause vasoconstriction and reduction in blood flow (56).

OPERATIVE TECHNIQUE

“Frostbite in January, amputate in July,” and “hurry up and wait before you ablate” characterize the historical treatment of frostbite. Difficulty in prediction of tissue loss has led to a very conservative approach, often awaiting autoamputation. Earlier prediction is now possible through triple-phase bone scanning, radionuclide angiography, and magnetic resonance imaging/MRA (Table 45.8).

Amputation, when necessary, should be performed in a guillotine fashion, with delayed closure or coverage. Acute amputation is necessary only in the setting of infection, most common in patients with a delayed presentation.

Sympathectomy may be performed either medically or surgically. Reserpin infusion intraarterially into the affected limb causes depletion of arterial wall norepinephrine for up to 2 to 4 weeks (56), however, no difference has been shown in conservation of tissue, edema resolution, pain reduction, or improved function. Surgical sympathectomy plays a delayed role in treatment of vasospastic syndromes following a cold injury.

Severe cases of hand frostbite may result in either hands without digits or loss of all but the proximal thumb. Reconstruction of this difficult problem is possible through tissue transfers and free flaps. An excellent report of 25 digitless hand reconstructions by Borovikov demonstrated a reliable technique of toe-to-hand transfers to regain opposition (6).

PITFALLS AND COMPLICATIONS

Many long-standing discomforts may result from a cold injury, many associated with vasomotor dysfunction (Table 45.9). Intrinsic injury affects strength and fine motor control in relation to both direct muscle freezing and neurologic injury. Arvesen studied 40 Norwegian soldiers following local cold injuries. Nerve conduction velocities were still markedly decreased 3 to 4 years following injury to the nerves in previously cold-injured limbs, even proximal to the level of injury (2).

Table 45.9. Vasospastic Symptoms

- Cold sensation
- Hyperhidrosis
- Color changes
- Vasospastic attack
- Raynaud phenomenon

The particular sensitivity of cartilage to cold injury and the destruction of articular cartilage by ice crystal formation explain the arthritis that can occur as early as months following injury. In children, both the physis and the epiphysis are susceptible. Classic radiographic findings in the juvenile frostbite injury include total absence of the distal phalangeal epiphysis and damage to the middle phalangeal epiphyses. Distal metaphyses are frequently irregular even in the absence of clinical frostbite (56).

Squamous cell carcinoma has been reported in the regions of previous cold injuries, 20 to 30 years following injury, similar to burns or chronic osteomyelitis.

AUTHORS’ PERSPECTIVE

The only current proven and definitive method of improving the outcome of frostbite injury is its prevention. The important role of inflammatory mediators in perpetuating tissue damage following cold injury will be a future focus of research to modulate this effect. Acute management must focus on the basic principle of doing no further harm and protecting viable tissue. Rapid rewarming may be of great benefit only when a patient presents with frozen tissue. Later reconstruction must be tailored to the unique needs of the injured individual, often requiring tissue transfer.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; †, basic research article; and +, clinical results/outcome study.

Amputating part of the hand is unpleasant for the patient and the surgeon. Nonetheless, a carefully planned and skillfully executed surgical procedure is essential for early restoration of pain-free, useful hand function. The ultimate goal of surgery is the restoration of a hand of acceptable appearance, capable of the highest degree of function consistent with its remaining musculoskeletal elements (1,27).

In general, optimal hand function is achieved through prompt wound healing and joint mobility in digits of maximal length. The surgeon must take care to preserve sensibility in retained elements and to prevent formation of painful neuromas.

Because the thumb is essential for both power and precision prehension, preservation or restoration of the thumb is of paramount importance. When the radial fingers are compromised, precision prehension is impaired, while loss of the ulnar digits reduces effective power grip (12). Preservation of length and sensibility is vital to radial digits, whereas preservation of joint mobility is more important to ulnar digits.

CLASSIFICATION OF INJURY AND INDICATIONS FOR TREATMENT

Amputation procedures may be classified as emergent or elective, by the mechanism of injury or etiology, or by the anatomic region of the hand removed. Secondary revision of initially emergent amputations may be elected to address issues of appearance, function, or pain.

Partial hand amputation procedures may be carried out as either primary or secondary procedures.

EMERGENT

Trauma is the most common indication for surgical amputation of portions of the hand. The management of acute traumatic amputation requires considerable judgment. The surgeon must often decide which parts should be retained by revascularization or replantation, which should be managed with direct wound closure, and which should be managed primarily by more proximal surgical amputation.

The mechanism of injury is important in understanding the likelihood of success with different treatment strategies. Sharp injuries preserve normal tissues in the proximal part and have a narrow zone of injury. Distal tissues that may be amenable to reattachment or revascularization are more likely to be preserved. Crush injuries often result in a wide zone of injury. Though the skin sleeve may have been preserved, the profound crushing of underlying bone, joint, and flexor and extensor tendons may preclude reestablishment of a supple, mobile digit. Avulsion injuries may result in substantial injury to neurovascular and tendinous structures proximal to the level of skin loss or disruption. Examination of amputated parts may aid in understanding the extent of injury to the residual parts of the hand or fingers.

In severe trauma affecting several digits, it often is easiest, initially, to preserve all viable tissue. Otherwise useless digits may be converted to fillet flaps for soft-tissue coverage or to supply digital nerve and bone for graft to be used in other digits. Although this approach is by design conservative, it will prove counterproductive if the decision to delete functionless digits is repeatedly postponed. Retained stiff, insensitive, or unstable digits will compromise the rehabilitation of the remaining, less severely affected portions of the hand. Also, the original decision to delete the irreparably compromised digit may be questioned and additional futile surgeries performed in an attempt to avoid amputation. Early, appropriate decision making is often difficult; Less experienced surgeons should seek prompt consultation to establish realistic expectations for both themselves and their patients.

ELECTIVE AMPUTATION

Digits may become ischemic and nonviable as a result of microvascular or macrovascular disease or a combination of the two. Microvascular disease, seen commonly in conditions such as scleroderma and diabetes mellitus, may result in digital ischemia. Irreversible digital ischemia may also result from macrovascular injury to the brachial artery after cardiac catheterization in the presence of systemic atherosclerotic macrovascular and microvascular disease.

Infection within the hand may necessitate partial hand amputation. The aim may be either to eliminate a refractory focus of infection, usually osteomyelitis, or to remove a part whose function has been irreparably compromised by infection. A painful, swollen finger rendered immobile after flexor sheath infection may occasionally be so impaired that the surgeon and patient elect digital amputation.

Malignant tumor may necessitate partial hand amputation. The histologic character of the tumor and its anatomic location should be the primary determinants of the level of amputation. The desire to preserve functional capability must be subservient to the need for appropriate tumor wound margins (see Chapter 74). Amputation may be confined to a single digit, a ray, or a more major segment of the hand—radial, central, or ulnar.

Congenitally anomalous hands may occasionally be improved functionally or aesthetically by the amputation of rudimentary digits. Small, floppy nubbins may be excised when they are insufficient for reconstruction. When macrodactyly distorts hand form and function, resection of one or two rays may be indicated. In cases of polydactyly, amputation of redundant elements must be carefully integrated with reconstruction of the remaining digits.

Various forms of thermal injury may lead to amputation. Frostbite injury characteristically affects the distal portions of the fingers. The thumb is less often involved since it is shorter than the fingers and is often protected by the fingers flexed around it against the palm. Patients who have experienced severe cold exposure may experience the effects of ischemia involving all the fingers, both thumbs, and all toes of both feet, profoundly limiting secondary reconstruction alternatives. The extent of remaining viable tissue is often uncertain for a number of days. In selected severe injury, bone scan or magnetic resonance imaging (MRI) may reveal preservation of osseous circulation in spite of overlying skin necrosis.

Heat may cause burns that primarily affect the dorsal structures, skin, and extensor mechanism without necessitating amputation. Electrical injury, by contrast, may have a more profound effect on deep tissues than on the skin. Early resection of the finger or ray that transmitted the electrical impulse is often necessary. Residual functional impairment after electrical injury may lead to secondary amputation.

Finally, it is occasionally wise to abandon local reconstructive surgical procedures in favor of prosthetic management. When a hand is painful, deformed, and without function, amputation may be the most effective reconstructive procedure (2).
SURGICAL TECHNIQUE

- Design skin incisions and skin flaps to provide sensate skin over the palmar surface of the residual digit.
- Isolate each digital nerve in the involved digit. Apply modest traction to the nerve, and sharply divide the nerve, allowing it to retract proximally into soft tissue.
- Identify transected tendons and draw them distally into the wound. Sharply divide each tendon and allow it to retract proximally. Do not sew flexor or extensor tendons to one another over the end of the amputated digit. To do so will restrict motion in the residual portion of the digit and severely compromise tendon excursion and motion in adjacent fingers (see the discussion of the "quadriga" effect in the section below, Pitfalls and Complications).
- Ligate bleeding vessels at wound margins.
- Traumatic amputations that create oblique or jagged distal surfaces may result in a painful digit. Trim bone ends transversely and free them of palmar prominences.

THUMB AMPUTATIONS

It is principally the attributes of position, stability, strength, and length that allow the thumb to carry out its unique range of activity (13). Motion, sensibility, and appearance are important but less vital attributes of normal thumb function.

Because of the thumb's unique position and essential role in prehension, preserving thumb length is a priority in the treatment of traumatic thumb injuries. A well-motored stiff thumb with basilar mobility and normal length is effective in most functions of the hand.

Acute Management

When traumatic amputation of the thumb occurs through the distal phalanx, local flap closure may be required. With disproportionate palmar skin loss, the Moberg palmar advancement flap allows preservation of thumb length with advancement of sensate skin distally (3). The radial nerve–innervated cross-finger flap from the dorsum of the index finger also brings sensate skin to the distal phalanx (see Chapter 38).

In the case of thumb amputation through the middle portion of the proximal phalanx or beyond, satisfactory function may be achieved if maximal length is preserved with local advancement flaps.

Amputation proximal to the metacarpophalangeal joints severely compromises prehension. Although thumb length may be sufficient for buttressing of objects in the palm in power grip, it is insufficient to reach the tips of adjacent fingers in precision prehensile activities. Secondary surgical reconstruction is usually advantageous when amputation occurs proximal to the middle of the proximal phalanx of the thumb. In such situations, the sacrifice of a few millimeters of skeletal length to allow direct soft-tissue closure over bone is usually preferable to extensive primary soft-tissue flap procedures. Once healing of the amputation has been achieved, reconstruction will be required to restore at least a portion of the lost thumb length.

Secondary Thumb Reconstruction

Late reconstruction procedures to improve the function of a thumb that has sustained amputation injury include phalangization, distraction lengthening, and pollicization, as well as toe-to-hand and wraparound flap microvascular transfers (see Chapter 34, Chapter 35 and Chapter 36 and Chapter 69).

Phalangization When ischemia or injury simultaneously shortens all other digits that could achieve pulp-to-pulp contact with the thumb, it makes little sense to lengthen the thumb beyond the arc of the remaining fingers. Phalangization restores primitive prehension to the hand. To be successful, it requires supple dorsal skin, normal thenar musculature, and a mobile carpometacarpal joint (24).

- Make a Z-shaped incision that provides generous web-space exposure and allows flap transposition, which shifts the web-space skin margin proximally (Fig. 46.1). Define the adductor pollicis and first dorsal interosseous muscles, and incise and release their investing fascia.

Figure 46.1. Phalangization procedure. A: Resection of the index metacarpal is achieved through Z-plasty flap elevation. B: Z-plasty flap transposition increases the exposed prehensile surface of the thumb.

- Resect the index metacarpal, taking care to preserve the proximal attachment of extensor carpi radialis longus and flexor carpi radialis. Excise the first dorsal and first palmar interosseous muscles.
- Release the adductor pollicis insertion from the sesamoid at the metacarpophalangeal (MP) joint level and reinsert it more proximally on the thumb metacarpal.
- Transpose skin flaps. See Hints and Tricks box on the next page.

Thumb Distraction Lengthening When at least two thirds of the thumb metacarpal remains with good soft-tissue coverage, distraction lengthening is an effective technique for regaining useful thumb length (6,16). If proximal joint mobility and thenar musculature are preserved, the patient should be able to use the thumb effectively for prehensile activity, although it may be stiff.

HINTS AND TRICKS

- A simple three-digit prehension pattern may be recreated by the removal of the ring metacarpal. This procedure increases the mobility and independence of the little-finger metacarpal.
- Flexion and closing-wedge osteotomy with radial deviation of the base of the little-finger metacarpal may improve pinch between the little metacarpal and the thumb metacarpal (6).

- Make a longitudinal skin incision to expose the middle third of the thumb metacarpal (Fig. 46.2) and incise the periosteum. Bunch up the skin between the pin insertion sites such that distraction will not put undue pressure on the skin–pin interface. Insert two parallel groups of pins transversely through the collapsed distraction apparatus in close proximity to the intended osteotomy site.
Amputation through an interphalangeal joint requires attention to bone as well as to soft tissue to avoid a bulbous distal contour (distant flap coverage may be indicated). If bone grafting is planned as a second procedure, circumferentially incise the periosteum at the level of the osteotomy, and then turn the screws on the distraction device to create at least 5 mm of immediate distraction at the osteotomy site.

If distraction osteogenesis is to be employed, repair the longitudinal incision of the metacarpal periosteum and then close the skin. Maintain osteotomy coaptation for 7 to 10 days, and then begin distraction of the osteotomy. Over the next 4 to 5 weeks, gradually lengthen the digit by advancing the distraction device about 1 mm per day; do this four times a day, in ¼ mm increments. The soft tissues will gradually stretch as the osteotomy gap is widened. Distraction takes place along the axis provided by the longitudinal pin. It is often possible to gain up to 3 to 5 cm of additional thumb length with distraction lengthening (8, 17).

Although bone consolidation may occur spontaneously in young patients, my custom in adults is to electively add iliac crest bone graft to span the gap between the proximal and distal metacarpal segments. Keep the device in place until graft incorporation is radiographically visible. Web-space deepening, as described above in the section on phalangization, is occasionally helpful as a secondary procedure.

Alternatively, remove the distraction device after distraction, and stabilize the bone graft by plate fixation. Transfer the insertion of the adductor pollicis tendon more proximally to help diminish the tendency of the lengthened thumb to adduct. This allows web-space deepening without sacrificing adductor pollicis strength.

**Pollicization**

Because pollicization allows restoration of both digital length and mobility, it is often recommended when traumatic thumb amputation results in basilar joint destruction (3, 4, 13). The index finger is usually the digit selected for pollicization. When the extent of trauma to the thumb has been severe enough to warrant pollicization, the adjacent index finger is often also compromised, but this is not necessarily a contraindication to pollicization. An injured digit with limited mobility may be a liability in the index position but may substantially enhance function when transposed to the thumb position.

Reconstruction of posttraumatic thumb injuries is similar to that of pollicization for the congenitally absent or hypoplastic thumb with individual modifications (see Chapter 69). If there is extensive scarring and soft-tissue loss over the radial border of the hand, preliminary flap coverage may be required.

- Skin incisions must be individualized when skin along the radial border of the hand is scarred. Design skin flaps to bring the best skin—palmar, dorsal, or a combination—into the web space created between the pollicized digit and the middle finger at the time of closure. Skin graft is often necessary dorsally and radially but should be avoided in the web space.
- Evaluate digital artery integrity of the index and middle fingers preoperatively by arteriography when there has been proximal injury. In some instances, the vascularity to the injured index finger may be insufficient to support disruption of collateral flow necessitated by pollicization. In such cases, plan to use a vein graft from the radial artery in the anatomic snuff box to the digital arteries of the transposed digit to effect microvascular revascularization of the digit.
- Identify and preserve the radial and ulnar index digital nerves and arteries. Preserve the digital nerves by splitting the common digital nerve to the index and middle fingers. Mobilize the ulnar proper digital artery to the index by ligating the radial proper digital artery to the middle finger.
- In adult pollicization, reestablish skeletal length by combining remaining thumb and index parts (Fig. 46.3). The goal is to achieve a reconstructed thumb whose tip extends to about 75% of the length of the proximal phalanx of the middle finger. If the index is of normal length and the thumb basilar joint is absent, use of the rotated index metacarpal head as a trapezium will prove most satisfactory.

**Figure 46.2.** Thumb distraction lengthening in an adult. A: Place pin groups adjacent to the mid-diaphyseal osteotomy site. B: Once the desired distraction has been achieved, lock the bone graft into the medullary canal of the distracted proximal segments.

**Figure 46.3.** Pollicization of a distally amputated index finger. A: The extent of index metacarpal resection depends on the residual length of both the thumb metacarpal and the index finger. B: Fix the transposed index metacarpal to the proximal thumb metacarpal remnant.

**DIGITAL AMPUTATION**

Fingertip and distal phalangeal injuries are discussed in Chapter 38. When amputation occurs at or proximal to the distal interphalangeal joint, digital flap coverage is rarely indicated. Modest bone shortening and contouring are usually preferable, unless the potentially sacrificed bone length is judged critical to preservation of the functional integrity of the affected finger.

In general, any digit that retains its superficialis insertion will continue to contribute effectively to grasp activity. When amputation occurs more proximally (e.g., proximal middle phalanx, proximal phalanx), the digit will have only limited value in the little-finger position and will probably be a nuisance in the index position. When amputation occurs proximal to the superficialis but distal to the midproximal phalanx, preservation of the digit in the middle or ring position may help prevent small objects from falling through the hand, although only limited MP joint flexion will occur through the pull of the intrinsic muscles.

When amputation or other severe mutilating injury has compromised multiple digits, it is best to preserve all available bone length. In multidigit degloving injuries, distant flap coverage may be indicated.

Amputation through an interphalangeal joint requires attention to bone as well as to soft tissue to avoid a bulbous distal contour (Fig. 46.4).
Figure 46.4. Interphalangeal joint disarticulation amputation. A: Remove palmar condylar prominences. B: The greater length of the palmar flap brings the suture line away from the contact surface.

- Create palmar and dorsal tongue-shaped flaps by bilateral midlateral incisions. Make the palmar flap slightly longer, if possible, so that the scar will be dorsal. Pull tendons distally and divide them sharply.
- Gently divide digital nerves without applying undue traction, and allow them to retract into proximal soft tissues. Ligate digital arteries.
- Identify the palmar plate and excise it. Remove the cartilage from the exposed phalangeal articular surface to facilitate bone contouring. Resect the palmar condylar prominences in line with the palmar cortex of the diaphysis. Shape the remaining flat condylar surface with a rongeur and rasp to resemble a paddle. Palpate the bone through the overlying skin to ensure that all prominences have been relieved.
- Close the skin with interrupted sutures. Extensive contouring of skin margins is unnecessary, since the skin contour will gradually model to the underlying bony contour.
- Handle diaphyseal phalangeal amputations in a similar fashion.

Index Ray Resection

The normal index finger is ideally situated to pinch and manipulate objects. Imperfections of the index finger are, however, poorly tolerated. When the index finger of an otherwise normal hand is compromised by loss of length, altered sensibility, or pain, many patients spontaneously shift to a prehension pattern that ignores the index finger in preference of a normal middle finger. The greater length of the middle finger allows it to meet the thumb easily for precision activity. When a short index finger is being ignored, it is often held in a hyperextended posture. Amputation of a short index finger is advised when patterns of disuse become fixed.

Amputation of the index finger may be accomplished by either MP joint disarticulation or index ray resection. MP joint disarticulation preserves the breadth of the palm, which is helpful in stabilizing objects held with a cylindrical grip but presents an obtrusive prominence in the web space (18). Ray resection narrows the palm and improves the appearance of the hand by achieving a broad, smooth web-space contour.

Design skin incisions to facilitate exposure and to provide a supple web space that will allow thumb mobility (Fig. 46.5). If the wedge of skin removed is too large, the distance from thumb to middle metacarpal will be diminished and thumb abduction may be limited. Dissect skin flaps from the index digit, taking care to preserve flap innervation.

Figure 46.5. Index ray resection. A: Dorsal view. B: Palmar skin resection. C: Wound closure preserves sensate skin throughout the widened web space.

- Divide the extensor indicis proprius tendon from its insertion ulnar to the index communis tendon and tag it. Apply traction to the extensor digitorum communis tendon, divide it, and allow it to retract.
- Osteotomize the index metacarpal obliquely through the proximal metaphysis, preserving the insertion of the extensor carpi radialis longus and flexor carpi radialis tendons.
- Although some authors advocate suturing the first dorsal interosseous tendon into the second dorsal interosseous insertion on the middle metacarpal to enhance the strength of lateral pinch, this transfer is occasionally too strong and may result in a fixed radial deviation and lumbrical plus (see Pitfalls and Complications, below) posture of the middle finger.
- Divide the deep transverse metacarpal ligament adjacent to the middle finger. Identify the index flexor tendons, pull them distally, divide them, and allow them to retract proximally. Take care in dealing with the digital nerves. The radial nerve to the index finger must not be extensively mobilized. Sharply divide digital nerves and allow them to retract into the soft tissue without tension. The ultimate neuroma end of the nerves must be distanced from further trauma.
- Remove the index finger. Sew the extensor indicis proprius into the middle finger extensor digitorum communis tendon at the level of its insertion to enhance independence of middle-finger extension. Trim the first dorsal and first palmar interosseous muscles as necessary to ensure a smooth web-space contour. Close the skin flaps with the thumb in palmar and radial abduction.

Central Ray Resection

Amputation of the middle or ring finger at the MP joint level leaves an awkward space between the remaining digits (15). When the hand is in a dependent, supinated position, the gap between fingers makes it difficult to hold or cup small objects in the palm of the hand because of the tendency of such objects to escape from the grasp (Fig. 46.6) (4). Ray resection and reconstruction by either soft-tissue coaptation (Fig. 46.7) or ray transfer (Fig. 46.8) closes this gap and improves the aesthetic appearance of the hand (22, 23). Both procedures narrow the palm and thus predictably weaken grasp and cylindrical grip palmar stabilization.

Figure 46.6. Absence of either the middle or the ring finger impairs the ability to retain small objects in the palm.
When amputation of the little finger at the MP joint level is required, consider ray resection (Fig. 46.8). The hand that has undergone little-finger ray resection has an

Patients who have undergone index ray resection retain 80% of predicted grip strength (18). Pronation strength, a measure of grip stabilization by the breath of the metacarpal, is diminished to 50% of predicted values after index ray resection (19). Transposition of the index ray to the middle metacarpal position results in 75% of predicted grip strength, while transposition of the little-finger ray to the ring finger metacarpal position results in retention of 85% of predicted grip strength (7).

**Central Ray Resection and Soft-tissue Coaptation**

- Make parallel zigzag incisions on the palmar surface overlying the metacarpal to be resected. Remove a generous wedge of dorsal skin. The dorsal skin resection will provide a demodnosis, which will stabilize the digit and prevent it from rotating into a position in which the fingers will scissors over one another in flexion.

- Resect the entire metacarpal subperiosteally. If the middle metacarpal is excised, preserve the proximal insertion of the extensor carpi radialis brevis within the periosteal sleeve, and take care to preserve the origin of the adductor pollicis muscle. When the ring metacarpal is resected, the entire metacarpal base may be removed, allowing radial shift of the little metacarpal on the hamate.

- Avoid injury to the deep motor branch of the ulnar nerve, which runs just palmar to the metacarpal and is vulnerable to injury when excising the metacarpal. Identify and ligate the proper digital arteries. Sharply divide the proper digital nerves distal to the common digital nerve bifurcation.

- Pull flexor and extensor tendons distally, divide them, and allow them to retract proximally. Divide the interosseous and lumbrical tendons.

- Retain a single continuous soft-tissue band, consisting of the palmar plate and the two adjacent deep transverse metacarpal ligaments, each of which is firmly attached to adjacent digits. Press the metacarpal heads together manually. Tightly secure the digits adjacent to the resected metacarpal to one another by dividing the ligament–palmar plate complex and weaving the two segments together. Then securely suture the shortened ligament–palmar plate complex with interrupted sutures.

- Close the palmar skin incision first. Observe the fingers with the wrist in both flexion and extension. Assess the extent of digital scissoring, if any, as the dorsal skin is approximated. If residual scissoring persists, excise further dorsal skin. Circumferential dressing and splinting maintains lateral metacarpal pressure and protects the ligament repair during the first 3 weeks after reconstruction.

**Central Ray Resection and Ray Transposition**

Re-creation of a normal web-space contour between the retained digits is facilitated if the skin of a single web space is preserved and shifted intact to the new web space (19,21). If possible, base the web-space flap on the digit that is not being transposed. For example, if the middle finger is being resected and the index finger is being transposed to the middle-finger position, the web-space skin of the middle–ring interval is retained based on the ring finger and is ultimately sewn to the ulnar border of the index finger.

- Create palmar zigzag incisions that converge over the middle third of the metacarpal to be resected. Resect a dorsal wedge of skin with its apex over the proximal third of the metacarpal.

- Identify the digital neurovascular structures. Sharply section the proper digital nerves, and ligate the proper digital arteries.

- Pull flexor and extensor tendons distally and divide them. Define the interosseous muscles inserting on the resected digit distally, dissect them free proximally, isolate them, and excise them. Divide the lumbrical tendon along the radial aspect of the digit being resected.

- When the middle metacarpal is resected, preserve the origin of the adductor pollicis on the middle metacarpal by subperiosteal dissection.

- Because nonunion of the bone-to-bone junction between transferred and recipient rays is a common complication of this procedure, careful planning of the bony osteotomy and secure internal fixation are essential (19). Transverse osteotomy through the proximal metaphysis rather than diaphysis provides maximal cancellous surface area and thus facilitates union. Alignment of the transferred digit is simplified by applying a T mini-fragment plate to the intact central metacarpal before osteotomy. Drill, tap, and secure the proximal screws, taking care to align the longitudinal limb of the plate with the long axis of the metacarpal to be removed. Then remove the screws and plate.

- Transversely osteotomize the metaphyseal base of both the recipient central metacarpal and the metacarpal to be transferred. Mobilize the transferred ray to allow transfer without tension. The interosseous muscle origins may need to be released. Suture the adductor pollicis origin to the ring metacarpal when the index ray is transposed to the middle position. Precisely fit the transferred ray onto the recipient base. Resecure the screws and plate proximally to the central metacarpal. Align the long axis of the transferred metacarpal to the longitudinal holes of the plate to reproduce the alignment of the excised metacarpal. Ensure that rotational alignment has been preserved, that the digit is clinically straight, and that the fingers do not overlap in flexion. Secure the shaft of the transferred metacarpal to the plate with additional screws.

- A distal transversely placed Kirschner wire may be helpful in further stabilizing the transferred digit during the first weeks following surgery. Approximate the deep transverse metacarpal ligaments from the adjacent sides of the resected metacarpal.

- Transpose the little-finger metacarpal to the ring position. The ultimate length discrepancy between the little and middle fingers may be minimized if the osteotomy is performed more proximally in the metaphysis of the little finger than in the metaphysis of the ring-finger metacarpal. This technique may add up to 1.5 cm in length to the shifted little-finger ray.

**Little-Finger Ray Resection**

When amputation of the little finger at the MP joint level is required, consider ray resection (Fig. 46.9). The hand that has undergone little-finger ray resection has an
excellent cosmetic appearance and acceptance. For this reason, ray resection is recommended in sedentary patients or those particularly concerned about cosmesis. In patients who depend on the breadth of the palm to stabilize a hammer, tennis racket, or other object with a cylindrical grip, removing the little-finger metacarpal will result in a significant loss of strength (11).

**CHAPTER REFERENCES**

**PITFALLS AND COMPLICATIONS**

**Quadriga** Quadriga, or flexor digitorum profundus blockage, occurs when the free distal end of a transected profundus tendon becomes fixed distally and cannot move to the proximal extent of its normal excursion (19,20).

Because of the extensive side-to-side interconnections between the profundus tendons at the wrist and distal forearm level, limitation of motion of a single tendon may have an adverse effect on the motion of adjacent uninjured digits. Patients who have sustained amputation may experience limitation of active distal joint flexion in adjacent digits and may complain of palmar or flexor forearm pain with attempted forceful flexion. The condition is provoked by sewing the profundus tendon over the end of a digital amputation stump. It is best avoided by early active motion of both amputated and adjacent digits. When quadriga is diagnosed, release of the adherent profundus tendon in the palm proximal to the lumbrical origin will predictably relieve this condition.

**Lumbrical Plus** The lumbrical plus phenomenon may be precipitated by digital amputation (20). When amputation occurs through a finger proximal to the insertion of the profundus tendon but distal to the proximal interphalangeal joint, the proximal pull of the profundus is transmitted through the lumbrical into the dorsal hood apparatus, increasing the force of proximal interphalangeal joint extension. As the patient tries to grip forcefully, the proximal movement of the profundus results in a posture of proximal interphalangeal joint extension. This paradoxical digital motion may be eliminated either by sectioning the profundus proximal to the lumbrical origin or by releasing the radial lateral band.

**Neuroma** Because amputation implies the removal of innervated skin, all amputations inevitably require transection of sensory nerve branches. Neuromas occur whenever a nerve is transected and thus are an inevitable consequence of amputation. With proper surgical and postoperative management, however, neuromas need not be tender or painful. When a neuroma is caught in overlying scar or is adherent to a fixed structure, it often becomes symptomatic. The best approach is prevention. Many initially tender neuromas improve with local massage and desensitization activity under the guidance of a therapist. Do not consider surgical revision of tender neuromas until the wound has become supple and the skin is no longer adherent to underlying soft tissue and bone.

Other neuromas become symptomatic when they are fixed distally and tethered by proximal joint motion. In such situations, the nerve must be freed distally and allowed to migrate proximally. Early digital motion is encouraged (see Chapter 53).

**AUTHOR’S PERSPECTIVE**

A properly planned and executed amputation procedure may simultaneously improve the function and the appearance of the residual hand. Simple procedures tend to be associated with less residual pain than complex reconstruction. Encourage early motion. Hand therapy may be invaluable in assisting patients to regain function.

Chapter References

The frequency of injury to the functionally important flexor and extensor tendons is confirmed by review of the operative logs of orthopaedic operating rooms and emergency facilities. The techniques used to treat lacerated flexor and extensor tendons are reviewed in Chapter 48 and Chapter 49, while this chapter provides principles and basic concepts for addressing tendon injuries. Some principles are well accepted, but others are still in the development stages.

The principles of tendon repair are based on traditional practices, clinical experience, and interpretation of experimental animal studies. An understanding of the anatomic features of the tendon, the nutrient pathways to the tendon, and the physiology of the healing process is essential to the formulation of a conceptual approach to tendon repair. Flexor and extensor tendons have distinguishing anatomic characteristics. Although there has been considerable experimental interest in the flexor tendon, there have been few investigations of the extensor tendon.

TENDON ANATOMY

FLEXOR TENDONS

The flexor tendons pass through several different anatomic environments or zones (Fig. 47.1). Nine flexor tendons pass through the synovium-lined carpal tunnel (zone IV) and enter the palm (zone III), where they are covered by a filmy paratenon. Two flexor tendons proceed to each finger (one to the thumb) and have an intricate arrangement within the digit (zone II). The superficialis tendon decussates into two tendon slips, which pass around the profundus tendon near the metacarpal phalangeal joint, and subsequently insert as a chiasma on the palmar surface of the middle phalanx. The profundus tendon passes through the decussation and inserts at the distal phalanx (zone I).

Figure 47.1. Diagram of the flexor tendon zones and the location of the annular and cruciate fibro-osseous pulleys. (From Kleinert HE, Kutz JE, Cohn M. Primary Repair of Zone 2 Flexor Tendon Lacerations. In: Hunter J, Schneider L, eds. American Academy of Orthopaedic Surgeons: Symposium on Tendon Surgery in the Hand. St. Louis: CV Mosby, 1975.)

The superficialis tendon maintains independent muscle function to each finger, although the musculotendon unit to the small finger is frequently hypoplastic. The four profundus tendons have a common muscle belly. Consequently, the flexion of any individual distal phalanx by the profundus tendon usually results in movement at the distal joint of the other three. This has been referred to as the quadriga effect.

Within the digit (zone II), the flexor tendons are in a unique environment; they pass through a synovium-lined fibro-osseous sheath. The tendons are attached to the periphery solely by two filmy, vascularized mesenteric vincula (longum and breve), which are located near the midportion and at the insertion of both tendons, respectively. The vinculum breve is located at the insertion of the superficialis tendon and is intricately associated with the vinculum longum of the profundus tendon (Fig. 47.2); damage to the superficialis tendon insertion necessarily affects the blood supply to the midportion of the profundus tendon.
The fibro-osseous sheath consists of a series of fibrous pulleys that are regularly interrupted longitudinally by a filmy synovium-lined membrane; together they form a continuous tunnel through which the tendons pass. The pulleys hold the sliding tendons against the phalanges and prevent tendon bow-stringing during finger motion. The pulleys are also thought to have a passive role in pumping fluid into the tendon during flexion and extension.

The microscopic anatomy of the tendon consists of a central core (the endotenon) that is composed primarily of acellular, longitudinal, collagenous fibers that are sparsely interspersed with fibroblasts. A thin epitenon layer of cells surrounds the central core. The epitenon cells are fibroblasts that may have different functional properties and characteristics from the internal fibroblasts of the endotenon. The epitenon cells are arranged in a matrix that is presumed to have a proteoglycan composition.

**EXTENSOR TENDONS**

The extensor tendons also pass through several different environments or zones (Fig. 47.3). The extensor tendons enter the hand through a series of synovium-lined, retinacular compartments on the dorsum of the wrist. Unlike the flexor tendon, these tendons are attached to the retinacular compartments by long, mesotenon, synovial sheets rather than by narrow, filamentous vincula. On the dorsum of the hand, the tendons emerge from the retinacular compartments and proceed individually to each digit. The extensor tendons are interconnected by tendinous bands known as juncturae tendinum. Distal to the metacarpophalangeal joint, the epitenon of the intrinsic extensor tendons that arise from the extrinsic extensor tendons and from the intrinsic musculotendinous units. This intricately arranged, digital, aponeurotic mechanism is essential to the synchronous movement of the three digit joints.

**TENDON NUTRITION**

Although vascular perfusion by the mesenteric vincula to the tendon in zone II is an obvious nutrient pathway to the flexor tendon (11), diffusion of nutrients into the tendon is a more significant pathway within the digital sheath (41). Synovial fluid produced by the lining cells of the digital sheath is an obvious source of diffusible nutrients (47). Corporeal tissue fluid can also effectively diffuse into and maintain the viability of tendons, as shown by experiments in which tendon segments were placed in an abdominal wall diffusion chamber and in an in vitro tissue culture environment (27).

Proximal to the digital sheath, the tendon (in the zone VII) is surrounded by filmy paratenon. This vascularized connective tissue is thought to be the source of nutrients to the tendon. Within the carpal tunnel (zone IV), the tendons are surrounded by a synovial mesotenon that arises from the floor of the carpal tunnel. The nutrition of the flexor tendon within the carpal tunnel has not been investigated, but it is presumed to be derived from the synovium.

The extensor tendons within the retinacular compartments (zone III) receive nutrients from the mesotenon synovial sheets arising from the floor of the compartments, with diffusion and perfusion serving as nutrient pathways (39). The filmy paratenon vascularizes the tendons on the dorsum of the hand and digit (zones I–VI).

**PHYSIOLOGY OF TENDON HEALING**

The process by which flexor tendons heal is controversial (37). The traditional concept is that peripheral fibroblasts from the surrounding connective tissue invade the laceration site and serve as the source of reparative cells; the tendon itself is thought to have no intrinsic capacity for repair. However, in vitro studies of various experimental animals have shown that the epitenon cells migrate into and across the laceration site along a fibrin lattice, and collagen fibers formed by the epitenon and endotenon fibroblasts bridge the laceration sites (38, 40, 42, 55). The repair site is vascularized by proliferation of vascular channels from within the proximal end of the tendon (18). These studies suggest that the tendon is a viable structure that possesses the intrinsic capacity for participating in the repair process.

The repair response of the tendon appears to be enhanced by the application of tension at the laceration site. Fibroblast migration, protein synthesis, and collagen deposition are increased by application of tensile forces to chicken tendons (5, 6). Static tension applied to in vitro rabbit tendon segments increased in strength at the repair site (45), and intermittent cyclic tension enhanced the cellular response of lacerated chicken flexor tendon segments in vitro (65).

In vivo studies on experimental animals have demonstrated actual increase in tensile strength at the repair site. Kubota et al. (21) attributed this increase to both motion and tension in experiments on injured chicken flexor tendons. Hitchcock et al. (25) and Acki et al. (1) demonstrated that the anticipated loss of tensile strength within the first 2 weeks following tendon repair can be avoided by actively mobilizing the tendon at the repair site.

The epitenon response is increased and a greater fibrous “callous” is produced if there is a large gap between the tendon ends (21).

Peripheral adhesions are known to attach to the healing tendon, potentially restricting tendon excursion during flexion and extension. Although the adhesions may contribute to the strength of the healing tendon, it is likely that the adhesions are not essential to the reparative process but only represent the response of the surrounding tissue to trauma (19). The concept of the tendon’s intrinsic capacity for healing is attractive to surgeons, because it eliminates the need for fibrous adhesions at the repair site and encourages rehabilitation protocols that prevent their formation and attachment to the tendon. Nevertheless, restrictive adhesions following tendon repair continue to be the bane of surgeons who perform flexor tendon surgery.

Extensor tendons are thought to heal by invasion of fibroblasts from the periphery, but studies have not yet specifically defined this process.

**PRINCIPLES OF MANAGEMENT**

There are basic operative principles that must be followed in caring for flexor or extensor tendon lacerations.

**CLINICAL EXAMINATION**

The first principle is to diagnose the flexor or extensor tendon laceration by careful clinical examination. Begin the examination with a visual inspection of the hand. A disruption of the continuity of the tendon should be suspected by the location of the wound and the resting position of the digit. For example, a skin laceration immediately overlying a flexor tendon on the palm, in association with a digit whose resting position is not as flexed as the adjacent fingers, suggests a lacerated flexor tendon. However, remember that sharp, stiletto-type, penetrating objects can lacerate tendons through a small, inconspicuous skin wound at a distance from the

**PHYSIOLOGY OF TENDON HEALING**

Although vascular perfusion by the mesenteric vincula to the tendon in zone II is an obvious nutrient pathway to the flexor tendon (11), diffusion of nutrients into the tendon is a more significant pathway within the digital sheath (41). Synovial fluid produced by the lining cells of the digital sheath is an obvious source of diffusible nutrients (47). Corporeal tissue fluid can also effectively diffuse into and maintain the viability of tendons, as shown by experiments in which tendon segments were placed in an abdominal wall diffusion chamber and in an in vitro tissue culture environment (27).

Proximal to the digital sheath, the tendon (in the zone VII) is surrounded by filmy paratenon. This vascularized connective tissue is thought to be the source of nutrients to the tendon. Within the carpal tunnel (zone IV), the tendons are surrounded by a synovial mesotenon that arises from the floor of the carpal tunnel. The nutrition of the flexor tendon within the carpal tunnel has not been investigated, but it is presumed to be derived from the synovium.

The extensor tendons within the retinacular compartments (zone III) receive nutrients from the mesotenon synovial sheets arising from the floor of the compartments, with diffusion and perfusion serving as nutrient pathways (39). The filmy paratenon vascularizes the tendons on the dorsum of the hand and digit (zones I–VI).

**PHYSIOLOGY OF TENDON HEALING**

The process by which flexor tendons heal is controversial (37). The traditional concept is that peripheral fibroblasts from the surrounding connective tissue invade the laceration site and serve as the source of reparative cells; the tendon itself is thought to have no intrinsic capacity for repair. However, in vitro studies of various experimental animals have shown that the epitenon cells migrate into and across the laceration site along a fibrin lattice, and collagen fibers formed by the epitenon and endotenon fibroblasts bridge the laceration sites (38, 40, 42, 55). The repair site is vascularized by proliferation of vascular channels from within the proximal end of the tendon (18). These studies suggest that the tendon is a viable structure that possesses the intrinsic capacity for participating in the repair process.

The repair response of the tendon appears to be enhanced by the application of tension at the laceration site. Fibroblast migration, protein synthesis, and collagen deposition are increased by application of tensile forces to chicken tendons (5, 6). Static tension applied to in vitro rabbit tendon segments increased in strength at the repair site (45), and intermittent cyclic tension enhanced the cellular response of lacerated chicken flexor tendon segments in vitro (65).

In vivo studies on experimental animals have demonstrated actual increase in tensile strength at the repair site. Kubota et al. (21) attributed this increase to both motion and tension in experiments on injured chicken flexor tendons. Hitchcock et al. (25) and Acki et al. (1) demonstrated that the anticipated loss of tensile strength within the first 2 weeks following tendon repair can be avoided by actively mobilizing the tendon at the repair site.

The epitenon response is increased and a greater fibrous “callous” is produced if there is a large gap between the tendon ends (21).

Peripheral adhesions are known to attach to the healing tendon, potentially restricting tendon excursion during flexion and extension. Although the adhesions may contribute to the strength of the healing tendon, it is likely that the adhesions are not essential to the reparative process but only represent the response of the surrounding tissue to trauma (19). The concept of the tendon's intrinsic capacity for healing is attractive to surgeons, because it eliminates the need for fibrous adhesions at the repair site and encourages rehabilitation protocols that prevent their formation and attachment to the tendon. Nevertheless, restrictive adhesions following tendon repair continue to be the bane of surgeons who perform flexor tendon surgery.

Extensor tendons are thought to heal by invasion of fibroblasts from the periphery, but studies have not yet specifically defined this process.

**PRINCIPLES OF MANAGEMENT**

There are basic operative principles that must be followed in caring for flexor or extensor tendon lacerations.

**CLINICAL EXAMINATION**

The first principle is to diagnose the flexor or extensor tendon laceration by careful clinical examination. Begin the examination with a visual inspection of the hand. A disruption of the continuity of the tendon should be suspected by the location of the wound and the resting position of the digit. For example, a skin laceration immediately overlying a flexor tendon on the palm, in association with a digit whose resting position is not as flexed as the adjacent fingers, suggests a lacerated flexor tendon. However, remember that sharp, stiletto-type, penetrating objects can lacerate tendons through a small, inconspicuous skin wound at a distance from the
tendon. Follow visual inspection with evaluation of the active motion of the joint mobilized by the tendon. The flexor profundus tendon to each digit can be examined by asking the patient to flex the distal joint of the involved digit (Fig. 47.4); inability to flex the distal interphalangeal joint indicates a lacerated profundus tendon. A laceration of both profundus and superficialis tendons is apparent when the patient is unable to actively flex the proximal and distal interphalangeal joints. Testing for a suspected superficialis tendon laceration in the presence of an intact profundus tendon is more difficult. The surgeon must eliminate the flexion force of the profundus tendon by making use of the quadriga effect (Fig. 47.5). To do this, manually hold the distal joints of the adjacent digits in full extension while the patient attempts to flex the involved finger. An inability to flex the involved digit actively at the proximal interphalangeal joint indicates a lacerated superficialis tendon.

Figure 47.4. Examination of an intact flexor profundus tendon.

Test the extensor tendons to the fingers by asking the patient to extend each digit. Failure to achieve complete extension indicates a tendon laceration. The ability to obtain full extension may be misleading, however, because this may be accomplished in the presence of an extensor tendon laceration by the interconnecting junctura tendinum from an adjacent tendon. The examiner must test the comparative strength of digital extension against resistance; a digit that is being extended solely by an interconnecting junctura tendinum has a weaker extension force than the adjacent fingers with intact extensor tendons.

ADEQUATE EXPOSURE

A second principle involves adequate exposure of the wound site. In many instances, exposure is necessary to confirm the diagnosis of tendon laceration if the clinical examination of the tendon is not conclusive, or if the extent of injury to adjacent structures is not apparent. This occurs in patients who are not able to cooperate fully (children or incoherent patients, for example), as well as in those with partial or incomplete tendon lacerations when function of the digit is thought to be sustained by the adjacent intact structures, such as a junctura tendinum or intact vincula. The burden of proof about whether a flexor or extensor tendon laceration exists rests with the surgeon; if this cannot be determined by clinical examination, surgical exploration of the wound is indicated.

Adequate surgical exposure is also necessary to identify and expose the tendon ends. Generally speaking, proximal or distal extension of the original wound is achieved through a zigzag approach, as described by Bruner (8), incorporating the original skin laceration (Fig. 47.6). Lacerated flexor tendons frequently retract into the palm or forearm unless prevented by an intact vinculum or lumbrical muscle. A second proximal incision may be necessary to retrieve the retracted tendon and pass it into the original wound site. Fortunately, proximal retraction of lacerated extensor tendons occurs infrequently because the tendon is usually held in place by the junctura tendinum or the synovial mesotendon beneath the retinaculum.

Figure 47.5. Examination of an intact flexor superficialis tendon using the quadriga effect to eliminate the flexion force of the profundus tendon.

When it is necessary to incise the digital sheath to expose the flexor tendon ends, avoid cutting the fibro-osseous pulleys, particularly A2 and A4, and limit the incisional area to the intervening synovial portion of the sheath. This is best accomplished by an L-shaped (or hockey stick) incision, which facilitates closure of the digital sheath (34).

ASSOCIATED INJURIES

The third basic principle in the treatment of tendon injuries is to identify any associated injuries to the adjacent bones, nerves, or blood vessels. Before repairing the lacerated tendon, define the injuries to these associated structures. If possible, repair all the injured structures during the initial surgery. The sequence of repair is usually bone, ligament, tendon, nerve, and important blood vessels. Not all vessels require reanastomosis; only those that are essential to the viability of the injured part. Additionally, the surgeon may choose to perform a delayed repair of crushed or explosion-injured nerves. In replantation surgery, this sequence of repair may be altered in the interest of quickly restoring circulation to the digit.

Primary repair within 24 hours of injury is preferred. However, if appropriate facilities and skilled personnel are not available and the wound is properly irrigated and debrided, repair may be delayed up to 21 days with satisfactory clinical results (36,46,56).
ATRAUMATIC TECHNIQUE

Handle the tendon in an atraumatic manner, because rough manipulation is associated with increased adhesions and the formation of restrictive scar tissue (9,48). This principle cannot be overemphasized. If possible, handle only the exposed, cut end of the tendon with the forceps. Do not apply crushing clamps to the tendon, and keep puncture holes made by suture needles or forceps inserted into the tendon substance to a minimum. Frequently, the surgeon draws the proximal and distal ends of the lacerated tendon into the wound site and holds them in position with straight taper needles placed transversely through the tendon and the adjacent soft tissue; this allows the repair to be accomplished without tension, minimizing repeated manipulation of the tendon ends.

SURGICAL TECHNIQUE

SUTURE TECHNIQUE

The basic objective of tendon surgery is to appose the lacerated tendon ends to allow the healing process to reestablish the continuity of the disrupted collagen bundles and the smooth gliding surface of the tendon. Restore the tubular form to the tendon, avoiding both gapping and bulging of tendon tissue at the repair site. This is particularly important for flexor tendon injuries within the digital sheath (zone II).

Numerous suture techniques have been described for flexor tendon repair. Most of them include a “core” suture, which passes through the endotenon substance of the tendon ends across the laceration site to provide strength and stability to the repair until healing takes place (Fig. 47.7). Additionally, a peripheral suture is placed circumferentially around the laceration site. Although this peripheral suture has been referred to as an epitenon suture, I prefer the term circumferential or peripheral suture because the technique of placing it includes more than the single layer of epitenon cells on the surface of the tendon. A properly placed circumferential suture coapts and invaginates the tendon ends, helping to prevent postoperative adhesions. This circumferential suture was once considered to be primarily of cosmetic importance to “tidy-up” the repair site; however, recent studies have noted the importance of this suture to improve tensile strength and gap resistance (51,53,55,66).

The suture technique for flexor tendons outside of zone II and for extensor tendons is not as critical, because the healed tendons do not have to glide in a confined sheath. Nevertheless, the surgeon is encouraged to use careful atraumatic techniques to minimize postoperative adhesions.

SHEATH REPAIR

There is controversy about whether the digital sheath should be repaired at the time of tendon repair. Repair of the digital sheath at the time of zone II flexor tendon injuries has become popular on the premise that this enhances tendon nutrition by restoring the synovial environment (34). This concept is contradicted by studies that show that tendons heal in an extrasynovial fluid environment (27), as well as by studies that indicate that the integrity of the digital sheath does not affect the uptake of nutrients into the tendon (51). Experimental animal studies following tendon laceration and repair have produced conflicting results about whether sheath closure or reconstruction minimizes adhesions and improves tendon gliding (22,50,64). Sheath closure in the presence of an edematous swollen tendon may produce relative narrowing of the fibro-osseous tunnel and restrict tendon gliding. Be meticulous if you are performing sheath closure at the time of tendon repair, taking care not to compromise the cross-sectional diameter of the fibro-osseous tunnel.

FACTORS AFFECTING TENSILE STRENGTH

The forces present at the flexor tendon repair site during passive digital motion, active digital motion, and active digital motion against resistance have been measured clinically in patients undergoing median nerve decompression at the carpal tunnel (59). Passive motion generates up to 0.9 kilograms force (kgf) in the digital flexor tendon. Active flexion against no resistance generates up to 3.9 kgf. Grasp against resistance generates up to 6.4 kgf, and tip pinch up to 12.0 kgf. Tendon repair rehabilitation protocols usually employ digital active or passive grasping activities. Consequently, 3.9–6.4 kgf is considered an appropriate approximation of the flexor tendon forces required to flex an uninjured finger. It should be noted that edema and increased tissue viscoelasticity associated with an injured digit probably result in increased resistance to flexion; therefore, the forces required to flex an injured digit following tendon laceration and repair are likely to be increased (23).

The tensile strength of standard two-strand suture techniques (e.g., Kessler, Bunnell) is approximately 2–3 kgf, as measured in human cadaveric tendons (2,6,66). These tensile strength values have been shown (44,67) to diminish more than 30% to 40% in experimental studies in immobilized tendons during the early (5–10 days) postoperative period; these values recover at approximately 2–3 weeks.

Several factors can impact the ultimate tensile strength and the resistance to gap formation at the repair site.

INCREASED NUMBER OF STRANDS

Increasing the number of core suture strands across the repair site can increase the tensile strength of the repair. Traditionally, suture techniques with two strands across the repair site were used (9,28). Increasing the suture strands to four nearly doubles the strength of two-strand repairs in human cadaver tendons (32,54). A six-strand suture technique described by Savage (57) has an ultimate tensile strength of 6.8 kgf.

Additionally, altering the standard core suture technique has been shown to increase the tensile strength. A longitudinal continuous running suture along both margins of the repaired tendon as described by Becker (Figs. 47.8) (4) increases the strength to 4.0 kgf, and a cross-stitch suture described by Silverskold and Anderson (Figs. 47.9) (65) increases strengths to 6.4 kgf in sheep cadaver tendons. The latter authors also reported tensile strength values of more than 10 kgf using a nylon mesh sleeve sutured to the tendon across the laceration site; again, the testing was performed in sheep cadaver tendons, and the values may not be comparable to studies using human cadavers.

Figure 47.8. A longitunal continuous running suture along both margins of the repaired tendon.
Potential mechanical advantage of the dorsal placed suture during simulated digital flexion, or to a real biological difference between the dorsal and volar aspects of its native environment within the flexor sheath of the digit. It has not been conclusively established whether the improved tensile strength is related principally to the material and tendon fibers; therefore, more tensile forces can be applied to the repair site before the suture fails. The four suture strands crossing the laceration site occupied 7% of the cross-sectional area of the tendon at the laceration site. Locating the four knots within the laceration site increased the occupied cross-sectional area to between 18% and 26%. The observation that there was no difference in the tensile strength at 6 weeks indicates that the knots within the repair site did not interfere with the healing process.

**LOCKING VERSUS GRASPING SUTURE CONFIGURATION**

There is debate over whether there is a difference in tensile strength related to the use of a locking or grasping suture configuration, as well as over whether more than one locking or grasping loop per suture strand increases the strength of the repair. The controversy is in part related to poorly defined terms: Unfortunately, the terms locking and grasping have often been used interchangeably. It is necessary to define a locking suture as originally defined by Pennington (49), who recognized the important relationship between the longitudinal and transverse components of the core suture (Fig. 47.10). When the transverse component is passed superficial (palmar) to the longitudinal component, it tightens around bundles of tendon fibers as tensile forces are applied; this is a locking suture. When the transverse component is passed deep (dorsal) to the longitudinal component, the suture does not tighten around the tendon bundles but rather pulls through the tendon fibers as tensile forces are applied; this is a grasping suture.

**KNOT LOCATION**

The knot is the weak link in the suture strand (3, 24). Therefore, a repair technique employing one knot is preferred to a technique using multiple knots. Location of the knots within the repair site or outside the repair site also influences the tensile strength of the repair. Comparison of knot position in human cadavers showed that tendon repairs with knots located within the repair site had 60% to 80% of the strength of repairs having the knots located outside the repair site (3). Similar in vivo studies in canines (53) showed that four-strand suture repairs with the four knots located within the laceration site had 65% the tensile strength at 1 week after repair compared to tendon repaired with knots located away from the repair site. This increased to 75% at 3 weeks, and there was no significant difference in the tensile strength related to knot location by 6 weeks. The explanation for this difference is that knots located within the repair are subject to all the tensile forces applied at the laceration site. When the knots are placed outside the laceration site, the tensile forces are in part dissipated and absorbed by the friction between the suture material and tendon fibers; therefore, more tensile forces can be applied to the repair site before the suture fails. The four suture strands crossing the laceration site occupied 7% of the cross-sectional area of the tendon at the laceration site. Locating the four knots within the laceration site increased the occupied cross-sectional area to between 18% and 26%. The observation that there was no difference in the tensile strength at 6 weeks indicates that the knots within the repair site did not interfere with the healing process.

Mashadi and Amis (43) studied the effect of the locking suture configuration as defined by Pennington on tendon strength and gap formation using stainless steel suture material. They found no significant differences using one, two, or three locking loops per suture strand. In a subsequent study, Hotokezaka and Manske (26) compared locking and grasping loop suture configurations using polyester suture material. They confirmed the previous observation that additional locking loops do not contribute to increased strength or resistance to gap formation. One locking loop per suture strand had greater tensile strength than one grasping loop and was equal in tensile strength to two locking loops and two grasping loops. With respect to gap strength, one locking loop was equal to two locking loops and one grasping loop; however, gap formation was greatest using two grasping loops per suture strand as the added suture material pulled through the tendon allowing a larger gap. These authors conclude that a single locking loop per suture strand is preferred when using two-strand suture techniques.

**DORSAL VERSUS VOLAR SUTURE PLACEMENT**

Experimental studies (29, 63) showed that placement of core sutures in the dorsal half of the tendon provided stronger repairs than core sutures placed in the volar half of human cadaver tendons. This was particularly evident using curvilinear testing techniques, whereby the tensile strength values were determined with the tendon in its native environment within the flexor sheath of the digit. It has not been conclusively established whether the improved tensile strength is related principally to the potential mechanical advantage of the dorsal placed suture during simulated digital flexion, or to a real biological difference between the dorsal and volar aspects of the...
tendon.

**CIRCUMFERENTIAL SUTURE**

A continuous running suture is usually placed circumferentially around the periphery of the repair site. Formerly, it was thought that this circumferential suture served only to tidy-up the repair, but recent cadaver studies have shown that it also contributes to the tensile strength and gap resistance of the repair site (50-53,56-68). Tensile and gap strength values, in general, are increased according to the number of suture strands. Additionally, tensile strength is related to the suture configuration (30); simple sutures add approximately 1 kgf, mattress sutures add approximately 2 kgf, and the locking mattress suture described by Lin (63) (Fig. 47.10) and the cross-stitch suture (Fig. 47.10) (60) add approximately 3 kgf. Finally, increasing the depth of circumferential sutures has also been shown to increase the tensile strength and gap resistance (14).

![Figure 47.11. Drawing of locking mattress circumferential suture. (Redrawn by permission. From Lin G-T, An J-K, Amadio PC, Cooney WP. Biomechanical Studies of Running Suture for Flexor Tendon Repair in Dogs. J Hand Surg 1988;13A:553.)](image)

**POSTOPERATIVE CARE**

The traditional postoperative management protocols following tendon repair have focused on minimizing tension at the repair site to allow the tendon to heal. Complete immobilization has been found to diminish the strength of the repair site, however, and to encourage formation of fibrous adhesions from the peripheral tissue to the repaired tendon (32,67). Ideally, these peripheral adhesions will become long and filmy strands of scar tissue, which do not impede tendon excursion; however, they often are tight, dense bands that restrict tendon gliding. In experimental animals, a program of early passive motion effectively restored the gliding surface and increased the strength at the repair site of canine flexor tendons at 3 weeks after surgery (19,20). Consequently, carefully supervised and controlled passive range of motion of the digit has been advocated in the treatment of repaired flexor tendons in the early postoperative period (15,35). Early controlled mobilization has also been advocated following extensor tendon repair (7).

Active mobilization has been shown to increase the tensile strength of the repair site in experimental animals (1,25,31). Aoki et al. showed that the observed loss of tensile and gap strength at the repair site during the initial 2 weeks could be obviated by applying tension to the repaired tendon (1). Several authors have reported good results using active tendon mobilization protocols following flexor tendon repair (13,16-18,62). Active mobilization has also been advocated following extensor tendon repair (12,17).

**AUTHOR’S PERSPECTIVE**

**Flexor Tendons**

My preferred technique for flexor tendon repair within the digital sheath follows the previously noted principles, but it also takes into consideration the ease or difficulty of suture placement. The core consists of two two-strand locking sutures (3-0 braided polyester) as described by the Pennington (49) modification of the Kessler technique (28), resulting in four strands across the repair site. (If surgical exposure allows, a third locking suture can be placed, resulting in six strands.) The knots for each of the two sutures are tied within the repair site. The circumferential suture is a criss-cross suture (60) using 6-0 Prolene.

My postoperative rehabilitation protocols encourage protective active mobilization; the specific protocol utilized depends on the ability of the patient to understand and conform to the guidelines. Treat reliable patients with a removable splint as described by Cannon (10); this allows active digital flexion with wrist extension and active digital extension with wrist flexion. Between exercise sessions, hold the digit in full extension at the proximal interphalangeal joint (with the wrist and metacarpophalangeal joints flexed 30°) to prevent flexion contracture of that digital joint.

Treat less reliable patients with the passive motion (rubber band traction) similar to that originally described by Lister et al. (35); modifications include passing the rubber band through a pulley located at the distal palmar crease in the hand, as well as including all four digits in the traction device. Additionally, encourage patients to assist the passive flexion by actively flexing the digit during exercise periods.

**Extensor Tendon**

My preferred technique for extensor tendons generally includes a core locking suture as described by Pennington (49), along with the circumferential criss-cross suture (60). An additional figure-eight can be added at the surgeon’s discretion. Postoperatively, early motion is obtained using dynamic splinting (7).

The principles associated with tendon repair continue to evolve. Perhaps it is best to regard these principles as dynamic and ever-changing concepts that the surgeon must reconsider as they are modified and redefined. Only in that way will the objective of restoring the continuity of the collagenous fibers and reestablishing the gliding surface of the tendon be realized.

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *; classic article; #; review article; !; basic research article; and *; clinical results/outcome study.

10.

Although discussions of the anatomy, physiology, and biomechanics of human flexor tendons are beyond the scope of this chapter, the recent works of Gelberman and Manske (17,18), Manske and Lesker (19), and Brand (3) form the basis of present approaches to flexor tendon repair technique. Within the past 20 years, this knowledge has changed most of the principles and techniques of flexor tendon surgery and—with the enthusiasm for replantation—the timing as well. The importance that each surgeon attributes to the blood supply will determine the following:

- Whether a midlateral incision is used for exposure, which to some extent decreases blood supply to the tendon from that side (Fig. 48.1).

![Figure 48.1. Segmental blood supply to digital theca. FDS, flexor digitorum superficialis; FDP, flexor digitorum profundus. (Modified from Leddy JP. Flexor Tendons—Acute Injuries. In: Green DP, ed. Operative Hand Surgery. New York: Churchill-Livingstone, 1982;1350.)](image)

- Whether a superficialis tendon, which has vascular interconnections with the profundus, is excised (Fig. 48.2).

![Figure 48.2. Vinculae to digital flexors.](image)

- Whether "strangulating" criss-cross suture techniques (e.g., Bunnell) are used or sutures are placed more palmarward to avoid disrupting the blood supply entering from and residing in the dorsal aspect of the tendon.
- Whether closure or reconstruction of the sheath is necessary to enhance intrinsic healing and the synovial fluid environment.
- Whether the effects of motion on tendon healing and strength determine the rehabilitation plan (8).

Acknowledged important principles include:

- A clean surgical wound is essential.
- One wound and one scar enhance outcomes.
- A poorer prognosis for function occurs with more damaged structures.
- A mature wound is better for tendon repair and reconstruction (2,22).
- Meticulous repair of all structures with stable bone fixation techniques permits immediate motion.
- Repair of the periosteum or the dorsal portion of the flexor sheath or pulley system, an interposing tissue minimizes adhesions.
- Repair of vessels is important to nerve regeneration.
- Repair of nerves is ideal for rehabilitation.
- Repair of tendons is necessary to prevent myostatic contracture and to allow rapid restoration of function, using a controlled rehabilitation plan.
TERMINOLOGY

Definitions of the timing of tendon repair are imprecise in view of the conflicting opinions of many authorities (16,17,20,25).

Primary repair is repair of a tendon when the wound is initially debrided—during the “golden period” of the first 6 hours after injury, when it can be assumed that the wound has not been sufficiently colonized with bacteria to prevent closure. However, some fresh wounds are so grossly contaminated primarily that there is no golden period.

In wounds over 6 hours old, repair of flexor tendons might be deferred in favor of initial debridement only. If a digit is revascularized or replanted 6 hours after injury, and tendon repair is also carried out, this is also considered a primary repair.

Delayed primary repair occurs when the initial wound is washed and debrided but tendon repair is delayed for 2 to 14 days when the wound is not yet fully healed.

A repair performed after skin wound healing is considered a secondary repair or reconstruction. However, some authors consider repairs between 2 and 6 weeks to be late delayed primary repair because myostatic contracture is not well enough established to prevent “primary” end-to-end repair of the flexor tendon without having to resort to secondary reconstruction (i.e., grafting) (25).

ZONES OF INJURY

Following Bunnell’s (2) admonitions about problems with flexor tendon repairs in the pulley area of the digital sheath (the “zone of the pulleys” or Bunnell’s “no-man’s land”), Verdan (32,33 and 34) classified flexor tendon injury sites into five zones, each with its peculiar anatomy and prognosis (Fig. 48.3). Doyle redefined the pulley zones of the digit and thumb (Fig. 48.4); this classification is now generally accepted (6,8).

**Figure 48.3.** Verdan’s thumb and digital zones (modified).

![Figure 48.3](image)

**Figure 48.4.** Digital and thumb pulley systems as described by Doyle and Strauch. A,B: Digital. C: Thumb (note annular pulleys at the metacarpophalangeal and just proximal to the interphalangeal joint with oblique pulley over proximal phalanx). (C modified from Doyle JR, Blythe WF. Anatomy of the Flexor Tendon Sheath and Pulleys of the Thumb. J Hand Surg 1977;2:150.)

Flexor tendons to the digits may be injured in the wrist or forearm proximal to the carpal tunnel, which begins at the distal palmar wrist crease (surface marking) or the proximal edge of the deep transverse carpal ligament, extending from the trapezium to the hook of the hamate. The site of the tendon injury is what defines the zone, not the site of the skin lacerations. The tendon injury site is the position of the tendon with the wrist in neutral and the fingers in full extension, although more properly the fingers should be in their resting position of normal muscle tension or digital stance. As the fingers and wrist move into flexion, as the flexor muscles contract, the tendon moves proximally. Therefore, if the injury occurred at the wrist level but the finger or wrist were still flexed, the tendon injury occurs more distally on the tendon (possibly in the carpal tunnel) when it resumes its neutral or more extended position.

**ZONE 5**

A tendon injury in the wrist or distal forearm is in Verdan’s zone 5. The musculotendinous junction area may be involved. Injuries can occur to the two wrist flexors, the palmaris longus, the median and ulnar nerves (and branches), the radial and ulnar arteries, and the nine flexor tendons of the digits and thumb. Multiple tendons and muscles may be injured. The prognosis for function, including individual function, in this area is good. Repairs need not be as meticulous as in other areas, but they still must be done well.

**ZONE 4**

The carpal tunnel, Verdan’s zone 4, extends from the distal palmar wrist crease or the proximal end of the deep transverse carpal ligament to its distal margin, as noted by the crossing of the proximal superficial palmar arch, formed from the ulnar side by the ulnar artery leaving the canal of Guyon. The surface determination of the distal extent of the tunnel is made by extending a line across the base of the palm from the palmar surface of the maximally extended thumb. In this zone, the nine flexors are tightly packed with the median nerve. Repairs must be meticulous, and results, especially for independent function, are more problematic than in any other area except the zone of the pulleys.

**ZONE 3**

Zone 3 extends from the end of the carpal tunnel to the proximal end of the pulleys, which begin at the metacarpophalangeal (MP) joints. Surface markings in the palm are the proximal palmar crease for the index, about midway between the proximal and distal crease for the long finger, and the distal palmar crease for the ring and little fingers. In this zone, both the flexor digitorum superficialis (FDS) and the flexor digitorum profundus (FDP) are oval tendons, and the lumbrical muscle originates from the FDP. The lumbrical tendon runs in its own sheath or tunnel radial to the long flexor. Although repairs in zone 3 generally have a good prognosis, secondary reconstructive procedures originating here should allow for problems with intrinsic imbalance and excessive lumbrical action.

**ZONE 2**

Zone 2, the zone of the pulleys, is the area of maximum concern and debate regarding aspects of tendon nutrition, healing, repair methods, and rehabilitation. Even the extent of the zone is argued. Investigators agree that the zone begins at the MP level [Bunnell’s first pulley, Doyle’s first annular (A1)], but the distal extent is not
defined. For prognostic purposes, the zone ends at the mid–middle phalanx, the site of Doyle's C3 (third cruciate) pulley but also the most distal extent of the superficialis slips' insertion (Fig. 48.4). Distal to this point only a one-tendon system, the profundus, exists, but Strauch has described the A5 (fifth annular) pulley at the distal interphalangeal (DIP) joint level (29). Zone 2 is peculiar in that actually three tendons (profundus and two slips of the superficialis) exist here in very close proximity; they are surrounded by the dense unyielding cover of a floor (dorsally) of bone, periosteum, and fibrous sheath and by sides and a roof (palmarly) of dense fibrous tissue, thicker even in the condensations of the annular and cruciate pulleys and dorsally at the palmar plates. Within the sheath and pulleys the tendons have an intrinsic blood supply as well as that from the parietal tenosynovium surrounding the tendons.

The superficialis tendon in this zone begins to split at the MP level to allow the profundus to pass through it. It then becomes two flat, slightly concave tendons that lie dorsal to the profundus and hug its sides and then join just proximal to the proximal interphalangeal joint to form the chiasm of Camper. The flat united tendinous structure then divides after the proximal interphalangeal (PIP) joint to form two flat slips, which insert along the middle phalanx to almost its midpoint.

Good results of surgical repair in this area depend on many of the surgical and rehabilitation techniques discussed in this chapter and are by no means routine.

ZONE 1

Zone 1 is the area between the FDS insertion (distal edge of C3 pulley) and the insertion of the profundus. Excellent technique is also required here, but with good conventional techniques the prognosis for function is good.

Five thumb flexor zones are described, but problems occur less often here with only one tendon of relatively uniform size and no intrinsics. These thumb flexor zones are listed below:

Zone 5 for the thumb flexor is also in the wrist, proximal to the carpal tunnel.
Zone 4 is the carpal tunnel.
Zone 3 is the relatively inaccessible thenar zone, extending from the distal edge of the tunnel to the MP joint.
Zone 2 is the pulley zone, consisting of an annular ligament at the MP joint and a long oblique pulley over three quarters of the proximal phalanx with a second annular pulley distally.
Zone 1 is distal to the pulley, just proximal to the interphalangeal joint, to the insertion of the flexor pollicis longus (FPL) just distal to the interphalangeal joint.

SURGICAL TECHNIQUES OF DIGITAL FLEXOR TENDON REPAIR

Given the option, we prefer delayed primary repair of flexor tendons. This implies a thorough wash and debridement of the wound initially, with tendon repair at 48 to 96 hours. Initial care is done on an outpatient basis in an adequate facility (usually the operating room, but possibly an emergency department suite where tourniquet control, anesthesia, and good sterility are available). The patient is placed on the elective surgical schedule in a few days.

Several situations, both medically moderated and socially dictated, preempt this approach. An unreliable patient is likely to be admitted and operated on at the next available elective operating time after initial wound care. If the patient has been referred from out of town with a day-old injury, surgery is done at the next elective opportunity. Medical conditions indicating acute repair include a zone 5 injury requiring the repair of multiple damaged structures and the repair of muscle and tendons before muscle retraction makes the surgery technically more difficult. Digits with vascular impairment requiring revascularization or replantation are also repaired acutely, as delay may endanger the viability of the digit (see Chapter 34).

- Begin by increasing the exposure proximally and distally, converting the original laceration into part of the zigzag Brunner approach Fig. 48.5 (4). The history of the injury suggests whether the actual site of tendon laceration will be at the skin level or more distally.

- Open the carpal tunnel area following the thenar crease, but 1 to 2 cm distal to the wrist crease, direct the incision ulnarily to the wrist crease, then change the direction sharply and curve the incision proximally back to the midline. From here, each zone is managed somewhat differently (see Chapter 37).

REPAIRS IN EACH ZONE

Zone 5

- After extending the exposure, check each structure to verify the findings at physical examination. Check each structure for continuity and function. The profundi are aligned at the same level just palmar to the pronator quadratus, with the index profundus frequently independent. The flexor pollicis is more radial yet and, although deeper, is just radial to the radial artery. The four superficialis tendons line up, with the long and ring finger tendons lying somewhat more superficially than the index and little finger tendons, which lie to either side and more dorsal. The little finger superficialis is closely associated with the ring finger tendon, although slightly more dorsal.

- If the profundus and flexor pollicis longus are intact, place an umbilical tape around them to avoid having to recheck their identity repeatedly. Similarly, mark the intact superficialis tendons and identify the more superficial wrist flexors—the flexor carpi radialis (FCR) and ulnaris (FCU)—and tag the median nerve with a vessel loop. Although any flexor motor can power any distal tendon, it is best to match the lacerated components because their lengths when repaired end to end should provide the appropriate tension. This is particularly important for the profundus. Because of their intimate interconnection, restoring tendon length is important to prevent the short tether syndrome (quadriga).

Tendons are identified based on their function, location, and appearance—that is, it, does what it is supposed to do, lies where it is supposed to lie, and looks the way it is supposed to look. The preferred end-to-end tendon repair is the Tajima modification of the four-corner grabbing stitch of Kessler (Fig. 48.6) (30). Use two double-armed 3-0 or 4-0 monofilament polypropylene sutures with pointed tendon needles. (For a discussion of recently advocated multistrand techniques, see Chapter 47 by Manske, particularly zone 2 repairs.) The multistrand repairs, although more technically demanding, have experimentally demonstrated greater strength, allowing more active motion in postoperative rehabilitation, and may supersede the Kessler modifications in common usage (10-34,35-37).
Pass the suture transversely through the tendon about 1 cm behind the cut edge, which is minimally trimmed with curved Stephen scissors. Then reinsert each needle just behind the transverse suture and direct it on its side to the open end. Hold the tendon at its cut end with a Beasley-Babcock forceps. This technique is preferred to the conventional or modified Kessler, as the needles are not directed into the cut tendon ends, which seems to create fraying.

While the assistant holds the tied suture, take up the slack on the untied side, just bringing the ends together, and tie the second side. In zone 5, additional tidying sutures are usually not necessary. Occasionally, a horizontal mattress stitch with 6-0 nylon or polypropylene might be used to tuck in an irregular edge.

Use a combination of horizontal mattress and locking horizontal mattress sutures for muscle repair. In the locking stitch, instead of tying the two ends of the suture in the conventional manner, make one or two throws on the needle end of the suture, then place the needle-holder tip through the loop end of the stitch, grasping the loose end on the far side and pulling it through the loop (Fig. 48.7). This maneuver not only creates the stitch tension away from the wound edge and everts the edges but also approximates the edges and prevents excessive eversion. This technique is also applicable in all tendon repairs where a horizontal mattress suture might be used (e.g., superficialis slips, chiasm of Camper), but excessive eversion is undesirable.

More meticulous tendon repair is required in zone 4.

After tying the Tajima sutures, do not cut the two tied suture ends. Leave them inside the tendon initially. Have the assistant hold the long ends and place a horizontal mattress or locking horizontal mattress stitch with 6-0 nylon in the outer layer of the tendon. Begin the circumferential running stitch away from your side with the tendon flipped over (i.e., on the dorsal or back side). Take the stitches toward yourself, return the tendon to the palmar side, and complete the suturing, tying finally to the initial stitch end.

Although simple bites (1 mm or so from the cut edge) are often satisfactory, invert these edges or at least make them even. To invert, take each stitch just behind the cut edge (Fig. 48.8), which rolls in the edge, leaving a repair without pouting edges. Healing is not adversely affected.

After the repair of the structures in the carpal tunnel, begin rehabilitation, either with the wrist in neutral or dorsiflexion to prevent palmar subluxation of the contents of the tunnel.

Because it is preferable to flex the wrist up to 30°, we prefer to repair the transverse carpal ligament. Direct suture is not usually feasible; zigzag cuts on opening the carpal ligament risk damage to the palmar cutaneous branch of the median nerve, which may run through the ligament, or to the motor branch of the median nerve. Consequently, we close the tunnel somewhat more loosely than its original ligament width by lacing it with a strip of tendon like a shoelace (usually using palmaris longus, but occasionally with a sagittal strip of FCR or an accessory tendon).

Perform zone 3 repairs in a similar manner. The lumbrical may be repaired, but if it is damaged in its muscle substance, it is probably better to excise it rather than to risk an imbalance caused by intrinsic contracture. Repair both the superficialis and profundus if they are lacerated, and also repair a single tendon laceration. Restoration of digital strength and total function requires both tendons.

In zone 2, the technique must be precise. Avoid scratching the tendon to avoid causing adhesions (27). Repair the bed, repair the tendon in a nonbulbous manner, and repair the sheath or pulley system.

Extend the wound into a zigzag or Bruner incision (Fig. 48.5). Expose the sheath and open it along the side to create a funnel, as described by Lister (Fig. 48.9) (15).
Partial Lacerations

SPECIAL CIRCUMSTANCES

The side cut joins the transverse wound in the sheath. If the tendon is sited proximally, make a second incision more proximally, a mirror image of the first. The distal tendon can usually be easily exposed in this manner, assisted by flexion of the distal joints. If the proximal end is not held by a vincula, or if the profundus alone is cut and not trapped at the MP level where it passes through the superficia, it is in the palm, held by the lumbrical. Fishing for the proximal end with grasping-type instruments is dangerous to the tendon, the bed, and proximally to blood vessels and nerves. If the proximal end cannot be kneaded and milked into the wound and then grasped with a mosquito hemostat in its cut end, make a proximal incision and find it.

Pass a pediatric rubber feeding tube or a silicone-dacron tendon rod distally to proximally through the sheath, suture the tendon with a single nylon suture through the cut end to the eyelet in the tubing or to the rod, and draw it back into the distal wound.

When both tendons are cut, bring them together distally. Bring the profundus through the superficia, in the normal anatomic position. If a problem arises passing it through the sheath, open the intervening skin bridge and create another sheath incision.

Once the tendon (or tendons) is returned to the distal area, close the sheath opening with 6-0 nylon.

When the tendons are brought into the distal wound, hold them in that position by skewering them with a milliner’s needle that passes through the sheath and the tendons proximally. Avoid the neurovascular bundles by placing the needle more palmarly. Keith needles have a cutting edge and are less desirable than the pointed milliner’s variety.

Except at the open end, where the tendon may be handled with the Beasley-Babcock forceps, handle the tendon with the thumb and index fingers with an interposed moist sponge.

Repair the superficialis slips or chiasm with horizontal mattress sutures or locking stitches, using 4-0 nylon. Collagen suture creates more reaction and is not advocated. Polypropylene is satisfactory; braided polyester sutures do not slide well and are no longer preferred by us. Braided nylon has also been satisfactory, but monofilament nylon and polypropylene are preferred.

Repair the profundus tendon with the Tajima technique with 3-0 or 4-0 nylon or polypropylene, with the cut edge repaired with a running stitch. If there has been damage to the periosseum under the tendons, repair it with 6-0 nylon. If it cannot be repaired, a graft of antebrazial fascia may be sutured in place as an interposing membrane. Fractures are repaired before tendons, of course, but if neurovascular repairs are indicated, particularly with an intact skeleton, it may be technically easier to retrieve tendons into the wound and place the Tajima sutures into the tendon but not tie them so that the neurovascular repair under the microscope can be done on a flat (unflexed) digit.

After the tendons are repaired, repair the sheath with 6-0 nylon (Fig. 48.10). Leaving a gap in the sheath may result in sagging of the edge of the sheath as the tendon attempts to pass through it, decreasing the vertical diameter and trapping the tendon (Fig. 48.11). Use simple or horizontal mattress sutures to repair the sheath. If a gap remains, fill it by sewing antebrazial fascia to and over the underlying sheath (Fig. 48.10). If a pulley is missing, reconstruct it, as described below.

**Figure 48.9.** Lister’s technique of opening the sheath to form a funnel.

**Figure 48.10.** Closure and reconstruction of the tendon sheath. A: Anteroposterior view of the sheath demonstrating direct repair and antebrazial fascial graft (P). B: Lateral view of repair and graft (P).

**Figure 48.11.** Buckling of the unrepaired sheath as the tendon attempts to pass through. Note loss of height of pulley (A–B to A1–B).

### Zone 1

Repair the profundus in zone 1 as described for zone 2. Also reconstruct the sheath. Full flexion of the digit to the distal palmar crease usually requires A5 pulley preservation or reconstruction. When the sheath is cut away, a sagging effect occurs as the tendon moves proximally into the sheath, blocking full motion. Advancement of the profundus tendon under the distal stump for a reinsertion into bone rather than a tendon repair is not recommended: the short-tether or quadriga effect may occur with this maneuver, with loss of full flexion of the adjacent digits (33). This technique can generally be used safely with the index finger because of its usual independence from the other profundi. Advancement still creates slack in the lumbrical, however, which may weaken or unbalance its action.

- If the distal stump is short, take the Tajima stitch proximally, then pass needles longitudinally through the stump, then adjacent to the sides of the distal phalanx or through drill holes (with a 0.045-in. pin) in the phalanx from palmar to dorsal, emerging proximal to the germinal matrix of the nail bed.
- Tie the sutures over a dorsal button.
- Place horizontal mattress sutures at the cut edge.
- We have used small (or mini) suture anchors for avulsions and short stumps in preference to dorsal buttons in the last 3 years; 2-0 suture is used. We have had satisfactory results, but the series is too small to advocate their use as yet.

### SPECIAL CIRCUMSTANCES

Partial Lacerations
Three concerns exist with partial lacerations (Fig. 48.12):

- The tendon may rupture if it is not repaired.
- The tendon will be weakened if sutures are placed in it.
- The unrepaired portion may not fully heal and cause triggering [catching on the edge of the fibrous sheath system (A1)].

Based on the available studies, lacerations of 25% or less of the tendon's cross-sectional area in zones 3 and 5 are best left unrepaired. Repair lacerations of 50% with horizontal mattress or locking-type stitches; lacerations of 75% or greater require full repair. In zone 4, tidy up lacerations of 25% with debridement. In zones 1 and 2, repair all partial lacerations; lacerations of 25% are repaired with simple sutures. Use the "frayed tendon" rehabilitation protocol postoperatively.

**Segmental Injuries**

If a tendon is cut in several locations, as in lawn-mower-type injuries, repair it similarly in each location. If a segment is missing, replace it with a segmental tendon graft (Fig. 48.13), using palmaris or a segment of flexor carpi radialis.

- Determine the length of graft needed by applying traction on the distal segment to place the digit in its normal stance position (Fig. 48.14). Then apply traction to the proximal end. Maximum traction determines the extent of the muscle's elasticity; no traction is the zero-tension position. Some 50% to 60% of the maximal elasticity is close to the resting tension of the muscle, which is the desired position.

- Take the amount of tendon graft and then a bit more, to achieve the normal stance position, suture it in tentatively, shorten it accordingly, and complete the suturing.

This segmental interpositional graft technique, frequently used for extensor tendons, is most applicable in zone 5, is applicable with longer grafts in zone 4, and is possibly applicable in zone 3. In zones 1 and 2, grafting of the entire distal segment is more appropriate, as discussed below.

**Frayed Tendons**

Debridement and a special postoperative protocol may be adequate for the minimally frayed tendon that is for the most part intact. For severely "chewed-up" tendons, replacement is indicated. Use segmental grafts in zones 3, 4, and 5. In zones 1 and 2, if the tendon is badly damaged and hence irreparable but the bed is unharmed (not a common occurrence), perform a one-stage graft, either primarily or as a delayed procedure. Options are discussed in the section on grafting. If the bed and tendon are damaged, perform two-stage grafting. Placement of a tendon rod in the acute injury is questionable; we prefer to do this in the clean wound at 10 to 14 days.

**Muscle Damage**

If a profundus muscle is significantly damaged, perform tendon transfer using the long or ring superficialis. When a lone superficialis muscle is injured and is irreparable, we perform no reconstruction. For multiple or massive injuries of the flexor tendons, a transfer from the extensors may be indicated.

**Thumb Flexor Injuries**

Lacerations of the FPL may be repaired with direct suture, advancement, or grafting, depending on the zone and surgeon's preference (see Fig. 48.5). Direct suture is used more often than not, but the usual independence of the muscle/tendon unit (it is occasionally associated with the profundus of the index) and the lack of lumbrical allow more repair options.

Urbaniak has shown that the FPL may be advanced to the bone insertion when the laceration has occurred within 1.2 cm from the insertion. Between the MP joint...
and this point, he advocates advancement with equivalent Z-lengthening at the wrist, with and without reinforcing tendon grafting at the wrist (Fig. 48.15). Within the thenar zone, he prefers grafting. We have used these methods successfully but usually prefer direct suture methods (30). The technique and sheath repair methods are the same as in the digits. While access to the thenar zone is difficult, the injury that exposed and cut the tendon usually makes the access quite easy. If not, the pediatric feeding-tube method to retrieve the proximal end and grafting may be necessary. The carpal tunnel often must be opened to retrieve the proximal end of the flexor pollicis longus. Direct suture methods have been most successful in achieving full active motion, which is represented by full extension of the thumb into the plane of the digits and full flexion to the distal palmar crease of the little finger.

Figure 48.15. Lengthening of the flexor pollicis longus at the wrist associated with distal advancement in thumb zone 2. Two methods of repair of the lengthening are depicted. (Modified from Urbaniak JR. Flexor Pollicis Longus Repair. Hand Clin 1985;1:73.)

LATE RECONSTRUCTION

ONE-STAGE TENDON GRAFTING

Although one-stage tendon grafting was once a common procedure, advocated for all injuries in zone 2, today it has only occasional indications (2, 34). It is indicated when the damage to the tendons in zone 1 or 2 is irreparable but the tendon bed is uninjured or minimally injured (Fig. 48.16). Prerequisites include a soft, pliable hand and digit with full passive motion of the joints.

Figure 48.16. One-stage tendon grafting from the palm. More extensive pulley preservation is more common than the minimal number depicted. These three (with the proximal one somewhat closer to the metacarpophalangeal joint) are the most critical.

- Expose from the profundus insertion to the palm, using a Bruner or midlateral incision, and extend into the palm as a zigzag or sequential transverse incision (Fig. 48.3B).
- Classically, the tendon sheath is partially excised, leaving only the three pulleys advocated by Bunnell. Today, however, most of the pulley and tendon sheath system is preserved, removing only enough to gain access to the remaining portions of tendon. Proximally, leave the profundus in the palm short enough so that it will not be drawn into the digital sheath when the digits are in full extension. Leave the lumbrical origin, along with an additional 1 to 2 cm.
- Distally, preserve a short stump of profundus. Leave the distal portion of the superficialis (the chiasm of Camper) and, if it is not already adhered, suture it to the sheath proximally as a tenodesis to prevent hyperextension of thePIP joint.
- The usual source of tendon graft is the palmaris longus. Take it through multiple transverse incisions in the forearm, starting just proximal to the distal palmar wrist crease, and remove it retrograde by passing a small hemostat from the proximal to the distal wound. Alternately, we use the short forearm Brand tendon stripper. Place it around the tendon distally and advance it into the forearm while tension is maintained with a hemostat on the distal divided tendon. The device then avulses the tendon at the musculotendinous junction. Whether to remove paratenon or not is a moot question. We remove all muscle and the bulk of the paratenon but do not compulsively remove all of it.
- Distally, just under the profundus stump and distal to the insertion of the palmar plate of the DIP joint, drill a hole with a 5/64-in. bit just through the palmar cortex of the distal phalanx. This is distal to the epiphyseal plate in children.
- Make two drill holes with an 0.045-in. pin through the dorsal cortex on either side within the palmar cortical hole. Pull the tendon through the digit from the tip to the palm, after suturing it to either a reusable tendon rod or a pediatric feeding tube.
- Make a Bunnell-type weave through the end of the tendon with 3-0 polypropylene on milliner's needles (Fig. 48.17).

Figure 48.17. The modified Bunnell suture, similar to that advocated by Kleinert.

- Pass the two needles through the bone and through dorsal skin proximal to the germinal matrix of the nail bed, through a rubber button pad (made from medicine-jar stoppers or the disposable irrigating syringe rubber bulb), and through the button. Pull the tendon end into the hole in the distal phalanx and tie the suture over the button (Fig. 48.18). When using a suture anchor, insert the anchor within the drill hole, to the side. Draw the tendon into the drill hole as described but secure it by the sutures from the suture anchor. Pull the polypropylene suture out distally.
Stage 1

- Suture the distal profundus stump down to the graft with two to four simple sutures using 4-0 braided polyester suture. Test the integrity of the button by gently attempting to lift it away from the skin, to ensure that the suctions to the profundus stump did not cut the polypropylene.
- Traction on the proximal tendon graft should flex the digit to the distal palmar crease. If bowstringing occurs, a pulley may need reconstruction. Then close the skin on the digit.
- Although each step is important, this next one is especially critical—setting the proper tension. Make a slit in the distal end of the profundus stump in preparation for a Pulvertaft interweave suture (Fig. 48.19). Pull the motor tendon distally to 60% of its maximum elasticity and pull the distal tendon graft through until the finger assumes a position slightly more flexed than its normal digital stance. Note that each finger, from radial to ulnar, is slightly more flexed (Fig. 48.14).
- Using 4-0 braided polyester, suture the graft and motor tendon together with a simple or horizontal mattress suture. Then withdraw all support, place the wrist in neutral, and observe the stance of the digit. If it assumes the desired posture, a tenodesis effect is noted by flexing and extending the wrist. If the digit moves appropriately with the other fingers and returns to the proper position, the tension is correct; otherwise, tighten or loosen it.
- When properly adjusted, make two additional slits at 90° from each other and from the first slit and complete the weave and suturing. Fold the distal end of the stump around the graft (Fig. 48.19). Making the slits can be facilitated with a "tendon-braiding" forceps. Otherwise, use a #11 blade or a #64 Beaver blade with a small hemostat placed through the slit to pull through the tendon. Some surgeons wrap the lumbral muscle around this connection; we prefer not to disturb the lumbrical.
- Close the incisions in the palm. When the finger is sutured before the tension has been set, the zigzag wound is more easily closed, the corner stitches fit more readily, and you need not assume a contorted position to achieve closure.

Variations in method include other sources of tendon graft (the sagittal section of the FCR, the superficialis of the little finger, the proximal superficialis of the involved digit, and from the leg the plantaris or toe extensors). An interesting technique known as tenoplasty involves suturing the cut ends of the proximal profundus and superficialis together at the time of the initial injury (20). After a month, when this connection is healed, the proximal superficialis is divided in the wrist, drawn into the palm, threaded through the pulley system, and attached distally, thus requiring only one connection in the second stage. However, we prefer palmaris or plantaris as grafts because of their usual ease of harvesting and lack of bulk. When they are not present, the alternatives are considered.

Variations in distal insertions include suture to the profundus stump, through bone and back to tendon, and through bone onto nail or fingertip. When the tendon is brought through the tip of the finger, the tension may be readily set distally, with increased traction until the desired position is achieved. We prefer our method described above, which creates fewer problems with nail growth disturbance or irregularity in the digital pad contour.

TWO-STAGE TENDON GRAFTING

Two-stage tendon grafting is a salvage procedure based on the concept that the first stage reconstructs the bed and the pulley system, and the second replaces the tendon (11,25).

Stage 1

- Place a silicone tube (Carroll (1) or a silicone or silicone-dacron rod (Hunter-Swanson or Hunter) (11), shaped like a tendon, into the digit, permitting a pseudosheath to form around the rod. Fix the rod distally and leave it unattached proximally, either at the palm or wrist level. We prefer the silicone-dacron Hunter rod and discuss this method below. The first stage of the procedure is usually performed under brachial plexus block anesthesia.
- Expose the digit through an extended Bruner incision from the profundus insertion to the palm and through a curvilinear incision in the wrist. The exposure in the hand is the same as in one-stage grafting.
- Preserve the distal profundus stump of about 1.5 cm as well as the tenodesis effect of the distal end of the superficialis. Preserve or rebuild the pulleys and carry exposure to the palm.
- Remove other residual bits of tendon by sharp excision with a Beaver blade (#64). Local scar tissue may be used to fashion a tunnel where the old pulley system was once located (Fig. 48.20). Preserve or create pulleys at the base of the proximal phalanx, over the PIP joint, and in the mid–middle phalanx.

In the wrist, locate the profundus to the involved digit, leave it attached distally to the lumbral to maintain its resting length, and tag it in the wrist with a colored button. The suture has been placed through the nail for postoperative therapy.
suture. The superficialis tendon is usually withdrawn into the wrist and excised; sagittal strips of it may be used for pulley reconstruction.

- Apply distal traction to the profundus at the wrist level to determine its elasticity, which should be equal to that of the uninvolved adjacent profundus tendons. If it has lost its elasticity because of severe myostatic contracture, the superficialis is left adhered in the palm, tested, and, if adequate, tagged as the future motor. If neither is adequate, choose and tag an adjacent superficialis.

- Select a tendon rod of appropriate width; usually a size 4 or 5 is correct for the digits, with the wider 5 needed for thumbs and the 3 for little fingers, smaller people, or children. The rod should fill the proposed sheath but move easily through it. It must also be large enough to create an adequate pseudosheath for the future tendon graft.

- Maintain the rod under saline or antibiotic solution in saline until usage to avoid lint accumulation. Handle primarily with smooth instruments or wet gloves. Pass the pointed end of the rod through the digital sheath from distal to proximal to the palm level. Then pass a long hemostat or Kelly clamp just palmar to the profundus and below the superficialis tendons (dorsal to them) through the carpal tunnel (usually on the proposed motor tendon) to the palm to the lumbilical level.

- Grasp the rod and draw it into the wrist. Distally, place the end of the rod snugly under the profundus stump and suture it securely with four simple or horizontal mattress stitches of braided polyester (Fig. 48.21). If a profundus stump is unavailable, alternatives include suture to periosteum or use of a special rod that has a screw attached that can be fixed to the distal phalanx.

**Figure 48.21.** The tendon rod is sutured under the old profundus stump. A: Lateral view. B: Anteroposterior view. C: Clinical photograph.

- With traction applied to the rod, the finger should flex to the distal palmar crease without bowstringing. Using a large hemostat, open the space palmar to the profundus at the distal forearm. The proximal end of the rod fits into this space (Fig. 46.22).

**Figure 48.22.** Tendon rod in first stage of two-stage tendon grafting. The tendon rod is sewn under the profundus stump but lies free in the wrist, under the superficialis and on the profundus. The proximal pulley is drawn somewhat too distally.

- Test passive motion of the finger in full flexion and extension to determine if there is any buckling in the digit or the wrist. Extra length of rod in the wrist can be excised. In the palm, a bridge or pulley can be loosened to prevent buckling or a new pulley reconstructed. If buckling persists after skin closure, erosion of the rod through the skin can occur.

**Pulley Reconstruction**

Reconstruction is often required. It may also be needed during acute repair or one-stage grafting and in or after tenolysis. Our preferred technique is that described by Kleinert and attributed to Weilby (12). Other methods (for example, that of Lister) can also be used (14). Use the residual base of the annular ligaments and underlying periosteum, along with a long narrow strip of tendon. If superficialis is used, create a sagittal strip about one-eighth the width of the tendon, several inches long.

- Make a slit through the remnant of the annular ligament on either side of the rod using a #64 Beaver blade or a #11 blade, and place the tips of a cardiovascular hemostat through the slit to grasp the tendon. Draw the tendon over the rod and down through the opposite slit.

- Make several more pairs of slits distally. Criss-cross the tendon over the rod and through the slits, like a shoelace through eyelets.

- Finally, cinch the lacing (pulley) tight enough to eliminate bowstringing and yet loose enough to allow passage of the rod during passive range of motion.

- Pass the tendon ends through themselves or through proximal criss-crosses and suture them.

The technique is effective for immediate use without healing, owing to the friction of the interweave and passage through the slits (Fig. 48.23). A simple pulley reconstruction, particularly applicable to the A3 area, over the PIP joint, involves the use of one residual slip of superficialis left attached distally, with the proximal end woven through or sutured to the annular ligament remnant (Fig. 45.24).

**Figure 48.23.** Building the pulley using the remnant of the old annular ligament system and a strip of tendon; method described by Kleinert and attributed to Weilby. A: Artist’s rendition. B: Clinical photograph of pulley built over a tendon rod.

---

- The superficialis tendon is usually withdrawn into the wrist and excised; sagittal strips of it may be used for pulley reconstruction.
- Apply distal traction to the profundus at the wrist level to determine its elasticity, which should be equal to that of the uninvolved adjacent profundus tendons. If it has lost its elasticity because of severe myostatic contracture, the superficialis is left adhered in the palm, tested, and, if adequate, tagged as the future motor. If neither is adequate, choose and tag an adjacent superficialis.
- Select a tendon rod of appropriate width; usually a size 4 or 5 is correct for the digits, with the wider 5 needed for thumbs and the 3 for little fingers, smaller people, or children. The rod should fill the proposed sheath but move easily through it. It must also be large enough to create an adequate pseudosheath for the future tendon graft.
- Maintain the rod under saline or antibiotic solution in saline until usage to avoid lint accumulation. Handle primarily with smooth instruments or wet gloves. Pass the pointed end of the rod through the digital sheath from distal to proximal to the palm level. Then pass a long hemostat or Kelly clamp just palmar to the profundus and below the superficialis tendons (dorsal to them) through the carpal tunnel (usually on the proposed motor tendon) to the palm to the lumbilical level.
- Grasp the rod and draw it into the wrist. Distally, place the end of the rod snugly under the profundus stump and suture it securely with four simple or horizontal mattress stitches of braided polyester (Fig. 48.21). If a profundus stump is unavailable, alternatives include suture to periosteum or use of a special rod that has a screw attached that can be fixed to the distal phalanx.
Interval between Stages 1 and 2

In the interval between stages, move the tendon rod back and forth with passive range of motion of the digit. This can be done with passive range using the opposite hand to move the digit through its range or by trapping the digit using adjacent fingers to draw it into flexion. The intact extensor mechanism extends the digit. If a capsulotomy or use of an artificial joint are accompanied placement of the extensor rod, use dynamic splinting. This may include a low-profile extensor-assist splint or band alternating with flexor-assist rubber band or thread devices or individual spring-loaded assistive joint extenders, flexors, and adjustable static devices. The hand therapist plays a very significant role in helping the patient to achieve a maximum range at this point. The maximum attainable range, actively, after the second stage will be no more than that achieved passively at this time.

Leave the rod in place for about 2 months, possibly 3, to achieve a good pseudosheath, which is also soft, sheer, and flexible. Do not maintain the rod in place beyond this time as it may lead to a thicker, fibrous, less flexible pseudosheath with a poorer result.

Before proceeding with stage 2, take tendon rod films to be certain that the distal end of the rod is in place, buckling is absent, and the excursion of the rod is 1 cm or more. If these criteria are not met, stage 1 may need to be revised. It is not unheard of for the distal end of the rod to break loose and piston into the wrist (25). Obtain anteroposterior and lateral views of the hand and forearm (fingertips to midforearm) in full extension and full passive flexion of the involved digit. To determine excursion, measure the proximal tip of the rod from any fixed bony landmark. Assuming all is well, proceed to stage 2.

The most common problem in stage 1 is achieving good range of motion. This is essential, however, so do not proceed without it. Occasionally, an inflammatory reaction may occur because of the rod or lint, and so on. Prescribe rest, immobilization, and antibiotics and antiinflammatorities for 10 to 14 days. If the problem resolves, resume therapy. If not, consider reexploration, rod removal, and debridement. If infection exists, use suction-irrigation and systemic antibiotics to clear the digit and attempt rerodding later. Most attempts at repeat tendon reconstruction are unsuccessful, however, and other approaches, such as fusions or amputation, may be indicated. If only inflammation occurs, it may be caused by lint contamination, and another attempt at rodding is warranted.

Stage 2

The second stage of this procedure is relatively straightforward for the experienced surgeon. Add the free tendon graft, connecting it properly at either end. In fact, these steps are identical to those used in one-stage grafting. Unfortunately, there are pitfalls peculiar to this stage.

- Perform the procedure under general anesthesia with the arm and a leg prepped (usually the contralateral leg, so a second team can take the plantaris tendon graft unencumbered).
- Locate the plantaris with a short transverse incision made over the medial edge of the Achilles tendon, about four fingertips above the tip of the medial malleolus, and, if you encounter the distally, the tendon may be located behind it. It is generally absent or deficient about 14% of the time. Assuming it is present and not hypoplastic, make a second incision, divide the tendon, and withdraw it into the proximal wound.
- Split the fascia proximally and place the ring of a Brand tendon stripper over the tendon, which is grasped through the ring with a hemostat.
- With the leg straight and level (usually resting on two folded towels), advance the stripper slowly with a twisting motion of the fingertips while the tendon is held relatively taut. There is one interval, as the stripper passes between the gastrocnemius and the soleus, where progress is slow, be patient so that you do not prematurely cut the tendon.
- Advance the stripper to the musculotendinous junction, avulse the tendon, and deliver it. Debride muscle and paratenon, but do not remove paratenon compulsively.

If the plantaris is not present or adequate, we prefer to use a toe extensor. If one is grafting for a little finger, only to the superficialis insertion (see the discussion below on salvage), or to a thumb, a palmaris may be long enough. It is easy enough, in the absence of the plantaris, to take the palmaris, and measure it (on the surface) before proceeding with the toe extensor, which is more difficult to harvest and can result in more morbidity.

The advantage of the toe extensors is that they are always present and are long enough. The extensor brevis substitutes for the communis in the foot. The disadvantages are the interconnections between the tendons under the extensor retinaculum and proximally, which make it impossible to harvest a smooth, unblemished tendon, and it takes time to deliver the specimen.

- Begin with a transverse incision, just proximal to the level of the metatarsophalangeal joint over the prominent tendon. The fifth is not used, as there is no extensor brevis. We find that the third and fourth usually are easiest to harvest.
- Locate the extensor brevis tendon and suture it to the longus, which is then divided proximally. With traction on the cut end, identify the tendon proximally and make a second transverse incision.
- With the fascia divided, pass a hemostat distally over the exposed proximal tendon to the distal wound, where the cut end is grasped and the tendon delivered retrograde into the proximal wound. Continue proximally until an adequate length is obtained. The maneuver is easy distally, but proximally the tendon must be separated from its mates. This is done partly by peeling the tendon from the others and partly by cutting with a scissors. Close-interval incisions proximally will facilitate this activity.
- Apply a bulky elastic dressing to the leg and foot for about 2 weeks.
- On the upper extremity, open the curvilinear incision on the wrist, exposing the tagged motor tendon and the proximal end of the rod. Again test the motor for elasticity; another motor can still be used.
- Remove the pseudosheath from the end of the rod and expose the incision over the distal end of the rod. We prefer to open the old zigzag, as a midlateral in a scarred finger at this point is more likely to injure digital nerve branches. Note the sutures taken through the profundus stump; locate the proximal extent of the stump and carefully lift the stump away from the underlying rod as the sutures are cut. Do not damage the pseudosheath under the rod or the palmar plate.
- A difference in the shade of the white palmar plate and the more opalescent pseudosheath distally over the bone should be apparent. Take the pseudosheath just distal to the plate off the bone with a No. 64 Beaver blade and drill a hole with a 1/32-in. bit through the palmar cortex (as with the one-stage graft). Make two more holes on either side with 0.045-in., pins, from inside the hole through the dorsal cortex, to emerge proximal to the nail and the germinal matrix.
- Suture the tendon graft to the rod proximally and pull it through the pseudosheath (Fig. 48.25). If the tendon pulls free, simply reinsert the rod through the pseudosheath.

- Place a hemostat on the proximal tendon and place a weave stitch (usually a Bunnell type) through the distal end with 3-0 polypropylene on milliner's needles, which are then placed through the drill holes to be tied over the dorsal button and button pad (Fig. 48.18). Draw the tendon snugly into the bone before tying the suture.
- Secure the graft to the residual profundus stump with safely stitches of 4-0 braided polyester suture. With traction on the proximal tendon, the digit should fully flex or do so to the extent achieved with passive motion.

---

**Figure 48.24.** Pulley built with remaining distal slip of supercilials, placed through and sutured to the remnant of the annular ligament. (Modified from Schneider LH, Hunter JM. Flexor Tendons—Late Reconstruction. In: Green DP, ed. Operative Hand Surgery. New York: Churchill-Livingstone, 1982:1425.)

**Figure 48.25.** Stage-2 tendon grafting. The tendon graft is attached to the rod, which is then drawn out of the hand distally, pulling the tendon through the pseudosheath. A: Clinical photograph of tendon graft sutured to the rod. B: Illustration of graft about to be drawn into the hand.
TENDON GRAFTING FOR THE FDP WITH AN INTACT FDS

Ideally, of course, if a profundus is lacerated and the superficialis is intact, the cut tendon is repaired. If, however, the injury is unrecognized or the repair has ruptured, the surgeon may be faced with a finger that functions well with full mobility at the MP and PIP joints, but which is not flail. The dilemma is whether to maintain full functional PIP motion, sacrificing DIP motion, stabilizing the tip in some way, or to risk the excellent motion; that is, to compromise the superficialis’ full function for the sake of some DIP control. Nongrafting measures are tenodesis or arthrodesis of the DIP joint.

HINTS AND TRICKS

- The potential problems with this stage of the procedure include detachment of the graft proximally or distally or both, rupture of the graft, adhesion to the sheath, and a flexion contracture of the DIP joint.
- To avoid rupture of the graft or pulling out of the suture distally, take an adequate graft; do not accept a graft of too-small diameter or one with iatrogenic defects. If the graft is detached from the hypotenar, it is not worth the hypotenar to harvest the too-elastic graft. It is not worth the hypotenar if the graft can be harvested from the base of the middle finger. If the graft is detached from the hypothenar, it is not worth the hypothenar if the graft can be harvested from the base of the middle finger.
- To confirm the integrity of the proximal polypropylene suture, test that the safety stitches have not cut it by gently lifting the button, making sure it is springy, and applying traction to the proximal tendon. Starting the polypropylene weave distally no more than 1.0 to 1.5 cm from the end of the graft is usually safe. The proximal attachment is usually safe with a three-slit interweave. Adhesion in the sheath should not be a problem if the motor muscle-tendon unit is elastic and has good excursion, the pseudo sheath is not thick and fibrous, and rehabilitation is appropriate. If the proximal attachment is in the forearm and not the carpometacarpal joint, the adhesions at this site can be worked out with activity.
- A flexion contracture at the DIP joint remains an enigma. Avoiding iatrogenic damage to the palmar plate and attending to the problem with therapy are obvious. Pseudosheath contracture may be a factor. Two additional controllable factors may be preserving the A5 pulley and placing the tendon insertion just distal to the palmar plate, not further distal on the distal phalanx.

- With attention to all these factors, flexion contracture of the DIP joint still occurs in some patients, and although the digit is functional, its appearance is compromised. An arthrodesis of the DIP joint is the solution in severe cases.

The goal is to prevent giving way or hyperextension of the DIP joint during pinch or grasp. In some cases, a tenodesis may already exist from adhesions of the profundus across the DIP joint. It may be sacrificed to be revascularized surgically by suturing the profundus stump down to the sheath, residual annular ligament, and peristeme. Pin the joint for 1 month and then mobilize. The position of immobilization is in 5° to 10° of flexion for the digits and in 0° or neutral for the interphalangeal joint of the thumb. Thermally, the digits are increasingly mobilized across the hand from radial to ulnar, allowing grip to the distal palmar crease. In reality, this is unnecessary for strength if the joint is stable. A flexed or a hooked finger is undesirable functionally and cosmetically.

Our problem with tenodesis is the stretching out of some and the further contraction of others. With these problems in mind, we prefer arthrodesis, which can be done in a variety of ways.

Tenolysis is indicated when active motion fails to equal the passive range and it is determined that this is caused by tendon adhesion or block. The extent of full motion required for functional status depends on the patient’s actual requirements and wishes and a realistic expectation of the results of surgery. A thumb, for example, that can pinch well to all the digits, particularly to the index and long fingers, but does not flex to the distal palmar crease proximal to the little finger is not disabled by most criteria. However, a digit that does not flex to the palm and defunctionalizes all the others as well (quadriga) is very disabling. The musician, specifically a string player such as a violinist or cellist, may be significantly more disabled than a keyboard player with the same loss of range. Therefore, the decision to perform a tenolysis must be individualized.

Timing is also important. It takes time to maximally mobilize a digit and for the tendon to be revascularized. Two complications of tenolysis are failure to maintain gliding and rupture of the repair. Premature tenolysis may well be the cause of the latter. At least 4 months should elapse after repair before tenolysis to allow adequate revascularization of the tendon so that it can tolerate the procedure. The contraindication to tenolysis—too-extensive adhesions—is discussed below.

Tenolysis is a potentially formidable procedure. The results are directly proportional to the extent of the adhesions. If there is a small “spot weld,” subsequent full function can be expected, and the extent of the passive motion (may be anticipated. If the adhesions are extensive and there will be multiple healing or raw areas, the likelihood of success is nil. The amount of the initial trauma, particularly the number of tissues injured (bone, sheath, tendon, vessels, etc.) and the extent proximally and distally of damaged structures, determines the density of the adhesions in many cases. However, a simple tendon laceration, with or without infection, may result in multiple adhesions for a considerable distance.

Our approach is to tenolize if the adhesions are limited or if there is a history of infection and to use two-stage tendon grafting (rod insertion) if the adhesions are extensive from trauma.

Many surgeons perform tenolysis under local anesthesia, preferring the patient to begin active mobilization immediately. We prefer to do the procedure under regional block. Therapy may be initiated with the block still in effect, and continuous passive motion seems to be helpful, particularly in controlling discomfort. Continuous passive motion is especially indicated if capsulitis is also performed. Leaving an indwelling catheter in the palm around the digital nerves, or around the median or ulnar nerve (if this is adequate), for the injection of a long-acting anesthetic is a valuable adjunct postoperatively.

The surgical technique consists of sharply releasing the adherent scar through generous incisions, as needed. The more incisions needed, the more postoperative scarring, of course. If pulleys need to be removed, they must be rebuilt. Usually tenolysis is first performed, the digit rehabilitated, and then the pulley rebuilt to eliminate the unsightly, uncomfortable bowstringing in a later operation. Using the surgical technique described earlier for constructing pulleys, immediate construction can be undertaken.

- Investigate the site of the initial trauma or surgery, extending in either direction to open the sheath and determine whether the tendon is free. Remove adherent sheath, using a Beaver knife blade and Penfield elevators (usually #4) for the dissection.

- Release the motor tendon from its distal attachment at the wrist crease level.
- Close the incision on the digit and attach the graft to the motor tendon at the proper tension, using the Pulvertaft interweave stitch (see one-stage graft technique, above). Again, this is achieved by making a slit in the motor tendon, which has been pulled up to 60% of its elastic length, and pulling the graft through until the tension is equal to the normal stance position relative to the other digits.
- After the first trial stitch, test the position with the tenodesis maneuver, flexing and extending the wrist. If the digit moves with the other fingers and then, with the wrist in neutral, achieves the proper digital stance, make two additional slits in the motor tendon and complete the interweave.
- Rehabilitation is described below. Immobilize in a bulky dressing with the wrist flexed 30°, the MP joints in 75° to 90° of flexion, and the interphalangeals toward extension (the intrinsic-plus position). Apply the bulky dressing with a posterior plaster splint above the elbow initially, to ensure elevation.
If the release seems sufficient, particularly if the digit only is involved, make an additional incision in the palm at the lumbrical level and apply traction to pull the tendons proximally. If motion is full with each tendon, apply traction distally to ensure the tendons glide well through the carpal tunnel.

POSTOPERATIVE CARE

Obstacles to successful rehabilitation following flexor tendon repair include the potential for rupture, adherence of the tendon to surrounding tissues, and joint contractures. Philosophies of postoperative management vary along a continuum from 3 to 4 weeks of complete immobilization, with the intent of minimizing the risk of rupture, to very early protected active mobilization, with emphasis on minimizing tendon adherence and joint contracture. Although controlled clinical studies are few, recent research definitely lends support to the concept of at least early passive mobilization.

Figure 48.26. Postoperative passive motion regimen described by Duran. A,B: With the proximal interphalangeal joint maintained in a flexed position, the distal interphalangeal joint is flexed and fully extended. C,D: With the distal interphalangeal joint maintained in flexed position, the proximal interphalangeal joint is carefully exercised. Both activities create gentle passive motion of tendons, promoting both strong healing and gliding.

Many variables must be considered in determining the best method of management for each patient. The degree of trauma and surgical technique will influence the strength of the repair and the degree of scarring. The experience and skill of the therapist are critical factors in the delicate balance between protection and mobilization during the early postoperative weeks. Consider the patient's behavior, attitude, and intelligence in terms of his or her ability to comprehend and implement instructions, degree of motivation, reliability, and availability for follow-up. Currently we use an early protected motion program.

PRIMARY REPAIRS

Although the potential for dense tendon adherence is greater in zones 2 and 4, where there is less yielding adjacent tissue and more confined space, early protected motion management is used for all zones.

Day 1

Using a bulky dressing, position the wrist at 30° flexion and the MP joints in 70° to 90° flexion. Allow full active interphalangeal extension. Elevate the extremity to control edema.

Attach elastic traction to a nail suture inserted at the time of surgery and proximally about 8 cm proximal to the palmar wrist crease. Tension should be adjusted to maintain the involved digits in a flexed position at rest yet allow full active interphalangeal extension.

Figure 48.27. Suture loops through nails for postoperative controlled passive motion method of Kleinert.

Instruct the patient to actively extend the interphalangeal joint fully 5 to 10 times every hour. If extension is difficult or painful, the patient may need to pull the traction distally with the other hand while extending to facilitate full active extension, then release slowly to return the finger passively to the flexed position.

Problems and Variations Among the problems that may occur are:

- No nail suture or loss of nail suture.
- Pain or apprehension limiting full, active interphalangeal extension.
- Inadequate fit of bulky dressing, allowing some MP extension as the patient attempts to extend the interphalangeals.
- Swelling, relieved by elevation and use of a compression wrap.
- Interphalangeal flexion contractures.

Days 3 to 7

Remove the bulky dressing and redress the hand in a light dressing. Place it in a thermoplastic splint with dorsal extension to the fingertips and joint positions maintained. Add a palmar piece to contour the palmar arch, ensuring stable positioning of the dorsum of the hand in the splint. Otherwise, the splint may tend to slip, and as the patient extends the interphalangeal joints, the dorsum of the hand may pull away from the splint, resulting in MP extension rather than full interphalangeal extension. Use Velfoam straps (2-inch) to the forearm and wrist, with a 1-inch strap across the palmar piece if necessary. Attach a pulley to the palmar piece. Attach nylon cord to the nail suture, run it through the pulley, and attach it to elastic traction. Attach the elastic to a safety pin on the proximal splint strap. The nylon should be just long enough so that the elastic does not catch on the pulley during active extension.
Continue elevation of the hand as well as compression wraps for the hand and digits if necessary to control edema. Continue the same exercises, with emphasis on full interphalangeal extension. Manage early flexion contractures with careful, gentle assistive extension of the involved joint with the proximal and distal joints flexed. See the patient twice a week if possible to ensure maintenance of positioning and good progress. This stage may be delayed at the discretion of the surgeon if there is excessive trauma or a tenuous repair.

Three Weeks

At 3 weeks, change the wrist splint position to neutral. Continue traction and the exercise program, adding an active flexion hold after the digit is passively flexed fully five times per hour. This step requires maximum tendon excursion without maximum tensile loading that results with active flexion from the fully extended position.

Problems and Variations If impending flexion contractures of the interphalangeal joints are noted, discontinue elastic traction at night and use a static extension strap to the dorsal extension of the splint, extending the PIP only. A static aluminum splint may be used for the PIP or DIP, but it must be directed to one joint only to avoid tendon tension. If soft-tissue contracture appears likely at the MP because of the level of injury, maintain the wrist at 30° flexion and increase MP extension to 40° to 45°.

Instruct the rehabilitation staff to discuss program changes with the surgeon if any question exists about the status of the patient. Very free joint mobility and tendon excursion may indicate minimal scarring, but the tendon may be more vulnerable to rupture.

Five Weeks

Discontinue the splint but continue traction to a wrist cuff. Allow full active wrist and digit motion, but with protection from full tendon tension because of a tenodesis effect. Begin joint blocking with the wrist and MP joints in neutral, along with full active flexion from the extended position, 10 times per hour. Dynamic flexion splinting can be added if necessary. Static individual joint extension splinting with the adjacent joints neutral or flexed may be indicated by lack of progress with active and assistive exercise alone.

Problems and Variations If wrist extension is limited significantly, or in the presence of MP or interphalangeal flexion contractures, continue neutral wrist splinting without traction. Remove the splint for exercise.

Six Weeks

Discontinue traction and continue exercise as at 5 weeks, but the wrist and digits may be extended simultaneously. Add individual dynamic joint extension splinting, if indicated, with the wrist neutral.

Eight to 12 Weeks

Full dynamic extension splinting may be added at 8 weeks if necessary. Add graded resistive exercise and activity at 10 weeks. By 12 weeks the patient may return to full activity.

Care of the Thumb

Postoperative management of primary flexor tendon repairs of the thumb is similar to that of the fingers, with the following exceptions:

- The wrist is flexed 30° to 35°.
- The thumb carpometacarpal joint is held in palmar abduction.
- The MP joint is in flexion, with elastic traction attached to the nail via a nylon cord run through the same type of palmar pulley as described for the fingers.

When full active flexion is initiated, in addition to joint blocking and opposition exercises, full tendon excursion is encouraged by full active extension of the carpometacarpal, MP, and interphalangeal, followed by flexion of the thumb toward the base of the little finger.

Precautions

Caution the patient during the first five postoperative weeks against attempted use of the uninvolved digits, as contraction of the FDS and FDP, particularly against resistance, may stress the repaired tendon. Close follow-up is essential for success. If positioning is lost, exercise techniques are incorrect, or adjustments are not made for impending contractures, the results will not be optimal.

TENOLYSIS

Postoperatively the primary goal is to maintain the degree of excursion of the lysed tendon achieved at surgery. Consider carefully all factors pertaining to each patient's clinical situation, including the patient's history, previous surgery, and preoperative status, the condition of the tendon, and the status of the pulley system. Excessive edema or pain, diminished vascularity from previous injury or surgery, previous infections, and poor tendon quality and pulley reconstruction are all factors that may require modification of postoperative care to achieve the maximum potential without complications.

Twelve to 24 Hours

Remove the bulky dressing and redress the wrist with Xeroform (Sherwood Medical, St. Louis, MO) and 4-inch stretch gauze bandages, using sterile technique. For pain control use TENS or an indwelling catheter with a 0.5% bupivacaine (Marcaine) injection before therapy. Control edema with elevation and a compression wrap if necessary.

With the wrist in neutral, perform joint blocking to isolate the flexor digitorum profundus and flexor digitorum superficialis 10 times each hour. Also with the wrist neutral, passively flex the involved digits, then ask the patient to actively maintain the position. Remove the passive force while the patient continues to hold. This is followed with active extension, and the patient repeats the exercise 10 times hourly. This requires maximum flexor and extensor excursion while reducing tensile loading of the lysed tendon.

See the patient three to five times per week to encourage exercise despite pain, with the goal of an active range of motion that is equal to the passive range. Achieving this goal within the first 2 weeks is critical. Measure joint range of motion, total active range of motion, and total passive motion twice weekly to monitor progress.
Splinting at night and between exercise sessions varies, depending on the tendency toward joint stiffness or the difficulty the patient has in initiating motion from either a flexed or extended position. Dynamic or static flexion is indicated if there is difficulty regaining preoperative passive flexion, or if active flexion is difficult and active extension is easily achieved. Gentle static individual joint extension splinting is helpful in the presence of impeding flexion contractions. Discomfort may be minimized by using a static wrist support in neutral position. Delay full dynamic extension splints that fully stress the lysed tendon until 2 to 6 weeks, depending on tendon status.

Two Weeks

Remove sutures and begin skin debridement and lubrication and scar-remodeling techniques. Scar massage and elastomer molds help soften and flatten dense elevated or adherent scars. Continue to emphasize exercise, adding joint blocking and full flexion and extension of the digits with the wrist in a dorsiflexed position.

Six to 12 Weeks

Begin graded resistive exercise at 6 weeks. By 8 to 12 weeks the patient may return to full activity, including heavy work.

If the tendon is of poor quality after tenolysis, additional protection may be required. Fit the patient with a dorsal protective splint, maintaining the wrist and MP joints in flexion to protect the lysed tendon. Elastic traction, as described, with primary tendon repairs may be applied until 4 weeks postoperatively. Limit active exercise to progressively flexing the involved digits; then ask the patient to actively maintain the position while the passive force is removed. This may be followed with full active extension within the protection of the splint, and will achieve the goal of maximum flexor excursion while reducing the potential risk of rupture.

Continuous passive motion devices and protocols, noted earlier, remain investigational. Their use following tenolysis, particularly when capsulectomy was also required, appears beneficial, but active motion with proximal blocking is also necessary, as with the standard technique.

STAGED FLEXOR TENDON RECONSTRUCTION

Postoperative Goals

The goal in stage 1 is to maximize joint mobility and soft-tissue pliability during new sheath formation around the implant. In stage 2, the goal is to restore passive mobility and achieve a gliding graft within the pseudosheath for optimum active mobility.

Precautions

Stage 1 Synovitis may occur, usually within 6 weeks postoperatively, as a result of implant surface contaminants, buckling of the implant, or overzealous therapy. This can usually be avoided with careful handling of the implant, appropriate pulley reconstruction at surgery, and careful postoperative management. Synovitis is characterized by discomfort in the operated digit and swelling with no signs of systemic illness. It is treated with immediate rest and immobilization. Concurrent procedures such as capsulectomy require specific management, but in harmony with the overall plan. Immediate postoperative dynamic splinting may be indicated if capsulectomies have been performed.

Stage 2 Complications include adhesions along the graft or at the proximal attachment and rupture of the graft. If it is apparent that adhesions are limiting motion during the first 5 weeks after the second stage (as indicated by the absence of gradual improvement of active motion in the protected position at serial evaluations), earlier active motion and less protective splinting may be indicated.

Absence of a nail suture following stage 2 may be dealt with by gluing hook velcro or a dress hook to a nail or by constructing a moleskin sling 3 in. long and ½ in. wide with an eyedlet midway. Apply tincture of benzonat to the lateral aspects of the finger to facilitate adherence and attach the two ends of the sling to the dorsolateral aspect of the distal phalanx. This is then attached to rubber-band traction.

Either Stage Pulley reconstruction may be a problem. Because stage 1 involved a passive gliding implant, there is no tension on the reconstructed pulleys. Pulley reconstruction at the time of tendon grafting may require protection of the pulleys for 6 weeks postoperatively, with either ½-in. paper tape or Orthoplast rings over the reconstructed pulley.

Flexor Digitorum Superficialis Finger Therapy is directed to the PIP joint with appropriate protection of the DIP, which will have been either tenodesed or fused.

Stage 1 Postoperative Management

One to 2 Weeks Remove the bulky dressing and redress with Xeroform and Kling bandages, using sterile technique. Splint the wrist in neutral if needed for comfort at night and between exercises. Control edema. Initiate active and assistive range-of-motion exercises for the uninvolved joints. Begin passive range of motion for individual involved joints and total flexion and extension with the wrist in neutral. Use buddy taping as well as static splinting for joint contractions.

Two to 6 Weeks Remove the protective splint and sutures. Soft-tissue management includes debridement, lubrication, and scar-remodeling techniques. Begin more aggressive range of motion and trapping and add dynamic or static splinting for joint or soft-tissue contractures. By 8 weeks the implant should glide without complication. Continue passive mobility techniques as indicated. The patient may return to work until stage 2 if the wrist is doing well.

Stage 2 Postoperative Management

Options include immobilization for 3 to 4 weeks, followed by protected active and passive flexion and extension until 6 weeks. Allow dynamic extension at 6 to 8 weeks and resistive exercise at 8 to 12 weeks. Early controlled passive motion can be initiated, as for primary flexor tendon repair.

PITFALLS AND COMPLICATIONS

Muscle–tendon units exist to move joints through their full range of motion. If, after injury and repair or reconstruction, this basic function is not restored, the source of the problem must be determined. Simply put, the muscle must function, the motor–tendon unit must be intact, and the tendon must glide. At times, loss of the normal mechanical advantage is a potential problem, as in the rheumatoid with extensor tendon subluxation, or a pulley may be lost, lessening the effective motion.

Certainly, loss of muscle function may occur from denervation at the time of injury or from loss of vascularity leading to fibrosis and ischemic contracture. Myostatic contracture and atrophy of disuse may also occur. Surface palpation of muscle contracture, elasticity of the muscle–tendon unit, and electrical studies (EMG) will help in these determinations.

In most cases, however, failure of functional gliding results from adhesion formation, disruption of the repair, or both. The intact gliding tendon can be demonstrated with the tenodesis effect (flexing and extending the wrist, which produces the reciprocal motion in the digits) or with the forearm squeeze test to demonstrate digital flexion.

Dehiscence of the repair can occur when excessive muscle contraction is allowed during emergence from anesthesia or early in the postoperative course. All methods of postoperative rehabilitation attempt to avoid this. Even if the suture slips only a little, the resultant gap in a repair may result in flexor lag (the muscle contraction is used up before full motion is achieved, and active motion does not equal passive) and in excessive achieved formation. This situation may be suspected if the resting posture or stance position of the digit is more extended than appropriate (Fig. 48.29). A complete rupture may actually be in continuity with pseudotendon in the gap. Some active motion is seen, fooling the surgeon into thinking that the problem is adhesion. At reexploration, an intact, even gliding tendon can be seen. It is easy to fail to note the opalescent appearance of the interposing pseudotendon and to appreciate that the extended position of the digit represents an actual rupture with gap formation. In one-stage tendon grafting, gapping distal to the lumbrical leads to an overly long distal tendon, overpull of the lumbrical, and the “lumbrical syndrome” finger. In the latter, as the digit is flexed at the MP joints, the interphalangeals extend.
Treatment of the ruptured repair or graft depends on how rapidly the problem is detected. With a repair, if the rupture is quickly detected, it is entirely appropriate to reenter the digit and redo the repair. The same is true for the graft. Late recognition of the ruptured tendon repair usually requires a graft, often with two stages, as scarring may be extensive.

The tendon graft may rupture in midsubstance or pull loose at either end. Proximal disruptions with the interweave are relatively rare, and midsubstance ruptures (discussed under the section on two-stage grafting) are often predictable, although uncommon. Pulling out of the insertion is the usual problem. Reininsertion is difficult, as there is no extra tendon to work with. If the pulley-sheath system can be easily reopened or was never closed (as demonstrated by passing a tendon rod), immediately repeat the second stage with a new graft. A transfer motor or an entire transfer unit of a superficialis for the thumb or little finger may now be appropriate. If the sheath cannot be readily opened, return to the beginning of stage 1. On one occasion, after a patient had suffered two successive distal pullouts, a new insertion technique was devised by drilling transversely across the distal phalanx and inserting the tendon through the bone before suturing it back to itself. This was successful but is not routinely needed.

Adherence of the tendon is determined by a gliding tendon with insufficient active excursion. This problem was discussed under tenolysis and two-stage grafting. It may be associated with partial rupture, as noted. Adherence of a tendon graft, particularly in two-stage grafting, seems to be more likely with thickened fibrous pseudosheaths after prolonging stage 1 but may occur related to inflammation or infection. Tenolysis of grafts, especially two-stage ones, has not provided good results for us. Redoing the entire two-stage procedure may be worth a try. Grafting only to the superficialis insertion (crossing two digital joints rather than three) has been a salvage maneuver used by Hunter and Schneider and by us and has been successful in such two-stage failures. Apparently, the lesser demands of moving only the PIP joint makes rehabilitation easier and improves the result in these cases.

An interesting additional complication of tendon repair in zone 2, observed by us and explained by Gilbert, involved trapping of the profundus dynamically in the superficialis division. When the patient slowly flexed his digit, he could do so to the distal palmar crease. When he attempted full flexion rapidly, the profundus was trapped, and the digit fully flexed at the PIP with the DIP extended. Removing one slip of the superficialis solved the problem.

The lumbral syndrome, secondary to laxity of the one-stage graft or increased lumbrical activity with distal tendon adherence, is resolved by excision of the lumbrical or more simply by a Little intrinsic release (removing the triangular area of the radial shroud ligament where the condensation of the oblique fibers meets the main portion of the extensor mechanism on the dorsoradial aspect of the digit) (21). This simple maneuver can be done under local anesthesia. If it does not resolve the problem, more anesthesia may be given if needed and tenolysis undertaken.

Infection is truly the most unsolvable complication of tendon surgery. The infection may be cleared, but reconstructive potential is extremely limited because after infection, scarring is extensive. A tendon rod (two-stage reconstruction) is needed but is contraindicated. Reftarring of the infection is all too common. Options include tenolysis (we will extend the tolerable limits of the procedure in this circumstance); one- and two-stage grafting; joint (PIP and DIP) arthrodesis in functional positions; and amputation. The sequence of attempted reconstructions is in the order cited.

“The hand,” wrote Sterling Bunnell, “includes exact machinery of much refinement and tissues of great delicacy and specialization” (8). The extensor mechanism is a prime example of the “machinery” Bunnell was describing. Because of its subcutaneous vulnerability, it is one of the most frequently injured structures in the hand.

Many anatomists have appreciated the complexity of the extensor mechanism, among them Albinus, who presented the first detailed structural description in 1734 (46). Reconstructive surgeons who attempt surgical correction of hand dysfunction resulting from extensor tendon injury or imbalance quickly gain respect for the structure.

Intrinsic muscle abnormalities aside (see Chapter 63), the diagnosis of most extensor lesions (acute and chronic) is relatively simple. Likewise, the surgical exercise of tendon suture is not as technically demanding as it is for flexor tendons, because the extensors are primarily extrasynovial. The thin nature of the extensors within the digits, however, as well as the intimate proximity of the extensor mechanism to periosteum and bone (to which it readily adheres) and the influence of the digital extensors on the critical function of the interphalangeal joints (49,58), all contribute to potentially poor functional results following surgical treatment of extensor tendon injuries (19,20,22,23,25,36,45,51,74).

In the fingers, proximal interphalangeal (PIP) and distal interphalangeal (DIP) motion are interdependent, and lack of or excess of extension in either joint reciprocally affects the other. The swan-neck or boutonnière positions are the classic examples of this interphalangeal reciprocity (see Fig. 49.10). The entire extensor mechanism, the total digital deformity, and the lack of motion or presence of abnormal motion at each joint must be considered in planning reconstruction (13). Eaton has aptly described the extensor mechanism as a “sleeping giant which is not appreciated until it becomes disorderly or out of balance. When out of control it can create great disturbances” (17).

Figure 49.10. The dorsopalmar translation of the conjoined lateral bands is demonstrated in the two classic reciprocal digital deformities: swan-neck (top) and boutonnière (bottom). The insets are transaxial representations of the condyles of the proximal phalanx, showing the normal positions of the conjoined lateral bands in extension and flexion of the PIP joint. The abnormal positions of the conjoined lateral bands in each deformity are represented in black.

Restoring a normally functioning extensor mechanism can be more difficult than reconstructing a flexor system. A surgeon contemplating such a restorative attempt must approach the problem with complete understanding and great care. Failure to comprehend the diverse and complex structure’s functional anatomy and to appreciate the need for proper dressing and appropriate rehabilitation may contribute to poor results in extensor reconstruction, regardless of the anatomic level or the mechanism of injury (22).

This chapter is not meant to be a compendium of procedures but rather a description of principles and concepts useful for devising appropriate management for each case. The primary focus of the chapter is the finger extensor mechanism; the thumb extensor system and the wrist extensor will be discussed briefly. Table 49.1 lists abbreviations and terminology that will be used.
FUNCTIONAL ANATOMY

FINGER EXTENSOR MECHANISM

The digital extensor system consists of three joints extended by a single confluent tendinous mechanism (Fig. 49.1, Fig. 49.2) formed by the interlinkage of two separate and neurologically independent components: tendons of the extrinsic, radial-nerve-innervated muscle and tendons of the intrinsic, ulnar/median-nerve-innervated muscles.

Figure 49.1. The extensor mechanism of the wrist and dorsum of the hand. The six extensor compartments at the wrist contain (1) the abductor pollicis longus (APL) and extensor pollicis brevis (EPB); (2) the extensor carpi radialis longus (ECRL) and brevis (ECRB); (3) the extensor pollicis longus (EPL); (4) the extensor digitorum communis (EDC) II–V and extensor indicis proprius (EIP); (5) the extensor digiti quinti (EDQ); and (6) the extensor carpi ulnaris (ECU). An important anatomic detail is the presence of a synovial sheath around each tendon unit within each fibro-osseous canal. These sheaths are often involved in rheumatoid disease.

Figure 49.2. Digital extensor mechanism. A: Dorsal view. B: Lateral view.

The radially innervated extrinsic extensors contributing to the extensor mechanism, and their fingers of action, are the extensor digiti communis (EDC) (all fingers), the extensor indicis proprius (EIP) (index), and the extensor digiti quinti (EDQ) (little finger) (Fig. 49.1). While this arrangement is considered normal, subtle variations in extrinsic extensor tendon anatomy are fairly common (2,15,27,77,79,83), especially the presence or absence of a discrete separate EDC tendon to the little finger (60). After passing beneath the extensor retinaculum (69) through synovial sheaths within each extensor compartment, the extrinsic extensor tendons are interconnected by juncturae tendinum on the dorsum of the hand (66,78,80). Laceration of individual extrinsic extensor tendons proximal to the juncturae may be masked by partial metacarpophalangeal (MP) extension transmitted through the juncturae by the adjacent tendons (15,66,78,80). The juncturae tendinum may act as force vectors in the dynamic stabilization of the MP joints during flexion (1).

At the MP level, the sagittal bands (Fig. 49.2, Fig. 49.3), which act to maintain centralization of the extensor tendons, form the most proximal insertion of the extensor mechanism (37). The sagittal bands surround the metacarpal heads and insert into the MP volar plate and intervolar plate ligaments (Fig. 49.3B). The sagittal bands also prevent dorsal prolapse of the extrinsic extensor tendons during MP hyperextension (Fig. 49.4).

Figure 49.3. A: Radial sagittal band of the middle finger. There is a natural cleavage plane (through which the scissors penetrate) between the transverse fibers of the sagittal band and the oblique fibers from the lateral slip (arrows) to the central slip (CS). B: Transaxial view at the MP level of the sagittal bands and their insertion into the periphery of the volar plate (VP) and intervolar plate ligament. Note the relationship of the interossei and lumbricals to the MP axis of rotation and intervolar plate ligament.
Figure 49.4. Hand of a 39-year-old woman with systemic lupus erythematosus, treated for 20 years with oral steroids. All five extensor tendons subluxate with digital flexion. With extension, marked MP hyperextension/dorsal prolapse of the EDC tendons is present due to incompetence of the MP sagittal bands.

Attenuation or injury to the radial aspect of a sagittal band may allow subluxation of the extensor tendon into the ulnar intermetacarpal sulcus with MP flexion (36). If this subluxation is reducible, the physical finding may simply be painful snapping as the tendon moves to and fro with MP flexion or extension (Fig. 49.5) (30,33,34,58,59). If, however, the extensor tendon becomes permanently fixed palmar to the MP axis of rotation in the ulnar intermetacarpal sulcus (frequently seen in rheumatoid disease; see Chapter 70), it becomes a strong MP flexor and contributes significantly to ulnar deviation of the fingers (56).

Figure 49.5. A: Ulnar subluxation of the EDC of the middle finger (arrow) with finger flexion in an elderly patient with extremely atrophic skin. B: Reduction of the subluxation occurs with finger extension.

Because the MP joint is proximal to the zone of convergence (Fig. 49.6) of the intrinsic and extrinsic contributions to the digital extensor mechanism, these two separate and distinct systems act as antagonists at this level. The intrinsics, being palmar to the MP rotational axis, act as MP flexors; the extrinsics, being dorsal, are MP extensors (Fig. 49.2B). This paradox of action at the MP joint is a primary factor contributing to difficulty in understanding the digital extensor mechanism (17,43).

Figure 49.6. The zone of convergence of the digital extensor mechanism, which begins at about the midportion of the proximal phalanx and ends at the level of the central slip insertion into the dorsal base of the middle phalanx. Proximal to the zone of convergence, the extrinsic and intrinsic components of the extensor mechanism are separate: The central slip is extrinsic, while the lateral slips are intrinsic. Within the zone of convergence there is complete reciprocal crossover of fibers from the central slip and lateral slips. The products of the completed convergence are the central slip insertion and the conjoined lateral bands, both of which have dual muscular activity (intrinsic and extrinsic) for extension of both interphalangeal joints. PIP, proximal interphalangeal joint; TRL, transverse retinacular ligament; ORL, oblique retinacular ligament; E, extrinsic contribution to conjoined lateral bands; I, intrinsic contribution to central slip insertion.

An insertion point of the extrinsic extensor is present in the dorsal MP capsule and dorsal base of the proximal phalanx (Fig. 49.7, Fig. 49.8). Although the insertion point has been described as indifferent (17) and variable (46), it is consistently present and represents the second of the insertion points of the extensor system, the first being the sagittal bands (Fig. 49.3) (75). These two insertion points are not firmly fixed bony insertions in the pure sense, as are those at the dorsal base of the middle and distal phalanges. In fact, these insertions have an excursion approximately equal to the excursion of the central slip at the PIP joint (Table 49.2) and therefore become taut only when the PIP joint is in full extension (18).

Figure 49.7. Lateral aspect of a finger demonstrating the four insertion points of the extensor mechanism. (1) Insertion through the sagittal bands into the volar plate and intervolar plate ligament. (2) Extensor insertion into the dorsal MP joint capsule and base of the proximal phalanx. This is a loose or indifferent insertion. (3) Central slip insertion into dorsal base of middle phalanx. (4) Terminal extensor insertion into dorsal base of distal phalanx.

Figure 49.8. Extensor insertion into the dorsal MP capsule and dorsal base of the proximal phalanx (arrow). This insertion is filmy and loose and has an excursion
equal to the extensor amplitude at the PIP joint. This "insertional excursion" allows PIP and DIP flexion while the MP joint is in maximum hyperextension. With PIP extension, however, this insertion becomes taut and assists extension of the proximal phalanx (PP). MC, metacarpal.

*Note: Measurements are not necessarily accurate to correspond in detail to all phalanges, as high efficiency. See text for discussion of normal anatomy and abnormalities.*

Table 49.2. Extensor Tendon Excision

This function can be easily demonstrated in a normal finger by maintaining the MP joint in maximum hyperextension and actively flexing and extending the interphalangeal (IP) joints. A fixed insertion of the extrinsic extensor at the MP level would obviate the possibility of this maneuver. If the entire extensor mechanism is laxermed at the proximal phalangeal level (nearly the case in isolated laceration of the tendon, because of its broad convex shape, but frequently seen in dorsal guillotine-type injuries with transection of the bone), the extensor mechanism retracts only a distance equal to or less than the available insertional excursion.

The intrinsic muscle group contributing to the extensor mechanism is composed of the interossei (all ulnar-innervated), the fourth and fifth lumbricals (median-innervated), and the second and third lumbricals (median-innervated). Along the proximal phalangeal segment, the fibers of the intrinsic tendons (lateral slips) merge, winglike, into the central slip (Fig. 49.8A). This configuration explains the necessity of the triangular (wing) excision (Fig. 49.8B) in cases of intrinsic muscle contracture proposed by Littler for complete intrinsic release (41). A smaller excision or simple lateral slip tenotomy will not completely eliminate the influence of abnormal intrinsic muscle tension on the central slip and its attendant limitation of IP flexion.

![Dynamic swan-neck deformity in a professional musician with PIP volar plate laxity. The conjoined lateral bands (arrows) bowstring dorsally as the transverse retinacular ligament stretches (see Fig. 49.10). The finger is locked in extension at the PIP joint, causing occupational disability. Successful surgical treatment was flexor superficialis tenodesis of the PIP joint blocking PIP hyperextension; this allowed complete DIP extension.](image1)

At about the midportion of the proximal phalanx, the central slip begins its trifurcation. Distal to this level of trifurcation, there is free exchange of fibers from the central slip to the lateral slips and from the lateral slips to the central slip (Fig. 49.6). Distal to the anatomic zone of convergence, the central slip and conjoined lateral bands are truly a dual extensor mechanism with both intrinsic and extrinsic contributions, either (or both) of which is capable of powering active IP extension.

Fowler recognized this dual nature of the extensor assembly in 1949 (24). Even Bunnell had held a different functional view of the extensor mechanism before Fowler’s observations (D. C. Riordan, personal communication, 1987) (6,46). This duality of extensor motor power at the IP joint (29,54), plus the mechanical concept of a dynamic IP tenodesis [the oblique retinacular ligament (ORL)], forms the basis for many procedures involving redistribution of forces in IP joint extensor dysfunction (42,47,73,76).

At the PIP joint, the transverse retinacular ligaments (TRL) act to gently maintain the conjoined lateral bands within certain limits of dorsopalmar excursion (Fig. 49.26). This dorsopalmar translation of the conjoined lateral bands (Fig. 49.10) was presented in 1923 by Hauck (31). Palmar displacement of the conjoined lateral bands occurs normally with PIP flexion, allowing synchronized distal interphalangeal (DIP) flexion (85). Smooth, unrestricted DIP flexion depends on normal PIP flexion, which allows relaxation of the conjoined lateral bands and oblique retinacular ligament.

Lax PIP volar plates (VP) in some people allow DIP flexion while the PIP joint is maintained in extension (usually slight hypertension). This maneuver is possible only in people with PIP-VP laxity and normal supple intrinsic muscles. Repeating this "trick" may result in further VP laxity, stretching of the TRL, allowing further dorsal migration of the conjoined lateral bands and development of painful locking of the PIP joint in hyperextension, a dynamic swan-neck deformity (Fig. 49.10, Fig. 49.11).

![Swan-neck deformity (PIP hyperextension and DIP flexion) and the boutonnière deformity (PIP flexion and DIP hyperextension).](image2)

This phenomenon clearly illustrates the participation of the static VP in the normal and abnormal dynamics of extension. Littler has emphasized the importance of the VP as an adjunct to the dynamic process of normal digital extension (49). VP stretching or contracture also contributes to the fixed reciprocal deformities, including the swan-neck deformity (PIP hyperextension and DIP flexion) and the boutonnière deformity (PIP flexion and DIP hyperextension).

The central slip terminates in a broad, strong bony insertion at the dorsal base of the middle phalanx (Fig. 49.12). The conjoined lateral bands merge over the dorsum of the middle phalangeal segment to form the terminal extensor tendon (Fig. 49.2A), which inserts into the dorsal base of the distal phalanx (Fig. 49.13). The triangular
ligament is composed of transverse fibers between the conjoined lateral bands distal to the central slip insertion and proximal to the merging of the bands (Fig. 49.6) (37).

Figure 49.12. Broad insertion of central slip (CS) into the dorsal base of the middle phalanx. The glistening, gliding layer is seen covering the dorsal aspect of the proximal phalanx.

Figure 49.13. Bony insertion of the terminal extensor (TE) into the dorsal base of the distal phalanx. The proximal ends of the conjoined lateral bands (arrows) are visible at the PIP joint level.

The ORL may play a unique and integral role in the extensor system. The existence and biomechanical significance of the ORL in normal digits is controversial (53, 55, 65). Westbrecht illustrated this structure in 1742 and named it the retinaculum tendini longi (62). The ORL (Fig. 49.14) originates palmar to the PIP axis of rotation from the periosteum of the proximal phalanx and flexor sheath and passes dorsally and distally to join the terminal extensor tendon (63). Walsh clearly demonstrated the ORL in a prize-winning monograph in 1897 (81). Landsmeer subjected the ligament to a sophisticated dynamic analysis, and the soundness of the mechanical basis of a “dynamic interphalangeal tenodesis” concept has induced procedures designed to augment DIP extension based on active PIP extension (38, 39 and 40, 42, 73). ORL tightness may also contribute to pathologic conditions such as fixed DIP hyperextension in the boutonnière deformity and DIP extension contracture in digital Dupuytren’s disease (see Chapter 62).

Figure 49.14. The oblique retinacular ligament, elevated by the probe, originates along the proximal phalangeal periosteum and flexor sheath, passes volar to the PIP axis of rotation, and joins the terminal extensor tendon. The principle of “dynamic interphalangeal tenodesis” is based on the biomechanical fact that a structure of fixed length extending from the proximal phalanx to the distal phalanx, palmar to the PIP axis, and dorsal to the DIP axis will relax with PIP flexion and tighten with PIP extension.

Complete understanding of the extensor mechanism is elusive, but functional understanding requires only time and assimilation of many small bits of information. The complete mechanism (Table 49.3)—extrinsic and intrinsic motors, merging tendons, dynamic and static retaining ligaments, and other contributing components—when functioning normally has been described as a “fugue of motion” (J. W. Littler, personal communication, 1987).

Table 49.3. Components of the Digital Extensor System

THUMB EXTENSOR MECHANISM

The abductor pollicis longus (APL) inserting on its dorsal base and into the fascia of the thenar intrinsic muscles provides extension and abduction of the first metacarpal (Fig. 49.1). The multiple slips of this muscle–tendon unit make it very useful in reconstructive procedures at the base of the thumb (70).

The variable extensor pollicis brevis (EPB) inserts into the dorsoradial base of the proximal phalanx and the extensor pollicis longus (EPL) into the dorsal base of the
distal phalanges (Fig. 49.1). These two muscle-tendon units exert extensor influence on multiple joints: the EPB on the trapeziometacarpal joint (extension/abduction) and MP joint (extension); and the EPL on the trapeziometacarpal joint (extension/abduction), MP joint (extension), and IP joint (extension).

The intrinsics of the thumb [abductor pollicis brevis (APB), flexor pollicis brevis (FPB), and adductor pollicis (AP)] contribute to IP extension through the extensor hood at the MP joint and frequently confuse the inexperienced examiner in cases of suspected EPL laceration (48). The intact thenar intrinsics will extend the IP joint to a near-neutral position, but the diagnosis of EPL rupture or laceration is obvious if the entire thumb ray is compared with that of the uninjured thumb.

CLINICAL SIGNS

EXTENSOR LACERATION OR RUPTURE

A “dropped joint” (lack of full extension with posture in flexion) at the site of extensor muscle tendon action is the simple sign of complete extensor functional deficit (43). An MP drop is seen with extrinsic extensor laceration or rupture, a PIP drop with complete central slip laceration or rupture, and a DIP drop (mallet) with terminal extensor tendon laceration or rupture.

In the thumb, laceration of the contents of the first extensor compartment (EPB, APL) will present as flexion/adduction of the first metacarpal and a lag in full extension of the MP joint. The EPL functions as both MP and IP extensor in this situation. Isolated laceration of the EPB is rare, and repair of this tendon is optional, depending on the functional deficit at the MP joint. This lesion is frequently undiagnosed in the emergency situation because of the presence of MP extension through the intact EPL. EPL extension of the MP joint, however, will usually be incomplete when compared with that of the opposite, uninjured side. The magnitude of the MP extensor lag secondary to EPB laceration is variable, and this factor determines whether EPB repair is warranted.

Two basic patterns of EPL laceration are seen, and the presentation depends on whether the laceration site is proximal or distal to the MP joint. Proximal to the MP joint, the entire thumb ray is affected and demonstrates metacarpal adduction, incomplete MP extension, and IP extension lag (some IP extension remains, by virtue of intact thumb intrinsics). The EPL retracts significantly when lacerated proximal to the MP extensor hood, and retrieval from the synovial extensor compartment or the distal forearm may be difficult and may require a proximal counterincision.

Extensor pollicis longus laceration distal to the MP joint is simpler, easily diagnosed by consideration of the injury location and loss of IP hyperextension. The tendon cannot retract more than a few millimeters because of its attachment to the MP extensor hood. It should be repaired and treated as a sharply lacerated terminal extensor tendon of a finger (discussed later).

EXTENSOR COMPONENT TENODESIS OR CONTRACTURE

Several simple maneuvers will establish the location of restriction of gliding (tenodesis) of the extrinsics or contracture/fibrosis of the intrinsic components (Table 49.4). The level of extrinsic tenodesis is frequently made obvious by scars. Intrinsic contracture and contracture of the ORL, however, cannot be appreciated without the use of clinical tests (49).

GENERAL PRINCIPLES OF MANAGEMENT

Bunnell in 1922 was the first surgeon to enumerate the reasons for poor results after tendon surgery (7). He was primarily discussing flexor tendons, and the reasons remain valid and apply equally well to extensor tendons (Table 49.5).

The integrity of the gliding layer between the extensor mechanism and the phalanges is important. This layer is often described as peritechnostium, and indeed the deep portion of the layer is phalangeal peristeum. The superficial cellular components of the gliding layer, however, are more areolar in nature and cannot be distinguished from paratenon. Absence of the gliding layer makes adherence to bone much more likely. Repair of a cleanly lacerated gliding layer, when possible, improves chances for more normal extensor excursion. Preserving the gliding layer in the exposure for reconstruction of phalangeal fractures improves the postoperative range of motion (14,58). Careful preservation of the gliding layer improves results after other elective procedures, and this specialized tissue should be considered an integral part of the extensor mechanism (71).

Surgical approaches that involve splitting the extensor tendon and gliding layer are unnecessary and should not be used. They do not facilitate bone reduction but rather create severe extensor mechanism trauma, resulting in adherence and loss of tendon amplitude. Incisions preserving the entire extensor mechanism allow access and reduction of all phalangeal fractures (14,58).

The major dualities in the digital extensor mechanism should be fixed in the surgeon’s mind (Table 49.6). A knowledge of these redundancies in the system facilitates decision making in both acute repairs and late reconstructions. A common power-saw injury, for instance, results in an ulnarily laceration of a lateral slip and portion of the central slip over the proximal phalangeal segment with destruction of the underlying gliding layer and abrasion or cortical chipping of the phalanges. Such an injury is best treated by debridement of the shredded tendon followed by early initiation of motion.

</table>

The level of extrinsic tenodesis is frequently made obvious by scars. Intrinsic contracture and contracture of the ORL, however, cannot be appreciated without the use of clinical tests (49).
Unnecessary repair of tendons in these circumstances is done when the surgeon does not realize that there is enough undamaged extensor mechanism to perform IP extension. Adequacy of the mechanism can be checked easily after digital anesthesia by asking the patient to straighten the finger. Recognizing the redundancy of the extensor mechanism, and therefore the expendability of certain elements, should prevent one of the complications of extensor repairs seen by hand surgeons—unnecessary suture of partial lacerations resulting in digits stiffly fixed in extension.

**ACUTE EXTENSOR REPAIR**

**FOREARM AND WRIST**

Little has been written about the repair of lacerated wrist extensor tendons, and the subject deserves mention. The wrist extensors maintain balanced alignment of the hand and provide stabilization of the hand during grip. They should be repaired when possible. Isolated laceration of a wrist extensor is rare, because of the intimate anatomic arrangement of the extensor complex in the forearm and wrist. Wrist extensor tendon lacerations are therefore usually associated with laceration of one or more of the digital extensors.

Careful physical examination to rule out associated neurovascular injuries is mandatory (stab wounds in the forearm with small entry wounds may be very misleading), followed by complete surgical exploration and repair. Dorsal laceration in the proximal forearm frequently involves branches of the radial nerve. Explore and repair them if feasible. Muscle bellies of the extensor muscles can be opposed with nonabsorbable or synthetic absorbable sutures (Table 49.7).

Because the brachioradialis (BR), extensor carpi radialis longus (ECRL), extensor carpi radialis brevis (ECRB), EDC, and EDQ have their origins from the lateral epicondyle, elbow flexion (in addition to wrist extension) facilitates repair (15). After surgery, use a long-arm dressing with elbow at 90° flexion, the forearm in neutral rotation, the wrist extended 45°, and the MP joints flexed about 15°. Allow the IP joints full, unrestricted motion throughout treatment of the injury. Allow active motion of the MP joints at 3 weeks, and of the elbow at 4 weeks (Table 49.8). At 5 weeks, gently institute wrist motion under the guidance of a hand therapist. Use a removable splint that maintains the neutral or slightly extended position between exercise sessions and at night for an additional 3 to 4 weeks. The development of sufficient tensile strength to allow application of significant stress across the repair requires at least 5 weeks (50). However, some motion at the juncture site is beneficial for the return of maximum postoperative tendon excursion.

The keys to the best results, therefore, are protection that is adequate for the specific repair and some motion that is prompt enough to achieve early tendon gliding. The surgeon determines the immobilization method and mobilization sequence. Observe the juncture directly before wound closure and assess the effects of passive MP and IP flexion. Because about 60% of the digital extensor amplitude occurs at the wrist, immobilization of the wrist in extension affords significant protection for extensor repairs (45). Graduated institution of range of motion for each of the joints possibly affected by extensor injuries, rather than prolonged immobilization of all joints, contributes to improved results (8,21).

In addition to individualized mobilization of joints, frequent clinical evaluation by the surgeon and close supervision by an informed, experienced hand therapist are necessary to achieve optimum results following extensor repair or reconstruction (6,21,81).

**DORSUM OF THE HAND**

Laceration of a single tendon of the EDC may be masked by juncturae tendini pull-through. Laceration of the EIP and EDQ results in loss of independent MP extension...
of the index or little finger. Repair all of these tendons (3) using appropriate core and outer sutures (Table 49.7).

The method of immobilization (Table 49.9) is similar to that for lacerations in the forearm and wrist. Involvement of the EDC tendons necessitates inclusion of all fingers in the dressings and splints, but isolated lacerations of the EIP and EDQ may be treated with immobilization of only the involved digit and the wrist.

### Table 49.9. Postoperative Management of Extensor Tendon Repairs in the Dorsum of the Hand

### METACARPOPHALANGEAL JOINT

**Laceration**

Delayed repair of a lacerated extensor tendon and MP joint capsule is prudent. The rationale for wound irrigation, inspection, open wound treatment, splinting, and delayed repair after 5 to 10 days of antibiotic treatment is to minimize the risk of infection from human bites, which is increased by primary closure (16). Primary closure, an inappropriate treatment for a human bite, frequently leads to septic destruction of the MP joint (see Chapter 73). Perform primary closure of lacerations of the extensor tendon and MP joint only if you are confident of the history, and if the wound appears compatible with that history. The methods and duration of immobilization are the same as those described for extensor lacerations on the dorsum of the hand (Table 49.8).

**Extensor Subluxation**

Closed subluxation of the extensor tendon at the MP joint (Fig. 49.5) can frequently be managed successfully with extension splinting for 4 to 6 weeks (57). Repair acute sharp injuries to the radial sagittal band of the MP joint to prevent ulnar extensor tendon subluxation. Chronic subluxation that does not respond to MP extension splinting requires surgical treatment. Release the ulnar sagittal band and, if possible, reef the radial sagittal band. If adequate substance for repair is not present in the radial sagittal band, several surgical reconstructions have been described using juncturae or strips of the tendon secured to soft tissue on the radial side of the joint to prevent the ulnar subluxation (15).

### PROXIMAL PHALANX

Complete laceration of the extensor mechanism at the proximal phalanx is very rare without transaction of the digit. Therefore, lacerations over the proximal phalanx are usually partial and affect only the tendon over the convex portion of the phalanx. These tendon injuries do not retract significantly, do not result in loss of extension at the IP joints, and are usually diagnosed only through direct visual inspection of the wound.

Repair of the central slip is indicated, but lateral slip repair, especially if the gliding layer is disrupted, is optional. Treat untidy injuries of a single lateral slip with debridement of the crushed tendon ends. Initiate motion after 10 days of splinting. Remember the dualities of the system and the concept of expendability in crushing and abrading injuries. Fine, synthetic, slowly absorbable sutures are preferable for repair of the central slip.

After repair of partial laceration of the central slip, ask the patient to actively flex and extend the MP and PIP joints. This exercise provides some indication of whether early motion will jeopardize the repair. If no tension on the repair is demonstrated with active flexion/extension of the MP or PIP joints, consider early motion. If there is significant tension on the repair, follow the postoperative regimen for laceration of the extensor tendon at the PIP joint (Table 49.10).

### Table 49.10. Postoperative Management of Extensor Tendon Repairs of the PIP Joint (Acute Boutonnière Deformity)

### PROXIMAL INTERPHALANGEAL JOINT

Untreated laceration of the central slip at the PIP joint allows development of the boutonnière (boutonnière) deformity. The inevitable flexion of the middle phalangeal segment due to unopposed FDS pull encourages herniation of the proximal phalangeal condyles through the central slip defect. As the PIP flexion deformity progresses, the conjoined lateral bands slide palmar to the PIP axis, maintaining and increasing PIP flexion and tightening the terminal extensor, which produces DIP hyperextension (Fig. 49.10). The boutonnière deformity, when allowed to progress, is one of the most difficult reconstructive challenges to confront a hand surgeon (9.47, 8.15).

The key to prevention, in sharp injuries, is careful exploration of all wounds over the PIP dorsum and extensor tendon repair. If there is a complete PIP extension deficit, the PIP joint should be maintained in full extension with a transarticular Kirschner wire before tendon repair. If the PIP extension deficit is not severe (less than 30° to 40°), tendon repair and external splinting will usually suffice. Careful postoperative management (Table 49.10) is necessary for optimum results.

Closed dorsal injury at the PIP level is the cause of many late-presenting, difficult, fixed boutonnière deformities. Prevention in these cases is simply based on an awareness of the potential problem and a high index of suspicion. Immobilize the PIP joint in extension and observe it with careful follow-up examinations. Unrestricted finger flexion after blunt trauma to the dorsum of the PIP region with central slip confusion/rupture may lead to severe deformity. PIP flexion, therefore, should be instituted gradually and only after follow up examinations reveal full active PIP extension. If there is significant periarticular swelling and pain with attempted flexion, a prudent assumption is that the injury is a closed boutonnière deformity until proven otherwise, adherence to the regimen presented in Table 49.10 is indicated.

### MIDDLE PHALANX AND DISTAL INTERPHALANGEAL JOINT

At least seven classifications of classic mallet-finger deformity (dropped distal phalanx) exist.
Most mallet fingers fall into the first four groups, and it is these that are the basis for discussion of mallet fingers in this chapter. Fortunately, injuries in the fifth group are relatively rare; they often require flap or graft coverage (see Chapter 8, Chapter 38) before extensor tendon reconstruction can be considered. The last two groups of fractures, because of marked palmar angulation at the fracture site, are usually associated with nail-root avulsions and are treated relatively easily (see Chapter 38).

All mallet fingers involving loss of terminal extensor contact with the distal phalanx (groups 1 through 5) may present with PIP recurvatum (swan-neck deformity), the magnitude of which depends on the ability of the PIP VP to resist the increased extensor force (central slip plus conjoined lateral bands) on the middle phalanx.

Mallet fingers in groups 1 and 2 can be managed satisfactorily by closed means in Stack splints (11,26,65). In group 2, the area of articular surface on the fracture fragment of the distal phalanx is not critical, as long as the DIP joint is not palmarly subluxated (11). Even though anatomic reduction may be impossible in a splint, results are good if joint alignment is maintained (11).

The presence of palmar subluxation of the distal phalanx indicates that enough of the DIP collateral ligament insertion is present on the fracture fragment to allow the unopposed FDP insertion to palmarly displace the distal phalanx. This circumstance usually does not occur until 50% or more of the articular surface of the distal phalanx is present on the fracture fragment (11).

If palmar subluxation of the distal phalanx is present, treat the injury surgically with reduction of the DIP joint, transarticular Kirschner wire fixation (Table 49.11), and open reduction of the fracture fragment. Methods for fragment fixation are diverse, and none have a clear advantage. The clear disadvantage of open treatment of any mallet deformity is loss of DIP flexion. A certain amount of flexion loss is the cost of accurate joint and fracture reduction in group 3 mallet deformities and tendon repair in group 4 mallet deformities. A patient who is advised about this problem in advance of surgery is usually satisfied with the surgeon’s efforts, while the unprepared patient is often disappointed.

The postoperative management of mallet deformity (Table 49.12) is also used in the treatment of closed mallet injuries. Open mallet deformities (group 4) are also managed as shown in Table 49.12. Place fine, synthetic, absorbable sutures in the tendon after the DIP joint has been fixed in neutral extension with a transarticular Kirschner wire.

### Table 49.12. Postoperative Management of Extensor Tendon Repair Over the Middle Phalanx or at the DIP Joint (Acute Mallet Deformity)

#### LATE RECONSTRUCTION

Delayed extensor reconstruction is controversial, and many procedures have been described. The following are a few simple guidelines divided into general anatomic levels for the management of chronic extensor deficits.

### FOREARM, WRIST, AND DORSUM OF THE HAND

Wrist and MP extension are the functional losses accompanying disruption of wrist extensors and extrinsic digital extensors. Without wrist extensors, the grasp function of the hand is disabled. Loss of MP extension eliminates the placement arc of the fingers, while digital encompassment (IP flexion through FDP/FDS, and IP extension through intact intrinsic musculature) is maintained (49). Loss of either wrist extension or MP extension results in marked disability. Tenodesis and stiffened joints may also contribute to the clinical presentation.

Reconstructive goals are independent wrist or MP extension using a technique that provides satisfactory power and amplitude to meet functional requirements. Normal amplitude is rarely achieved, but adequate power for extensor function is a reasonable goal, since normal digital extensor strength is 10% of that of all the muscles below the elbow, and digital extensor work capacity is less than one third of that of the digital flexors (65). Indeed, according to Brand, the FDS and FDP of the middle finger alone are as strong as the extensors of all the other fingers (5).

The three options available for late reconstruction of extrinsic wrist and digital extensor loss are attempted delayed repair, interpositional tendon graft, and redistribution of power through tendon transfer. In general, tendon transfers are the most successful. Delayed repair and interpositional tendon graft suffer in comparison because the lacerated muscle–tendon unit is usually compromised by retraction, adherence, and weakness. There are multiple options for tendon transfers to restore wrist and MP extension; these methods are most fully described in treatises dealing with reconstruction following radial nerve palsy (see Chapter 55). If composite tissue loss on the dorsum of the hand or forearm necessitates flap coverage, the use of silicone rods beneath the flap will facilitate later tendon transfer (61).
Posttraumatic tenodesis of the extensor tendons over the metacarpals and phalanges is a relatively common clinical problem, presenting after extensor tendon injuries with or without fractures. The gliding layer has been disrupted in these cases and dense adhesions are present between the bone and extensor tendon. Extensor tenolysis in the hand or digit with or without use of synthetic interpositional material (silicone sheets, which eventually require removal) is a worthy surgical attempt to improve functional range of motion. The long-term results, however, are highly variable.

The gains in range of motion may be dramatically good in some patients and dimly poor in others. Adhesions may extend far beyond the level of injury; other factors, both objective (e.g., stiffened MP or IP joints, loss of muscle amplitude, altered tendon nutrition) and subjective (e.g., pain perception and tolerance, psychological understanding and motivation), are as important as simply lysing tendon from bone. The gains in flexion will be more significant than the reduction in extensor lag, and the necessity for joint capsulotomy will decrease the overall benefit of extensor tenolysis (12). If the joints are supple, however, and a well-motivated patient understands the rigors of maintaining postoperative tendon excursion, tenolysis is an acceptable surgical option.

The IPJ joint, which accounts for 85% of final interphalangeal encompassment, is most affected by extensor tenolysis of the central slip over the proximal phalanx (48-49). Consider the feasibility of separation of the extrinsic and intrinsic contributions to the extensor mechanism at the proximal phalangeal level. The extraintrinsics would then be isolated as MP extenders. Excise the area of tenodesis to eliminate the extensor tether of the IPJ joint. If the lateral slips are normal and the area of tenodesis is proximal to the zone of convergence (Fig. 49.6), the intrinsic muscles then become the sole IPJ extensors. When possible, this technique to the problem can be very successful (44-45).

Few patients complain of loss of DIP flexion after extensor injury followed by tenodesis over the middle phalanx, even though DIP flexion is uniformly decreased after such injuries. Tenolysis at the middle phalangeal level could be considered in a patient with unique occupational demands (e.g., a professional musician, requiring maximum DIP range of motion).

LATE BOUTONNIERE DEFORMITY

Reconstruction of the chronic boutonniere deformity is not easily accomplished and often frustrates the most experienced hand surgeons. The fixed or flexible nature of the IPJ flexion deformity is extremely important in operative planning. All reconstructions in late boutonniere deformities depend on attainment of maximum passive PIP extension followed by appropriate distribution of the available extensor power (9,13,45,58,61,68-76).

LATE SWAN-NECK AND MALLET DEFORMITIES

Many innovative reconstructive procedures have been proposed and used in restoration of swan-neck deformity. If the DIP joint assumes the extended position when PIP hyperextension is blocked at neutral or slight flexion, direct treatment simply at limiting PIP extension to a neutral or slightly flexed position.

A more challenging swan-neck deformity follows rupture of the terminal extensor in patients with lax PIP volar plates. The increased extensor pull on the middle phalanx (Fig. 49.10) causes progressive PIP hyperextension. In these cases, surgical management can be divided into two basic categories: procedures designed to shift extensor pull from the middle to the distal phalanx, and procedures using the dynamic interphalangeal tenodesis concept to limit PIP hyperextension and augment DIP extension.

The prime example of an extensor shift procedure is the Fowler central slip tenotomy (4,28,32). Tenotomy of the central slip reduces extensor tone on the IPJ joint and allows proximal shift of the conjoined lateral bands, increasing DIP extensor tone. This procedure is simple and is usually effective in improving DIP extension and reducing PIP hyperextension. DIP extension will not be complete in most cases, however, and PIP extension lag is a potential problem following central slip tenotomy (71). Use this procedure exclusively in swan-neck deformities resulting from rupture and separation of the terminal extensor tendon.

Several procedures have been described that create a strong oblique retinacular ligament homologue; they have been reported to be effective (30,42,43,73). These procedures provide predictable methods for correcting loss of DIP extension and PIP hyperextension.

If the deformity is purely DIP extension loss (mallet finger) with no tendency toward PIP hyperextension, direct treatment toward reconstituting the terminal extensor tendon by excision of interposed scar and secondary repair, tendon graft, or tendodermadesis (54).

THUMB

Late extensor deficits are less common in the thumb ray than in the fingers because of the thumb’s recessed and palmar abducted position, which provides relative protection from longitudinal dorsal trauma. The thumb of the nondominant glove hand in baseball and softball is an exception to this rule, but athletes tend to sustain fractures and ligament injuries rather than extensor tendon deficits after thumb trauma.

Most late extensor deficits in the thumb occur secondary to the deformities of rheumatoid disease or attritional rupture of the EPL following a distal radial fracture. Reconstruction of the rheumatoid thumb is discussed in Chapter 70. Tendon transfer, especially EIP, provides the most satisfactory solution to late EPL deficit, if the joints are supple (76). All procedures discussed in this chapter regarding late mallet deformities are applicable, but rarely applied, to the thumb.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

NORMAL FUNCTION OF THE HAND REQUIRES THE SMOOTH AND ALMOST TRACTIONLESS GLIDING OF FLEXOR AND EXTENSOR TENDONS. INFLAMMATION OF THE TENOSONVIVUM, ESPECIALLY AT POINTS WHERE A TENDON CHANGES DIRECTION, CAN LEAD TO STENOSIS OF THE TENDON SHEATH, WHICH INTERFERES WITH THE ACTION OF THE ENCLOSED TENDON. SYMPTOMS INCLUDE PAIN AND LIMITATION OR IRREGULARITY OF JOINT MOTION. STENOSING TENOSYNOVITIS MAY AFFECT ANY OF THE FLEXOR OR EXTENSOR TENDONS, ALONE OR IN COMBINATION.

CAUSES OF STENOSING TENOSYNOVITIS INCLUDE ACUTE TRAUMA, REPETITIVE TRAUMA RELATED TO OCCUPATION OR SPORTS, TUMOR, INFECTION, GOUT, RHEUMATOID ARTHRITIS, AND METABOLIC DISORDERS. THE PRINCIPLES OF TREATMENT INCLUDE CESSATION OR MODIFICATION OF THE ACTIVITIES CONTRIBUTING TO PAIN, HAND THERAPY, USE OF ANTIINFLAMMATORY AGENTS, AND SURGICAL CORRECTION OF THE OBSTACLES TO TENDON MOTION.

TRIGGER DIGIT

Trigger digit is usually the result of constriction of the first annular pulley of the flexor tendon sheath, which causes pain and difficulty in extending or flexing the proximal interphalangeal joint (44, 65, 84). In the case of trigger thumb, the patient has difficulty extending or flexing the interphalangeal joint (45, 89). It appears that fibrocartilaginous metaplasia of the A1 pulley is the cause of the crepitus (69). Repetitive flexion and direct trauma may also cause stenosing tenosynovitis of the flexor tendons in the fingers (49, 102, 26, 48, 64, 68). The patient feels pain when the digit is forcibly straightened or flexed. Extending the distal interphalangeal joint before straightening the proximal interphalangeal joint often avoids the characteristic painful snap. On palpation, there is usually tenderness just proximal to the metacarpophalangeal joint on the palmar side.

Traumatic flexor tenosynovitis is a reactive swelling in the flexor digitum profundus or flexor pollicis longus tendon, which is proximal or distal to the A1 pulley. A ganglion within the substance of the first or second annular pulleys may be found in cases of stenosing tenosynovitis of the flexor tendons of the digits.

Not all joint “catching” is due to stenosing tenosynovitis. Interphalangeal joint locking may be caused by interference with the normal gliding mechanism of the lateral bands or by irregularities within the interphalangeal joints. Osteophytes and malunited fractures of the proximal interphalangeal joints can block extensor hood function and the normal motion of the collateral ligaments, and joint “mice” can restrict proximal interphalangeal joint mobility.

Trigger digit occurs most commonly in healthy women who are in their sixth decade of life (17, 24, 54, 58, 64, 80, 81, 83). It is associated with de Quervain’s disease, with carpal tunnel syndrome, and with triggering of any of the other nine digits of the hand (1, 6, 8, 36, 54, 58, 80, 81). It occurs more commonly in de Quervain’s disease than in carpal tunnel syndrome.

The incidence of trigger finger is increased in patients with Dupuytren’s disease, rheumatoid arthritis, or diabetes mellitus (15). It is associated with another type of tenosynovitis in more than two thirds of patients, and it is bilateral in 25% (76, 80). Congenital trigger digit is the most common form of digital flexion contracture in infants (22). Trigger thumb is sometimes hereditary, and it occurs more commonly than trigger finger (16, 21, 22, 45, 86, 93). Surgical correction can be deferred until 1 year of age without permanent loss of motion. Thirty percent of congenital cases correct themselves spontaneously before 1 year of age. Splint immobilization and steroid injection in the flexor tendon sheath may be curative (69).

Surgery is warranted if symptoms persist despite conservative management. Percutaneous release is less reliable than other surgical techniques and offers little advantage in the middle and ring fingers (3, 79). For nonrheumatoid patients, percutaneous release is an available but less reliable form of treatment than others (3, 79). It is indicated in the middle and ring fingers, or in the middle and ring fingers, or in the middle and ring fingers, where the risk of nerve damage is less than in other digits. It may be indicated in the elderly patient with Dupuytren’s disease. The best cure rates are obtained when the patient is actively locking. The technique involves the use of a 19-gauge needle to cut the A1 pulley distal to proximal over the hyperextended metacarpophalangeal joint. Partial laceration of the superficialis tendon is common but generally does not result in clinical sequelae.

PERCUTANEOUS RELEASE

- Infiltrate the area of the proposed skin incision with local anesthetic. In the case of stenosing tenosynovitis of the index finger, incise the proximal flexor crease of the palm. In treating triggering of the middle, ring, or little fingers, make a 15 mm incision in the distal flexion crease. In the thumb, incise the proximal flexion crease in the area between the two sesamoids (Fig. 50.1).
With pneumatic tourniquet control, clear fat from the palmar surface of the flexor tendon sheath by blunt dissection. Use medial and lateral Ragnel retractors to protect the neurovascular bundles (Fig. 50.2).

Identify the proximal edge of the first annular band by its thickened transverse collagen bundles, which contrast with the longitudinal striations of the paratenon proximally.

Incise the radial half of the proximal pulley and resect the redundant tenosynovium from the flexor tendons (Fig. 50.3). Withdraw both flexor tendons from the wound to examine them for thickening.

If there are tendon nodules and triggering persists, perform a mid-lateral partial wedge resection of the tendon substance and primary closure.

If triggering still persists, partially section no more than 5 mm of the second annular band by gentle pressure with open blunt dissecting scissors.

In patients with rheumatoid arthritis, strip the flexor tendons at their nodules and tenosynovium through a zigzag incision from the distal flexor crease at the palm to the volar distal interphalangeal joint crease. Preserve annular pulleys when the flexor sheath is opened. Repair them afterwards if their release is necessary. Resistance to ulnar drift is thereby improved.

De Quervain’s disease occurs most commonly in healthy women in their sixth decade of life (19,53,56,59,68,89,96). An increased incidence of de Quervain’s disease has been found in patients with Dupuytren’s disease, rheumatoid arthritis, gout, or diabetes mellitus. Many patients with de Quervain’s disease develop trigger finger or
carpal tunnel syndrome, or both, although the reverse is not true (1,25,38,54,63,80,81). Bilateral involvement eventually occurs in 30% of patients with de Quervain's disease (80,81).

Osseous malformations, fracture nonunions, and arthritis of the radiocarpal and carpometacarpal joints must be identified before treatment. Try brief periods of splint immobilization of the wrist, including the first metacarpal, and glucocorticoid injections of the first dorsal compartment; these are, however, less successful in treating de Quervain's disease than other forms of stenosing tenosynovitis. Avoid prolonged splinting. Instead, initiate active and passive stretching exercises early to promote tendon gliding. Surgery is indicated if the symptoms persist despite conservative treatment.

DECOMPRESSION OF FIRST DORSAL COMPARTMENT OF THE WRIST

- Infiltrate the area of the proposed skin incision with local anesthetic before inflating the pneumatic tourniquet (Fig. 50.5). Make the dorsal half of the incision along a transverse extensor crease of the wrist about 10 mm proximal to the tip of the radial styloid (Fig. 50.6). Follow Langer's lines in a palmar direction, making a 30 mm incision centered over the radial styloid. Radial sensory nerve branches are encountered just deep to the dermis; protect them by gentle retraction (Fig. 50.7).

![Figure 50.5. Infiltration of the skin in surgery for de Quervain's disease.](Image)

![Figure 50.6. Skin incision for surgical treatment of de Quervain's disease.](Image)

![Figure 50.7. Exposure of the thickened roof of the first dorsal compartment.](Image)

- With a scalpel, incise the thickened sheath of the first dorsal compartment distally and proximally (Fig. 50.8). There may be more than one septum separating the numerous slips of the abductor pollicis longus or the extensor pollicis brevis; carefully identify each tendon.

![Figure 50.8. Elevation of the roof of the first dorsal compartment.](Image)

- Excise thickened tenosynovium and retinacular ganglia. Examine the floor of the first dorsal compartment for bony, neoplastic, and calcific irregularities or anomalous tunnels containing aberrant tendons. These must be unroofed. Ask the patient to flex and extend the thumb to demonstrate unimpeded motion. After the tourniquet is released, achieve hemostasis. Close the skin with a nonabsorbable intracuticular suture (Fig. 50.9). To prevent palmar subluxation of the tendons, apply a palmar spica splint for 2 weeks until the skin suture is removed.
**PITFALLS AND COMPLICATIONS**

Failure to free the extensor pollicis brevis completely from thick adhesions to the abductor pollicis longus or failure to identify and to incise its separate sheath may cause symptoms to persist. The abductor pollicis longus may have multiple slips inserting into the first metacarpal and into the trapezium, carpometacarpal joint capsule, fascia of the opponens or abductor pollicis brevis, or flexor retinaculum. Failure to identify and separate all of the tendons may result in incomplete resolution of symptoms.

Laceration of the radial sensory nerve branches warrants immediate microsurgical repair to reduce the likelihood of painful neuroma formation. Compression of the terminal branches of the radial nerve may also produce pain in the area of the first dorsal compartment. Symptoms include numbness and tingling over the dorsal surface of the thumb and index finger. Paresthesias are accentuated by percussion in this area. In making a diagnosis, be careful to differentiate this nerve compression syndrome (Wartenberg's disease) from de Quervain's disease.

**LATERAL EPICONDYLITIS**

Lateral epicondylitis is inflammation of the common extensor origin of the elbow. It is often referred to as “tennis elbow” (8, 18, 33, 36, 60, 70, 71 and 72). Usually, there are small tears of the tendon of origin of the extensor carpi radialis brevis, although the extensor digitorum communs may be involved as well (70, 72). The pathology ranges from angiofibroblastic proliferation to complete tendon rupture (24, 71). Pain over the lateral epicondyle and extensor muscle mass when lifting objects palm down and when playing racket sports is characteristic. Throwing and wringing motions may also be painful. Grip strength is decreased as a result of pain on attempts to stabilize the wrist in extension. Tenderness to palpation occurs over the lateral epicondyle of the elbow and radial collateral ligament. Wrist extension against resistance causes pain at the lateral epicondyle. Radiographic evaluation of the elbow may demonstrate a lateral exostosis, bone fragments, or calcific deposits over the lateral epicondyle.

Lateral epicondylitis must be differentiated from radial tunnel syndrome, in which the posterior interosseous nerve is compressed under the fibrous arch of the supinator muscle (60). Radial tunnel syndrome is characterized by tenderness over the supinator, just distal to the radial head. Pain is reproduced by the patient resisting forearm pronation, or by resisting middle finger extension with the wrist supported. A lidocaine injection at the arcade may help to distinguish them. The two entities may coexist.

Treat lateral epicondylitis with rest, local application of ice, and nonsteroidal antiinflammatory drugs (49, 72). A 90° long-arm splint with the wrist slightly extended and supinated may be used in recalcitrant cases, although it rarely affects the outcome. Local injections of glucocorticoids are helpful in severe cases; repeated injections, however, may cause delayed tendon rupture resulting from their catabolic effects. Advise patients to change to “palm-up” lifting and analyze their sport technique and form to prevent relapse.

A proximal forearm counterforce brace may help to prevent relapses. Because the condition is attributable to overuse, gentle and then progressive wrist curls to strengthen forearm extensors, and proper stretching exercises are indicated after the initial recovery is well under way (32). Surgery is indicated in the few cases that do not respond to conservative therapy. Endoscopic and arthroscopic releases do not have the outcome studies yet to justify their use (2, 37).

**REPAIR OF EXTENSOR TENDON ORIGIN**

- After administration of regional or general anesthesia, make a 5 cm longitudinal incision centered over the radial head (Fig. 50.10).

![Figure 50.10](image)

*Figure 50.10. Skin incision used in the surgical treatment of lateral epicondylitis.*

- Retract and incise the antebrachial fascia over the extensor carpi radialis brevis, and identify the common extensor origin (Fig. 50.11). Gross disruption may be visible. Chronic inflammatory changes may be seen in the proximal margin of the extensor tendon, but angiofibroblastic changes become apparent after exposing the deep surface of the tendon of origin.

![Figure 50.11](image)

*Figure 50.11. Exposure of the common extensor muscle group with their tendons of origin after retraction of the antebrachial fascia.*

- Incise the extensor aponeurosis longitudinally, where the damage is most accessible. You may need to elevate the extensor carpi radialis brevis completely as a flap (Fig. 50.12). Do not damage the radial or lateral ulnar collateral ligaments.

![Figure 50.12](image)

*Figure 50.12. Partial elevation of the tendon of origin of the extensor carpi radialis brevis, demonstrating tendinous degeneration on its undersurface where it is*
attached to the lateral epicondyle and radial collateral ligament of the elbow.

- Remove proliferative synovium from the anterolateral joint if crepitus was felt preoperatively. Excise granulation tissue from beneath the extensor carpi radialis tendon (Fig. 50.13) and the extensor digitorum communis, if necessary. Debride degenerated tendon to healthy tissue. The deep surface of the tendon should be free of all granulation tissue (Fig. 50.14).

**Figure 50.13.** Excision of granulations from the deep surface of the extensor carpi radialis brevis tendon and decortication of the lateral epicondyle.

- Decorticate the lateral epicondyle to punctate bleeding corticocancellous bone. Remove exostoses and calcifications.
- Suture the extensor carpi radialis brevis tendon to the surrounding periosteum and to the extensor digitorum communis tendon (Fig. 50.15). If adequate tendon length remains, suture it through connecting drill holes in the epicondylar ridge. When inadequate tissue remains for a repair, I use a tendon graft figure-of-eight. Place a bone tunnel or two suture anchors across the ridge. Capture the fascia and septa of the affected muscles distally (Fig. 50.16).

**Figure 50.14.** Well-debrided tendon of origin of the extensor carpi radialis brevis and lateral epicondyle, which are decorticated and prepared for tendon reattachment.

**Figure 50.15.** Reattachment of the extensor carpi radialis brevis tendon of origin to the extensor aponeurosis and periosteum of the lateral epicondyle.

**Figure 50.16.** Figure-of-eight tendon graft. See text for details.

- Suture the common extensor aponeurosis closed, and then close the skin. Immobilize the forearm in a long-arm splint in neutral rotation with the elbow flexed 90° and the wrist extended 20°. Remove the splint in 2 to 3 weeks, depending on the degree of extensor tendon repair. Encourage patients to begin gentle range-of-motion exercises, but they should avoid stress for 5 weeks. After that time, gradually initiate progressive, resistive exercises. Advise patients with complete tears to forego vigorous sports for 6 months.

**PITFALLS AND COMPLICATIONS**

Lateral epicondyritis must be differentiated from other causes of lateral elbow pain. Rheumatoid arthritis, gout, radial tunnel nerve syndrome, osteochondritis dissecans, and loose bodies may cause lateral elbow pain alone or in concert with lateral epicondyritis.

**MEDIAL EPICONDYLITIS**

The symptoms of medial epicondyritis include pain at the tendons of origin of the flexor pronator muscle group, most commonly the pronator teres and the flexor carpi radialis (30,32). Overuse in golf and throwing are common causes of microtearing in this near mirror-image of its lateral counterpart. During physical examination, pain on resisted pronation or wrist flexion helps to make the diagnosis.

Advise the patient to avoid provocative activities, as well as forceful gripping and twisting. Counterforce bracing over the proximal muscles of the pronator and flexor carpi radialis may be useful; be careful to avoid ulnar nerve compression. Injection of a corticosteroid usually provides fast relief but no long-term benefit (87). Begin flexor
and pronator strengthening exercises when symptoms persist. Encourage sports technique training since medial epicondylitis is usually an overuse syndrome. Reserve surgery for at least 6 months in cases unresponsive to conservative care.

**REPAIR OF FLEXOR TENDON ORIGIN**

- Make a skin incision 4 cm long, parallel and 1 cm proximal to the course of the ulnar nerve, beginning at the medial epicondyle. Take care to avoid branches of the medial antebrachial cutaneous nerve. Reflect the affected tendons—the pronator teres and flexor carpi radialis—off the medial epicondylar ridge. Reflect them as far posteriorly as the septum between the flexor carpi radialis and the palmaris longus (when present) or the humeral head of the flexor carpi ulnaris. While undermining distally, carefully consider the depth of dissection to avoid the anterior band of the medial collateral ligament.
- Roughen the epicondyle before reattaching the tendons to surrounding tendon and fascia. Use a suture if necessary through connecting drill holes, or one attached to an anchor, to affix the common tendon of origin more securely to the medial ridge.
- Place the arm into a long-arm splint for 3 weeks with the elbow flexed 90°, the forearm in neutral rotation, and the wrist at 0°. Begin strengthening exercises at 4 to 6 weeks and sports at 4 to 6 months.

**PITFALLS AND COMPLICATIONS**

Medial epicondylar pain can be mimicked by nonunion, valgus instability, and medial antebrachial cutaneous or ulnar neuropathy. Plain and stress radiographic views may demonstrate nonunion of the medial epicondyle and laxity of the medial collateral ligament of the elbow. Tenderness to palpation and Tinel’s sign may demonstrate more distal ligamentous laxity, superficial medial antebrachial cutaneous neuropathy, or posterior ulnar neuritis. Cubital tunnel syndrome and its subtle variations must be completely treated because they may coexist with medial epicondylitis (51,52). In such cases, even the additional release of the transverse humeral ligament will fail. Subcutaneous, ulnar nerve transposition must be added to the reconstruction to achieve a high level of success.

**TENDINITIS ABOUT THE WRIST**

**FINGER FLEXOR TENDINITIS IN THE CARPAL TUNNEL**

Thickening and fibrosis of the digital flexor tendons can occur in the carpal tunnel (51). Usually, it is idiopathic in origin, causing compression of the median nerve (see Chapter 52) (4,8,13,59). Repetitive motions of the digits and wrist and direct trauma may cause or exacerbate flexor tendinitis. Many conditions may precipitate symptomatic digital flexor tenosynovitis at the wrist. These include rheumatoid arthritis; gout; collagen vascular disease; anomalous muscles, tendons, and arteries; tumors; congenital dysplasias; fungus; tuberculosis bacillus; and atypical bacteria (1,4,10,39,41,50,58,82,63,67,78,83,97). Occasionally, local steroid injections or flexor tenosynovectomy are necessary in recalcitrant cases. Cases involving infection require surgical decompression and intravenous antibiotics. The treatment of dysplastic, neoplastic, toxic, and metabolic sources of flexor tendinitis usually requires surgical decompression and tenosynovectomy of the flexors or the carpal tunnel and pharmacologic therapy to protect the contents of the carpal tunnel from irreparable damage and to eradicate the underlying disease process.

Splinting of the wrist, application of ice, and administration of oral antiinflammatory agents are usually successful in treating noninfectious causes of this condition.

Flexor tenosynovectomy at the wrist can be performed through a limited incision distal to the transverse flexor crease of the wrist, or through a more extensive exposure involving a 4 cm zigzag proximal extension of the original thenar crease incision to include the distal forearm (see Fig. 50.17). The latter is more commonly used in patients with rheumatoid arthritis. Bone spurs need to be excised and large areas of raw bone covered with ligamentous rotation flaps or patch grafts of transverse retinacular origin.

**FLEXOR TENOSYNOVECTOMY**

- In performing tenosynovectomy of the flexors of the carpal tunnel, be careful to avoid lacerating the large, aberrant sensory branches of the ulnar and median nerves in the subcutaneous fat, or those penetrating the transverse carpal ligament, or damaging the median nerve.
- Split the dorsiflexed wrist for 2 weeks after surgery to allow a new, loose retinacular "ligament" to form, preventing painful recurrent subluxation of the flexor tendons into the carpal tunnel when the hand is used to grip in the flexed wrist position. If subluxing flexor tendinitis occurs at the carpal tunnel, do a reconstruction of the transverse retinacular ligament using ligamentous remnants or the adjacent fascia.
- Fashion the new ligament at the distal margin of the carpal canal to prevent compression of the median nerve (Fig. 50.17, Fig. 50.18). Because Dupuytren's disease or its diathesis is exacerbated by this procedure, weigh the pros and cons of surgical management of flexor tendinitis carefully for patients with coexistent Dupuytren's disease.

**Figure 50.17.** Formation of a distally based "ligament" that is 5 mm in diameter.

**Figure 50.18.** A new transverse carpal ligament is sutured to the old ligamentous stump on the opposite side of the carpal tunnel.

**WRIST FLEXOR TENDINITIS**

Inflammation of the tendons of the flexor carpi radialis and that of the flexor carpi ulnaris occur independently and are usually related to repetitive flexion, direct trauma, wrist fracture, cysts, or excessive wrist extension (28). Calcifications may exist within the tenosynovium (Fig. 50.19). Rheumatic, metabolic, infectious, and neoplastic diseases may also involve these tendons. Inflammation of the flexor carpi radialis tendon occurs in its fibrousseous tunnel within the transverse carpal ligament (28).

The flexor carpi ulnaris tendon may become inflamed just proximal to the pisiform (77). The latter may also be involved in an arthritic process at its articulation with the triquetrum. Ulnar neuritis at Guyon’s canal may be secondary to flexor carpi ulnaris tendinitis (77).
When overuse is the cause, treatment includes volar splinting in neutral flexion, administration of oral antiinflammatory drugs, and local application of ice.

**DECOMPRESSION OF WRIST FLEXOR TENDONS**

- Decompress the flexor carpi radialis tendon using a 4 cm zigzag incision that begins at the tuberosity of the scaphoid and extends proximally.
- Open the fibro-osseous tunnel of the flexor carpi radialis and release adhesions and attachments to the trapezium (7, 30). Look for and remove space-occupying lesions and exostoses.
- Repair or Z-lengthen a contracted flexor carpi radialis tendon.
- Close the skin with interrupted sutures and apply a dorsal splint in 20° flexion, which the patient must wear for 2 weeks.
- Advise the patient to begin active exercises after the sutures are removed.
- For surgical treatment of chronic flexor carpi ulnaris tendinitis, use a palmar-ulnar zigzag incision (Fig. 50.20).

![Figure 50.20](image)

*Figure 50.20.* The incision used to expose Guyon's canal and the distal portion of the flexor carpi ulnaris tendon.

When signs of ulnar nerve compression are present, section the palmar fascia and the origin of the abductor digiti minimi muscle; also divide the pisohamate ligament, decompressing Guyon's canal (Fig. 50.21). Protect the ulnar nerve and artery proximally and distally, and preserve the pisiform metacarpal ligaments.

When pisotriquetral arthritis is present, enucleate the pisiform subperiosteally from its capsule through a palmar longitudinal incision (Fig. 50.22, Fig. 50.23) (77).

![Figure 50.21](image)

*Figure 50.21.* Incision of the pisohamate ligament.

![Figure 50.22](image)

*Figure 50.22.* Incision of the capsule of the pisiform.

![Figure 50.23](image)

*Figure 50.23.* Removal of the pisiform.

- Just proximal to the pisiform, perform a Z-plasty of the flexor carpi ulnaris tendon to allow 5 mm of tendon lengthening (Fig. 50.24, Fig. 50.25) (77). Suture the
capsule of the pisiform closed.

Figure 50.24. Incision used to Z-lengthen the flexor carpi ulnaris tendon, with subsequent closure of the capsule of the pisiform.

Figure 50.25. Lengthening of the flexor carpi ulnaris tendon by 5 mm using a Z-plasty.

■ After the tourniquet is released and hemostasis is achieved, close the skin. Immobilize the wrist for 2 weeks in a dorsal splint in 20° of palmar flexion until the sutures are removed.

PITFALLS AND COMPLICATIONS

The palmar cutaneous branch of the median nerve must be carefully protected in the radial wrist exposure. The ulnar nerve and artery are in proximity to the flexor carpi ulnaris and can be injured by laceration or too-vigorous traction. The pisiform metacarpal ligament should be kept intact to avoid weakening wrist flexion in a palmar-ulnar direction.

FINGER EXTENSOR TENDINITIS AT THE WRIST

Inflammation of the finger extensor tenosynovium can occur over the dorsum of the wrist, distal to and including the extensor retinaculum. Extension of the fingers causes heaping of the tenosynovium at the distal margin of the extensor retinaculum (Fig. 50.26). It is usually attributable to repetitive extension of the fingers and wrist or to direct trauma (9,10,64).

Figure 50.26. Heaping up of the extensor tenosynovium distal to the extensor retinaculum during finger extension.

Rheumatoid arthritis, collagen vascular disease, gout, tumors, fungus, congenital dysplasias, and typical or atypical bacterial infections may also cause symptomatic extensor tenosynovitis of the wrist (4,5,10,39,41,50,67,58,62,63,67,78,83,87). Palmar splinting of the wrist in 20° extension, local application of ice, and dorsal administration of antiinflammatory drugs are usually successful in treating the condition. Local injections of steroids around the inflamed tenosynovium or extensor tenosynovectomy may be necessary in severe cases.

Isolated tenosynovitis of the extensor pollicis longus, known as “drummer boy” palsy (29,65), is caused by repetitive flexion and extension of the thumb with ulnar and radial deviation of the wrist. Treatment includes splinting, application of ice, and oral administration of nonsteroidal antiinflammatory drugs. Local instillation of steroid preparations or surgery is occasionally warranted.

DECOMPRESSION OF FINGER EXTENSOR TENDONS

■ After administering regional or general anesthesia, make an oblique incision from the base of the second metacarpal to the metaphysis of the distal ulna (Fig. 50.27). Identify and protect the sensory branches of the radial and ulnar nerves. If possible, retract rather than transect large veins while exposing the tendons in the distal part of the wound (Fig. 50.28).

Figure 50.27. The incision used to expose the extensor retinaculum.
Incise the extensor retinaculum at the septum between the first and second dorsal compartments. Preserve the proximal 20% of the extensor retinaculum to prevent bow-stringing of the extensor tendons, and raise the extensor retinaculum as an ulnar-based flap until the sixth compartment is decompressed (Fig. 50.29). Remove Lister's tubercle using a rongeur.

Figure 50.29. The extensor retinaculum is raised as an ulnar-based flap.

Excise the tenosynovium from all of the finger and wrist extensors (Fig. 50.30). Pass the flap of extensor retinaculum deep to the finger and wrist extensor, and sew it back to adjacent soft tissues in the area of the first dorsal compartment of the wrist (Fig. 50.31).

Figure 50.30. Extensor tenosynovectomy.

After the tourniquet is released and hemostasis is achieved, close the wound. Drainage may be continued for 2 days, if necessary. Have the patient wear a 20° dorsiflexed palmar splint until the skin sutures are removed; then begin gentle active range-of-motion exercise.

Treat isolated tenosynovitis of the extensor pollicis longus by incising the third dorsal compartment and by removing Lister's tubercle. Do this through a 2 cm transverse incision extending in an ulnar direction from Lister's tubercle. Protect the sensory branches of the radial nerve. Transpose the extensor pollicis longus tendon radially, away from Lister's tubercle, which has been removed. Suture the tendon sheath closed, and then close the skin. Have the patient wear a palmar splint for 2 weeks until the skin sutures are removed.

**PITFALLS AND COMPLICATIONS**

The sensory branches of the superficial radial nerve and dorsal cutaneous branch of the ulnar nerve can be lacerated during surgery; take care to avoid them, and repair them if injured. The extensor pollicis longus tendon can also be lacerated as it crosses the radial wrist extensors obliquely. Immediate tenorrhaphy is necessary.

**RADIAL WRIST EXTENSOR TENDINITIS**

Radial wrist extensor tendinitis (intersection syndrome) is caused by inflammation of the tenosynovium of the extensor carpi radialis longus and brevis within the second dorsal extensor compartment of the wrist (40). Pain and swelling are elicited on palpation where the two wrist extensors cross the abductor pollicis longus and extensor pollicis brevis (8,40,43,92). The condition may be attributable to repetitive extension and flexion of the wrist or to direct trauma. It is known as “bugaboo forearm” in helicopter skiers (76).
Conservative therapy includes a palmar wrist splint in 20° extension, application of ice, administration of oral nonsteroidal antiinflammatory agents, and local injections of steroid preparations. Changing sports techniques and equipment is helpful. Surgery is reserved for recalcitrant cases that are unresponsive to prolonged conservative therapy, including steroid injections around the tendons just proximal to the extensor retinaculum.

**DECOMPRESSION OF WRIST EXTENSORS**

- Using regional or general anesthesia, make an ulnar-based chevron incision over the second dorsal compartment, crossing the wrist creases diagonally. Protect the branches of the radial nerve.
- Incise the second dorsal extensor compartment and remove exuberant tenosynovium from the two radial wrist extensors back to their junction with the tendons of the abductor pollicis longus and extensor pollicis brevis (40). Attempt to leave intact a portion of the distal extensor retinaculum. Examine the tendons, and remove their tenosynovium. Achieve hemostasis after the tourniquet is released.
- Close the skin and apply a palmar splint in 20° dorsiflexion. Remove skin sutures 2 weeks later, and discard the splint.

**PITFALLS AND COMPLICATIONS**

Intersection syndrome can be differentiated from de Quervain's disease on the basis of their different points of maximal tenderness. Sensory branches of the radial nerve should be repaired if lacerated.

**ULNAR WRIST EXTENSOR TENDINITIS**

Ulnar wrist extensor tendinitis (i.e., chronic or recurrent subluxation of the extensor carpi ulnaris tendon) may result in painful tenosynovitis. This condition is usually attributable to a single forceful or repetitive hypersupination motion of the wrist with ulnar deviation (14). The infratendinous retinaculum of the wrist is stretched or ruptured, allowing palmar subluxation of the extensor carpi ulnaris tendon (14,35). Conservative management consists of splint immobilization in a dorsiflexed position, pronation, and radial deviation of the wrist. Administration of oral antiinflammatory agents and local injection of steroids may alleviate symptoms. Surgical reconstruction is indicated in selected individuals in whom conservative therapy fails to resolve symptoms (20).

**RECONSTRUCTION OF THE SIXTH DORSAL COMPARTMENT RETINACULUM**

- After administration of general or regional anesthesia, pronate the wrist and make a hockey-stick incision from the base of the fifth metacarpal; extend it 2 cm radially and 4 cm proximally (Fig. 50.32). Protect the sensory branches of the ulnar nerve as they cross the distal portion of the wound. Expose the supratendinous portion of the retinaculum, and identify the sixth dorsal extensor compartment.

**Figure 50.32.** Incision to reconstruct the sixth dorsal compartment of the wrist.

- Make a radially based flap about 1 cm wide and about 5 mm proximal to the distal margin of the retinaculum through the supratendinous extensor retinaculum. Make the window palmar enough to view the extensor carpi ulnaris tendon, which is subluxed into the depths of the wound (Fig. 50.33) (11).

**Figure 50.33.** Preparation of the flaps in the supratendinous portion of the extensor retinaculum.

- Locate the stretched or torn infratendinous retinaculum, which normally creates a medial wall against palmar subluxation of the extensor carpi ulnaris tendon. After assessing the proper dorsal replacement position for the extensor carpi ulnaris tendon, create a second radially based flap, about 1 cm wide, from the proximal portion of the extensor retinaculum. Make it long enough in a palmar-ulnar direction to allow creation of a sling around the tendon of the extensor carpi ulnaris (35). After the proximal flap has been wrapped around the extensor carpi ulnaris tendon and sutured to itself with two horizontal mattress sutures, repair the infratendinous retinacular leash around the same tendon, using a pull-out wire suture (Fig. 50.34) (14).

**Figure 50.34.** Creation of an extensor carpi ulnaris sling and repair of the infratendinous retinaculum using a pull-out wire technique.

- If the septal tissues are irreparable, use the distal flap portion of the extensor retinaculum as a free fascial graft. A portion of the extensor carpi ulnaris tendon proximal to the extensor retinaculum may also be used as a free graft (14). Close the retinaculum (Fig. 50.35).
After the tourniquet is released, achieve hemostasis and close the skin. Place the extremity in a long-arm splint for 6 weeks with the wrist dorsiflexed at 25° with the forearm in neutral rotation. Remove the splint and encourage the patient to engage in active motion of increasing intensity over the next 6 weeks.

**PITFALLS AND COMPLICATIONS**

The dorsal cutaneous branch of the ulnar nerve may be lacerated; if it is, repair it microscopically. Use a free graft to repair a deficient infratendinous retinaculum,

In general, extensive soft-tissue injuries with a major inflammatory response lead to a greater degree of fibrosis. In traction, crush, and missile injuries, fibrosis may coaptation; it may create a barrier at the lesion that is difficult for the axon sprouts to traverse; and it may tether the nerve to surrounding tissues, impairing its mobility. Second obstruction to successful natural repair is the development of fibrosis in the vicinity of the lesion. Fibrosis may distort the nerve architecture and destroy repair, malaligned axon sprouts grow into epineurial tissues and reach a blind end or grow into inappropriate tubules to establish connections that are nonfunctional. A retraction of the severed ends and motions of the extremity destroy coaptation, and axon sprouts do not grow into the distal endoneurial tubules. After a noncongruent retraction of the severed ends and motions of the extremity destroy coaptation, and axon sprouts do not grow into the distal endoneurial tubules. After a noncongruent retraction, the distal portion of the nerve, cut off from trophic support of proximal cell bodies, undergoes wallerian degeneration. This process involves disintegration of the axon and myelin sheath, which are absorbed by macrophages and Schwann cells, leaving a tubule along the pathway of the former axon. Proximal to the lesion, some retrograde degeneration occurs, which is likely to be greater in more proximal lesions. The endoneurial tubes remain intact, and regenerating axons can reestablish their functional connections. Good recovery, usually within a year, is likely. Neurotmesis is a severe injury with disruption of axons and connective tissues of the nerve. Fibrosis, loss of coaptation, and loss of continuity mitigate against successful natural recovery. Recovery from compression injuries depends on how long the nerve has been compressed and the degree of compression. A lacerated nerve has no chance of spontaneous recovery, and the discontinuity must be surgically repaired. If the wound is a clean one from a sharp object such as a knife or glass, the damage to the nerve is likely to be local; this is unlike a crush, traction, or missile wound, in which damage may extend a considerable distance proximally and distally. The likelihood of functional recovery after accurate surgical repair depends on which nerve is involved, the level of the injury, the condition of the wound, and, most important, the age of the patient. Results of nerve repair in children are always better than those in adults. More distal injuries have a better prognosis for recovery than proximal ones, and a pure motor or sensory nerve has a better prognosis than a mixed nerve. Seddon proposed a simple classification of nerve injuries based on degree of damage rather than on mechanism of injury (25,26). Neurapraxia is a minor injury resulting from traction or compression in which ischemia or local demyelination interfere with nerve function. Damage to motor function is usually greater than to sensation, and recovery is within hours or days. Axonotmesis is a moderate injury in which continuity of axons is disrupted with wallerian degeneration distal to the lesion. The endoneurial tubes remain intact, and regenerating axons can reestablish their functional connections. Good recovery, usually within a year, is likely. Neurotmesis is a severe injury with disruption of axons and connective tissues of the nerve. Fibrosis, loss of coaptation, and loss of continuity mitigate against spontaneous recovery. Surgical repair is indicated. Sunderland classified peripheral nerve lesions into five types, representing increasing degrees of damage (Table 51.1) (28). Millesi has added a second variable, the degree of fibrosis, to Sunderland’s classification (see Chapter 60).

Acute traumatic damage to a peripheral nerve may occur as a result of traction, contusion, compression, or laceration. The mechanism of injury determines the nature of the lesion, its management, and its prognosis. A nerve trunk can be stretched by as much as 15% of its length without injury. Much of this elasticity derives from the geometry of the nerve. The nerve trunk runs an undulating course in its bed; the funiculi run an undulating course in the epineurium; and the nerve fibers run an undulating course inside the funiculi (28). The straightening of these undulations provides elasticity in the physiologic range of stretching. As the nerve is stretched beyond this limit, the axons (efferent) and dendrites (afferent), which have little tensile strength, fail before the surrounding connective tissues (epineurium and perineurium), which are stronger. When the tensile strength of the perineurium is exceeded, which occurs at about 20% of stretching, the region between the elastic limit and the mechanical limit, the nerve fibers are damaged to various degrees without gross disruption of the nerve trunk. Traction injuries may be associated with fractures, at the time of injury or during reduction or fixation; with dislocations and stretch injuries; and with gunshot wounds. Although spontaneous recovery is typical of most of these injuries, complete nerve loss can also occur. Contusion injuries from a blunt blow to the nerve carry a similar prognosis to traction injuries, with spontaneous functional recovery the normal prognosis. Recovery from compression injuries depends on how long the nerve has been compressed and the degree of compression. A lacerated nerve has no chance of spontaneous recovery, and the discontinuity must be surgically repaired. If the wound is a clean one from a sharp object such as a knife or glass, the damage to the nerve is likely to be local; this is unlike a crush, traction, or missile wound, in which damage may extend a considerable distance proximally and distally. The likelihood of functional recovery after accurate surgical repair depends on which nerve is involved, the level of the injury, the condition of the wound, and, most important, the age of the patient. Results of nerve repair in children are always better than those in adults. More distal injuries have a better prognosis for recovery than proximal ones, and a pure motor or sensory nerve has a better prognosis than a mixed nerve. Seddon proposed a simple classification of nerve injuries based on degree of damage rather than on mechanism of injury (25,26). Neurapraxia is a minor injury resulting from traction or compression in which ischemia or local demyelination interfere with nerve function. Damage to motor function is usually greater than to sensation, and recovery is within hours or days. Axonotmesis is a moderate injury in which continuity of axons is disrupted with wallerian degeneration distal to the lesion. The endoneurial tubes remain intact, and regenerating axons can reestablish their functional connections. Good recovery, usually within a year, is likely. Neurotmesis is a severe injury with disruption of axons and connective tissues of the nerve. Fibrosis, loss of coaptation, and loss of continuity mitigate against spontaneous recovery. Surgical repair is indicated. Sunderland classified peripheral nerve lesions into five types, representing increasing degrees of damage (Table 51.1) (28). Millesi has added a second variable, the degree of fibrosis, to Sunderland’s classification (see Chapter 60).

Table 51.1. Classification of Nerve Injuries

NATURAL HISTORY OF NERVE INJURY

Experimentally, a sharp surgical division of a peripheral nerve is the model that has been best studied: traction and crush injuries are less well understood. Within a month after laceration, the distal portion of the nerve, cut off from trophic support of proximal cell bodies, undergoes wallerian degeneration. This process involves disintegration of the axon and myelin sheath, which are absorbed by macrophages and Schwann cells, leaving a tubule along the pathway of the former axon. Proximal to the lesion, some retrograde degeneration occurs, which is likely to be greater in more proximal lesions. Within about 96 hours, the cell bodies whose axons or dendrites have been severed enlarge and their metabolic activity greatly increases. At the same time, axons sprout at the proximal stumps (3). If the two severed ends are still congruously opposed, axon sprouts grow at a rate as much as 1 mm each day down the endoneurial tubules of the degenerating distal axons to eventually reestablish connection with the sensory, motor, and sympathetic nerve end points. The actual rate of recovery is affected by age. In an animal model, Choi showed that the speed of wallerian degeneration, axonal regeneration, and myelin regeneration was greater in 2-month-old rats than in 10-month-old rats (5). Spontaneous recovery from mild axonotmesis may take from 1 to 6 months, with more proximal lesions requiring more time to heal. In more severe lesions, several factors mitigate against successful natural recovery. The chief of these is loss of coaptation. If the nerve is completely transected, retraction of the severed ends and motions of the extremity destroy coaptation, and axon sprouts do not grow into the distal endoneurial tubules. After a noncongruent retraction, malaligned axon sprouts grow into epineurial tissues and reach a blind end or grow into inappropriate tubules to establish connections that are nonfunctional. A second obstruction to successful natural repair is the development of fibrosis in the vicinity of the lesion. Fibrosis may distort the nerve architecture and destroy coaptation; it may create a barrier at the lesion that is difficult for the axon sprouts to traverse; and it may tether the nerve to surrounding tissues, impairing its mobility. In general, extensive soft-tissue injuries with a major inflammatory response lead to a greater degree of fibrosis. In traction, crush, and missile injuries, fibrosis may...
extend a considerable distance proximally and distally.

The management of peripheral nerve lesions must be designed to enhance the natural pathways of repair. This involves the reestablishment and maintenance of coaptation, avoidance of traction, and excision of excessive fibrosis.

CLINICAL ASSESSMENT OF PERIPHERAL NERVE INJURY

Severance of a peripheral nerve causes acute loss of sensory, motor, and sympathetic functions of that nerve distal to the lesion. Clinically, the acute picture is often confused by associated injuries. Fractures and dislocations; damage to muscles, tendons, or vascular structures; and head injury or altered psychological state can mask or mimic a peripheral nerve injury. Assessment of peripheral neuropathy should be done as early as possible after stabilization of the patient's other injuries so that proper therapy can be planned (Fig. 51.1).

![Figure 51.1. Algorithm for management of peripheral nerve injuries. EMG, electromyograms; FIBS, fibrillation potentials; NCV, nerve conduction study; PSW, positive sharp waves; VMP, voluntary motor unit potentials (interference pattern). (From Frykman G, Wolf A, Coyle T. An Algorithm for Management of Peripheral Nerve Injuries. Orthop Clin North Am 1981;12:240, with permission.)](image)

A number of diagnostic tests have been devised to evaluate the function of a peripheral nerve (Table 51.2); these are reviewed by Omer (22). Accuracy and consistency in performing the initial diagnostic tests is critical, because these are the standards by which spontaneous recovery and the need for surgery are judged. Sometimes assessment can be made only by surgical exploration, as in young children or in head trauma victims.

Table 51.2. Tests of Peripheral Nerve Function

NERVE REPAIR

INDICATIONS FOR SURGERY

If nerve damage is suspected in the context of an open wound, direct inspection of the nerve at the time of irrigation and debridement is indicated. An acute primary repair may be undertaken if the wound is clean, the mechanism of injury is a sharp laceration, the patient's condition is stable, and the surgical team and its facilities are available (8). If this constellation of circumstances is not encountered, perform a delayed primary repair within 8 to 15 days. If repair is to be delayed, the nerve ends can be tagged with wire suture to facilitate later identification at the time of acute exploration of the wound. Tagging is not critical, because later surgery is based on identifying normal nerve proximal and distal to the lesion and dissecting toward the injury, rather than on searching for suture tags in a bed of scar. The wire is useful for locating nerve ends on radiographs, however. If the severed ends can be easily approximated, they may be loosely sutured together to resist retraction during the interval before the delayed repairs.

Early repair is preferable in a clean wound, because extensive nerve retraction has not yet occurred and less mobilization is required. The delay of 1 or 2 weeks after injury may offer some advantages, however, besides allowing the surgical team opportunity to prepare. The posttraumatic edema of the cut ends has time to resolve, and the nerve cell bodies greatly increase their anabolic activity in association with axon sprouting. The extent of proximal and distal damage to the nerve is easier to assess. The location of early axon sprouts can help define the necrotic terminus of the proximal stump.

In a closed injury with suspected neuropathy, after an acute compartment syndrome is ruled out, quantitative diagnostic tests should be performed (Table 51.2) to serve as a standard by which the recovery of the deficit may be measured. These tests must be performed in a meticulous and consistent way so that comparisons are valid. Although no single test is infallible, the combined weight of several tests with similar results allows a reasonably secure diagnosis. The patient should be reevaluated at intervals of 4 to 6 weeks.

Secondary repair (>2 weeks after injury) is indicated in heavily contaminated wounds, if soft-tissue coverage is poor and requires flaps, if the amount of nerve damage cannot be assessed early (e.g., in patients with gunshot wounds, head injuries), or if the diagnosis is initially missed. Some motor recovery may be expected after repairs as late as 1 year after injury; partial sensory recovery may result from repairs as late as 2 years after injury. Success diminishes with delay, however, because muscle atrophies and endoneurial tubules undergo fibrosis.

ANATOMIC BASIS OF NERVE REPAIR

The anatomic goal of neurorrhaphy is, simply, to exactly realign the axons so that regenerating axon sprouts will reconnect to their preinjury end points. A number of factors frustrates the surgeon's attempt to achieve this. Edema in the proximal stump and shrinkage of the distal stump prohibit exact coaptation of formerly congruent ends, as will any distortion caused by less-than-perfect suture technique. A greater problem is segmental loss of even a few millimeters of nerve due to necrosis resulting from the injury. The pioneering studies of Sunderland in mapping the topography of the fasciculi in the peripheral nerves reveal a complex arrangement of branching, joining, and wandering pathways. Consequently, the number, size, arrangement, and neurologic content of the fascicles as seen in cross section vary along the nerve. With greater segmental loss, the cross-sectional arrangements of the two ends are increasingly dissimilar and the possibility of excellent coaptation diminishes accordingly.

Sunderland's diagram of the fascicular topography of a segment of the musculocutaneous nerve (Fig. 51.2) has been often reproduced and stands as a graphic display of the impossibility of obtaining perfect coaptation after segmental loss. Jabaley et al. (14,32) have found that in several regions of the median and radial nerves, the fascicular topography is considerably less variable than in Sunderland's diagram, and that precise coaptation of most fascicles is theoretically possible despite segmental loss. Even over a longer distance encompassing various fascicular plexi, a bundle of axons tends to remain in the same quadrant of the nerve.
If segmental loss is minimal, aligning epineurial features (vessels) at the two stumps and by sketching the cross-sectional appearance of the two ends and approximating them accordingly can ensure correct rotational alignment. When segmental loss is greater, a sketch of the cross-sectional fascicular arrangement can be compared with published maps, which may facilitate alignment. Finally, intraoperative electrical stimulation can be used to distinguish predominantly motor from sensory fascicles. With the patient awake and the tourniquet released, stimulation of the distal stump may identify motor fascicles, and stimulation of the proximal stump may identify sensory fascicles. Silent fascicles proximally are presumed to be motor, and silent fascicles distally are presumed to be sensory (19).

A staining technique based on acetylcholinesterase has been shown to help differentiate motor from sensory fascicles within a nerve. Because it requires 24 hours of incubation time, it is not usually suitable for intraoperative use, although it has provided confirmation of mapping of fascicles done by other means. Similar histochemical techniques with shorter development times show promise, but they are not now in general use (24).

TYPES OF NEURORRHAPHY

Three surgical techniques of neurorrhaphy are in current use: epineurial repair, fascicular repair, and group fascicular repair. Each technique is appropriate to certain circumstances. Appreciation of microneuroanatomy is essential to understanding the techniques of nerve repair (Fig. 51.1). At present, all repairs are done with microsutures. In countries other than the United States, commercially available fibrin glue is often used in combination with a limited number of sutures. This glue is made from donated blood products. It is possible to make fibrin glue from the patient's own donated plasma by mixing it with thrombin, but the cost, time, and effort needed to be weighed against the benefits. Experimentally, there is some evidence that fibrin seals are efficacious (22), but the true value has not been established.

Epineurial repair is the standard method of nerve repair carried out by placing several sutures peripherally in the epineurium after aligning the nerve ends according to fascicular pattern and epineurial landmarks. This technique has the advantage of being less technically demanding, being less traumatic to the nerve ends, and placing less suture material in the repair site. Epineurial repair is indicated for small nerves, for nerves with only one or two fascicles, and for primary repair of a clean laceration in a larger nerve.

In fascicular (also called funicular) repair, individual fascicles are dissected free of enveloping epineurium and sutured fascicle to fascicle through the perineurium. In principle, this method should lead to a more precise coaptation and better recovery. In practice, fascicular repair is technically demanding, inevitably causes some trauma to the nerve ends, and leaves suture material within the nerve, which may stimulate a fibrotic response. Nonetheless, in the hands of those skilled in the technique, fascicular repair produces good results, especially in nerves to nerves with two to five large fascicles or if epineurium constitutes a large part of the cross-sectional area of the nerve.

Group fascicular repair is similar in principle to fascicular repair except that recognizable groups of fascicles are joined instead of individual fascicles. The repair of more than five fascicles or groups is impractical, because it excessively injures the nerve end and leaves too much suture material within the wound. Group fascicular repair is the technique employed in nerve grafting.

Epineural and fascicular repair may be combined, as in repair of a laceration of the median nerve at the wrist, where fascicular repair of the motor component may be combined with epineurial repair to approximate sensory elements. The choice of technique depends on the topography of the nerve at the site of the lesion. The superiority of fascicular or group fascicular repair over epineurial repair has not been clearly demonstrated clinically or experimentally. The immediate environment of wound healing, the condition and age of the patient, and the skill of the surgeon are probably more important than the type of neurorrhaphy.

NERVE GRAFTING

If segmental loss prohibits end-to-end repair without excessive tension, interfascicular nerve grafting is indicated. This technique was developed and refined by Millesi, whose series shows a high percentage of good or excellent results (20–21). The nerve stumps are stepcut, and the fascicles are debrided of enveloping epineurial tissues. Corresponding fascicles or groups of fascicles are identified by geometry or electrodiagnostic tests. Graft segments long enough to bridge the gap without tension are sutured through the perineurium to connect appropriate fascicles or groups of fascicles in the proximal and distal stumps. Although the regenerating axons must cross two suture lines, it is thought that the prognosis is better for crossing two suture lines without tension than one suture line under tension. The sural nerve is typically used as the graft; this can yield a usable graft segment as long as 40 cm. The lateral antebrachial cutaneous nerve can also be used (27).

Although nerve repair under tension has a poor prognosis, what constitutes excessive tension (and thus an indication for grafting) is not universally agreed. Wilgis more than 90° or the wrist beyond 40° to close a gap is contraindicated. The surgeon must judge the potential morbidity of postoperative immobilization of the joints in a flexed position against the morbidity of nerve grafting in light of his or her own skills and experience.

OPERATIVE TECHNIQUES

- Prepare and drape the entire extremity into the operative field, because it is often necessary to mobilize the nerve proximally and distally for considerable distances.
- Prepare and drape one or both lower extremities if nerve grafting is a possibility.
- Apply a tourniquet to each extremity being draped.
Use a generous, extensile incision.

In freeing the nerve, work from normal nerve toward the lesion: distalward in the proximal portion and proximalward in the distal portion. Keep exposed portions of the nerve moist with saline-soaked sponges.

Handle the nerves very gently using a jeweler's forceps to grasp only the epineurium.

Avoid applying any pressure to the fascicles, which may result in further injury.

Use magnifying loupes in the initial identification of the nerve and its dissection. Final preparation of the nerve ends and suturing are facilitated by an operating room microscope, enabling proper grouping of similar nerve fascicles, aligning of epineural landmarks with proper orientation, and more accurate placement of sutures. Use microsurgical instruments to perform nerve repair and nerve grafts.

**Epineural and Group Fascicular Repairs**

- Place a moist wooden tongue depressor beneath the end of the nerve.
- While an assistant applies gentle traction on the nerve end with a jeweler's forceps, use a Weck blade to cut back the nerve ends sharply until noninjured tissue is reached.
- Inspect the proximal portion of the cut ends under the microscope to look for bulging axons.
- Repeat these steps on the opposite nerve end.
- After both ends have been resected until normal-looking structures are seen, the repair can begin.
- Have the assistant take the tension off the nerve by grasping the proximal and distal segments of the nerve about 1 cm away from the repair and approximating the nerve ends. If the tension is observed to be great or approximation is not possible, consider further mobilization of the nerve or grafting.
- In an epineural repair, after alignment of the nerve, pass the appropriate suture proximally and distally in the epineurium only, and tie the knot firmly. Pass a second suture 180° opposite to the first suture in a similar fashion. Leave the strands of these two initial knots long may assist in turning the nerve. Use the minimal amount of sutures necessary to close the entire epineurium on the anterior side, and repeat this, having turned the nerve around, on the posterior side.
- Use a nonabsorbable 9-0 suture (nylon) for larger nerves, and a 10-0 nonabsorbable suture for smaller nerves (Fig. 51.4).

**Figure 51.4.** Epineurial repair. A: Nerve ends are freshly cut back to well-visualized fascicles. B: Two sutures are placed into the epineurium at 180° from each other, maintaining alignment of the fascicles in the proximal and distal stumps. C: The remainder of the epineurium is approximated using the minimal number of simple sutures necessary to complete the closure.

In a fascicular repair:

- Identify the fascicles proximally and distally by observing the cross-sectional anatomy under the microscope.
- Coapt the ends of the matching funiculi, placing 10-0 nylon interrupted sutures through the interfascicular epineurium and the perineurium of the individual fascicles.
- Avoid all tension (Fig. 51.5).

**Figure 51.5.** Fascicular repair. A: Individual fascicles are identified proximally and lined up with their distal counterpart. B: These individual fascicles are then approximated with minimal sutures. The epineurial layer is then repaired as shown in Figure 51.4B and Figure 51.4C.

In a grouped fascicular repair:

- Identify groups of fascicles by observing proximal and distal cross-sectional anatomy, and join these groups with interrupted 10-0 nylon suture placed in the interfascicular epineurium.

In mixed fascicular and epineural repair:

- Line up the major group of fascicles that can be identified, and perform a grouped fascicular repair.
- Then repair the epineurium circumferentially around the entire nerve as described under epineurial repair.

**Nerve Grafting**

- Explore and prepare the nerve stumps, as described previously.
- Examine the cross-sectional anatomy, and isolate the fascicle groups.
- Measure the distance between the two stumps, with the elbow and wrist joints extended.
- Pass a 10-0 nylon stitch between the fascicles of the graft, catching the interfascicular epineurium, and pass this stitch into the proximal stump of one group of fascicles.
- Approximate the distal end of the graft to the stump of the corresponding distal fascicle group in a similar fashion.

The usual donor site for nerve graft material is the sural nerve. The use of this nerve creates a sensory loss at the lateral side of the foot below the lateral malleolus, which causes no problem in the vast majority of patients.

- Locate the nerve behind the lateral malleolus with a 1 cm longitudinal incision.
- Tag the nerve with umbilical tape. A few centimeters proximal to this incision, make a small transverse incision over the nerve.
- Pull on the nerve distally with slight tension so that it can be easily palpated in the proximal incision.
- Place two to three more incisions proximally over the nerve at equal intervals to identify its full length. Then transect the nerve through the most proximal incision to harvest the entire segment of the sural nerve.
Close the wounds as usual and drain if appropriate. Avoid suction drains placed close to a nerve repair or nerve graft, because they may disrupt the suture line.

A tendon stripper can be used to harvest the nerve through a single distal incision, but great care must be taken not to cut the nerve too short. Other sources of donor nerve include the lateral and medial antebrachial cutaneous nerves and the terminal articular branches of the posterior interosseous nerve, but the sural nerve provides the longest nerve segment with the least morbidity.

It is essential to document in the operative notes exactly where the location of repair is in relation to surface anatomy. Each juncture should be measured and noted so that after surgery it is possible to follow the progression of Tine's sign (i.e., distal tingling on percussion). Using a long interfascicular graft, progression may cease at the distal nerve juncture. The surgeon knows that this is happening if the progression of Tine's sign ceases at the same point noted for the distal juncture.

POSTOPERATIVE CARE

Immobilize the extremity in the same position as it is in duration for the operation to 10 to 14 days. After wound sutures are removed, place the extremity in a plaster cast in a position to relax all suture lines. For example, a median nerve repair in the forearm requires the wrist to be in slight flexion and the elbow placed at 90° of flexion. Continue immobilization for a total of 6 weeks, but at 4 weeks start to straighten out the joints that have been splinted in a position to avoid tension on the nerve suture line.

REHABILITATION

Preoccupation with the technical intricacies of nerve repair should not cause the surgeon to lose sight of the goal, which is a functional patient. Although nerve repair is feasible, the patient may be better served by other procedures, such as tendon transfers. If an older patient is well adapted to the disability, it may be better not to intervene despite the possibility of improved function.

It is inevitable that after nerve repair, some regenerating neurons will make connections to sensory or motor end points different from those to which they were formerly connected (7). Although they recover sensory function and transmit signals to the brain, the meaning of these signals is garbled if they are evaluated in the cortex according to preinjury habits of interpretation. The patient must be reeducated to correlate sensory input with external reality. In children, this is readily accomplished. Hudson et al. reported their results on 18 children with lacerations of the median nerve treated by primary epineural repair (13). The mean return of motor power to the opponens pollicis was 4.5 and the mean static two-point discrimination was 5 mm (13). Older patients are less flexible and may ignore sensory information supplied by heterotopically regenerated nerves. In this case, the anatomicly successful nerve repair is in vain. An aggressive program of therapy aimed at sensory reeducation may considerably improve the results of a peripheral nerve graft when training the patient to adapt to the altered arrangement of the peripheral axons.

NEWER (FUTURE) TECHNIQUES

There has been some interest in allotraft sural nerve grafting. Experimentally, nerve regeneration across peripheral nerve allotrafts compared favorably with control autografts in primates when they were immunosuppressed with Cyclosporin A (1). It does not seem worthwhile, however, to run the risks of immunosuppressing patients for this purpose. Others have experimented with various biologic materials to act as nerve conduits (4,6-8,11-29,23).

Injury to a peripheral nerve is followed by local synthesis and release of neurotrophic factors, which play a role in the regeneration process. There has been significant interest in using silicone tubes for nerve repair both to handle a small gap and to capitalize on these neurotrophic factors (12,39) to increase the specificity of neural connections (motor to motor and sensory to sensory). Animal studies have shown some conflicting results. Some have demonstrated that there is merit to this technique (12,19). Bruschart's experiments demonstrated no evidence for neurotropic interactions promoting correct fascicular reinnervation in a mixed nerve (2). Using a silicone tube, he could not find any neurotropic factors that promote fascicular specificity and thus stated that an "enclosed gap is not an acceptable substitute for nerve graft when reconstructing a nerve that serves multiple functions" (2).

Lundborg et al. adopted this concept for repair of transected human median and ulnar nerves in the forearm (17). Lundborg used silicone tubes of appropriate size to enclose the injury zone, intentionally leaving a gap measuring 3 to 4 mm between the nerve ends inside the tube. His early results from a prospective, randomized, clinical study comparing this technique with conventional microsurgical technique for repair of human median and ulnar nerves showed no difference between both techniques, with the exception of perception of touch, which showed a significant difference at the 3-month checkup in favor of the tubulization technique. Furthermore, at reexploration 11 months after the initial procedure Lundborg reported that the former gap was replaced by regenerating nerve tissue in direct continuity with the proximal and distal parts of the nerve trunk, with the exact level of the former injury being impossible to identify (17). I witnessed this reexploration when I visited Lundborg and confirmed that this finding was quite accurate.

Lundborg et al. have also developed a biartificial nerve graft in which multiple polyamide (nylon) filaments were placed inside silicone tubes to make an intrinsic and extrinsic framework, respectively, for regenerating axons. Early animal experiments have shown that the new artificial nerve graft can be used to support regeneration across extended gaps in nerves (15,16,29).

Another future avenue for nerve repair is the use of the concept of end-to-side repair. The possibility that collateral sprouting can occur from intact axons in an undamaged nerve, induced by factors from the attached nerve segment, and subsequently can make functional peripheral connections may permit damaged nerves to be sutured to nearby normal nerves. Lundborg et al. studied this concept in the rat by suturing either a 7-day predegenerated or a fresh nerve segment in an end-to-side fashion to the sciatic nerve proper (18). Although they recover sensory function and transmit signals to the brain, the meaning of these signals is garbled if they are evaluated in the cortex according to preinjury habits of interpretation. The patient must be reeducated to correlate sensory input with external reality. In children, this is readily accomplished. Hudson et al. reported their results on 18 children with lacerations of the median nerve treated by primary epineural repair (13). The mean return of motor power to the opponens pollicis was 4.5 and the mean static two-point discrimination was 5 mm (13). Older patients are less flexible and may ignore sensory information supplied by heterotopically regenerated nerves. In this case, the anatomicly successful nerve repair is in vain. An aggressive program of therapy aimed at sensory reeducation may considerably improve the results of a peripheral nerve graft when training the patient to adapt to the altered arrangement of the peripheral axons.

PATHOPHYSIOLOGY

Whenever A Nerve Is Contained In A Space That Has Limited Compliance, Such As The Carpal, Cubital, Or Ulnar Tunnels, Or It Lies Deep To Fibrous Bands And Tendinous Arches Of Origin, It Is Vulnerable To Compression. An Increase In The Volume Of Material Within One Of These Limited Spaces Or A Decrease In Size Of The Space Can Lead To Increased Pressures, Which In Turn Can Compress The Nerve. Other Factors That May Lead To A Mechanical Peripheral Neuropathy Include Stretching Of The Nerve And Abnormal Nerve Motion About Or Adherence To Fibrous Bands Or Fascial Edges. The Intrinsic Response Of The Nerve To This Mechanical Insult Varies Little Regardless Of The Location Of The Injury Or The nature of the offending agent. The sequence of pathologic changes within the median nerve and the resulting clinical progression are the same whether the entrapment is secondary to synovitis within the carpal tunnel or secondary to a bone fragment from a fracture of the distal radius. Relief of the compression, generally accomplished by releasing the confining tunnel or compressive fibrous band, reverses these changes partially or completely. If damage to the nerves is irreversible (i.e., if entrapment is chronic), release can halt progression. All three major nerves of the upper extremity, the median, ulnar, and radial, may be injured by compression in locations where they are anatomically vulnerable.

Compression of a nerve has an effect on its structure and function. The severity of the resulting lesion depends on the magnitude of the compression as well as its duration. Both direct mechanical factors causing myelin damage and alterations in blood flow to and within the nerve likely play roles of varying degrees in causing the nerve changes seen in compression neuropathies. Ischemic changes caused by blood-flow alterations play an important part in acute, easily reversible nerve-function alterations (124). Experiments have shown that elevation of pressure in and about the nerve to within 40 mm Hg of diastolic blood pressure cause profound changes in sensory nerve function of the median nerve, which are reversible with restoration of blood flow. Motor dysfunction of the nerve requires higher and more sustained elevations in pressure. These changes in function are not associated with structural changes in the nerve (132). Ischemia also plays a role in chronic compression. It is believed to contribute to intraneural scarring as well as edema from prolonged loss of blood supply to the nerve. Structural changes, particularly alterations in or loss of the myelin coatings of nerve fibers, are seen in chronic, higher-pressure compressions, especially those involving an edge such as a fibrous band or tendon. These changes resolve only in some cases, after enough time has elapsed for repair of damaged myelin. Compression of the nerve has also been shown to inhibit axoplasmic flow, both antegrade and retrograde, diminishing nerve function and contributing to the bulging appearance of the nerve proximal and distal to the site of compression (72).

The mechanism whereby surgical decompression works is not entirely understood. The frequently dramatic response to treatment can be explained only by the removal of the causative agent. However, this theory, the mechanical factor responsible for producing the compression obstructs venous return, followed by segmental anoxia, capillary vasodilatation, and edema (33,125). The nerve edema aggravates the compression and leads to abnormal axonal and cellular exchange (34,124,131). Surgical release at this stage is a rewarding procedure. Prolonged compression results in intraneural fibrosis, after which nerve recovery is less likely to occur despite decompression.

ASSESSMENT

Clinical evaluation of an entrapment syndrome and determination of the site of compression are greatly aided by a knowledge of the anatomic distribution of a nerve and its function. Clinical evaluation of nerve compression neuropathies includes sensory threshold testing, provocative testing, and evaluation of muscle weakness or atrophy. The most consistent and reliable way to evaluate sensibility in nerve compression is to use threshold testing (126,127,132,133,134). Threshold tests evaluate how well a single nerve fiber innervating a receptor or group of receptor cells is functioning. These include vibrometry, Semmes–Weinstein monofilaments, and vibration testing. To test with Semmes–Weinstein monofilaments, apply pressure to the fingertip with the filament until the filament bends (Fig. 52.1). The pressure required to bend the filament is directly related to its diameter. Apply filaments of successively increasing diameter to determine the sensory threshold of slowly adapting nerve fibers. Perform vibration testing with a 256 cycles-per-second (cps) tuning fork to evaluate the sensory threshold of quickly adapting nerve fibers (Fig. 52.2).

Figure 52.1. Threshold testing with Semmes–Weinstein monofilaments.
Electromyography employs needle electrodes placed within muscle to evaluate the activity of a single motor unit consisting of the nerve cell, its fibers, and the group of muscle fibers it innervates (Fig. 52.5). Normally, a muscle fiber at rest is essentially electrically silent. After a brief burst of electrical activity that occurs while the electrode is inserted, the needle measures only occasional background impulses. When the muscle is voluntarily contracted, the electrode senses the electrical activity of the motor unit, which is a waveform called the motor unit potential (MUP). In the pathologic state, different waveforms may be detected that give insight into the disease process affecting the muscle as well as the chronicity of the condition and whether recovery or further loss is occurring. (Some names of these waveforms and their general implications are offered here, but this information should not be considered a definitive reference.)

Figure 52.2. Vibration sensation testing with a 256 cps tuning fork.

Figure 52.3. Two-point discrimination testing.

Innervation density tests (i.e., two-point and moving two-point discrimination) (Fig. 52.3) measure multiple overlapping peripheral receptor fields and the density of innervation—how many nerve fibers are present and correctly represented in the cerebral cortex. Early in compression neuropathies, nerve fibers are not lost; rather, the nerve fibers that are present are not functioning well. In nerve laceration, in contrast, nerve fibers to the innervated area are lost. Innervation density tests are more useful for evaluating nerve laceration and recovery after repair than for evaluating compression neuropathies. These tests are abnormal in only 20% of patients with electrically proven carpal tunnel syndrome (CTS), whereas threshold tests detect more than 80% of electrically proven CTS patients (133).

Provocative tests compress, stretch, or percuss the nerve to elicit numbness and paresthesias in its sensory distribution. Provocative tests are especially important in patients with exertional compression neuropathies, where symptoms and signs may be minimal or absent at rest. For this reason, it may also be advisable to perform sensory testing before and after activity (122). The examiner evaluates weakness and atrophy subjectively. Muscles innervated by the nerve suspected of compression are tested for bulk and strength. Comparison to the uninvolved extremity is especially helpful.

DIAGNOSTIC STUDIES

Although not a substitute for a thorough clinical examination, electrodiagnostic studies may help to corroborate clinical impressions. They truly are the only objective test of nerve compression. Additionally, they may indicate a level of severity of nerve damage that may have prognostic implications for treatment. A detailed explanation of neurodiagnostics of the upper extremity is beyond the scope of this chapter. Here we offer a brief, basic description of methods and definitions of terms. For a more complete understanding, read review articles and book chapters published on this subject (49,51,56). The neurodiagnostic study, when used for the majority of upper extremity compression injuries, is composed of two parts: the nerve conduction or velocity (NCV) and the electromyography (EMG) needle examination. The NCV measures the speed of conduction of an impulse along a segment of nerve. The EMG measures the response of muscle fibers to conducted nerve impulses.

When stimulated, a segment of nerve conducts or propagates an electrical impulse. This impulse can be detected by a surface electrode on the skin overlying a nerve or a muscle innervated by a nerve. In an NCV test, the nerve is stimulated electrically at one point and the impulse measured at another point along its length. When the study measures an impulse traveling in a physiologic direction, it is known as an orthodromic study; when it measures an impulse traveling in the opposite direction, it is called antidromic. Impulses propagated by sensory nerves or the sensory fibers of a mixed nerve are measured by surface electrodes as a waveform called the sensory nerve action potential. Motor nerves or the motor fibers of mixed nerves are measured by the electrical response of multiple muscle fibers, which produce a waveform known as the composite muscle action potential. The interval from stimulation of the nerve to the time at which the sensing electrode detects the waveform is known as the latency. In motor nerves, latency also encompasses the time it takes the nerve impulse to be transmitted across the neuromuscular junction and to activate the muscle fibers. Neurodiagnosticians often report latencies, especially when evaluating nerve conduction across short nerve segments at the wrist. Latencies are reported in units of time (msec). Conduction velocities are reported in units of meters per second and can be calculated from the measured latency and knowledge of the length of the nerve segment over which the latency was measured. Velocities are reported for longer lengths of nerve segments tested, such as from the midforearm to the hand. Additional measurements can be obtained by evaluating the waveforms. These include the amplitude, duration, and area of the waveform (Fig. 52.4). These parameters can aid the electromyographer in characterizing the conduction of the nerve. The amplitude and duration depend on the number of nerve fibers and the speed of conduction of the different nerve fibers transmitting the stimulated impulse, respectively.

Electromyography employs needle electrodes placed within muscle to evaluate the activity of a single motor unit consisting of the nerve cell, its fibers, and the group of muscle fibers it innervates (Fig. 52.5). Normally, a muscle fiber at rest is essentially electrically silent. After a brief burst of electrical activity that occurs while the electrode is inserted, the needle measures only occasional background impulses. When the muscle is voluntarily contracted, the electrode senses the electrical activity of the motor unit, which is a waveform called the motor unit potential (MUP). In the pathologic state, different waveforms may be detected that give insight into the disease process affecting the muscle as well as the chronicity of the condition and whether recovery or further loss is occurring. (Some names of these waveforms and their general implications are offered here, but this information should not be considered a definitive reference.)
Positive sharp waves and fibrillation potentials commonly indicate recent muscle denervation (Fig. 52.6A). The development of small highly polyphasic MUPs (Fig. 52.6B) and decreased fibrillations is considered evidence of early reinnervation of muscle. MUPs that are of great duration and amplitude are considered evidence of chronic denervation with collateral reinnervation resulting from adjacent nerve sprouting. Many waveforms are characteristic of neuropathies, and others of myopathies. The significance of the different electrical events is subject to the clinical setting and the interpretation of the electromyographer.

![Figure 52.5. Electromyography (EMG). APB, abductor pollicis brevis; MUP, motor unit potential. (From Hillburn JW. General Principles and Use of Electrodiagnostic Studies in Carpal and Cubital Tunnel Syndromes. Hand Clin 1996;12:205, with permission.)](image1)

When evaluating the electrodiagnostic report, it is important to understand that “normals” for particular tests are laboratory, machine, and operator dependent because of variations in how measurements are calculated, technique, and environmental factors such as skin temperature. However, rule-of-thumb normals may be useful. For the median nerve at the wrist, distal motor latencies of more than 4.5 msec and distal sensory latencies of more than 3.5 msec are considered abnormal. In a patient with unilateral involvement, a difference from one hand to the other of more than 1.0 msec for motor latency and 0.5 msec for sensory latency is also considered abnormal (Table 52.1) (126). It is helpful to develop a relationship with an electromyographer who produces reliable and consistent results and whose interpretations of these studies are useful in your evaluation and treatment of patients.

Certain clinical and metabolic disorders can affect nerve function. Conditions commonly associated with nerve dysfunction include hypothyroidism with myxedema (69), obesity (84,85), cervical radiculopathy, diabetes mellitus, alcoholism (83), and exposure to neurotoxic chemicals or chemotherapeutic agents. These disorders in and of themselves can cause polyneuropathy, independent of compression neuropathy; they may increase the susceptibility of nerves to compression; or they may negatively affect recovery of nerves after adequate treatment. When suspected, these disorders should be investigated and managed. They are not, however, contraindications to treatment of coexisting compression neuropathies.

Recently, some members of the medical community, of the popular media, and in the medicolegal and workers’ compensation arena have included certain compressive neuropathies, most notably CTS, in a category of disorders known as cumulative trauma disorders or repetitive stress injuries. The association between repetitive stress or activity, and compression neuropathies has been described (41). It is fairly well accepted that certain activities or prolonged positioning of the extremities can incite the symptoms of compression neuropathies, but controversy exists about whether certain activities or occupations can cause them (129).

**PRINCIPLES OF TREATMENT**

The critical component of effective treatment of compression neuropathies of the upper extremity is an accurate diagnosis. A perfectly performed surgical procedure is likely to provide no benefit to the patient if it is not indicated for the condition causing the symptoms. Remember that each of the compression neuropathies is related to a syndrome, which is a constellation of symptoms and signs (123). Positive neurodiagnostic studies in the absence of symptoms and signs cannot make the diagnosis of any of the compression neuropathy syndromes.

Categorizing patients based on the relative severity of their compression neuropathies may be helpful in determining treatment options. Mild cases are those with a short history of symptoms that are intermittent rather than continuous, and with negative or minimally abnormal electrodiagnostic findings. Severe cases are those with histories of symptoms for more than a year, profound and persistent numbness with atrophy of involved musculature, and both very prolonged (or absent) conduction velocities and advanced EMG findings. Mild cases are likely to respond to nonoperative measures (40), whereas severe cases do not, and therefore initial treatment should be operative.

Nonoperative treatment includes splinting, medications, physiotherapy, corticosteroid injections, and correction of metabolic abnormalities. The nerve may be protected through avoidance of positions that are deleterious to nerve function. For instance, prolonged extreme positioning of the wrist in flexion in patients with CTS or of the elbow in flexion in patients with cubital tunnel syndrome aggravates symptoms and should be avoided. Splinting is employed, usually at night, to prevent this type of positioning. Therefore, nerve protection involves educating the patient about activities and postures that may lead to compression of nerves at vulnerable sites, and
how to avoid them.

Oral medications, most commonly nonsteroidal anti-inflammatory drugs (NSAIDs) and diuretics, have been used in treating compression neuropathies. No medications, however, have any documented efficacy. Physiotherapy may be helpful in treating certain types of nerve compression but is most helpful in postoperative rehabilitation. Corticosteroid injection is usually employed after failure of the previously described nonoperative treatments. A powerful anti-inflammatory agent is delivered directly to the tissues about the nerve, at a specific location. Since few cases of CTS are the result of acute or chronic inflammation in the flexor tenosynovium (62,82), the mechanism whereby steroid injections relieve symptoms is unknown. In addition to their therapeutic value, injections may help in confirming a diagnosis, providing a prognostic indicator of the potential effectiveness of operative treatment (45).

Treat CTS induced by pregnancy with splints and elastic gloves at night until delivery of the child, when it will likely resolve spontaneously. For severe symptoms, local injections of steroids may help. If symptoms persist thereafter, operation may be necessary.

Indications for surgery include failure of nonsurgical management; acute, rapidly progressive involvement; severe cases; and symptom recurrence. Tourniquet control during surgery is preferred unless the site of compression is too proximal or unless specific contraindications exist. Meticulous hemostasis is imperative during the exposure, especially in patients with a coagulopathy and in those who are taking aspirin or are on anticoagulation treatment to reduce postoperative bleeding and swelling. Facilitate this by exsanguinating the extremity through elevation rather than by elastic wrapping, so that vessels remain partially filled and are easier to identify and coagulate or tie off.

Decompression is generally an outpatient procedure and may be performed under general, regional, or local anesthesia. Local anesthesia is reserved for less involved cases and can be used with tourniquet control, which is well tolerated for brief procedures. Make the incision to allow adequate visualization of the nerve and all suspected sites of compression. The choice of treatment of the nerve depends on its appearance under direct visualization, the location of the entrapment, and the clinical findings. If the bed in which the nerve lies is scarred or makes the nerve vulnerable to potential mechanical trauma, consider nerve transposition or flap coverage.

COMPRESSION NEUROPATHIES OF THE MEDIUM NERVE

Compression of the median nerve typically occurs within the carpal tunnel or deep to the origin of the pronator teres (PT). A third form of median nerve entrapment is isolated compression of the anterior interosseous nerve (AIN).

CARPAL TUNNEL SYNDROME

Pathophysiology and Anatomy

At the level of the wrist, the median nerve lies within the confined space of the carpal tunnel along with the long flexor tendons to the fingers and thumb. The tunnel is bounded on three sides by the bones of the carpus, which make up the floor of the canal, and on the fourth by the transverse carpal ligament (TCL), which forms the roof (Fig. 52.7). Compressive neuropathy of the median nerve within the carpal tunnel may result from any space-occupying lesion under the TCL (19,67,145). A frequent cause is flexor tenosynovitis; other causes are fractures and dislocations of the floor of the canal and distal radius, and other space-occupying lesions such as tumors and ganglia. These space-occupying lesions increase the volume of the contents of the noncompliant carpal tunnel, raising the pressure on its contents, which include the median nerve. In many cases, there are no particular identifiable causes even though the nerve is clearly compressed. Although many of these cases are attributed to “nonspecific synovitis,” pathologic examination of the synovium obtained from the carpal canal in these cases usually fails to reveal signs of inflammation. Rather, fibrosis and/or edema changes are seen, which may themselves be secondary to compression rather than the primary cause of the entrapment neuropathy (62,82).

Assessment

The diagnosis of CTS is strongly suggested by the patient’s history. Typically, he complains of aching or burning pain along the median nerve distribution and of numbness and tingling in the median-nerve-innervated digits (Fig. 52.8A) during the night and early morning as well as during activities. Numbness may extend into the ulnar digits in some patients. These symptoms are aggravated by elevation, repetitive activities, and prolonged flexion positioning of the wrist (130). Radiation of symptoms proximal to the wrist is not unusual. Complaints of the hand feeling fat, clumsiness in manipulation, and dropping items are also frequent. The incidence is greater in women than in men, although the difference is decreasing. In the past, postmenopausal women were the most common patients; commonly associated diagnoses were rheumatoid arthritis and distal radius malunion. Recently, a large, younger group of patients with essentially equal distribution of women and men has emerged. In this group the carpal tunnel disease has been labeled idiopathic (62).

Examination includes sensory, provocative, sudomotor, and strength testing. Sensibility may be reduced throughout the area normally supplied by the median nerve except for the thanar eminence, the distribution of the palmar cutaneous branch (Fig. 52.8A), which does not enter the carpal canal (115). As noted previously, the most consistent and reliable way to evaluate sensibility in nerve compression is to use threshold testing (Semmes–Weinstein monofilaments, vibrometry, and 256 cps vibration testing) (126,127,132,133,134). Provocative tests compress or percuss the median nerve to elicit numbness and paresthesias in the distribution of the median
nerve in patients with CTS. Phalen's wrist flexion test, in which the wrist is maximally flexed with the fingers slightly curled, is sensitive (Fig. 52.9) (43). A positive test for CTS is reproduction of symptoms within 60 sec. Tinel's nerve percussion test, in which the median nerve is percussed as it enters the carpal canal to elicit symptoms (Fig. 52.10), is specific and indicates CTS in cases in which Phalen's test is also positive (65). Another useful test is the direct compression test, which is sensitive and specific. The examiner’s thumbs apply direct pressure to the median nerve as it enters the carpal tunnel (Fig. 52.11) (29). A positive test is reproduction of symptoms, which appear within 30 sec and disappear with release of compression. Together, these tests provide added clinical evidence of median nerve compression at the wrist (Table 52.2).

Figure 52.9. Phalen's wrist flexion test.

Figure 52.10. Tinel's nerve percussion test.

Figure 52.11. Durkan's median nerve compression test.

Table 52.2. Diagnostic Tests for Carpal Tunnel Syndrome

Sudomotor activity (sweating) may be diminished. This is easy to detect clinically by sliding a metal object (e.g., a pen) between the patient's fingers, which are held together. The object slides much more easily on dry skin than on skin with normal perspiration. Strength testing is difficult and somewhat subjective. The most easily evaluated muscle of the thenar eminence is the abductor pollicis brevis (APB) muscle. Most often, this muscle is innervated solely by the median nerve, but it can also have a contribution from the radial nerve. It is the most superficial of the thenar muscles and can be palpated during active opposition or resisted palmar abduction of the thumb. Relative weakness of palmar abduction of the thumb against resistance or muscle atrophy occurs in more advanced cases. Flattening or concavity of the normally bulging thenar eminence indicates atrophy of the APB (Fig. 52.12A). A weak, soft, or small APB is seen in severe cases of CTS and indicates denervation of the muscle.

Figure 52.12. A: A flattened thenar eminence indicates atrophy of the abductor pollicis brevis. B: Abductor pollicis brevis (arrow). (From North ER, Kaul MP.)
Radiographic examination is not indicated in all cases because there is a low yield of findings (2); it should be restricted to patients with a history of trauma or arthritis and those with decreased wrist range of motion on examination. One of us (JT) obtains radiographs to rule out Kienböck's disease in younger patients and periteral radiographs in older ones. Additional diagnoses uncovered by preoperative radiographs include scapholunate advanced collapse (SLAC) wrists, ununited fractures of the scaphoid, and radiopaque masses within the carpal tunnel (136). The views recommended include posteroanterior (PA), lateral, and carpal tunnel views.

Additional examinations include electrodiagnostic studies and laboratory tests. Positive nerve conduction velocities show increased latencies. In severe cases, EMG exams may show abnormalities and may give information regarding treatment prognosis. In mild or exertion-related cases, electrodiagnostic studies may be negative. This negative finding does not rule out CTS in the presence of typical signs and symptoms. Provocative nerve conduction evaluation may help to uncover these dynamic forms of CTS (14). EMG examination may be helpful when a cervical radiculopathy is suspected. Order laboratory testing to screen for metabolic disorders that may contribute to or cause CTS, (a) when there is suspicion of these disorders, (b) when there is bilateral presentation, and (c) in children who may have rare mucopolysacchariodosis or mucopolysclerodipiosis (139). Tests include erythrocyte sedimentation rate, rheumatoid factor, serum glucose level, uric acid, thyroid panel, and renal indices. Liver function tests may be indicated if alcohol-related peripheral neuropathy is suspected. If doubt persists about the correct diagnosis, an injection of a small amount of a steroid preparation mixed with local anesthetic into the carpal tunnel (not into the nerve) can be a therapeutic and diagnostic aid (Fig. 52.13) (Table 52.3) (45). The entry site for the needle is slightly proximal to the distal wrist crease, ulnar to the palmaris longus (PL) to avoid impaling the median nerve, and approximately 1 cm radial to the flexor carpi ulnaris (FCU) to avoid entrance into the canal of Guyon. Insert the needle at a 45° angle, beneath the proximal margin of the TCL and directed in line with the ring finger ray. Palpation in the midpalm just distal to the TCL while injecting can help confirm proper needle placement by enabling you to feel the flush of fluid into the canal.

![Figure 52.13. Injection into the carpal tunnel.](image)

**Table 52.3. Carpal Tunnel Syndrome Summary**

| Classification | Patients with CTS may be classified into three categories. The mild group consists of patients with intermittent symptoms that have been present less than 1 year, who have normal two-point discrimination, no thenar weakness or atrophy, no denervation potentials on EMG, and mildly elevated NCV. With conservative treatment and steroid injection, 40% will be free of symptoms at 12 months. The severe group consists of those with profound, persistent symptoms that have been present longer than 1 year, thenar weakness or atrophy, and marked abnormalities on electrodiagnostic studies (45). Patients in the severe group fail to respond adequately to conservative therapy and should receive operative treatment, which may include tendon transfers concurrent with carpal tunnel release. In the moderate group, conservative treatment shows findings and gives results intermediate between those of the mild and severe groups. The presence of underlying disorders or advanced age in any of these patients diminishes the response to conservative (and possibly operative) care.

**Nonoperative Treatment**

Initially, institute nonoperative treatment in all patients except those with severe disease. Splint the wrist in neutral to slight extension at night and during activities that exacerbate symptoms. In exertional or dynamic cases, modification of activities that exacerbate symptoms may be helpful. Vitamin B6 has no effect on the natural history of CTS (5,4). Steroid injection offers transitory relief in 80% of patients, with only 22% being free of symptoms at 12 months. The patients in the mild group fare better than others with steroid injection (46). Treat or correct underlying disorders if possible.

**Surgical Indications and Relative Results**

Indications for surgery include failure of nonoperative treatment, persistent or progressive symptoms, acute onset with profound sensory loss associated with trauma, and weakness or atrophy of thenar muscles. Results of surgery vary according to severity of disease, choice of surgical treatment, and individual patient physiology and social issues. As a general rule, we believe that with adequate release of the carpal tunnel, major or complete relief of discomfort associated with CTS is likely, as is relief of transient numbness. Persistent or profound numbness may not disappear with release if it has been present for a prolonged period (over 12 months). Weak or atrophied muscle is not expected to recover with release, but if it is not complicated by underlying disease, its progression will likely be halted. Nolan et al. (67) showed that patients with severe disease, followed for more than 2 years after carpal tunnel release, show improvement. Therefore, surgery is indicated in these patients, especially if symptoms of discomfort are present.

**Preoperative Planning**

Make the decision to perform surgical release in a patient with CTS in the context of the patient's general condition. You must be certain of the diagnosis of CTS and that its cause is compression of the median nerve at the wrist. Within reason, exclude other potential sources of the symptoms and maximally correct any contributing conditions. With these issues resolved, you must include the particular considerations of the patient in the surgical care. If malunions and carpal instabilities are severe enough to compromise results, treat them prior to or concurrently with release. In patients with severe atrophy of the thenar musculature, perform opponensplasty at the time of release. A particularly suitable procedure for restoration of thumb palmar abduction in the patient with severe CTS is the Camitz opponensplasty, in which the PL is harvested and extended with a strip of palmar fascia, then routed subcutaneously and sutured into the thumb at the level of the metacarpophalangeal (MP) joint along the APB tendon (Fig. 52.14).
Multiple limited- and minimal-incision methods and systems have been developed for carpal tunnel release and are commercially available. If endoscopic tunnel release is considered, preoperative manufacturer’s technique manual for each system. The surgeon must verify absolutely that the endoscope is within the carpal tunnel and not in the canal of Guyon atypical anatomy, and (c) difficulty in manipulating the endoscope. The surgeon must place the endoscope in the ulnar aspect of the carpal tunnel and keep it aligned difficulty in visualization that results from equipment problems, fogging, or the inability to clear synovium from the undersurface of the ligament, (b) presentation of endoscopic and an open carpal tunnel release, because several conditions may necessitate aborting the former and proceeding with the latter. These include (a) experience, it can be a safe and effective treatment in appropriate patients if the surgeon adheres to several tenets. The surgical consent form must specify both an relief of symptoms from endoscopic release has been shown to be related to incomplete release of the TCL. This improves after subsequent open carpal tunnel release. A risk of cutting neurovascular structures or tendons exists because of limited visualization and deviations from proper technique. As endoscopic release systems have been refined and experience with the technique gained, results have improved. The procedure remains hazardous in inexperienced hands and requires specialized training. There have been significant differences of opinion about whether internal neurolysis improves the results of carpal tunnel release in patients with severe CTS manifested by thenar atrophy or fixed sensory deficit. In a combined series of patients (69 hands) from San Diego and Sacramento, added benefit from internal neurolysis in the treatment of severe CTS could not be demonstrated. We therefore no longer perform or recommend internal neurolysis in the treatment of CTS. Concomitant release of the canal of Guyon in patients with evidence of compression of the ulnar nerve at the level of the wrist in conjunction with CTS is not recommended. Transection of the TCL during carpal tunnel release alone results in an increase in the volume of the carpal tunnel of approximately 24% and a change in the orientation and shape of the canal of Guyon. Clinically, this results in resolution of the symptoms referable to ulnar nerve compression at the wrist in these patients.

Endoscopic Carpal Tunnel Release

Open carpal tunnel release is considered the preferred surgical technique, especially for surgeons not doing a large volume of these surgeries, because it offers good visualization of the TCL, the superficial arch, and the carpal canal contents. It is a proven, reliable method. Nonetheless, some herald endoscopic carpal tunnel release as a step forward in the treatment of CTS. Proponents of the latter technique claimed decreased morbidity as a result of the smaller scar, which occurs away from the base of the palm, and more rapid rehabilitation. Several systems exist for the purpose of endoscopic release; they have in common visualization of the undersurface of the TCL with an arthroscope as the ligament is divided from within the canal using special knives or a blade mechanism. Agee et al. demonstrated a decrease in early postoperative pain and morbidity using his device, but by 6 weeks, results were comparable to those of standard carpal tunnel release.

Additional studies have evaluated endoscopic release. Although scar pain has been reduced and time to recovery of preoperative grip and pinch strength minimally shortened, pillar pain and palmar tenderness have not been eliminated. In cadaver studies, incomplete release of the TCL has been demonstrated to occur in up to 50% of the specimens. Clinically, however, patients do obtain symptomatic relief from the endoscopic technique. As endoscopic release systems have been refined and experience with the technique gained, results have improved. The procedure remains hazardous in inexperienced hands and requires specialized training. A risk of cutting neurovascular structures or tendons exists because of limited visualization and deviations from proper technique. Recurrent or incomplete relief of symptoms from endoscopic release has been shown to be related to incomplete release of the TCL. This improves after subsequent open carpal tunnel release.

Endoscopic carpal tunnel release remains a controversial method for treatment of CTS. However, with a thorough knowledge of the pertinent anatomy and with experience, it can be a safe and effective treatment in appropriate patients if the surgeon adheres to several tenets. The surgical consent form must specify both an endoscopic and an open carpal tunnel release, because several conditions may necessitate aborting the former and proceeding with the latter. These include (a) difficulty in visualization that results from equipment problems, fogging, or the inability to clear synovium from the undersurface of the ligament, (b) presentation of atypical anatomy, and (c) difficulty in manipulating the endoscope. The surgeon must place the endoscope in the ulnar aspect of the carpal tunnel and keep it aligned with the ring finger ray to prevent injury to the median nerve and the superficial vascular arch. The surgeon must verify absolutely that the endoscope is within the carpal tunnel and not in the canal of Guyon before making any cuts. Endoscopic carpal tunnel release is inappropriate in patients with bony deformity caused by fracture or dislocation and in those with inflammatory synovitis who require synovectomy or whose synovitis may make visualization difficult. If endoscopic tunnel release is considered, preoperative radiographs are necessary to evaluate these issues.

Multiple limited- and minimal-incision methods and systems have been developed for carpal tunnel release and are commercially available. These differ from...
endoscopic techniques in that the TCL is divided by a relatively blind method rather than being visualized with an arthroscope. The benefits of this technique over open carpal tunnel release are similar to those of the endoscopic methods, as are the risks.

Figure 52.16. Endoscopic carpal tunnel release with the system developed by John M. Agee. A: Insertion of the blade assembly beneath the transverse carpal ligament. B: Division of the transverse carpal ligament. (From Gelberman RH, North ER. Carpal Tunnel Release. In: Gelberman RH, ed. Operative Nerve Repair and Reconstruction. Philadelphia: Lippincott, 1991:899, with permission.)

Postoperative Care and Rehabilitation

Immediately postoperatively, encourage active, gentle finger range-of-motion exercises. Patients should also maintain mobility of the elbow and shoulder. Elevation is crucial, especially during sleep, to reduce edema. Remove bulky dressings and splints 5 days postoperatively. The patient then wears a removable prefabricated wrist splint for comfort only. (One of us [MNH] instructs the patient to wear the splint full time.) The wrist is put through gentle range-of-motion exercises several times a day, independently of finger motion. Continue the splint for 2–3 weeks for patient comfort only, during which time encourage progressive use of the hand. Then discontinue daytime splinting. Continue nighttime wear for an additional 3–4 weeks if desired (86). Use physiotherapy selectively for patients who are progressing poorly. Recovery takes months, so patients who are told that the carpal tunnel release is a minor operation and full recovery can be anticipated in 2 weeks are grossly misled and usually unhappy.

The patient's return to work depends largely on the demands of his occupation. Gelman et al. (44) have shown that grip strength returns to preoperative levels 3 months after surgery, and pinch strength returns at 6 weeks. Their work provides us with an indication of when patients ought to be able to return to their previous levels of occupational activity. Many studies employ “return to work” as a measure of outcome without clearly correlating what criteria are to be met to determine when a patient should return to work. Many factors influence the actual return-to-work time. Palmar tenderness, a particularly important consideration in manual laborers, may persist for longer than 6 months. Full recovery of nerve function may not occur, depending on the severity of nerve damage. Persistent palmar pain and early recurrent symptoms in workers’ compensation cases are increasing, unsolved problems for patients, physicians, and industry. Without job modification for these patients, carpal tunnel release alone may lead to failure in returning the patient to gainful employment.

Complications

Complications are caused by misdiagnosis or technical factors. Conditions associated with peripheral neuropathies must be suspected, recognized, and treated before surgery, or concurrently with the surgical release. Upton and McComas (137) proposed a “double crush” syndrome as a hypothesis to explain the failure of distal decompressions in nerves subjected to compression at multiple sites. Many patients with CTS have a cervical radiculopathy. Others may have concomitant compression of the radial or ulnar nerves. Hypertrophic synovium, if not removed at the time of surgery, may cause persistent compression despite ligament release.

Complicating technical factors include improper placement of the incision (i.e., usually too far radially), which jeopardizes the median nerve and its motor branch, as well as leading to injury or entrapment of the palmar cutaneous nerve or its branches (Fig. 52.17). Poor exposure may result in incomplete division of the TCL or in injury to the superficial palmar arch. Do not use transverse incisions at the wrist crease for blind decompression of the carpal tunnel.

Figure 52.17. The palmar cutaneous branch of the median nerve and its divisions crossing a carpal tunnel incision placed too far radially.

A rare complication is a tendency of the flexor tendons to the little finger to sublux during strong gripping. This is often only a transitory problem. Bowstringing of the flexor tendons with flexion of the wrist has been noted. This complication is easily prevented by postoperatively immobilizing the wrist in slight dorsiflexion for 2–3 days (136), which additionally may prevent adherence of the nerve and tendons to palmar structures and improve grip strength (86). Reserve reconstruction of the TCL for instances where immobilization of the wrist in flexion is necessary after carpal tunnel release. Complications from deficient postoperative management usually result from swelling and edema or poor control of pain, leading to loss of finger or wrist motion (particularly if a synovectomy was performed) and to reflex sympathetic dystrophy. The benefits of a good postoperative dressing, an aggressive exercise program, and elevation cannot be emphasized enough.

Pillar pain—pain at the base of the thenar and hypothenar eminences after carpal tunnel release—is a common finding in patients. It varies greatly from case to case in both severity and duration of its symptoms. Its etiology is poorly understood, although many theories have been proposed. It generally subsides and resolves over time. Seradge and Seradge (113) noted ulnar-sided wrist pain in 1% of their patients after carpal tunnel release. They attributed this pain to the pisotriquetral joint, whose mechanics are altered by division of the TCL. Treatment consisted of excision of the pisiform in cases with transient response to steroid injection of the joint. We have had no evidence to substantiate this theory or to recommend this approach.

PRONATOR SYNDROME

The term pronator syndrome was initially coined to describe compression of the median nerve in the proximal forearm beneath the pronator teres muscle. Since then, common usage has evolved so that it now denotes compression of the median nerve in the proximal forearm and about the elbow (86).

Pathophysiology and Anatomy

The median nerve lies anterior to the brachial artery and medial to the biceps muscle in the midarm. In the distal arm, it crosses the brachial artery to lie medial to it, coursing on the brachialis muscle. The supracocondylar process is an anomalous spur arising on the anteromedial aspect of the distal humerus, 5 cm proximal to the medial epicondyle, in as many as 3% of individuals. The ligament of Struthers is a fibrous band that may arise from the supracocondylar process (spur) of the humerus (7) and attaches to the medial epicondyle, forming a fibro-osseous tunnel through which the median nerve and, at times, the brachial artery pass (Fig. 52.18) (66). The median nerve enters the antecubital fossa coursing beneath the lacertus fibrosus (bicipital aponeurosis), then travels between the superficial (humeral) and deep
(ulnar) heads of the PT muscle. It continues distally beneath the arch of origin of the flexor digitorum superficialis (FDS), coming to lie between it and the flexor digitorum profundus (FDP). The median nerve maintains this relationship throughout its course to the wrist. Potential sites of compression include the supracondylar process and the ligament of Struthers, the lacertus fibrosus, the arch of the origin of the PT, and the arch of the origin of the FDS (Fig. 52.26, Table 52.4).

<tr>
<th>Assessment</th>
</tr>
</thead>
<tbody>
<tr>
<td>The symptoms arising from compression of the median nerve at this level, including numbness in the radial three and one-half digits and thenar weakness, may be attributed to CTS. In pronator syndrome, unlike in CTS, paresthesias are typically absent at night. Important additional symptoms that may help differentiate this condition from CTS are pain in the anterior aspect of the proximal forearm and numbness in the thenar region—the territory of the palmar branch of the median nerve that does not travel through the carpal tunnel, having branched from the median nerve several centimeters proximal to the wrist. Sensory threshold testing detects decreased sensation in the radial three and one-half digits, as in CTS, with the addition of numbness in the thenar eminence, the area innervated by the palmar cutaneous branch (Fig. 52.8A). The findings of weakness and atrophy in the thenar musculature may be indistinguishable from those seen in CTS, although they are less severe and are most often absent.</td>
</tr>
</tbody>
</table>

The portion of the physical examination that will further differentiate pronator syndrome from CTS is provocative testing. Phalen’s test should be negative, but it may be positive (47,95). Tinel’s percussion test, in which the median nerve is percussed at the level of the pronator muscle, elicits paresthesias in the distribution of the median nerve in the proximal forearm rather than at the carpal tunnel (Fig. 52.19). To perform the pronator compression test, place direct thumb pressure just proximal and lateral to the proximal edge of the PT muscle belly (Fig. 52.20). The brachial pulse will be palpable lateral to the nerve. A positive test is reproduction of paresthesias in the median-nerve-innervated digits within 30 seconds, and it supports the diagnosis of pronator syndrome (38). According to Olehnik et al. (95), the pronator compression test is the most accurate diagnostic test. Several tests have been designed to give clues to the specific site of compression of the median nerve in pronator syndrome. The production of pain or aggravation of paresthesias with simultaneous resisted forearm supination and resisted elbow flexion beyond 120° indicates probable entrapment of the median nerve at the lacertus fibrosus (Fig. 52.21) (7,33,58,115,122). Entrapment of the nerve between the two heads of the PT muscle is indicated by elicitation of paresthesias in the median nerve sensory distribution with resisted forearm pronation while the elbow is slowly extended from full flexion (Fig. 52.22) (33,58,121,122). Paresthesias elicited in the radial three and one-half digits with resisted independent flexion of the proximal interphalangeal (PIP) joint of the long finger suggest entrapment beneath the superficialis arch of origin (Fig. 52.23, Table 52.5) (33,122).

Special diagnostic procedures include electrophysiological studies and radiographs of the elbow. Median nerve conduction velocities from the elbow to the wrist are decreased in less than one third of cases (16,47,95). The value of obtaining these studies is to evaluate for the presence of CTS. A normal conduction velocity at the level of the wrist supports proximal compression of the median nerve in the presence of symptoms and signs of pronator syndrome. A study consistent with CTS indicates the necessity of treatment directed at the wrist but does not rule out a double crush phenomenon, with compression both at the carpal tunnel and in the proximal forearm. Failed carpal tunnel releases that respond to subsequent operative release in the proximal forearm support the occurrence of simultaneous compression of the nerve at these two sites (95). Four views of the elbow—anteroposterior (AP), lateral, and two obliques—are obtained to evaluate the presence of a supracondylar process. Although its presence is suggestive of compression of the median nerve beneath the ligament of Struthers, it is not pathognomonic; this is a very rare site of entrapment. The absence of a supracondylar process does not rule out the presence of a ligament of Struthers and entrapment at this site (Table 52.6).
Table 52.6. Pronator Syndrome Summary

**Preoperative or Nonoperative Management**

Nonoperative treatment consists of anti-inflammatory medications, splinting, and rest for 4–6 weeks. Modification of activities is particularly important because symptoms are often related to repetitive elbow flexion and extension and to forearm pronation and supination. Physiotherapy in the form of massage, stretching, and iontophoresis to mobilize and relax potentially tight structures may be helpful. Carefully placed steroid injections in the site of maximal tenderness and pain (but not into the nerve) may be useful for diagnostic and therapeutic purposes.

**Surgical Indications and Relative Results**

Surgery generally is not necessary because most patients respond to nonoperative care. Surgery is indicated in those cases where symptoms persist longer than 6 weeks to 3 months following adequate conservative management.

Improvement after surgical release is reported in approximately 80% to 90% of cases (38,47,59,95). Complete relief of symptoms occurs in only about one third of those who improve. There appears to be no preoperative indicator of which patients will have the better results (95). As in CTS, return to work will depend in part on the demands of the patient's particular vocation. Of the 36 patients in the series reported by Olehnik et al. (95), 25 returned to their preoperative or similar occupations and eight returned to work but had to change jobs. The final work status of the remaining three patients was unknown.

**Preoperative Planning**
