Some postoperative complications are common to many surgical procedures, including spinal surgery. These include metabolic problems such as postoperative confusion states and SIADH, pulmonary conditions such as atelectasis and pneumonia, genitourinary complications such as urinary retention, and gastrointestinal complications such as atelectasis and pneumonia.

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion is a condition characterized by the release of antidiuretic hormone (ADH) from the posterior pituitary gland in the absence of the usual osmometric or volumetric stimulus of dehydration or hypovolemia. This results in the failure to excrete free water, resulting in decreased urine output, dilutional hyponatremia, and edema. SIADH should always be considered as a cause of low urine output and dilutional hyponatremia during and immediately after surgery.

The method I prefer is the up-and-in method described by Krag and others (Fig. 147.3C) (64,65,69). The entry point for the pedicle screw is at the junction of a line running slightly inferior to the transverse axis of the transverse process and a line along the lateral aspect of the facet joint. The screw is oriented slightly cephalad and is angled medially to the sagittal plane. By making the pedicle screw entry point slightly more cephalad than the other methods, damage to the facet joint is minimized and the risk of subsequent adjacent level degeneration is theoretically less. The screw must be angled superiorly in order to maintain its path within the pedicle.

In summary, I favor decompression and fusion with pedicle fixation in active, healthy, physiologically young patients with spinal stenosis associated with degenerative spondylolisthesis who have relatively few degenerative changes promoting stability at the level of the slip. I usually manage the elderly, low-demand patient with multiple comorbidities who has significant associated degenerative changes at the isthmic level by limited decompression without fusion.

PITFALLS AND COMPLICATIONS

Complications related to surgical decompression for spinal stenosis may be either general in nature, sharing features in common with all types of spinal surgery, or they may be specific and related only to spinal stenosis decompression. Those that are specific to only spinal stenosis decompression include complications related to posterior approaches for spinal stenosis decompression and those complications associated with spinal fusion.

GENERAL COMPLICATIONS

All lumbar spine surgery, and indeed all surgeries generally, share certain broad groups of potential complications, which can be thought of as occurring either preoperatively, intraoperatively, or postoperatively.

Preoperative Complications

Preoperative factors that are important determinants of surgical outcomes involve primarily surgical decision making, and therefore, complications of this process can be thought of as being judgment errors of patient selection. In general, surgery is more reliable in producing relief of leg pain than LBP. The difficulty with surgery for LBP lies not with the technical aspects of the surgical procedures but with the difficulty in determining the genesis of the back pain. Discography has been advocated as a diagnostic test for determining the source of pain (22). The role of discography is controversial and may not accurately predict the painful level, even when the pain might be coming from the disc (46). See Chapter 144 and Chapter 145 for more details.

Intraoperative Complications

Anesthetic complications related to spinal surgery are comparable to the complications associated with other nonspinal surgery. These complications include airway complications; fluid management problems, including shock, fluid overload, and transfusion reactions; pulmonary complications; cardiac risks related to perioperative myocardial infarction, cardiogenic shock, or congestive heart failure; and vascular complications related to blood loss, hypertension, hypotension, and thrombotic or embolic phenomena.

Posterior decompression for spinal stenosis poses particular problems related to positioning of the patient in the prone position, which is the least physiologic position for the patient under general anesthesia (118). These problems include potential difficulties with ventilation and airway management. In addition, there is the risk of pressure to sensitive structures such as the eyes, which can result in blindness. Pressure can result in compression of various neural structures, which can result in temporary or permanent nerve palsies. Such structures include the sciatic nerve or its branches from prolonged pressure of the buttocks against a buttress while in the kneeling position, the ulnar nerve at the elbow, the anterior interosseous nerve in the cubital tunnel, the axillary nerve (84), brachial plexus from excessive shoulder abduction (23), and cervical area from prolonged positioning of the neck in a rotated position.

The optimum patient position for surgery is one in which the abdomen is hanging free in order to reduce inferior vena cava (IVC) pressure and thereby minimize intraoperative bleeding. This may be accomplished by placing the patient in a kneeling or a knee-chest position, or by placing the patient prone with the abdomen hanging freely. In vivo IVC pressure measurements have shown that pressure in the IVC is 1.5 times greater when the patient is in the prone position than when the patient is on a frame that allows the abdomen to hang freely. Problems associated with the kneeling position include sciatic nerve palsy, deep venous thrombosis (DVT), and compartment syndrome. Ophthalmic complications associated with spinal surgery have only recently been recognized and reported (66,62). Such complications include posterior optic nerve ischemia (66,62), occipital lobe infarcts, central retinal vein thrombosis (62), and cerebral ischemia (62). Although the etiology of the diminished visual acuity or blindness associated with these conditions is not always clear, identifiable causes include prolonged operative time, hypotension, blood loss, and direct pressure on the eye.

Anesthetic problems related to spinal anesthesia include persistent spinal fluid leak from spinal needle puncture and hypotension from venous pooling of blood in the lower extremities. The advantage of spinal anesthesia in posterior spinal surgery is that some of the positioning complications previously described can be obviated by having the patient remain awake and in control of the head and upper extremities. This approach minimizes the risk of pressure on the eyes, compression to the umbilical nerve at the elbow, and brachial plexus palsies.

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion is a condition characterized by the release of antidiuretic hormone (ADH) from the posterior pituitary gland in the absence of the usual osmometric or volumetric stimulus of dehydration or hypovolemia. This results in the failure to excrete free water, resulting in decreased urine output, dilutional hyponatremia, and edema. SIADH should always be considered as a cause of low urine output and dilutional hyponatremia during and immediately after surgery.

Postoperative Complications

Some postoperative complications are common to many surgical procedures, including spinal surgery. These include metabolic problems such as postoperative confusion states and SIADH, pulmonary conditions such as atelectasis and pneumonia, genitourinary complications such as urinary retention, and gastrointestinal conditions such as atelectasis and pneumonia.
problems such as ileus and stress ulcer. Although they are uncommon, some spinal conditions such as cauda equina syndrome may predispose the patient to urinary retention owing to impairment in function of the nervous system to the bladder. When urinary retention is due to acute cauda equina compression, prompt surgery is imperative. Chronic urinary retention may require a straight catheterization or an indwelling catheter. The presence of a catheter, particularly a long-standing indwelling catheter, may predispose the patient to a urinary tract infection requiring treatment with antibiotics.

Postoperative ileus is a condition that can occur following any surgery, and is common following large posterior spinal procedures such as multilevel decompressions for spinal stenosis and instrumented lumbar fusions. When the intervertebral space is violated during postero-lateral fusing, bleeding into the retroperitoneal space may occur, and ileus is more likely.

DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLUS

PE is the third most common cause of death in the United States, accounting for up to 200,000 deaths annually. In hospitalized patients, PE is the most common presenting manifestation of hospital death with pulmonary emboli detectable in more than one quarter of all routine autopsies. The etiology of pulmonary embolism includes the immobilization associated with hospitalization as well as factors related to surgery itself, which produce a hypercoagulable state. DVT is the precursor to PE in 90% of cases and is common in hospitalized patients. The risk of DVT following general surgery ranges between 5% and 63% and is particularly high with certain orthopaedic conditions, such as fracture of the hip, and following some orthopedic procedures, particularly total hip and total knee arthroplasty, in which the incidence of DVT following unprotected joint replacement is as high as 60% to 80%.

Although it is uncommon, DVT has been reported to occur following scoliosis surgery. DVT following routine spinal decompressions, however, was thought to be a rare occurrence. More recently, DVT has been recognized following spinal surgery (106,119). Using postoperative duplex scanning, the incidence of DVT in unprotected patients undergoing posterior lumbar surgery has been reported to be 14% (119). The use of elastic compression stockings or intermittent pneumatic compression stockings (PCS) has been shown to reduce the incidence of DVT diagnosed by duplex scanning to 0.9% to 6% (108). Bell et al. reported the incidence of venographically proven DVT following unprotected surgery for lumbar disc herniation or spinal stenosis performed under spinal anesthesia to be 25.8% (6A). This rate is significantly higher than that reported using duplex scanning as the method of diagnosis, thereby reflecting the greater accuracy of venography in diagnosing DVT (30a,30b,119). Prophylaxis with PCS reduced the incidence to 4.5% in patients receiving spinal anesthesia. PCS seemed to provide no significant protection from DVT in patients receiving general anesthesia, in whom the incidence of DVT was 13.6% in unprotected spinal surgery and 8.1% with PCS protection. This study suggested that the best combination of type of anesthesia and DVT prophylaxis in terms of prevention of DVT was spinal anesthesia with PCS. The worst combination was spinal anesthesia without PCS. See Chapter 5 for more details as well as recommendations for treatment.

SPECIFIC COMPLICATIONS RELATED TO POSTERIOR DECOMPRESSION FOR SPINAL STENOSIS

Both laminectomy and laminotomy share common bony, soft-tissue, and neural anatomy, and therefore, share a common list of potential complications. These complications include inadequate neural decompression, recurrent stenosis, incidental durotomy, neural injury, epidural hematoma, neural compression from either fat grafts or other barriers to scar formation, vascular injury, and late instability.

INADEQUATE NEURAL DECOMPRESSION

Although it is not a complication in the usual sense of the term, failure to obtain symptomatic relief of radicular leg pain that is not due to an error in surgical decision making should be considered a failure at least as an indication of surgery. Its avoidance requires precise correlation of the preoperative imaging study with the clinical picture and surgical anatomy, and demands that surgery be continued until the offending neural compression is found. It also requires a thorough knowledge of surgical anatomy and of the potential sources and sites of neural compression, as described by MacNab (70). In addition, it is imperative that the surgeon have a precise understanding of the potential anatomic variations in the location of disc herniations so that he will know precisely where to look for neural compression, particularly when the predicted pathology is not found (110).

It is important for the surgeon to recognize and look for additional sites of neural compression that may account for inadequate relief following decompression of only one site. This condition is sometimes referred to as a “double crush phenomenon” and is thought to be at least partially due to venous congestion of the neural segment located between the two sites of compression resulting in a compartment syndrome-like condition of the intervening segment. Multiple sites of compression are common in stenosis, which is frequently a multilevel, bilateral neural compression. Sites of compression include central compression of the cauda equina and lateral compression, either within the lateral recess, within the neural foramen, or extraforaminal. It is important to identify all clinically significant sites of neural compression and to decompress those levels adequately.

RECURRENT STENOSIS

Distinguishing recurrent symptoms due to neural compression from those due to scar formation is a complex decision-making process that requires a precise history and high-quality radiographic imaging. Failure to obtain even temporary pain relief following decompressive lumbar surgery suggests either inadequate neural decompression, irreversible neural damage already present at the time of surgery, or a nonsurgical cause for the pain. A short pain-free interval of less than 6 months suggests development of scar formation as the cause of recurrent pain. Recurrence of pain following a long pain-free interval of more than 6 to 12 months suggests a new process such as a recurrent disc herniation or recurrent stenosis.

Because spinal stenosis may occur in association with disc herniation, recurrence of symptoms following decompression involving discectomy could be due to recurrent disc herniation. The overall reported incidence of recurrent disc herniation is approximately 3% (38). Its incidence following laminectomy or laminotomy associated with discectomy is unknown but could be even greater if decompression involved destabilization from facetectomy and resulted in instability (63).

Several studies have reported that the surgical results of spinal stenosis surgery deteriorate over time (18,56,60,91). Although this may be due to many factors, such as associated comorbidity and advanced patient age, surgical and pathologic factors are also important. These factors include progression of degenerative changes at unoperated levels (60), regrowth of bone at the operated levels (90,91), pre-existing instability (degenerative spondylosis or spondylolisthesis) (35), and development of postoperative instability (for example, due to resorption of one or more facets at a single segmental level (1) or development of a facet fracture at the level of decompression during or following decompression (65)). All of the above-mentioned factors can lead to recurrent LBP or radicular leg pain following decompressive surgery for spinal stenosis.

DUROTOMY

Incidental violation of the dura (durotomy) is a well-recognized complication of spinal surgery that has a reported incidence of 0.3% to 13%. It most commonly occurs when the edge of a biting instrument, such as a Kerrison rongeur, inadvertently grabs the dura and produces either a punctate hole in the dura or a frank laceration. Incidental violation of the dura (durotomy) is a well-recognized complication of spinal surgery that has a reported incidence of 0.3% to 13%. It most commonly occurs when the edge of a biting instrument, such as a Kerrison rongeur, inadvertently grabs the dura and produces either a punctate hole in the dura or a frank laceration.

This approach not only provides a drier operative field but also minimizes the tendency for the individual roots of the cauda equina to float to the surface, which can result in their inadvertent injury during dural repair.

For safe closures of large tears, place a small cottonoid patty over the exposed nerve roots for the initial portion of the repair and then remove it just before dural closure (28). For tears associated with loss of tissue, or for tears in difficult to repair locations, an autologous fat graft, a piece of autograft fascia (thoracolumbar fascia or fascia lata), or a freeze-dried fascia allograft may be required to close the defect (28). Perform a watertight closure with a running 5-0 or 6-0 nonabsorbable suture (e.g., silk or nylon).

After meticulous closure, return the patient to a neutral or slightly head-up (reverse Trendelenburg) position and perform a Valsalva maneuver in order to assess the integrity of the closure. The use of a fibrin glue may also be considered for additional strength and integrity of the repair.

The remainder of the surgical wound closure proceeds as usual, except that a drain is often not employed in order to minimize risk of development of a CSF}
If a postoperative dural leak is suspected due to persistent spinal headache or a pseudomeningecele, confirm the diagnosis by myelography or MRI, and return the patient to the operating room for dural repair and watertight closure (75). Alternatively, a subarachnoid drain can be inserted at the bedside and the patient placed on bed rest until the leak subsides. This generally involves removal of approximately 300 ml of CSF in a sterile blood collection bag daily. The volume and rate of CSF removal is titrated by adjusting the height of the bag to produce the appropriate rate of CSF flow (63).

The long-term outcome of spinal surgical infection complicated by incidental durotomy is generally favorable (117). When identified intraoperatively and repaired primarily, periprosthetic surgical morbidity and long-term outcome is comparable to that of surgery not associated with incidental durotomy (117).

Nerve Root Injury

Neural injury may occur due to direct trauma to the nerve root itself during surgery. This injury may be due to excessive neural retraction, contusion, laceration, or electrocauterization (111). The incidence of neurologic complications following lumbar spine surgery has been estimated to be 0.2%. Such injury may be suspected postoperatively by the presence of a new or increased objective neurologic deficit, or by the onset of new parasthesias. This condition, sometimes referred to as the “battered root,” may occur either as an unavoidable consequence of severe neural compression or as a result of indelicate surgery (11). Meticulous surgical technique, therefore, is of paramount importance in order to minimize such complications. Adequate surgical exposure is imperative in order to minimize excessive neural retraction. In cases of a large midline disc herniation or a disc herniation associated with spinal stenosis, for example, a bilateral laminectomy rather than a keyhole laminotomy may be required in order to remove the disc fragment safely.

It is important to perform an anteroposterior x-ray study of the lumbar spine in order to identify bony anatomy that might be of surgical significance. Note the presence of spinous bifida occulta or a pre-existing laminectomy defect, for example, on the preoperative radiograph because the presence of either of these features mandates cautious surgical exposure in order to minimize risk of damage to underlying dura and nerve roots. Carefully examine other pre-operative studies to identify other potentially significant anatomic variants, such as longitudinal nerve roots, that could be injured during surgical decompression (111).

It is important always to visualize the lateral edge of the nerve root during surgical decompression to be sure that exposure is not inadvertently being performed in the axilla of a nerve root where accidental dural laceration and neural injury could occur and where repair of such injuries is particularly difficult. This is also important during revision lumbar surgery, in which dissection should usually be performed lateral to the root along the lateral edge of the bony canal to avoid a potentially dangerous midline scar.

When performing lateral nerve root decompressions, work parallel, rather than perpendicular, to the long axis of the nerve root in order to minimize risk of cutting across a root.

Scalp Tissue

Although scarring is a common event following all surgeries, it has been implicated as a potential cause for continued pain following spinal surgery. Postoperative scar tissue may be located either intradurally (arachnoiditis) or extradurally (epidural fibrosis). Arachnoiditis is an inflammation of the pia-arachnoid membrane that surrounds the dura and spinal cord. It can result in surgical failure and continued pain following decompressive surgery. Its etiology is often unclear, but it has been associated with many conditions, including oil-based myelographic contrast agents and prior surgery (63). The exact mechanism by which arachnoiditis occurs following surgery is not completely understood, but it is thought to be more likely to occur following dural laceration in which blood gains entry into the dural sac and mixes with neural elements. It is also associated with intraoperative trauma to neural structures. Arachnoiditis exists as a spectrum of severity, from mild pia-arachnoid thickening to severe scarring with complete blockage of the flow of contrast agents or spinal fluid. Diagnosis can be made by water-soluble myelography, MRI, or CT myelography in which the individual nerve roots of the cauda equina appear clumped together rather than as well-defined structures. Surgical treatment of arachnoiditis is not indicated because surgery rarely produces any significant pain relief and may be complicated by further damage to neural structures and more scar ing (17).

Epidural fibrosis is extradural, rather than intradural, scar tissue in which adhesive constrictions can form around neural tissue. It commonly arises from contact with the paraspinal musculature and is probably a relatively frequent event following spinal surgery. Although such scar tissue can result in postoperative pain, symptoms are relatively infrequent. When postoperative pain exists, the primary differential diagnosis is between scar and recurrent disc herniation. Radiographic distinction between these two conditions is best made with gadolinium-enhanced MRI or post-contrast CT (67).

Efforts to prevent postoperative scar formation include deliberate surgical technique with adequate illumination and magnification, meticulous hemostasis and drainage, and the use of some form of an interposition membrane as a barrier to scar formation. These barriers include a thin layer of fat or synthetic agents such as an absorbable gelatin sponge. The use of a free fat graft has been considered the gold standard interposition membrane, although use of large grafts has been associated with postoperative cauda equina syndrome (79).

Superficial Wound Infection

Postoperative scalp infections may be divided into either superficial or deep infections. Although the treatment for both types of infections is often similar (i.e., debridement and antibiotic therapy), it is useful to make this distinction because duration of treatment (e.g., short-term antibiotics for superficial infections versus long-term intravenous antibiotics for deep infections), morbidity, and long-term outcome are often very different for the two types.

Superficial wound infections are located beneath the dura and subcutaneous tissue but superficial to the deep thoracolumbar fascia and are characterized by tenderness and localized erythema. They usually have associated drainage and fluctuance, although in milder cases consisting only of cellulsitis these may be absent. Patients may be febrile but usually show no other systemic signs of illness (67). Laboratory data usually show elevation of the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), although the white blood cell count (WBC) is usually within normal limits.

Treatment of superficial wound infections consists of local wound care, ranging from simple packing of a small area of localized infection, followed by a short course of oral antibiotics, to more aggressive surgical debridement of necrotic tissue with short-term parenteral antibiotics. In cases requiring surgery, the wound can usually be closed primarily, although delayed closure is an option if there is any question about the adequacy of the debridement. The use of short-term suction-irrigation tubes is at the discretion of the surgeon, although there are usually not required.

Deep Wound Infections

As opposed to superficial infections, in which the diagnosis is usually readily apparent, deep infections may be difficult to diagnose and a high index of suspicion is often required (67). Because delay in diagnosis is common, the amount of tissue necrosis is often extensive. Symptoms include disproportionate back pain or leg pain. The wound may be relatively painless and uneventful immediate postoperative period. The patient may feel and look ill and may exhibit generalized malaise. Fever is often present but may be deceptively low grade. If an epidural abscess is present, radicular leg pain and neurologic deficit may occur. Although the patient may exhibit a leukocytosis, elevation of the WBC count is frequently absent. The ESR and CRP are usually elevated.

Radiographic imaging studies are usually required to confirm the diagnosis. MRI provides the best and most useful information by revealing both the presence and extent of a deep abscess. Typically, an abscess is demonstrated by the presence of a well-demarcated area of increased signal intensity on the T2-weighted image. When MRI is not available, diagnosis may be confirmed radiographically by the presence of a circumscribed area of fluid density visualized by CT. If a deep abscess is strongly suspected, diagnosis may be confirmed by aspiration, with subsequent culture and sensitivity of any fluid obtained (61).

Treat deep wound infection aggressively with surgical debridement of all necrotic tissues, followed by appropriate parenteral antibiotics. Begin surgical exposure of the affected area with careful segmental debridement, and irrigate each layer before proceeding to the next deeper layer to avoid inadvertent contamination of potentially uninfected deeper tissues. If the infection extends deep into the laminectomy site, take care to remove any fat graft or absorbable gelatin sponge material. Following removal of infected or suspicious tissues, thoroughly irrigate the wound with pulsatile lavage. Do not remove rigid fixation and bone graft from an instrumented spinal fusion because this may increase the risk of subsequent pseudarthrosis. Loose hardware, on the other hand, no longer performs its function of providing stability to the spine and, therefore, should be removed and thoroughly debrided. Place a drain and close the wound meticulously. Tightly close the deep fascia with interrupted absorbable sutures, followed by a continuous running stitch. Close the wound primarily, particularly in the presence of spinal fixation hardware, but also in a single layer to avoid the ingestion of a particularly virulent organism. This may require extensive undermining of wound margins in order to avoid tension on fragile wound edges. It is usually advisable to close the wound using large throws of a sturdy, nonabsorbable suture rather than staples. Use of suction-irrigation tubes for a few days may be considered, although this is usually not necessary.
EPIDURAL ABSCESS

Epidual abscess, because of its risk of paresis or frank paralysis, is one of the most feared complications of spinal surgery. Fortunately, it is a rare occurrence following spinal surgery, with only 16% of epidural abscesses resulting from postoperative infection (4). Signs and symptoms are obvious and constitute a typical presentation (4). Patients nearly always have significant back pain, and often present with obvious neurologic findings such as nuchal rigidity and weakness or paralysis of the lower extremities. The patient appears to be much sicker than with either postoperative discitis or vertebral osteomyelitis and typically has a fever. Both the WBC and acute phase reactants are elevated. MRI is the diagnostic imaging modality of choice and clearly visualizes the abscess as a discrete, well-circumscribed entity within the subarachnoid space. It clearly delineates the upper and lower extent of the abscess and, therefore, is invaluable in the preoperative planning of the extent of decompression.

Treatment of an epidural abscess must be prompt and decisive: surgical evacuation of the abscess and any adjacent necrotic tissue, followed by parenteral antibiotics. The preferred surgical approach is generally posterior, although an anterior approach may be indicated in the presence of a significant kyphotic deformity in which bony collapse has compromised the neural structures and simultaneous anterior reconstruction and bone grafting are required to restore stability.

EPIDURAL HEMATOMA

Epidural hematoma causing symptomatic neurologic compression is another devastating complication of spinal surgery. Fortunately, the risk of this complication can be minimized by meticulous attention to preoperative, operative, and postoperative detail. Preoperatively, advise the patient to stop all nonsteroidal anti-inflammatory drugs (NSAIDS) for approximately 1 week before surgery. In addition, it is important that the patient is not hypercoagulable. When indicated, check the prothrombin time (PT), partial thromboplastin time (PTT), platelet count, and platelet function. Intraoperatively, maintain the patient's abdomen hanging freely in order to minimize epidural venous congestion. Keep the blood pressure below 100 mm Hg systolic, if possible, in order to minimize bleeding. Use electrocautery, and seal raw bone surfaces with bone wax to minimize bleeding during the surgical exposure. Control epidural bleeding with bipolar electrocoagulation. At the end of the surgery, when the deep paraspinal muscle retractors are removed, check the muscle walls for persistent bleeding, because prolonged muscle retraction may temporarily occlude potentially significant muscle bleeders that could begin bleeding after muscle layer closure. In general, I prefer to use a drain postoperatively in order to minimize the formation of postoperative hematoma. Postoperatively, leave the drain in place for 24 to 48 hours or until the amount of collected blood is less than approximately 30 ml per 8-hour shift. I do not prescribe NSAIDS during the immediate postoperative period (during the first 48 hours) in order to minimize bleeding from the fresh wound.

A characteristic clinical feature of epidural hematoma is the presence of severe pain that appears out of proportion to what is normally expected. This is usually associated with a progressive neurologic deficit. Diagnosis depends on the extent and location of the surgical exposures and the magnitude of the hematoma, the neurologic deficit may be focal and unilateral, or it may be widespread and may involve multiple muscle groups in both legs.

The key to diagnosis of this condition is having a high index of suspicion. Confirm the diagnosis with MRI, myelography, or CT. Once the diagnosis is suspected, immediately return the patient to the operating room for decompression and drainage of the hematoma.

COMPRESSION BY FAT GRAFTS OR SYNTHETIC SCAR BARRIERS

Postoperative neurologic compression may be due to structures other than epidural hematoma. The use of free fat grafts as a barrier to scar formation has been associated with symptomatic neurologic compression mimicking epidural hematoma (73). Although this risk can be minimized with the use of a smaller (3 to 5 mm thick) piece of fat, the fear of epidural compression by fat graft has led some surgeons to abandon fat grafts in favor of other synthetic scar barrier substances. Even these substitutes, however, may cause neural compression if proper care is not exercised. For multilevel laminectomy requiring the use of a lengthy piece of scar barrier material, I prefer an absorbable gelatin sponge material rather than fat because the fat could theoretically become balled up and exert focal compression on the underlying dura, and result cauda equina syndrome.

VASCULAR COMPLICATIONS

Vascular injuries associated with posterior lumbar spinal procedures are nearly always associated with surgical discectomy, rather than laminectomy. Vascular injury occurs most commonly at L4–L5, followed by L5–S1 (24). Although to some extent this reflects the most common levels of spinal surgery, regional differences in vascular anatomy of the lower lumbar spine also play a role. Injury of a major abdominal vessel typically occurs from aggressive use of the pituitary rongeur, with penetration through the anterior annulus. Such injuries may be recognized early or late. Brisk bleeding from acute laceration of a major abdominal vessel presents early as hypotension and abdominal distention and is associated with a high mortality rate. The mortality rate from arterial injuries has been reported to be 78%, whereas that for venous injuries is 89% (24). Vascular injuries may be recognized late by the development of high-output cardiac failure or abdominal bruits from formation of an arteriovenous fistula. Arteriovenous fistula formation is the most common result of a vascular injury. It occurs most commonly between the right common iliac artery and vein (29.1%), between the left common iliac artery and vein (25.5%), the right common iliac artery and the IVC (21.8%), and the right common iliac artery and left common iliac vein (12.7%). Late arteriovenous fistula formation is more compatible with long-term survival, with mortality reported between 9% and 11% (23).

POSTOPERATIVE INSTABILITY

Instability following surgical decompression is usually an iatrogenic complication of spinal surgery. Such instability can occur in either the anteroposterior plane (spondylolisthesis), in the mediolateral plane (lateral listhesis and scoliosis), or in both planes simultaneously. In general, the risk of postoperative anteroposterior instability can be minimized by maintaining the integrity of at least one facet joint at the level decompressed (1). In other words, if a unilateral complete facetectomy is performed on one side, then the integrity of the opposite facet must be maintained. Similarly, if half of one facet is removed during a surgical decompression, then at least half of the contralateral facet joint should be spared. If a total of more than one facet is removed during a decompression, consider prophylactic fusion of that level.

When decompressing a stenotic level associated with a degenerative spondylolisthesis, concomitant fusion should generally be performed because surgical outcome has been shown to be better with fusion than with decompression alone (64). This seems to occur even in the absence of solid bony arthrodesis, suggesting that even the presence of a stable pseudoarthrosis results in better clinical outcome than when no fusion is attempted. This is thought to be due to a reduced risk of a subsequent increase in the slip, although a direct relationship between increase in magnitude of a subsequent slip and poorer surgical outcome has not been demonstrated. Although the use of segmental spinal fixation with pedicle screws has been shown to increase the rate of fusion compared with posterolateral fusion without instrumentation, there is no convincing evidence that such instrumentation leads to better clinical outcome (52).

Isthmic spondylolisthesis with frank fracture of the pars interarticularis may also occur in the absence of prior slip as a result of surgical decompression. In such cases, the indication for fusion is not clear. Whether a decrease in evidence of a de novo spondylolisthesis occurs at one of the levels decompressed or at a level above the level of decompression.

The presumed mechanism is either a mechanical stress fracture or perhaps an impairment of the blood supply to the affected level (16,106). Instability may also occur as a result of fracture of the facet joint following decompressive surgery.

AUTHOR’S PERSPECTIVE

Spondylolisthesis is a common pathologic clinical entity that is largely degenerative in nature, although it may have a predisposing congenital component to it. It may be accompanied by other structural changes (degenerative spondylolisthesis) producing instability. The natural history of spinal spondylolisthesis is unclear, but it appears that approximately 20% of patients worsen over time, 40% improve slightly, and 40% remain unchanged.

The surgical treatment of spinal spondylolisthesis involves decompression of the symptomatic level or levels. At the time of decompression of symptomatic levels, the role of surgical decompression of clinically asymptomatic levels that show compression on imaging studies is controversial. However, because long-term failures are frequently characterized by restenosis at previously decompressed levels, or by the development of symptoms at levels that were previously stenotic but asymptomatic, it is better to decompress any questionable levels. Such decompression may be performed through laminectomy or may be more limited in extent by multilevel laminotomies.

The role of fusion depends on whether or not there is associated spondylolisthesis. In general, fusion is indicated for spinal spondylolisthesis associated with degenerative spondylolisthesis. The indications for the use of concomitant segmental (pedicle) fixation are unclear, but we use fixation more commonly in relatively young, well-circumscribed entity within the subarachnoid space.
healthy patients who lack significant degenerative changes at the level of the slip. Patients with more severe degenerative changes, particularly if they are elderly and of low demand, may do well with focal decompression (laminotomies) without fusion.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Cervical spine surgery is usually successful. The population of chronic, failed cervical spine surgery patients is smaller than for the lumbar spine. However, cervical spine surgery is becoming more common. Fusion procedures increased 70% between the periods of 1979–1981 and 1988–1990. With this increase, more complications will be encountered and the need for revisions will rise. This chapter will focus on pseudarthrosis, residual compression, postlaminectomy kyphosis, hardware failure, and progressive or adjacent segment degeneration.

CAUSE OF FAILURE

PATIENT-RELATED FACTORS

Patients with active medicolegal issues or complex, unresolved psychosocial problems are less likely to achieve a satisfactory outcome from primary cervical spine surgery. Unrealistic expectations and poor compliance with postoperative care also reduce the chances for successful post-surgical outcome. Nutrition, smoking, diabetes, and steroid use all have implications in wound healing, bony fusion, and recovery.

Poor patient selection will predispose to failure of primary cervical surgery and will make revision surgery even more difficult. When failure is the result of, or compounded by, any of these factors, the issues must be addressed before surgical revision is likely to succeed.

SURGEON-RELATED FACTORS

Preoperative factors leading to poor outcome include errors in diagnosis, surgical timing, and intended procedure. Common errors of surgical judgment include choosing the wrong approach, selecting improper fusion levels, or recommending improper postoperative care. These errors will be considered in terms of their outcome: deformity, pseudarthrosis, or inadequate decompression. Perioperative events, including infection, dural leak and pseudomeningocele, and hematoma are not uncommon causes of clinical failure and must be evaluated before planning a revision procedure.

Pseudarthrosis

Pseudarthrosis complicates both anterior and posterior fusion procedures, but it is not always the cause of postoperative neck pain. Anterior cervical discectomy and fusion (ACDF), without fusion, relieves radicular and axial neck pain in many patients. The success of ACDF highlights the fact that nonunion is not always painful. Nonetheless, the most common cause of axial pain or radicular symptoms after anterior cervical discectomy and fusion (ACDF) is still pseudarthrosis. Published reviews of ACDF outcomes report pseudarthrosis in up to 26% of patients. Patients at increased risk for pseudarthrosis after ACDF include those undergoing multilevel, individual fusions and those fused with allograft.

In their analysis of anterior cervical fusion, Lowery et al. defined pseudarthrosis as having the following components:

- Continued or worsening axial pain 6 months after the index procedure
- Complete radiolucency at the host–graft interface
- Vertebral body motion of >2 mm on flexion–extension films

Symptomatic pseudarthroses were seen mainly at the interface between the graft and the vertebral body below. Only 9% of patients with pseudarthrosis felt better after their initial surgery; 27% felt the same, and 64% felt worse.

The literature regarding pseudarthrosis after posterior cervical fusion is relatively sparse. Posterior fusions do not enjoy the biological advantage of grafting under compression, but overall, fusion rates are felt to be high. Reported pseudarthrosis rates following traditional wiring techniques range from 0% to 50%, but it can be expected in 10% of patients. Outcomes after rigid posterior plating are reported with rates of 0% to 1.4% pseudarthrosis.

Residual Compression

Residual compression of the neural elements is a common cause of failure in both anterior and posterior cervical spine procedures. The diffuse nature of degenerative changes in the cervical spine sometimes requires more global or comprehensive procedures than the surgeon is initially willing to entertain. Residual compression after an index spine procedure may result from any of the following:

- Failure to perform a complete decompression at the injured/involved level
- Failure to decompress adjacent involved levels
- Migration of graft or fixation materials into the canal or foramen
- Wrong-level surgery

After ACDF, posterior osteophytes in the region of the posterior longitudinal ligament (PLL) may be a significant source of residual compression. Some surgeons feel that posterior osteophytes will resorb after successful fusion. Therefore, they avoid PLL resection and the dangers of operating near the spinal cord. However, the extent of osteophyte resorption is controversial. Recent studies have noted little remodeling or resorption after solid ACDF. Some authors have advocated more complete decompression in this area through PLL resection and direct visualization with an operating microscope or loupes.

Similarly, persistent neural compression following fracture may impair neurologic recovery. While stabilization alone affords some protection of neurologic tissues, adequate decompression of bony and soft-tissue elements increases neurologic recovery.

Postlaminectomy Kyphosis
Postlaminectomy kyphosis is a focal and often dramatic angulation of the cervical spine occurring after posterior decompression (21). Wide decompression necessarily sacrifices all or part of the facet and eliminates the attachments for the posterior spinal musculature. Bilateral facetectomy of more than 25% of the facet increases cervical motion in all planes and should prompt posterior fusion to prevent deformity (27,28). After extensive laminectomy, glacial progression toward scoliosis or kyphosis occurs in 30% to 50% of younger patients, and fusion is indicated (39).

Risk factors for postoperative kyphosis include (23) the following:

- Young age (into third decade)
- Preoperative deformity [particularly S-shaped or kyphotic deformities (25)]
- Removal of more than four laminae
- Destruction of facets
- Tumors
- Removal of C-2 posterior elements (major semispinalis insertion)
- Paralysis with paraspinal muscle weakness
- Anterior instability following fracture

**Hardware Failure**

If due consideration is given to the biomechanical status of the cervical spine and its relationship to the construct employed, the likelihood of failure of most modern instrumentation is small. Fixation failure reflects the types of failure already described:

- Persistent pseudarthrosis results in fatigue failure or failure at the host–hardware interface.
- Underestimated or unrecognized biomechanical loads cause acute failure.
- Aggressive postoperative mobilization, particularly in osteopenic bone, causes acute or progressive hardware loosening.
- Noncompliant patients can accelerate all these processes, particularly when smoking retards the healing process.
- Progressive destruction by tumor or infection further destabilizes the spine.

**Progressive or Adjacent-Segment Degeneration**

Cervical spine fusion may accelerate degeneration of neighboring, unfused levels (3). These changes may reflect local biomechanical alterations that result from an existing fusion (adjacent segment degeneration) or may simply reflect the natural history of that patient’s cervical spondylosis. As such, this degeneration may take the form of recurrent stenosis, recurrent disc herniation, or degenerative disc disease. Up to 89% of ACDF patients report symptomatic degeneration at long-term follow-up (17,43). Anecdotal evidence suggests that fusions ending at C-5 or C-6 are particularly associated with recurrent axial neck pain, perhaps because of the increased segmental motion at these levels (40).

In patients with continued pain despite a solid arthrodesis, rule out inadequate decompression first. Then evaluate radicular or myelopathic symptoms for evidence of foraminal or canal stenosis or recurrent disc herniation. In patients with predominantly axial pain, assessment of the cervical discs above and below the fusion mass remains controversial. Some authors recommend cervical discography with anterior fusion for concordant pain (33).

**PREOPERATIVE ASSESSMENT AND PLANNING**

**PRESENTATION**

**Failed Cervical Spine Surgery**

Patients with failed cervical spine surgery present with the following:

- Residual axial pain
- Recurrent or residual myelopathy
- Recurrent or residual radiculopathy
- Development or progression of deformity

Evaluation algorithms are presented in Figure 148.1, Figure 148.2, Figure 148.3.

**Figure 148.1.** Evaluation algorithm for patients with failed cervical spine surgery

**Figure 148.2.** Evaluation algorithm for radiculopathy and myelopathy.
Figure 148.3. Evaluation algorithm for postsurgical deformity.

**Pseudarthrosis**

Patients with pseudarthrosis typically present with the following:

- Axial neck pain
- Recurrent radiculopathy or myelopathy from regrowth of posterior osteophytes
- Deformity from failure of intended fusion after wide posterior decompression

**Inadequate Decompression or Adjacent-level Degenerative Disc Disease**

Patients with inadequate decompression or progressive or adjacent-level degenerative disc disease present with the following:

- Neural compression after cervical spine surgery, most commonly related to inadequate decompression, recurrent disc herniation, or recurrent stenosis
- Radicular pain (radiculitis), one of the earliest symptoms of neural compression, often relieved by distraction and increased with axial loading
- Weakness and sensory changes, presenting in a radicular pattern (radiculopathy) with increasing compression
- In some cases, lower motor neuron findings, including weakness and diminished reflexes, at the level of compression; below the compression, upper motor neuron signs, including hyperreflexia and spasticity
- Ataxia, clumsiness, diffuse lower extremity weakness, and bowel and bladder problems (i.e., myelopathy) after cervical spine surgery, often related to the following:
  - Large central disc (less common)
  - Severe, unaddressed osteophytosis (with normal or stenotic canal)
  - Hardware displacement
  - Postoperative deformity

**Postlaminectomy Kyphosis**

Patients with postlaminectomy kyphosis present with a history of prior posterior cervical spine surgery and an often subtle, progressive pattern of pain and neurologic change (18):

- Neck pain (75%)
- Severe neck deformity (30%)
- Progressive myelopathy (90%)
- Radiculopathy (50%)

**Hardware Failure**

Hardware failure may result in any of the symptoms described in this section. In dramatic cases, patients complain of tracheal or esophageal impingement. Sudden changes in alignment, neurologic status, or pain often indicate failure of hardware. Patients may be aware of a “pop” or acute onset of instability. However, slow pull-out of lateral mass plates, for example, can present with slowly increasing deformity, such as is seen in postlaminectomy kyphosis.

**HISTORY AND PHYSICAL EXAMINATION**

Understand the patient's spine thoroughly before making treatment decisions. First, obtain complete records of previous procedures and determine the following:

- What types of postoperative immobilization were employed?
- What was the condition of the bone?
- Was allograft or autograft employed?
- Was the PLL resected?

A complete motor and sensory examination is critical. Patients with prior cervical spine surgery are likely to demonstrate complex abnormalities. Perform a detailed and stepwise assessment of sensory, motor, and reflex abnormalities, as well as a careful search for evidence of myelopathy to define new or residual neurologic deficits. Note bowel or bladder changes, gait disturbance, and the unilaterality or bilaterality of symptoms. The following may be a useful checklist:

- Recognize possible aberrant innervation patterns (23).
- Map complex sensory deficits on the skin with a skin marker.
- Chart complex motor and reflex changes.
- Distinguish cervical problems from those of shoulder, cardiac, cranial, or peripheral origin.
- Assess the location and healing of the prior incision(s).
- Assess cervical range of motion (ROM) and neck and body posture.
- Note areas of tenderness and spasticity of paravertebral and anterior strap muscles.

**IMAGING STUDIES**

Compare plain anteroposterior (AP), lateral, and oblique views with prior studies to assess progression of spondylosis, fusion, deformity, or hardware migration. New degeneration most often presents with narrowing of adjacent disc heights and increase in osteophyte formation. Space available for the cord, from the posterior vertebral body to its lamina, is normally over 17 mm; an AP diameter of less than 13 mm suggests spinal cord compression (17). Oblique views assess the fusion mass, intervertebral foramina, pedicles, and facets, and they show persistent compression due to uncovertebral joint spurring.

If postoperative instability or pseudarthrosis is suspected, flexion–extension lateral films are useful. Dynamic x-rays are also helpful in evaluating new instability secondary to adjacent-level degenerative disc disease. In a patient with postoperative deformity, 5 pounds of axial traction may be used to determine reducibility (15).

Correlate radiographic findings with presenting complaints and physical exam. For example, pseudarthrosis is often difficult to identify. As in the lumbar spine, shingling of the bone mass may obscure the fusion defect (5). Therefore, clinical criteria (intractable neck pain with or without radicular symptoms) must be correlated with radiographic criteria (6). Radiographic signs of pseudarthrosis include the following (6):

- Gross motion at previous fusion site on dynamic radiographs
Persistence of disc-space lucency  
Graft displacement or failure to incorporate  
No dissolution of endplates  
Hardware failure

Advanced imaging modalities may also prove useful. Single photon emission computed tomography (SPECT) scanning employs a tomographic camera to remove three-dimensional superimposition from scintigraphic images, thereby improving image contrast and offering more complete spatial information than conventional bone scans. It is increasingly being used to demonstrate increased focal uptake at sites of pseudarthrosis.

Computed tomographic myelography demonstrates neural compression indirectly through contour of the dural sac. While myelography is invasive, it is helpful in the presence of spinal deformity. Further, it offers information on conjoint nerve roots and other pathologies not readily appreciated with magnetic resonance imaging (MRI). When spinal instrumentation is in place, myelography may be the only way to visualize neural structures.

Magnetic resonance imaging elucidates disc degeneration and intrinsic changes in the cord. However, major abnormalities are commonly encountered in asymptomatic patients. In postoperative patients, gadolinium enhancement reveals recurrent discs as nonenhancing space-occupying lesions, which scar enhances.

Some authors advocate cervical discography for patients with undetermined axial pain, reporting 70% good to excellent results with anterior fusion after concordant discography. However, others cite higher failure rates, including one report of 54% fair to poor results. These authors cite a 13% complication rate with cervical discography, including one case of acute epidural abscess resulting in quadriplegia. Discography is likely to remain controversial for some time.

Finally, root injections are occasionally used to determine painful levels. Resolution or mitigation of pain indicates specific root-level pathology and the likelihood of surgical relief of symptoms following surgery.

**TREATMENT**

Principles and operative indications are the same as for patients requiring primary treatment. Early operative treatment should be considered in any patient demonstrating the following:

- Progressive motor or gait impairment
- Persistent disabling pain and weakness (3 months)
- Progressive deformity
- Instability
- Static neurologic deficits with significant axial or radicular pain

Surgery should not be contemplated in patients without consistent findings in both clinical examination and imaging studies. Pseudarthrosis alone, for example, is not an indication for revision surgery. Nonoperative treatment should be fully explored in the majority of “failed neck” patients.

**NONOPERATIVE TREATMENT**

A trial of nonoperative treatment is useful even in those patients for whom later surgery is felt to be unavoidable. During this period, develop rapport with the patient, document compliance with prescribed treatment, maximize medical status, and optimize nutritional and smoking status. In certain patients, urine nicotine levels may be obtained.

![Figure 148.4. Algorithm for treatment of patients with failed anterior surgery.](image)

**OPERATIVE PLANNING AND TREATMENT**

The operated neck is different in many ways from the “untouched” spine:

- Prior decompression may have rendered the spine unstable.
- Prior fusions create significant lever arms that must be considered in any subsequent construct.
- Surgical soft-tissue injury from the prior surgery interferes with blood supply, healing potential, and local biomechanics.

While many authors report acceptable results with allograft use in both index and revision cervical spine procedures, the decreased vascularity and altered biomechanics of the revision situation are an indication for autograft bone.

**Anterior Pseudarthrosis**

Posterior Repair of Cervical Pseudarthrosis Posterior fusion for symptomatic anterior pseudarthrosis was proposed by Riley and Robinson. The additional stabilization offered by posterior wiring encourages the anterior fusion mass to consolidate. This approach remains the gold standard today, with 94% to 100% union rates reported.

![Figure 148.5. Treatment algorithm for failed anterior surgery.](image)
Several randomized, prospective series have been undertaken to compare anterior and posterior treatment of anterior pseudarthrosis (4,22,29). Interestingly, while over 80% of patients treated posteriorly felt better than before surgery, only 70% of those treated circumferentially reported symptomatic improvement. These results argue for a posterior approach unless specific hardware concerns require an anterior approach.

- Use a standard, midline approach to the involved level.
- Several wiring methods may be employed. If the spinous processes are intact, a triple wire technique provides good resistance to torsional and flexion forces (Fig. 148.6).
- If the posterior elements are absent or inadequate, lateral mass plates provide greater resistance to torsional and extension forces.
- Use lateral mass plates for multilevel fusions as well.
- Postoperative immobilization includes a Philadelphia collar for 6–12 weeks.

**Anterior Repair of Cervical Pseudarthrosis**

An anterior approach to failed anterior cervical fusion is often required in cases of residual radiculopathy, or failed or migrated hardware. Although repeat anterior surgery was felt to have lower success rates than posterior surgery, recent authors, citing modern anterior osteosynthesis techniques, report increased fusion rates with good results in 83% (6).

Proponents of the repeat anterior approach cite lower rates of wound problems, the biomechanical advantages of anterior column grafting, and the ability to explore the decompression site and to remove any remaining osteophytes. Anterior repair is being increasingly recommended for patients with collapse of a previous anterior graft in conjunction with pseudarthrosis.

Some authors recommend using a contralateral approach to avoid operating through the scarring on the previously approached side. Contralateral exposure should not be carried out until laryngoscopic evaluation of the vocal cords has confirmed that both cords are functioning normally. This approach limits the risk of sequential injury to both recurrent laryngeal nerves.

- Use a transverse incision to approach the cervical spine in the standard fashion (see Chapter 138).
- Carefully measure the disc space for height, depth, and width.
- Fashion the graft to fit the distracted disc space by cutting it 2–4 mm longer than the interspace is high.
- Carefully contour the superior and inferior endplates with the burr.

For revision surgery, a tricortical block iliac crest autograft is preferred to dowel techniques.

Revision ACDF is a strong indication for anterior plate osteosynthesis. We use a unicortical fixation system with screws that lock to the plate.

- Carefully measure the disc space for height, depth, and width.
- Measure the sagittal depth of the vertebral body and preset the drill depth.
- When drilling, be aware of the endplate angle to avoid penetrating the intervertebral disc space above or below the intended body.
- Immediately mobilize the patient in a Philadelphia collar (usually worn for 6–12 weeks).
- When plate fixation is impractical or bony purchase is tenuous, longer postoperative immobilization in a rigid collar or a four-poster brace is advocated. In some circumstances, adjuvant posterior fixation may be employed as well, as mentioned.

**Revision ACDF**

The principles of treatment of residual compression are fairly straightforward. If significant compression remains anteriorly, the approach must be anterior. If significant compression remains posteriorly, the approach must be posterior. Similarly, posterior hardware problems are addressed posteriorly, and so on.

**Anterior Decompression**

Anterior decompression of residual or recurrent cervical spine disease is indicated in patients with less than three levels of disease. Occasionally, large central osteophytes will militate against posterior decompression in even multilevel spondylosis.

In patients with prior posterior procedures, an anterior procedure for recurrent or residual radiculopathy or myelopathy most often involves anterior corpectomy with strut graft fusion (Fig. 148.7). The likelihood of posterior instability represents a strong indication for anterior plate osteosynthesis in conjunction with well-fashioned struts. In patients with single-level and radicular findings, standard ACDF is recommended. Plate fixation may be helpful in these patients as well (7). Preoperative flexion-extension radiographs will better define the stability of the cervical spine.

**Figure 148.6.** Posterior stabilization for failed anterior cervical discectomy and fusion. A: Graft collapse and pseudarthrosis result in focal kyphosis, fragmentation, and instability. B: Posterior instrumentation and fusion are carried out without disturbing the anterior graft. The simplest approach is a triple wire technique, which can be modified for single- or multilevel fusion. C: Apply the split autograft to either side of the intact spinous processes and compress the “sandwich” with a pair of 22-gauge wires. C: Posterior wiring will most often cause the anterior graft to consolidate at the same time the posterior fusion is healing.

**Figure 148.7.** Treatment of residual cord compression after inadequate decompression. A: In patients who have undergone previous but inadequate surgical treatment, the original compressive lesion is densely consolidated, and access may be hindered by surgical scarring, old hardware, and, often, a well-integrated strut graft. B: Remove the strut graft with rongeurs and a high-speed burr, back to the posterior vertebral cortex. Study the preoperative CT scan to determine whether there...
is a distinct interval between the back of the graft and the residual vertebral body. C: Use a burr and microcurets to thin the posterior cortex in the lateral recess of the side with least compression. D: Enter the canal with a small curet or elevator directed toward the neural foramen and away from the cord. Thin the compressive mass with the burr, and use a diamond tip burr to thin the lateral recess to eggshell thickness. E: Use a small elevator or curet to reflect the residual bone fragments directly away from the canal and spinal cord. Dural adhesions may be divided with a fine Penfield elevator or microcuret.

**Anterior Decompression** Techniques for ACDF are discussed in Chapter 143. Anterior cervical corpectomy in the revision situation is discussed in the context of postlaminectomy kyphosis later. Key elements of the anterior decompression procedure include the following:

- Incise the annulus and remove adjacent discs with a pituitary rongeur and a small, angled curet.
- Remove the anterior portion of the vertebral body with rongeurs.
- Carefully thin the posterior cortices with a burr.
- Use a micro-Kerrison rongeur or curets to decompres the cord.
- Fashion a strut graft with iliac crest (two or fewer levels) or use allograft or autograft fibula.
- Contour and apply a plate.
- Use standard closure and postoperative immobilization (as described previously).

**Postlaminectomy Kyphosis**

Several approaches to postlaminectomy kyphosis have been described. They include anterior corpectomy and fusion, posterior fusion with lateral mass plates, and circumferential procedures (Fig. 148.8).

Correction of postlaminectomy kyphosis begins with preoperative traction. In most cases, moderate correction of the deformity is achieved and fusion is planned to the next normal level above and below the deformity (24,39).

A repeat posterior approach is often limited by inadequate bone stock, and corrective osteotomy through this approach is generally ineffective (2). Anterior cervical corpectomy with strut graft fusion and plating has become the favored approach in all cases without new posterior pathology (35,42,47).

A circumferential approach includes anterior corpectomy with posterior osteotomy and internal fixation (Fig. 148.9). This approach is particularly beneficial in patients with significant anterior instability as well. Generally, the circumferential approach allows for greater correction of the sagittal plane deformity. While reasoning of this surgical approach is sound, the added risks of a second operation make its use less compelling in the majority of postlaminectomy kyphosis patients (10,35).

Herman and Sonntag (18) found that anterior corpectomy and plate yielded a mean correction of only 16° of kyphosis, but that 95% of these patients reported improvement of their presenting complaints. The authors report limited correction of the deformity due to fusions of the remaining levels at the facet and posterior element levels. Moreover, the goals of stabilization and prevention of further progression having been met, 10% reported complete relief of their symptoms and 55% noted substantial improvement.

**Combined Approach for Postlaminectomy Kyphosis**

- Begin the anterior approach with the patient supine. Tape the shoulders caudally and turn the head slightly away from the operative side. Place a bolster between the shoulders to provide mild hyperextension. A bolster may not be useful in patients with a fixed-flexion deformity due to the wedging of the vertebral bodies.
- A transverse incision may be used in most cases up to five levels. In longer procedures, an extensile incision along the anterior border of the sternocleidomastoid muscle can be used instead. A standard, left-sided approach is recommended.
- Use blunt, finger dissection to dissect the platysma from overlying and underlying tissues.
- Carefully develop the intervals between the tissue planes. This will increase the extensibility of the incision.
- The omohyoid may cross the surgical field, depending on the level of dissection. Division for increased exposure is rarely required.

A variable amount of scar may be seen anteriorly at the apex of the kyphosis (19). This scar may exert a tethering effect. Debridement of the scar will allow increased exposure of the anterior bodies. Overly aggressive lateral dissection threatens the sympathetic chain.

- To achieve correction of the deformity, completely excise the intercalary discs to the level of the PLL.
- Use a rongeur to remove large portions of the intervening bodies.
Once the anterior reconstruction is completed, the patient is turned and prepared for posterior instrumentation and fusion. While this procedure is not necessary in two- or three-level fusions, we routinely add posterior fusion to reconstructions of four or more levels, and to those with poor bone quality, translational instability, or risk factors for pseudarthrosis.

- Expose the posterior cervical spine in the usual fashion, taking care to document levels and protect levels not instrumented anteriorly.
- Use a burr to decorticate the laminae and facets, and remove articular cartilage from the facets with a small curet.
- Use a 2.0 mm drill to prepare pilot holes for lateral mass plating.
- Contour the lateral mass plate to neutralize the alignment obtained during the anterior procedure. Increasing lordosis at this point will tend to loosen the anterior construct.
- Graft the facet joints and the articular processes.
- Close in layers and apply a sterile dressing.

A hard cervical collar is used for 8–12 weeks. Halo immobilization for 12 weeks may be useful in patients with poor bone, previous failures, or multiple-level procedures. These patients may also benefit from a posterior stabilization procedure, often with lateral mass plates.

**Hardware Failure**

As in pseudarthrosis, not all failed hardware requires surgical intervention. In some cases, external immobilization can be used until fusion occurs. However, when failed hardware results in neurologic or soft-tissue compression, instability, or progressive deformity, surgical treatment is offered.

Anterior hardware impinging on anterior structures must be approached anteriorly. Failed posterior hardware may be approached posteriorly. However, in cases of poor bone quality, deformity, or three-column destabilization, circumferential stabilization procedures are recommended.

Take care when approaching displaced anterior hardware. The inflammation and tissue reaction around the old hardware will make the exposure difficult and will distort tissue planes. Inadvertent entry into the carotid sheath, esophagus, or thoracic duct can result in potentially lethal complications.

After hardware removal, spinal instability must be addressed. In some cases, postoperative halo immobilization suffices. Typically, however, revision internal fixation is employed in conjunction with postoperative immobilization (7).

Failed spinous process wires are easily removed and replaced with lateral mass plates. Sublaminar wires are more problematic, and they may be retained or removed. In cases where dense scar makes dissection difficult, the broken wire may be repositioned around the intact lamina and left in place. If monofilament wire must be removed, contour the end to be pulled through the canal so that it can be pulled out smoothly. Place a Woodson or Penfield elevator between the wire and the thecal sack and extract the wire by winding the free end up with a needle-holder. Cut braided wires close to the lamina to remove as much of the frayed portion as possible before trying to remove them.

**Adjacent-Level Degeneration and Recurrent Stenosis or Disc Herniation**

Adjacent-level degeneration in the cervical spine is related to recurrent compression. Recurrence of stenosis or disc herniation often reflects the same global nature of cervical spondylosis seen in patients with recurrent axial symptoms. Whether or not surgical intervention accelerates degenerative changes at neighboring levels, principles governing their treatment remain the same.

Treatment options for recurrent disc herniation include ACDF of the new level or posterior keyhole foraminotomy. There are proponents of each approach. In the patient with a previously operated neck, the same principles apply, with the caveat that repeat anterior surgery requires special attention to the status of the recurrent laryngeal nerves and vulnerable soft-tissue structures of the neck (as previously discussed).

When recurrent or residual root compression is the result of soft disc pathology at one or two levels, keyhole foraminotomy may be indicated. Most often, this is seen in patients with a prior ACDF and an incompletely excised disc, or with recurrent soft disc pathology at a neighboring level.

The advantages of keyhole foraminotomy include the avoidance of fusion-related problems and the need for only minimal laminar resection to decompress the cord and stabilize the spine. Laminoforaminotomy is contraindicated in patients with cervical kyphosis or major anterior cord compression (17).

As in primary cervical spine procedures, debate continues as to the best method to treat multilevel recurrent or residual stenosis. Laminoplasty is recommended for recurrent stenosis above and below a previously, anteriorly fused level, or in the case of disease affecting more than three levels (28). Others report success with vertebrectomy and strut graft fusion techniques (42).

Laminoplasty preserves the cervical facets and decreases the incidence of instability associated with multiple-level laminectomies. However, decomposition may be incomplete if foraminal stenosis is not addressed. Contraindications include cervical deformity (especially kyphosis) and major anterior cord compression.

Anterior vertebrectomy and strut graft fusion is recommended for patients with recurrent or residual stenosis after laminectomy and in those patients who are not candidates for posterior decompressive laminoplasty.

In patients with no evidence of stenosis and predominantly axial pain, the possibility of adjacent-segment disc degeneration must be considered. Advocates of cervical discography recommend anterior fusion for concordant pain (41).

**Keyhole Foraminotomy for Recurrent or Residual Disc Herniation**

- With the patient prone, obtain precise radiographic localization prior to skin incision. Employ a standard midline approach with careful, unilateral exposure to the lateral aspect of the facet capsule.
- Thin the lateral portion of the lamina and the medial portion of the facet with a burr.
- Carefully develop the interval between the medial facet capsule and the ligamentum flavum with a fine curved curet or Penfield.
- Remove the medial 25% of the facet with Kerrison rongeurs. Remove the volar facet capsule to visualize the root and the lateral margin of the thecal sack.
- Expand the laminotomy over the junction of the root and dura taking care to preserve over 50% of the facet.
- If a contained herniation is found, incise the PLL to retrieve the fragment.
- Apply a collar for comfort for the first 2–3 weeks after surgery. If more than 50% of both facets, or more than 75% of one facet, is removed, consider fusion with lateral mass plates.

**Laminoplasty for Multilevel Residual or Recurrent Stenosis**

Open-book laminoplasty requires a wide exposure of the posterior elements and lateral masses of the involved cervical spine, as well as exposure of at least one normal level above and below the compression. The surgeon must elevate laminae at the margins of stenosis as well as those directly over the narrowed segment.
The most common complications of revision posterior cervical spine surgery are wound infection (1.2%) and failure of healing. Correction of identifiable nutritional overretraction of the longus colli is ostensibly more likely if the longus muscles are encased in scar, or the dissection difficult. Other problems related to anterior surgery could be increased in the revision situation as well. Horner's syndrome from injury to the sympathetic chain and the literature regarding incidence of vocal cord paralysis after revision anterior cervical spine surgery is varied (30, 36, 37, 42). Although the ipsilateral operative approach requires dissection through scar, the contralateral approach should not be undertaken without confirming the function of both vocal cords through laryngoscopy. Other problems related to anterior surgery could be increased in the revision situation as well. Horner's syndrome from injury to the sympathetic chain and overretraction of the longus colli is ostensibly more likely if the longus muscles are encased in scar, or the dissection difficult. The most common complications of revision posterior cervical spine surgery are wound infection (1.2%) and failure of healing. Correction of identifiable nutritional

Repeated dissection through anterior soft tissues increases the possibility of transient sore throat or swallowing difficulty. Further, dissection through scar requires meticulous attention to detail and great caution. Perforation of the esophagus is a life-threatening injury, and only one third are recognized at the time of surgery. Mortality for injuries recognized early is 15%. If recognized late, mortality rises to 30% (30, 36).

The literature regarding incidence of vocal cord paralysis after revision anterior cervical spine surgery is varied (6, 22). Although the ipsilateral operative approach requires dissection through scar, the contralateral approach should not be undertaken without confirming the function of both vocal cords through laryngoscopy. Other problems related to anterior surgery could be increased in the revision situation as well. Horner's syndrome from injury to the sympathetic chain and overretraction of the longus colli is ostensibly more likely if the longus muscles are encased in scar, or the dissection difficult. The most common complications of revision posterior cervical spine surgery are wound infection (1.2%) and failure of healing. Correction of identifiable nutritional
deficiencies may decrease these problems. The incidence of dural tear also rises when dissecting through posterior scar (!27.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: classic article; review article; basic research article; and clinical results/outcome study.

Management of the patient with recurrent or residual back pain following previous surgery on the lumbar spine is a complex challenge. It is estimated that, in the United States alone, more than 300,000 lumbar laminectomies and 70,000 fusions are performed annually; at least 15% of these patients fail to achieve long-lasting pain relief (15,36).

An individual in whom prior surgery has failed represents a unique challenge and opportunity; many patients can be made better with appropriate operative or nonoperative treatment, but there is a great chance of succumbing to the assumption that another operation, in the absence of objective indications, will be the solution to the patient's problem. The inherent complexity of these cases necessitates an approach to evaluation that is precise and unambiguous—one that, it is hoped, will lead to accurate identification of the source of the patient's pain and to appropriate treatment.

The best solution for failed low-back surgery is prevention. Although the technical aspects of performing surgery on the lumbar spine are very important, proper patient selection is probably the most important factor in avoiding postoperative failure (see Chapter 144). Long et al. (25) reviewed 78 patients with so-called failed back surgery syndrome (FBSS) in a chronic pain program. They noted that, when original records were reviewed from before the first operation, 68% of these patients failed to fulfill any objective criteria available in either the orthopaedic or neurosurgical literature for surgery. Fifty-six percent were found to have an underlying psychiatric abnormality.

They concluded that improper patient selection was the most common factor associated with failure. Thus, it is clear that the initial decision to operate is the most important one and should be arrived at only when clear identification of the source of the patient's pain is made and objective criteria for the proposed surgery are met. See the objective patient evaluation system in Chapter 144. Once low-back surgery has failed, the potential for a solution is limited.

In evaluating recurrent symptoms following surgery, distinguish between a mechanical source for the complaint from nonmechanical causes. The types of mechanical conditions that respond, in select cases, to revision surgery include recurrent disc herniation, discogenic pain, segmental instability of the spine, and spinal stenosis. Nonmechanical entities that can lead to recurrent symptoms include local scar tissue formation (either arachnoiditis or epidural fibrosis), abdominal or pelvic disorders, systemic medical diseases, or psychosocial instability. These nonmechanical problems will not be helped by additional spinal surgery.

The keystone of successful treatment is to obtain an accurate diagnosis. Although this factor is seemingly obvious, this essential step is often neglected and the rehabilitation of the patient is therefore inadequate.

EVALUATION AND IMAGING

A structured approach to the evaluation of the patient with recurrent symptoms following previous lumbar spine surgery is essential. Use a standardized form to detail the medical history and to list any and all previous back operations, including dates and the type of operation performed. Consider obtaining previous operative notes.

The symptom complex before the original operation can help to determine the appropriateness of the procedure itself.

It is also useful to know the extent of postoperative pain relief and the length of the pain-free interval to determine the source of the patient's current pain. No relief of preoperative sciatica suggests failure to relieve root compression, which may be due to a retained disc fragment, surgery at the wrong level, or an improper original diagnosis. If the patient relates that the preoperative sciatica was relieved, note the percentage of relief and duration of that improvement. A pain-free interval of more than 6 months and certainly more than 12 months, suggests that the patient's pain may be caused by recurrent disc herniation. A pain-free interval lasting only 2 to 6 months, particularly with the gradual recurrence of symptoms, suggests that epidural fibrosis may be the cause of the pain (13).

Also, record the number of previous operations on the lumbar spine. It is well documented that each subsequent operation, including dates and the type of operation performed. Consider obtaining previous operative notes. The symptom complex before the original operation can help to determine the appropriateness of the procedure itself.

It is also useful to know the extent of postoperative pain relief and the length of the pain-free interval to determine the source of the patient's current pain. No relief of preoperative sciatica suggests failure to relieve root compression, which may be due to a retained disc fragment, surgery at the wrong level, or an improper original diagnosis. If the patient relates that the preoperative sciatica was relieved, note the percentage of relief and duration of that improvement. A pain-free interval of more than 6 months and certainly more than 12 months, suggests that the patient's pain may be caused by recurrent disc herniation. A pain-free interval lasting only 2 to 6 months, particularly with the gradual recurrence of symptoms, suggests that epidural fibrosis may be the cause of the pain (13).

Also, record the number of previous operations on the lumbar spine. It is well documented that each subsequent operation, including dates and the type of operation performed. Consider obtaining previous operative notes. The symptom complex before the original operation can help to determine the appropriateness of the procedure itself.

It is also useful to know the extent of postoperative pain relief and the length of the pain-free interval to determine the source of the patient's current pain. No relief of preoperative sciatica suggests failure to relieve root compression, which may be due to a retained disc fragment, surgery at the wrong level, or an improper original diagnosis. If the patient relates that the preoperative sciatica was relieved, note the percentage of relief and duration of that improvement. A pain-free interval of more than 6 months and certainly more than 12 months, suggests that the patient's pain may be caused by recurrent disc herniation. A pain-free interval lasting only 2 to 6 months, particularly with the gradual recurrence of symptoms, suggests that epidural fibrosis may be the cause of the pain (13).

Also, record the number of previous operations on the lumbar spine. It is well documented that each subsequent operation, including dates and the type of operation performed. Consider obtaining previous operative notes. The symptom complex before the original operation can help to determine the appropriateness of the procedure itself.
The most helpful initial study is plain radiography, which may reveal the extent of the laminectomy defect, the level of the previous operation, changes consistent with spinal stenosis, and evidence of instability on dynamic films. Perform plain films and dynamic films with the patient standing (weight bearing). Assess any evidence of abnormal motion, progressive deformity, or progressive anterolisthesis (Fig. 149.1). Plain radiographs, including dynamic views, also help assess the quality of any fusion mass that may be present. On a lateral view, a successful interbody fusion is indicated by the continuity of bone between the outer margins of the adjacent vertebral bodies. A posterior fusion mass can be difficult to evaluate, particularly at L5–S1; a Ferguson anteroposterior (AP) view (with the x-ray beam tilted cephalad 30° to run parallel to the L5–S1 disc space) highlights the fusion mass between the L-5 transverse processes and the sacral ala.

![Figure 149.1](image1)

**Figure 149.1.** A 49-year-old woman approximately 1 year after a decompressive laminectomy, with worsening low-back pain and recurrent leg pain. **A:** The AP view demonstrates the extent of the laminectomy defect (arrows). **B:** On the lateral view, subluxation of L-3 on L-4, not present before surgery, is seen, demonstrating postlaminectomy instability.

Indirect evidence of nonunion includes hardware failure such as screw loosening or breakage, rod breakage, progressive deformity across the fused levels, and evidence of motion on lateral flexion and extension views. Plain radiographs are relatively sensitive (90% to 95%) but fairly nonspecific (37% to 60%) in detecting pseudarthrosis following lumbar spine fusion (2,8).

In this setting, metrizamide myelography can still be of value. Although extradural compression is well seen on myelography, distinction between the presence of disc material and epidural scar formation is limited (8). Myelography is most helpful in confirming the diagnosis of arachnoiditis when it is otherwise uncertain.

Postmyelographic computed tomography (CT) has increased sensitivity for demonstrating changes of arachnoiditis. We still use it quite frequently in assessing spinal stenosis in a patient who has undergone previous surgery. The size of the spinal canal, the presence of bony defects and the extent of posterior element resection, and hypertrophic bony changes causing stenosis are all well visualized (Fig. 149.2).

![Figure 149.2](image2)

**Figure 149.2.** A 76-year-old woman, 9 months after a left L3–L4 hemilaminectomy, with persistent back and leg pain. This shows AP and lateral flexion and extension views with myelography **(A)** Multi-level stenosis, most severe at L3–L4 and L4–L5; **(B and C)** axial postmyelogram CT images, which clearly define the pathologic anatomy. The failure of the previous decompression to address the pathology is appreciated (arrowhead).

CT scanning is quite useful in evaluating postoperative hardware placement. Although metallic scatter diminishes the quality of the images, careful scrutiny of the bony windows following plain CT scanning can usually establish whether or not a screw has broken out of the pedicle (usually medial) and is causing nerve root compression.

Magnetic resonance imaging (MRI) is, with rare exception, the most helpful diagnostic tool for imaging the lumbar spine that has previously undergone surgery. The most noteworthy use of MRI has been in the diagnosis of recurrent disc herniation, using images obtained before and after the injection of intravenous paramagnetic contrast material (Gadolinium-DTPA). MRI has 100% sensitivity, 71% specificity, and 89% accuracy (19). A nonenhancing soft-tissue mass causing nerve root compression is strongly suggestive of recurrent disc herniation, whereas Gd-DTPA enhancement suggests the presence of scar tissue (Fig. 149.3).

![Figure 149.3](image3)

**Figure 149.3.** A 37-year-old woman with a history of three previous discectomies who had recurrent, severe right leg pain, numbness, and a positive straight-leg raising sign. **(A)** The sagittal MRI demonstrates an apparent disc herniation at L4–L5; **(B)** the axial T2 image, without contrast, through the L4–L5 disc space demonstrates a soft-tissue mass consistent with disc herniation; **(C)** the T1 image, following contrast administration. The absence of contrast-enhancement of the mass (white arrow) is diagnostic of recurrent disc herniation, rather than epidural fibrosis; **(D)** a solid fusion 2 years following repeat discectomy and fusion; the patient continued to have significant back pain.

It should be noted that in the first 6 months following surgery, gadolinium-enhanced MRI frequently demonstrates pathologic changes and may suggest recurrent disc herniation, despite a good clinical result. Take care not to overinterpret gadolinium MRI in the early postoperative period; overreliance on this study may lead to negative findings on repeat surgical exploration (4).

MRI is also extremely sensitive for identifying inflammatory processes such as discitis, and in fact, it is the test of choice when a postoperative disc space infection is suspected. Decreased signal intensity in the disc on the T1-weighted images and increased signal on the T2-weighted images, particularly with enhancement following...
Gd-DTPA injection, all suggest an inflammatory process (23).

A final use for MRI is for the definition of noninflammatory degenerative changes in the lumbar discs. Although the significance of disc degeneration in the lumbar spine remains controversial, MRI unquestionably gives the best picture of the discs involved with degenerative changes, the extent of disc desiccation, bulging, and reactive changes in the vertebral bodies. It may be beneficial in the evaluation of a patient with persistent mechanical back pain following a lumbar discectomy in whom discogenic back pain is considered a potential diagnosis (19).

Discography is occasionally used in the evaluation of the patient whose previous back surgery has failed. The indication for discography is to assess the reproduction of the patient's characteristic pain on disc injection and to compare it with the injection of control levels above and below. It should be stressed that, although discography gives a clear picture of abnormal disc morphology, this information rarely contributes meaningfully to surgical decision making and should not be used except in the context of reproduction of the patient's pain.

The role of discography in identifying the pain generator continues to be debated. Proponents believe that reproduction of pain during disc injection, in a manner and distribution concordant with the patient's characteristic pain complaints, identifies that disc as the source of the pain (Fig. 149.4). Conflicting reports regarding the specificity of discography have appeared, with Holt in 1968 reporting a false-positive rate of 37% (23), compared with Walsh et al., who recently noted no false-positive results in their study of normal subjects (39).

Suffice it to say that discography remains controversial, with its ability to predict the pain generator as well as to predict the results of surgical intervention still unproven. We agree with the North American Spine Society position statement on discography, which advocates discography only in the evaluation of a patient with unremitting spinal pain of more than 4 months' duration and only when the patient and physician have decided that surgical treatment is under consideration (23).

**DIFFERENTIAL DIAGNOSIS**

Burton et al. (7) have described the conditions that contribute to FBSS, including recurrent or persistent disc herniation (12% to 16%), lateral (58%) or central (7% to 14%) stenosis, arachnoiditis (1% to 16%), epidural fibrosis (6% to 8%), and instability (5%). Superimposed on many of these conditions is discogenic back pain, a relatively common cause of back or leg pain following surgery.

**NONORTHOPAEDIC CONSIDERATIONS**

First, rule out nonorthopaedic or systemic causes of pain such as pancreatitis, diabetes mellitus, or an abdominal aortic aneurysm. Other systemic disorders to be considered include fibromyalgia, ankylosing spondylitis, and osteoporosis or osteomalacia.

Also, assess the patient's psychosocial makeup. Identify specific factors such as alcoholism, drug dependence, depression, and the presence of compensation or litigation issues. Strongly weigh such factors when calculating the risk–benefit ratio of surgery. People with profound emotional disturbances and those involved in litigation rarely derive significant benefit from additional surgery (37). Even in the face of a specific orthopaedic diagnosis, make every attempt to address psychosocial problems such as drug dependence and depression before considering further surgery; in many cases, once a patient's underlying problem has been successfully treated, the somatic back complaints and disability improve.

**HERNIATED INTERVERTEBRAL DISC**

Three possibilities exist if the patient's pain is caused by a herniated disc. First, the disc that caused the original symptoms may not have been completely removed, as can occur if the surgery was performed at the wrong level, if inadequate decompression was performed, or if a fragment of disc material was simply left behind. The predominant complaint is leg pain, and the neurologic findings, tension signs, and radiographic pattern remain unchanged from presurgical findings. The distinguishing feature is that there is typically no pain-free interval; this patient will have awakened from surgery complaining of the same pain that he or she had preoperatively.

Patients in this group are helped by a correctly performed discectomy.

A second possibility is a recurrent disc herniation at the previously decompressed level. In this case patients complain of recurrence of sciatica and have similar neurologic findings and tension signs. The distinguishing characteristic in this group is the presence of a well-defined pain-free interval that is usually of 6 months' duration or longer. The diagnosis is confirmed with gadolinium-enhanced MRI; a recurrent disc herniation is avascular, with only a thin enhancing rim at the periphery of the lesion (19). If nonoperative treatment fails, repeat discectomy is indicated in this group of patients.

Finally, a disc herniation may occur at a completely different level or on the opposite side. In this case, patients will also describe a pain-free interval of 6 months or longer following their original surgery. Otherwise the development of their symptoms, with leg pain predominating, is similar to that for a typical disc herniation. A tension sign is usually present, as are appropriate neurologic findings. A neurologic deficit should be different from that associated with the original operation, because the source of the pain is compression of a different nerve root. Repeat surgery in these patients has the same prognosis as a primary discectomy.

**LUMBAR SPINAL STENOSIS**

Lumbar spinal stenosis (LSS) in patients who have had previous back surgery can result in either back or leg pain but typically causes both. The etiology may be progression of the patient's underlying degenerative spine disorder, failure to decompress the patient's stenosis adequately at the time of the original operation, overgrowth of a previous posterior fusion mass, or transition syndrome.

Transition syndrome refers to the development of degenerative changes and frequently instability at a level adjacent to a previous lumbar fusion. The patient's report of a pain-free interval will vary when LSS is the cause of the symptoms; failure to recognize and relieve stenosis at the time of the original procedure may result in no pain-free interval whatsoever. Alternatively, a period of months or even many years may pass before stenosis develops in a patient who has undergone an otherwise successful operation.

In general, the history and physical examination of patients with postoperative LSS do not differ significantly from those of patients without prior surgery. Back and leg pain are typically seen. Worsening of the leg symptoms with walking or standing is a common finding, but not essential to the diagnosis, and many patients with LSS do not report neurogenic claudication. A normal neurologic examination is common, and neurologic findings, when present, are usually subtle. Tension signs are usually negative (14,33).

The plain radiographs can be suggestive of LSS, and they may display facet degeneration, decreased interpedicular distance, decreased sagittal canal diameter, and disc degeneration. Degenerative spondylolisthesis and degenerative scoliosis are commonly seen in patients with stenosis of the spinal canal and lateral recesses.
Neuroradiographic imaging of the postoperative patient with suspected LSS may be accomplished using plain CT, postmyelographic CT, or MRI. Advantages of MRI include the ability to image sagittal and parasagittal views of the thecal sac and foraminal narrowing, and to identify disc degeneration, which may be helpful in planning for a fusion. Its sensitivity in identifying other causes of back pain in this population, including metastatic disease and occult infection, is also an advantage. State-of-the-art technology in MRI has provided sufficient bony detail to diagnose adequately facet overgrowth, osteophyte formation, and other causes of LSS in most patients. This is our routine test of choice (Fig. 149.5). In some patients with previous surgery, however, it is helpful to use postmyelographic CT scanning, which still provides better bony detail and shows encroachment on the thecal sac and on the nerve roots in the lateral recesses and foramina. Postmyelographic CT is not as specific as MRI in identifying and differentiating postoperative scar tissue from normal soft tissue, when differentiation is a consideration.

![Figure 149.5](image)

**Figure 149.5.** A 52-year-old man with recurrent back and right leg pain 8 years following a lumbar decompression and fusion from L4–S1. On T1-weighted axial MR images, right lateral recess stenosis at L2–L3 (arrows) is clearly demonstrated. Following repeat decompression and extension of his fusion to L-2 he had near-complete pain relief.

The properly selected patient with symptomatic LSS, having failed nonoperative treatment, has at least a 70% chance of obtaining satisfactory results following surgery. If nonoperative treatment is unsuccessful, thorough decompression of any bony or soft-tissue compression is likely to relieve symptoms significantly. If, however, a significant component of the compression is due to epidural fibrotic scar, then the results of surgery are far less predictable. Patients undergoing repeat decompression who have either pre-existing instability or in whom instability may result from the decompression should also undergo a posterolateral fusion at the involved levels.

SEGMENTAL INSTABILITY

Lumbar instability is a poorly understood condition that can cause mechanical back pain following previous surgery. Instability results from the spinal motion segment's inability to bear physiologic loads; the result is abnormal motion between two vertebrae. Most commonly, it causes back pain, but leg pain or neurologic findings from dynamic stenosis may also be seen.

The diagnosis can be made on the basis of excessive motion on flexion and extension radiographs or by the development or worsening of spinal deformity. Instability following lumbar spine surgery may be the result of a pre-existing condition, as in a patient with spondylolisthesis treated with decompression alone, or it may be the result of an excessively wide or aggressive decompression. It is not uncommon to see either frontal or sagittal plane instability occur in a patient who has had unilateral thinning of the inferior facet and pars, resulting in facet fracture. Unilateral facet resection is commonly believed to be benign, but this degree of resection in the presence of an incompetent disc, particularly after an extensive discectomy, may lead to instability. Another sign of instability would be painful motion occurring at the site of a pseudarthrosis.

![Figure 149.6](image)

**Figure 149.6.** A 53-year-old man 18 months following a decompressive laminectomy at L4–L5, with discectomy, for degenerative stenosis. (A and B) Coronal and sagittal MRIs demonstrating the alignment of his lower lumbar spine before surgery; (C and D) similar images taken 16 months later, demonstrating progressive development of deformity, indicative of instability.

Patients with instability complain predominantly of back pain, although 20% to 25% report radiating leg symptoms with weight bearing. The physical examination is frequently negative, although some patients have a characteristic reversal of normal spinal rhythm on return from forward bending. A key to diagnosis in these patients is the plain radiograph. Weight-bearing lateral flexion and extension views are diagnostic for instability when they demonstrate:

- Sagittal plane translation greater than 12% of the AP diameter of the vertebral body,
- Relative sagittal plane rotation greater than 11°,
- Sagittal translation greater than 25% at L5–S1,
- Relative rotation greater than 19°.

Although these criteria represent absolute evidence of instability, indirect evidence may be seen in the patient who following surgery has developed:

- Progressive deformity in either the sagittal or frontal planes;
- Short-segment angular collapse at the level of the decompression.

Frontal plane segmental collapse is seen commonly with postoperative instability and may result in dynamic stenosis, with leg pain resulting from root compression in the concavity of the collapse. Scrutinize the plain AP radiograph for evidence of extensive or excessive resection of the posterior elements, such as the pars interarticularis and facet joints, which can lead to instability.
If there is radiographic evidence of instability in a symptomatic patient, spinal fusion, facet injections, or discography may help clarify the precise origin of the patient's symptoms. Rule out other possible causes of back pain before performing repeat surgery.

**DISCOGENIC BACK PAIN**

Degeneration of the disc may result in ongoing back pain in as many as 14% of patients who have had previous back surgery (19). Although the exact etiology of this pain may vary, a certain subset of patients is believed to suffer from primary disc-related or discogenic pain. The existence of this entity continues to be debated, as does a reliable method of diagnosis. The difficulty in arriving conclusively at the diagnosis of discogenic back pain is magnified in the patient who has had prior back surgery because of the potential contributions of instability, epidural fibrosis, and generalized deconditioning.

In our experience, the typical patient with discogenic back pain following previous surgery had a history of leg pain as well as significant back pain before the initial operation. A period of improvement in leg pain following the surgery is noted, but very often the back pain continues unabated or even worsens. Gradual worsening of the leg pain is frequently reported, although this symptom may be related to epidural fibrosis. The pain is typically relieved by rest. Generalized limitation of motion of the lumbar spine is seen on examination, but otherwise the physical examination is usually unremarkable.

Evaluate the patient radiographically with plain films including dynamic views to rule out instability. MRI, with or without gadolinium, may demonstrate disc degeneration at the previous surgical site, and possibly at other levels of the lumbar spine.

Modic et al. (27) have described three types of signal changes in the vertebral bodies adjacent to a degenerated disc degeneration. Type I changes show decreased T1 intensity and increased T2 intensity, which correlates histologically with disruption and fusing of the endplate and vascularized fibrous tissue within the marrow of the vertebral body. These changes, which can be suggestive of vertebral osteomyelitis, can be differentiated from infection by the absence of increased signal intensity on T2-weighted images.

Type II changes have strong signal intensity on both T1- and T2-weighted images. Histologically, these changes represent yellow marrow replacement in the vertebral body. Finally, Type III changes show decreased signal intensity on both T1- and T2-weighted images, reflecting relative absence of marrow in the vertebral body; this finding correlates with bony sclerosis seen on plain radiographs. The significance of these discogenic changes in the vertebral bodies, as seen on MRI, has not been clearly defined; such changes, when present, suggest that the intervening disc is the source of the pain.

Next, perform pain provocation discography. Because of the invasive nature of the procedure and the potential risks, in particular discs, perform discography only in patient's in whom you are considering fusion and they have agreed to proceed. The morphologic picture seen with contrast injection typically correlates closely with the MRI of disc degeneration, but it is the patient's report of reproduction of his or her characteristic pain that is essential in attempting to determine that a given disc is the pain generator. Do not use extensive sedation during the test because it renders the patient's feedback meaningless. It is also important to inject three or even four levels to find at least one control level. If every level injected reproduces the patient's pain pattern, then the test result is unreliable, and surgery based on this discogram is less likely to result in adequate pain relief.

If one or two degenerated levels can be identified as clearly reproducing the patient's characteristic pain pattern, then the patient may be a candidate for surgery. It should be noted there is no conclusive evidence that a confirmatory discography can predict surgical success. The patient and surgeon should be aware that no spine-fusion technique for discogenic back pain has been conclusively shown to have a high success rate.

In the carefully selected patient, we favor interbody fusion (see Chapter 146) rather than relying solely on posterolateral fusion. These techniques are in evolution, but success depends on using abundant autologous iliac bone graft with adequate graft-endplate contact, adequate stabilization provided by the implant, and a minimum of destruction of normal anatomy. Available techniques include:

- Transforaminal interbody fusion (TLIF) combined with transpedicular instrumentation,
- Anterior lumbar interbody fusion (ALIF), or
- Posterior lumbar interbody fusion (PLIF) with fusion cages packed with autologous bone, and
- ALIF with structural allograft replacement.

As of this writing, all of these procedures should be considered investigational. These are discussed in further detail in Chapter 146.

**ARACHNOIDITIS AND EPIDURAL FIBROSIS**

Arachnoiditis and epidural fibrosis are nonmechanical causes of back or leg pain in patients who have had previous back surgery. Scar tissue occurring beneath the dura is commonly referred to as arachnoiditis. Scar tissue can also form extradurally, compressing either the cauda equina or the nerve root, and is referred to as epidural fibrosis.

Arachnoiditis is strictly defined as an inflammation of the pia-arachnoid membrane surrounding the spinal cord or cauda equina (21). The condition may be present in varying degrees of severity, from mild thickening of the meninges to solid adhesions. The scarring may be severe enough to obliterate the subarachnoid space and block the flow of contrast agents. The etiology of this condition has been attributed to many factors; prior surgery and particularly a history of myelography with oil-based contrast are frequent precipitating factors. A dural tear with blood mixing with cerebrospinal fluid (CSF) or a postoperative infection may also play a role in its pathogenesis. The exact mechanism by which arachnoiditis develops from these events is not clear. There is no uniform clinical presentation for arachnoiditis.

The patient's history usually reveals more than one previous operation and a pain-free interval lasting from 1 to 6 months. Often, the patient complains of back and leg pain. Physical examination is inexcusive; alteration in neurologic status may be on the basis of a previous operation. Myelography, CT, and MRI can all be helpful in confirming the diagnosis (43).

There is no effective treatment for arachnoiditis. Reconstructive or decompressive surgery has not proven effective in eliminating the scar tissue or significantly reducing the pain. Salvage procedures such as spinal cord stimulation or implantation of a morphine pump have been advocated, with some promising results reported (40).

Use nonoperative measures for most patients. Epidural steroids, transcutaneous nerve stimulation, operant conditioning, bracing, and patient education have all been tried. None leads to a cure, but all can provide symptomatic relief for varying periods of time. Patients should be detoxified from narcotics and encouraged to pursue physical activity as much as possible. Gabapentin (Neurontin) and amitriptyline (Elavil) are pharmacologic adjuncts that may be effective. Treating patients with arachnoiditis is a real challenge, and the physician must be willing to devote time and patience to achieve optimal results.

Formation of scar tissue outside the dura on the cauda equina or directly on the nerve roots is a common occurrence. This epidural scar tissue can act as a constrictive force around the neural elements and may cause postoperative pain. Although most patients have radiographic evidence of epidural scar tissue formation, only an
Patients with epidural fibrosis may become symptomatic at almost any time, from several months to years after surgery. The onset is typically gradual, with complaints of back pain, leg pain, or both. Commonly the neurologic examination is normal, but the presence of a tension sign may occur due to nerve root constriction from fibrotic changes. The diagnosis is best differentiated from recurrent disc herniation or LSS by gadolinium-enhanced MRI.

As with arachnoiditis, there is no definitive treatment for epidural fibrosis. Prevention may be the best answer, and fat, Gelfoam, and other interpositional membranes have been suggested to minimize the formation of scar tissue following laminectomy (22). Once scar has formed, decompressive surgery with the goal of resecting scar tissue has not proven successful because of the almost inevitable recurrence of even worse fibrosis. It is our experience, however, that a fibrosed nerve root may be more susceptible to the deleterious effects of instability or stenosis than a nerve that has not been surgically treated.

**DISCITIS**

Discitis is an uncommon but debilitating complication of lumbar disc surgery. Its pathogenesis is postulated to be direct inoculation of the avascular disc space at the time of discectomy, but it is not completely understood (1,9). The onset of symptoms usually occurs 2 to 4 weeks following surgery.

Most patients complain of rapid onset of severe back pain. Pain is unrelenting, even at rest, and sometimes extends to the buttocks. Pain does not usually follow a dermatomal pattern down the leg. The patient may have a low-grade fever. Physical examination usually reveals marked paraspinal spasm and rigidity, and pain is present with any type of motion. Straight-leg raising may be limited, but the presence of a true tension sign or new neurologic abnormality is unusual. Occasionally, a superficial wound infection is seen, but in most cases, wound healing has been uneventful.

If you suspect discitis, obtain blood cultures, a white blood cell count with a differential, erythrocyte sedimentation rate (ESR), and a C-reactive protein level. Plain radiographs are usually normal in the early stages; later, endplate erosion may be seen, but it may not be present for several weeks. Contrast-enhanced MRI is the test of choice in suspected disc space infection. Increased signal intensity in the disc space on T2-weighted images suggests discitis, which can be confirmed by enhancement of the disc space with use of gadolinium.

Treatment options include bed rest, bracing, antibiotics, or combinations thereof. Initially, place the patient on bed rest to immobilize the lumbar spine, with or without a brace or corset. Begin empiric antibiotic treatment and continue it for 6 to 12 weeks. Cefazolin, a third-generation cephalosporin with improved staphylococcal coverage as well as pseudomonicidial activity, is administered, to 1 to 2 g every 12 hours. If the patient fails to respond rapidly to antibiotics and immobilization or manifests constitutional signs and symptoms, perform a needle biopsy of the affected disc space. Open biopsy is reserved for patients who fail to respond to treatment, as evidenced by improvement in pain and decline of the ESR, or for patients with neurologic compromise (5). Once the patient is comfortable at bed rest and is afebrile, institute progressively increasing activity as symptoms allow. Most authors report good long-term results with resolution of infection and adequate pain control.

**LUMBAR PSEUDARTHROSIS**

Nonunion following fusion of the lumbar spine has been reported to occur in as many as 40% of cases. Risk factors include a history of cigarette smoking, multiple-level fusion, and instability that has not been adequately addressed with internal fixation or external immobilization at the time of surgery. Nonunion may occur with or without instrumentation, although the presentation may be somewhat delayed in cases in which rigid internal fixation is initially used. Patients with persistent symptoms due to pseudarthrosis complain primarily of back pain. Leg pain may be present, but direct causes of nerve root compression should be sought, and an assumption that the pseudarthrosis is the cause of the leg pain is frequently unwarranted.

A pain-free interval following surgery may be variable; patients may say that their symptoms never improved following surgery, or they may report many months or even years of relatively good pain relief. It should be noted that unlike a simple discectomy, in which it is not uncommon for the patient to describe truly complete relief of pain, patients who have undergone spine-fusion surgery, even when it is successful, rarely describe complete relief of their symptoms. Patients who have undergone internal fixation, however, are more likely to describe a clear-cut pain-free interval that begins to deteriorate when the implant either loosens (the most common mode of failure) or breaks.

Pseudarthrosis may result in instability and mechanical back pain. It has long been recognized, however, that the correlation between radiographic failure of fusion and symptoms is uncertain. It is very difficult to identify accurately the source of the patient's pain following lumbar fusion; solid fusion is no guarantee of pain relief, and many patients with an obvious nonunion do remarkably well. Patients who have undergone spine fusion for pseudarthrosis may have been exposed to the deleterious effects of instability or stenosis than a nerve that has not been surgically treated.

It is essential to think twice before offering patients with a pseudarthrosis revision fusion. Undertaking repeat surgery for pseudarthrosis repair in the absence of motion at the affected level and without a thorough search for alternative causes for the patient's symptoms has limited chances for success. Most authors report compromised results after such surgery, particularly when leg pain is noted in the absence of a compressive etiology (24).

Begin evaluation of the patient with a possible pseudarthrosis with plain radiographs, including Ferguson AP and weight-bearing, dynamic lateral radiographs. Solid fusion, either posteriorly or anteriorly, should eliminate virtually all motion on flexion and extension views. Although the landmarks may be somewhat difficult to identify, careful scrutiny of dynamic views can usually identify whether or not motion is taking place (Figs. 149.8).

![Figure 149.8](image)

A 17-year-old man, 18 months following L5–S1 fusion for spondylolisthesis, who now reports worsening low-back pain. (A) A Ferguson AP view shows abundant fusion mass on the right, although a defect can be seen (arrowhead), whereas on the left, most of the graft has been resorbed (arrow). Lateral flexion and extension radiographs demonstrate 17° of angular motion; (B) clear-cut evidence of pseudarthrosis, which was confirmed at surgery; (C) clear-cut evidence of pseudarthrosis, which was confirmed at surgery; (D) revision fusion posteriorly, with transpedicular instrumentation, led to complete pain relief.

The AP views may be difficult to interpret, but many times, a serpiginous cleft in the fusion mass can be visualized. Although a number of other radiographic modalities, including CT scanning and single photon emission computed tomography (SPECT) scanning, have been suggested to diagnose nonunion, we rely almost exclusively on plain radiographic findings of motion or progressive deformity to identify the patient who is likely to benefit from repeat surgery.

In many cases, it is difficult to identify a pseudarthrosis clearly; additionally, the correlation between pseudarthrosis and symptoms in a given patient is uncertain. For these reasons, an aggressive attempt at nonoperative treatment is indicated. When the nonsurgical approach is unsuccessful, revision surgery may be undertaken. A failure rate as high as 50%, both clinically and radiographically, has been reported, however, Lauerman et al. (24) reported improved results in patients who had undergone only one prior operation on the lumbar spine and in patients who had a clear-cut original indication for fusion, such as spondylolisthesis.

**NONOPERATIVE TREATMENT**

It is axiomatic that, for the patient with pain following surgery on the lumbar spine, there is always another operation that can be considered. Experience tells us, however, that the results following revision surgery on the lumbar spine are frequently unsatisfactory, and particularly when there is a history of two or more previous operations, the patient has a significant chance of being made worse rather than better with another surgery (37). In light of this, treat nonoperatively most
patients who have failed prior surgery, even when it is possible to identify an etiology of their pain that is potentially amenable to surgery.

Nonoperative treatment involves generalized back care as well as some more specific interventions. Realistic goals for pain relief are essential. Close questioning of the patient often reveals that he or she is significantly better now than before the previous operation; any consideration of further surgery simply to “get rid of all of the pain” is likely to be unsuccessful and is unwarranted. Furthermore, it is apparent on questioning some patients that there has been almost no postoperative attempt at rehabilitation. These patients respond quite readily to a generalized back exercise and aerobic exercise program with judicious use of medication.

A generalized back treatment program consists of:

- Weight reduction when appropriate;
- A defined program of aerobic exercise, particularly involving walking, riding an exercise bicycle, or swimming;
- A supervised program of active physical therapy consisting of specific back stretching and strengthening exercises; and
- Use of nonsteroidal anti-inflammatory medications.

Make every attempt to detoxify the patient from chronic narcotic usage. Elavil is useful for the patient with chronic pain and sleep disturbance, as are several other antidepressants. Neurontin, an antiepileptic, appears to be beneficial in some patients with chronic radicular pain.

Other psychopharmacologic agents are available for use in the patient with chronic pain and are becoming increasingly popular. It is up to the individual physician to decide to what extent his or her practice includes prescribing these medicines. The authors find it more effective, in most cases, to refer such patients to a pain management center for pharmacologic management. A final adjunct that is occasionally useful is external immobilization, which may be provided by something as simple as a lumbar corset or as elaborate as a custom-made polypropylene lumbosacral orthosis. It is widely believed that these devices decondition the lumbar musculature, although there is little objective evidence to document this belief. Corsets and orthotics do, however, provide significant pain relief for many patients, and they are particularly effective in elderly patients.

In patients with leg pain and evidence of epidural fibrosis or recurrent mechanical compression from stenosis or disc, a trial of lumbar epidural steroids is worthwhile. The long-term benefits are quite variable, but a certain percentage of patients will obtain lasting relief or will tolerate a more aggressive program of rehabilitation once the inflammatory radicular symptoms are controlled. Local trigger-point injections, facet joint blocks, and sacroiliac injection may also be tried, although none of these methods has consistently proven effective.

INDICATIONS FOR SURGERY

The principal indication for surgery in the patient with failed prior low-back surgery is persistent, unacceptable pain that has failed to respond to aggressive and persistent nonoperative treatment. In addition, it is explained by and correlates with either objective evidence of instability, mechanical nerve root compression, or both. The challenge in managing patients who have had prior back surgery, and the primary reason for the increased rate of failure with further surgeries, is the difficulty of clearly correlating the patient’s pain with the radiographic findings. Adherence to guidelines that are as strict as or stricter than those used for primary surgery is essential. Our experience has been that attempts to extend these indications leads to consistently unsatisfactory results. Further, viewing fusion as a generally applicable salvage procedure for previously unsuccessful back surgery rarely results in significant and long-lasting pain relief.

Surprisingly good results can be obtained by operating on patients who fit into one of three categories. These include patients who have

1. Radicular leg pain and confirmatory evidence of nerve root compression on high-quality neuroradiographic imaging that demonstrates either recurrent disc herniation or LSS not caused by epidural fibrosis;
2. Back pain due to radiographically documented instability, as confirmed either by progressive deformity (scoliosis or spondylolisthesis), excessive motion on flexion and extension radiographs, or a failed fusion with motion demonstrated on dynamic radiographs;
3. Back pain believed to be emanating from one or two painful degenerated discs, confirmed on pain-provocation discography.

Although the results are generally good when operating on this subset of patients, it should be stressed that only a relatively small percentage of patients with FBSS fit into one of these three categories.

Other indications for surgery in this patient population include the presence of a clearly documented progressive neurologic deficit. Although this condition is uncommon, it does occasionally occur, more often in elderly patients with severe stenosis. A progressive neurologic deficit is an indication for urgent surgery. Cauda equina syndrome, a distinctly rare occurrence in patients who have had unsuccessful back surgery, merits emergent imaging and surgical treatment. Finally, one occasionally encounters the patient with radiographic evidence of progressive spondylolisthesis or progressive collapsing scoliosis, which itself suggests the need for surgical stabilization. It rarely occurs in the absence of concurrent incapacitating pain but might be a situation in which a more aggressive approach is called for.

INSTRUMENTATION

Since the early 1980s, transpedicular instrumentation has gained increasing popularity in North America as an adjunct to lumbar fusion. This trend has, in several ways, complicated the approach to the treatment of patients whose back surgery has failed. First, an increasing number of patients are undergoing lumbar spine fusion, and unfortunately, in many cases, it has been carried out in the absence of traditional, objective indications. The usual result is failure. The presence of the implant itself raises several technical considerations relating to the possible need for repeat surgery, including the significance of screw breakage, implant loosening, infection, and malposition of one or more screws. Finally, adverse publicity related to these devices has led to a climate in which either medicolegal concerns or, at the least, undue patient anxiety further clouds a complicated clinical picture.

Pedicle screw instrumentation systems are composed of metal alloys that have a very low incidence of true allergy; therefore, allergy is rarely, if ever, the cause of pain. Failure can occur in one of several ways, but mechanical failure does not necessarily represent an indication for removal of the implant or revision surgery. Screw breakage is the most dramatic mode of failure, but with current technology, it is quite rare. A broken screw does not preclude the possibility of a successful fusion and, therefore, is not an absolute indication of clinical failure (26-35).

On the other hand, the patient who, having had good relief of back pain following an instrumented lumbar fusion, now has the sudden recurrence of pain and is noted to have new screw breakage may well have had a nonunion that was adequately stabilized when the implant was intact. Such a patient would benefit from revision fusion. Another mechanism of failure is screw loosening in the pedicle and vertebral body. This is much more common than screw breakage. The loosening is seen as a small zone of radiolucency about the screw on routine radiographs. There is no clear-cut relationship between screw loosening and symptoms, and unless failure of fusion and motion on flexion and extension views are demonstrated, continued observation is indicated.

Finally, the risk of infection appears to be increased with the use of these bulky implants, and the rate of infection has been reported to be from 2% to 5% (35). Acute and subacute infection is readily diagnosed, but late infection may represent the source of recurrent back pain after a relatively long pain-free interval. Consider infection when evaluating the patient with the late onset of pain after an otherwise successful fusion. On CT scan, look for a fluid collection around the implant. Aspirate the wound to look for purulent fluid. Send any fluid aspirated for Gram's stain and culture.
**Figure 149.8.** A 59-year-old woman who, 1 month following revision fusion with transpedicular instrumentation, reported worsening left leg pain and weakness. A plain CT scan demonstrates, on the bone windows, medial placement of the L-5 screw, correlating with her symptoms. Prompt screw removal led to complete resolution of her leg pain, although she had mild residual weakness.

Thin-cut plain CT scanning of the lumbar spine, using bony windows, is a sensitive modality for identifying a screw placed outside the pedicle. Because screw misplacement is asymptomatic in as many as 20% of patients, close correlation between the patient's signs and symptoms and the root compromised by the screw in question is essential before deciding on repeat surgery (41). The most common location for screw impingement is medial to the pedicle, particularly at L-5, but it is important to keep in mind the potential for a screw to erode the transverse process or facet fracture unexpectedly. Furthermore, if a screw is identified, it is then necessary to determine if it is radioographically involved. If a central laminectomy is required either proximal or distal to the previous laminectomy, proceed in standard fashion, first developing the interval between the caudal half of the lamina and the underlying ligamentum flavum. Then resect the lamina piecemeal. Once normal dura is encountered proximally, reverse direction, working caudally to remove the intervening ligamentum flavum from the underlying dura. If, at the junction of the previous decompression and the ligamentum flavum, you find adherent scar tissue, leave a small amount of ligamentum flavum over the thecal sac if it cannot be safely dissected free. Address the nerve roots laterally, as previously described.

**SURGICAL TECHNIQUES**

Operating on the lumbar spine after one or more previous surgeries can be a challenge. The technique of a repeat laminectomy or a repeat fusion is somewhat different from first-time surgery. The risk of complications is certainly greater, with the ever-present danger of a dural tear or neurologic injury.

**REPEAT LAMINECTOMY**

The goal of a laminectomy in repeat back surgery is the same as that for the initial procedure—to decompress the neural elements without injury or excessive hemorrhage. Unfortunately, once the spine has already undergone surgery, the anatomy is not as clear and a great deal of scar tissue can be present. Thus, several technical aspects of a repeat laminectomy are different from those of a primary procedure.

The first difference involves the operative approach: It is not possible to strip the paraspinous muscles away with impunity because of absence of the spinous processes, lamina, or ligamentum flavum at the sites of previous surgery.

- Begin the approach at a new level with normal anatomy and normal protection of the cauda equina. Find the normal depth of the posterior elements and cauda equina, and carefully extend the dissection into the area of the laminectomy defect.
- Working laterally, identify and expose the facet joints.
- Proceeding distally, define the pars interarticularis at the caudal base of the superior articular facet; follow the pars further distally and medially onto the remaining lamina and inferior articular facet of the next/lower facet joint.
- Carefully scrutinize the preoperative plain radiographs, CT scan, and MRI scan to determine the extent of previous resection. It is not uncommon to encounter a pars or facet fracture unexpectedly.
- Beginning at each facet joint, use sharp curets and a Penfield dissector to subperiosteally expose the remaining normal posterior elements while minimizing risk of injury to the dura and underlying cauda equina.

The surgeon may also be tempted, once the depth of the neural elements is determined, to remove the extradural scar tissue directly over the dura. This is a technically difficult procedure with the potential for a great deal of hemorrhage and a strong possibility of dural injury. Even if the scar tissue can be successfully removed, there is no reliable means available to prevent its regrowth. We recommend, for the most part, that extradural scar tissue be left intact; remove only the tissue covering the area of previously documented nerve root compression.

The object of the surgical procedure is to visualize the nerve roots laterally and remove any mechanical (nonscar) tissue pressure from them. Do so by extending the laminectomy from the new level down the lateral gutters, leaving the central scar tissue as is:

- Use sharp curets to follow the medial border of the laminectomy defect ventrally, developing a plane between the epidural scar tissue and the residual bone.
- Once this plane is developed, introduce a Kerrison rongeur at a 45° angle, and undercut the bony enroachment, usually arising from the medial overhang of the superior articular facet.
- Carry this decompression out proximally, distally, and laterally until all bony overgrowth has been removed back to the medial wall of the pedicle.
- You may also use an osteotome to remove the most medial portion of the facet, thereby gaining entry to the spinal canal and nerve roots.
- If the goal of the repeat procedure is decompression of recurrent stenosis, extend the laminectomy laterally to the pedicle on either side at whatever levels are radiographically involved.
- Leave the midline epidural fibrosis intact.
- If a central laminectomy is required either proximal or distal to the previous laminectomy, proceed in standard fashion, first developing the interval between the caudal half of the lamina and the underlying ligamentum flavum. Then resect the lamina piecemeal.
- Once normal dura is encountered proximally, reverse direction, working caudally to remove the intervening ligamentum flavum from the underlying dura.
- If, at the junction of the previous decompression and the ligamentum flavum, you find adherent scar tissue, leave a small amount of ligamentum flavum over the thecal sac if it cannot be safely dissected free.
- Address the nerve roots laterally, as previously described.

**REPEAT DISCECTOMY**

The use of Repeat surgery for a recurrent disc herniation is common. Many of the same caveats as described for repeat decompressive laminectomy apply. Usually, a recurrent disc herniation occurs in a patient who has had a previous relatively limited hemilaminotomy, with the majority of the posterior elements being preserved.

- Expose the affected side only by carefully dissecting along the involved laminae and following them laterally as they join to become the facet joint. Place a retractor lateral to the facet joint to visualize the previous laminotomy.
- As with a more extensive laminectomy, bear in mind at all times the risk of a dural tear when performing a repeat discectomy. This risk can be minimized, and safe entry into the canal achieved, by using sharp curets to define clearly the remaining bony landmarks around the prior laminotomy.
- Scar tissue that is encountered can be thinned out, but as with a decompressive laminectomy, attempts to remove epidural fibrosis from the dura completely increase the risk of injury and are not indicated in most cases.
Once the hemilaminotomy has been completely defined, use either a Kerrison rongeur or osteotome to remove a small portion of residual bone, first from the inferior facet of the cephalad level and then from the medial aspect of the superior facet of the caudal level.

This new entry into the spinal canal and lateral recess is slightly more lateral to the original hemilaminotomy site. Extend the exposure until you are flush with the medial wall of the pedicle.

The traversing nerve root is usually encased in a layer of scar tissue of variable thickness, but can be palpebral with a Penfield dissector.

Carefully dissect along the lateral border of the root to mobilize it and retract it medially. Expose the underlying disc.

Although it can be fairly time consuming, careful mobilization of the nerve root is essential to avoid root injury.

Once the root is safely retracted medially, expose the underlying disc and resect it in standard fashion.

Whether or not to fuse in the face of a recurrent disc herniation is a highly controversial decision; we favor fusion when the patient has significant back pain or when there is any suggestion of instability. We are more inclined to fuse at the L4–L5 level than at L5–S1.

A second recurrence (third disc herniation) merits strong consideration of fusion.

**FUSION EXPLORATION AND REVISION**

Do not undertake repeat surgery on the lumbar spine with the specific goal of repairing a nonunion unless other potential causes of pain have been excluded. We rarely undertake nonunion repair in cases in which evidence of motion on dynamic lateral x-ray studies or progressive deformity has not been documented. Once the decision has been made to proceed with revision fusion, several technical points facilitate the procedure.

- If there has been a prior laminectomy, expose carefully, starting at normal levels as described above.
- Carry the exposure lateral to the facets joints and out all the way to the tips of the transverse processes on each side.
- In cases in which there is a laminectomy defect from previous surgery and no further decompression is planned, use a paraspinal muscle-splitting approach, which affords excellent visualization of the facet joints, pars interarticularis, and laterally placed fusion mass. It also facilitates pedicle screw placement.
- After exposure, carefully explore the fusion mass.
- In places where fixation devices are still in place, it is very difficult to determine whether the fusion is solid until the instrumentation is completely removed.
- Therefore, once exposure has been obtained, disassemble the implant and remove it piecemeal.
- Remove the fibrous scar tissue to visualize the fusion mass clearly.
- Use Cobb elevators and sharp curets to remove all soft tissue from the dorsal cortex of the fusion mass extending from cephalad to caudal and from the most medial extent to the lateral margins of the transverse processes and fusion mass.
- A well-consolidated fusion is easy to strip, although it is not uncommon to find islands of fibrous tissue surrounded by bridging trabecular bone. Soft tissues are attached strongly to nonunions and are difficult to strip.
- Once the fusion has been completely exposed, check not just for continuity but for adherence as well to the proximal and distal spinal elements; occasionally, well-formed bone is not adherent to the transverse process or, more commonly, the sacral ala.
- In order to verify the adequacy of fusion, take an osteotome and carefully remove the dorsal cortex of the fusion mass to verify that there is underlying cancellous bone in continuity with the transverse processes and alae.
- When a defect in the fusion mass is found, it is frequently narrow and wanders in a serpiginous fashion through the fusion. It can take fairly extensive exploration of a defect to document that it does indeed track through the entire fusion mass and allows motion.
- If the fusion is found to be solid, close the wound in standard fashion. If a defect in the fusion mass is found, use curets and a high-speed burr to remove all soft tissue from the dorsal aspect of the defect.
- Complete excision of all soft tissue is not necessary; remove the accessible dorsal soft tissue and decorticate the area around the defect. Then apply abundant autologous bone graft to the nonunion.
- Then stabilize the nonunions with a pedicle screw system and apply compression across the nonunion.
- Identification of the normal landmarks for pedicle screw placement can be difficult. Use interoperative fluoroscopy for identification of the appropriate starting point and path for the screws.

In addition to discovering a defect in an otherwise well formed fusion mass, fusion nonunion is seen in many patients in whom there has been complete or near-complete resorption of the previously placed bone graft. It is more common in patients in whom an allograft is used and in smokers. In these patients, it is usually readily apparent that the original fusion has failed.

- Thoroughly expose out to the tips of the transverse processes.
- Carefully decorticate the transverse processes and sacral ala.
- Apply a massive bone graft to provide the best chance for successful repair.
- In these cases, in which there is no stabilization from the original fusion, rigid internal fixation is essential.

Another alternative when considering repair of a previously failed fusion is interbody fusion. It can be performed through a transfemoral or posterior approach or, more commonly, through an anterior approach.

- Use allograft, if desired, as a block graft to provide stability, but supplement it with autologous bone from the iliac crest or from the adjacent vertebral body.
- We consider performing a combined posterior and anterior fusion in patients in whom a previously well-done fusion with rigid fixation has led to nonunion, in smokers, or in cases in which it is determined, at the time of posterior exploration, that there has been sufficient attenuation of the bone posteriorly to suggest that the chances of obtaining a solid fusion are minimal (Fig. 149.10).

**Figure 149.10.** A 37-year-old man 2 years following his third attempt at L4–L5 and L5–S1 fusion for isthmic spondylolisthesis. **A:** At the last posterior surgery, malpositioned left L-4 and L-5 screws were removed and it was elected only to instrument the right side. Because of the recurrent pseudarthrosis, and the ability to instrument only one side, it was elected to proceed with anterior interbody fusion, using a femoral ring allograft at both levels. **B:** At 2 years follow-up, solid fusion is seen, and the patient, who had not worked in 3 years, is minimally symptomatic and back to full-time employment.

**POSTOPERATIVE MANAGEMENT**

For the most part, postoperative management of patients undergoing revision low-back surgery is similar to that for primary surgery. Although the hospital stay is usually unchanged, the overall length of recovery can be prolonged compared with first-time surgery. The patient should be prepared for an extended time away from work or other pressing duties. Fixation after revision fusion may be less than ideal; therefore, we commonly supplement fixation with a brace. We use a physical therapist to mobilize the patient after surgery by facilitating transfers and ambulation; otherwise, we delay back rehabilitation for 3 to 4 months following surgery.

Try to detoxify patients from narcotics before surgery. The early postoperative period following a revision operation is not the time to withdraw narcotic medication. Work with a pain management specialist to lessen narcotic usage gradually with a goal of discontinuing narcotic medication altogether by 6 to 12 months postoperatively. Although this is an extended period of time, it is impractical to assume that quicker withdrawal is possible.

**PITFALLS AND COMPlications**

**DURAL TEAR**
The risk of encountering a dural tear is definitely greater in the patient who has undergone previous back surgery. Although each dural tear is different, certain basic principles always apply and certain steps should be followed.

A dural tear usually occurs as the surgeon is gaining visualization of, and entry into, the spinal canal. Although a large majority of dural tears do not result in any long-term morbidity, the repair of an intraoperative tear is time consuming and bears with it the potential for persistent CSF leakage, wound problems, and nerve root injury. The risk of dural tear is increased in repeat surgery because previous resection of the posterior elements obliterates the usual landmarks. Other risks include the difficulty of separating scar tissue from the dura to develop a plane between the thecal sac and nerve root, and the pathologic anatomy related to whatever is causing recurrent neural compression.

- Lessen the risk of dural injury by beginning the deep exposure of the posterior elements, proximally and distally, where there are retained normal spinous processes and laminae.
- Dissect proximally and distally along a normal lamina to the facet joints and then work caudally from the proximal end and distally from the cephalad end to expose the length of the entire laminectomy defect safely.
- Expose the preserved facet joints and pars interarticularis superiosteously, and leave a layer of scar tissue over the dura.
- Use a curet to define the medial border of the retained posterior elements.
- Rather than try to directly peel off or resect scar tissue from the dura, resect a small amount of normal, retained lamina or medial facet to expose an area of spinal canal, thecal sac, or nerve root uninvolved with scar tissue. Entry to the canal in such a way usually permits decompression without dural injury.

If the goal of surgery is to remove epidural scar tissue that is contributing to the nerve root or thecal sac compression, then the technique described earlier is less likely to be adequate and the risk of a dural tear is increased.

Once a tear occurs, the wound usually fills quickly with CSF, obscuring the extent of the damage. The surgeon's first impulse is to try to see the tear by using suction in the approximate area of the problem. This is a mistake, because the individual nerve roots may be sucked out of the thecal sac, causing significant neurologic damage. Suction should be used only over a cottonoid so that no further damage to the nerve roots is done. After visualizing the tear, place a piece of Gelfoam over the injury site, cover it with a large cottonoid, and complete the original procedure. The patient's head may be tilted downward into the Trendelenburg position to decrease the flow of CSF into the wound.

Once the definitive procedure is completed, refocus on repair of the dural tear. The goal is to achieve a watertight closure; if not, a CSF fistula can form, raising the risk of meningitis or a subarachnoid cyst. A dry operative field with hemosclerosing maintained throughout the repair is essential. Similarly, achieve adequate exposure in both the cephalad and caudal directions in order to define the extent of the tear adequately and to allow access for repair. Failure to maintain hemosclerosis and to obtain adequate exposure are the two most common causes of difficulty in repairing a dural tear. Magnification loupes and adequate lighting also facilitate the repair.

The actual technique of closure used depends on the size and location of the tear:

- For simple dural lacerations, we prefer 4-0 or 5-0 silk sutures on a tapered one-half circle needle. A running locking suture or simple sutures incorporating a free fat graft provide a watertight closure.
- If a tear is large or irreparable, harvest a fascial graft from the lumbarpedal fascia and suture it around the periphery of the defect with interrupted silk sutures.
- If the defect is in an inaccessible area, introduce a small tissue plug of muscle or fat through a second midline durotomy, pulling the tissue plug into the tear, thereby closing the dural defect from inside the dura (12).
- Use Fibrin glue to reinforce the repair if any question about the adequacy of the repair.
- Test the repair by placing the patient in the reverse Trendelenburg position and performing a Valsalva maneuver to increase intrathecal pressure. Close the fascia with a heavy, nonabsorbable suture, which must be watertight.

Most authors prefer not to use drains to avoid the possibility of the development of a draining fistula if there is persistent CSF leakage. Keep the patient on bed rest for at least 3 or 4 days to reduce pressure on the repair while it heals.

The diagnosis of a CSF leak in the postoperative period can be difficult to make. If relatively clear drainage occurs, consider the possibility of a dural leak. Similarly, a history of headaches when the patient sits or stands suggests CSF leakage. No completely reliable noninvasive diagnostic technique is available at present. The presence of glucose in the fluid draining from an incision is not a reliable determinant, because glucose is normally present in both noninflammatory and inflammatory exudates. The best diagnostic test, a myelogram performed with water-soluble contrast medium, is recommended if a dural leak is suspected but the diagnosis is uncertain. Once a postoperative CSF leak is diagnosed, pursue aggressive treatment. In the early postoperative period, placement of a subaorticnoid drain for 4 to 5 days has been reported with good results (21). If this procedure is unsuccessful or a leak is diagnosed late, timely return to the operating room for dural repair is in order.

**AUTHORS’ PERSPECTIVE**

We stress that an organized methodical approach to the evaluation of the patient who has had previous back surgery is essential. In many cases, the problem resulted from inadequate or incorrect indications for the original surgical procedure. In such patients, further exploratory surgery is not warranted and would lead only to further disability. Another surgery is indicated only when objective findings for a specific diagnosis are present.

In the few patients who do require an additional operation, it must be appreciated that the surgery is usually more extensive than the original operation with certain inherent risks. One must approach the spine at a new level to identify the normal anatomy of the neural elements and visualize the appropriate nerve root or roots laterally, leaving the midline epidural scar tissue intact.

If the dura is injured during the course of the procedure, repair it in a watertight fashion. If nonunion of a prior fusion is suspected, then carefully explore the fusion mass when a nonunion is found, perform a thorough decortication, removal of scar tissue, massive bone grafting, and rigid fixation.

Those involved with treatment of patients undergoing repeat back surgery must realize that the chance of returning these patients to a pain-free status is low. Depending on the type of previous surgery and the patient’s symptoms, usually some form of permanent impairment persists. These patients need counseling and must be strongly encouraged to resume as functional a role as possible in society.

Each reference is categorized according to the following scheme: *, classic article; #, review article; A, basic research article; and *, clinical results/outcome study.

PYOGENIC AND GRANULOMATOUS INFECTIONS OF THE SPINE

Tuberculosis played an important role in our learning about the treatment of infections of the spine. Tuberculosis patients with deformity and paralysis forced us to address this devastating process with aggressive surgical and medical treatment. Even with the decrease of tuberculosis in developed countries, the principles of treating infections, pyogenic or granulomatous, have been influenced by the experience of treating tuberculosis.

Pyogenic infections have a spectrum of presentation from discitis in children, to osteomyelitis in adults, to postsurgical infections. The infection usually affects the vertebral body and disc and, less commonly, the posterior elements, except in cases of postsurgical infection (Fig. 150.1). The lumbar spine is the most common location of infection, followed by the thoracic spine; cervical spine infection is least common (132). The least common sites for spinal osteomyelitis are the occiput, atlas, and axis, with only a few isolated cases reported (175).

![Figure 150.1. Hematogenous osteomyelitis most commonly invades first the anterior portion of the vertebral body, just adjacent to the endplate. Radiographic changes take time to appear and the usual picture is that of simultaneous involvement of two adjacent endplates with narrowing of the intervertebral disc space. This tomogram of the lumbar spine shows endplate destruction of the lower vertebral combine with loss of a good deal of the body of the upper vertebra.](image)

Hematogenous pyogenic osteomyelitis is characteristically a disease of men 50 years of age and older and is usually caused by Staphylococcus aureus. An increased incidence in younger male intravenous drug abusers has been noted. Pyogenic spinal osteomyelitis is usually monomicrobial, unless it is secondary to a systemic disease, in which case a polymicrobial infection is more common. There has been an increase in gram-negative infections compared with the more common gram-positive infections (19). The increased infection rates from gram-negative organisms may be due to wide use of broad-spectrum antibiotics.

Granulomatous infections of the spine, tuberculosis being the most common, readily infect the vertebral bodies and discs, with more than 50% of tuberculosis infections of bone occurring in the spine. The onset is insidious, with destruction of the vertebral bodies, discs, and ligaments if the disease progresses unchecked by medical and surgical treatment. As structural stability is destroyed, kyphosis combined with inflammatory debris and necrotic material can cause progressive paraplegia. Therefore, in the treatment of spinal infections, it is critical to make the diagnosis early so that antibiotic therapy or surgical debridement and fusion can be done before bony collapse and neurologic compromise occur.

ETIOLOGY: HEMATOGENOUS SPREAD

Hematogenous inoculation provides the most common source of organisms for both discitis and vertebral osteomyelitis. Other etiologies include surgery, direct spread from a pulmonary abscess, penetrating trauma, and soft-tissue deficits, such as a decubitus ulcer. Batson (10) demonstrated venous return from the pelvis into the venous plexus of the vertebral column. He theorized that the paravertebral venous reservoir could allow continued venous return and mixing in the setting of changing abdominal and intrathoracic pressures. In his view, these interconnecting venous systems provided an explanation for the presence of vertebral metastases in the absence of lung metastases.

Wiley and Truea (155) doubted the importance of Batson's venous plexus, demonstrating by injection studies an arterial system of nutrient vessels that supplies the vertebral bodies under physiologic arterial pressures. They found that the richly vascular metaphyseal bone near the anterior longitudinal ligament correlates with the most common site of infections.

Ratcliffe (126) emphasized metaphyseal cancellous infarction caused by a septic embolus. The vascular anatomy of the spine, which changes as a child matures, provides the most likely explanation for the differences in spinal infections in children and adults, as well as for the characteristic locations of infections in the vertebral unit. The interosseous arteries in children are anastomotic; therefore, occlusion of a single nutrient artery leads to destruction of only a small portion of bone because of collateral flow. In adults, a larger portion of bone is destroyed because the interosseous arteries are end arteries, and septic thrombus spreads into peripheral interosseous arteries. The disc is avascular and is attacked by infection equally in all ages.
A process related to vertebral osteomyelitis is spinal epidural abscess (Fig. 150.2). Hlavin et al. (68) reported an incidence of this infection of 1.9 per 10,000 admissions per year. Spinal epidural abscess tends to occur in an older, more medically debilitated population and to be monomicrobial, despite its frequent occurrence in a more medically complex environment. The most common organism is S. aureus. Epidural abscess may be due to direct seeding from invasive procedures, such as spinal anesthesia or epidural steroid injection, may form adjacent to an area of osteomyelitis, or, less commonly, may occur from spontaneous hematogenous spread (2,27,107). The distribution of this infection parallels the distribution of vertebral osteomyelitis: It is more common in the lumbar spine and less common in the thoracic and cervical segments (41).

Figure 150.2. Epidural abscess formation occurs in about 15% of vertebral infections. MRI shows an epidural abscess compressing the thecal sac. A: Lateral view. B: Transverse section.

While there are case reports of spinal infection following abdominal stab wounds and, rarely, gunshot wounds, the National Spinal Cord Injury Model System reported no cases of spinal infection in a series of 90 patients, despite a 20% incidence of alimentary perforation (64,65,116,164).

RISK FACTORS

Risk factors for spinal osteomyelitis include diabetes mellitus; chronic steroid use; drug and alcohol abuse; rheumatoid arthritis; urinary, respiratory, or abdominal sepsis; previous surgery; dental infection or extraction; urinary tract manipulation; and any type of spinal needle procedure: acupuncture, spinal anesthesia, epidural catheters, or steroid injections (10,22,27,63,103,112,118,124,145,148,165,166). Increasing age may be an independent risk factor, with the increasing incidence of gram-negative or anaerobic infections in elderly patients, often in the absence of any concomitant risk factors (23).

Malnutrition, urban overcrowding, and immunocompromising disease are prominent risk factors for granulomatous infection. Tuberculosis is found most commonly in underdeveloped nations. Big cities in Western countries still have cases of tuberculosis in higher risk patients such as the homeless, immigrants, alcoholics, and other immunocompromised individuals such as those with human immunodeficiency virus infection (67). Other granulomatous infections have geographic risk factors, such as coccidioidomycosis in the San Joaquin Valley of California or histoplasmosis in the central United States.

PATHOPHYSIOLOGY: TUBERCULOSIS OF THE SPINE (POTT'S DISEASE)

Like any other osteoarticular tubercular lesion, spinal tuberculosis is the result of hematogenous dissemination from a primary infected visceral focus. The primary focus can be active or quiescent, apparent or obscure, and located in the lung, lymphatic system, kidney, or other viscus. In a typical lesion, the tuberculous bacilli find their way to the paradiscal area of two contiguous vertebrae, which supports the concept that the spread is via the arterial blood supply. Anterior extension of the lesion, with involvement of multiple vertebral bodies, is caused by extension of the abscess beneath the periosteum and anterior longitudinal ligament. The anterior and posterior longitudinal ligaments and periosteum are stripped from the vertebral bodies, which results in loss of periosteal blood supply and destruction of the anterolateral surfaces of several contiguous vertebrae.

Vertebral destruction takes place by bone lysis. Periosteal stripping combined with arterial occlusion due to endarteritis causes ischemic infarction leading in turn to necrosis of the involved bone. The body of the vertebra is thus softened and yields to compressive forces. The intervertebral disc is not involved primarily because it is avascular. However, involvement of the paradiscal regions of the vertebra compromises disc nutrition. A disc may then be invaded by the infectious process and destroyed. Radiographically, it is typical to see more than one vertebra involved (average, 3.4 vertebrae) (71). The most common finding is narrowing of the disc space and vertebral osteolysis. In more advanced disease, a paravertebral shadow is produced by extension of the tuberculous granulation tissue and formation of an abscess in the paravertebral region (Fig. 150.3); later, vertebral collapse and angulation of the spine occur.

Figure 150.3. A,B: This patient with osteomyelitis has complete loss of the disc space with partial destruction of the contiguous vertebral bodies. The lateral x-ray (B) shows kyphotic angulation of L-4 in relation to L-5. This 70-year-old woman was having severe pain and muscle spasm. The physical examination revealed loss of L-5 nerve root function on the right. C: The patient elected nonoperative care. After a needle biopsy revealed the causative organism, she was treated with antibiotics and a body jacket. At 4 months, a tomogram of the involved level shows osteophyte formation that is starting to bridge the disc space. D: A lateral x-ray taken at 4 months reveals correction of the kyphotic angulation. After 2 months of bed rest, a body jacket was applied and molded in hyperextension. E,F: Radiographs taken after 1 year show fusion of L-4 to L-5. She returned to work as a farm wife, pain free and with resolution of the foot drop due to the L-5 root lesion. This patient shows that nonoperative treatment can be successful.

DIAGNOSIS

The workup for suspected vertebral infection includes a history and physical examination, a complete blood cell count and erythrocyte sedimentation rate (ESR), venous blood cultures if temperature spikes are noted, nuclear medicine imaging (technetium Tc 99m or gallium Ga 65), plain radiographs, and magnetic resonance imaging (MRI) if symptoms are present for more than 1 month. Computed tomography (CT) may be useful for delineating bony destruction and can be used to guide needle biopsy. Lateral tomograms may also be indicated for preoperative evaluation, particularly to delineate bony destruction in the thoracic spine.

HISTORY AND PHYSICAL EXAMINATION

A significant delay of weeks to months is common in the diagnosis of vertebral osteomyelitis (46,163). This delay may be due to a lack of any distinctive early physical or radiographic findings or to a failure to look for spinal infection. Dramatic regional pain that is worsened by motion or compression is the most common symptom. The pain persists despite bed rest and is classically exacerbated with motion. Pain, particularly at night, may not be relieved with analgesics. Fever is not a consistent finding. Anorexia and weight loss have been noted, and although the presentation may be acute, the most typical presentation is subacute or chronic. Chills, night
sweats, hemoptysis, or chronic bronchial cough are also suggestive of infection.

On physical examination, the most common finding is severe paraspinal muscle spasm associated with marked tenderness to palpation. A pseudoscoliosis due to spasm may be present. Loss of spinal motion is typical. Patients tend to split and guard in an attempt to decrease pain; they may be unwilling to bear weight, particularly children. There may also be a mass and a concomitant deformity visible in the area of infection. Neurologic findings may vary from meningeval signs to mild weakness and, finally, paraplegia. One of the earliest findings of spinal cord involvement from tuberculosis is sustained clonus in the ankle.

**LABORATORY DATA**

The most consistent laboratory finding in the diagnosis of vertebral osteomyelitis is an elevated ESR, usually greater than 40 mm/h (Westergren method). However, Schofferman et al. (135) reported normal values for the ESR in seven of nine patients with occult infections by indolent organisms, such as diphtheroid or coagulase-negative staphylococci. Serial ESR readings are valuable for following a patient’s response to intravenous antibiotic therapy (121). C-reactive protein (CRP) is an acute-phase protein synthesized by hepatocytes. An elevated CRP level is seen in various conditions, including infection, inflammation, and malignancy, as a response to tissue injury. Healthy individuals show only trace amounts of CRP. CRP levels rise after surgery but also drop quickly thereafter. An elevated CRP is more helpful for determining postoperative infection during the immediate postoperative period because the ESR can remain elevated at that time (99,151).

The peripheral white blood cell (WBC) count is unreliable. In a series of 38 patients with documented spinal infection, the average WBC count was only slightly increased over the usual high-normal value of 10,000 cells/mm³ (162).

Blood cultures are an important part of the workup of vertebral osteomyelitis, particularly if the blood culture is obtained during a febrile episode (47,123). Negative culture results are common, however. The tuberculin purified protein derivative (PPD) test is usually positive in patients with tuberculosis. Before administering a PPD test, do anergy battery to detect immune compromise.

**ORGANISMS**

By far the most common organism encountered in vertebral osteomyelitis is *S. aureus*. There has been a relative increase in other organisms over the last few years, particularly gram-negative organisms (163). *Pseudomonas aeruginosa* infections are often seen in the setting of intravenous drug abuse, trauma, or immune compromise (19). Staphylococcus epidermidis and Enterococcus species have also been noted with increasing frequency in postoperative infections (43). At least 27 other organisms have been found to cause vertebral osteomyelitis (Table 150.1). The most common granulomatous infection is tuberculosis.

![Table 150.1. Unusual Organisms Causing Pyogenic Vertebral Osteomyelitis](image)

Immunocompromised patients may present with uncommon or exotic pathogens, and often with multiple organisms. Oral flora is commonly cultivated from intravenous drug abusers and patients with dental abscesses or extensive oral surgery. Resistant strains of bacteria are of particular concern in chronically ill or hospitalized patients.

**IMAGING STUDIES**

The radiographic findings in pyogenic vertebral osteomyelitis tend to differentiate it from tuberculous involvement of the spine, which classically shows relative sparing of the disc space. With pyogenic vertebral osteomyelitis, the earliest x-ray finding is usually disc-space narrowing, which is noted at about 2–3 weeks after the onset of infection. Disc-space narrowing is followed by endplate erosion, then by progressive vertebral body destruction (Fig. 150.3) (121).

The next roentgenographic change seen is vertebral endplate sclerosis, with increased density noted in the subchondral bone secondary to deposition of new bone on the existing trabeculae and new subperiosteal bone formation (195). This subchondral sclerosis may be preceded by a period of relative radiolucency at about 6 weeks postinfection. The process of increasing postinfection sclerosis will then proceed and can ultimately lead to spinal fusion at about 6 to 24 months.

In tuberculous vertebral osteomyelitis, plain radiographs may not reveal disc-space narrowing until 24–36 months after the onset of the disease process. There may be loss of vertebral density, but reactive new bone is rarely seen and fusion is rarely noted. With tuberculous vertebral infection, a common finding is a large paravertebral soft-tissue mass with calcifications, which is often noted on plain radiographs and CT. This is relatively pathognomonic for tuberculosis. Vertebral pyogenic osteomyelitis, as well as vertebral discitis, tends to be more common in the lumbar spine, less common in the thoracic spine, and least common in the cervical spine. In contrast, tubercular spondylitis is most common in the thoracic spine and at the thoracolumbar junction.

Lateral tomograms may be useful to highlight subtle plain radiographic findings. They can be particularly helpful in imaging the thoracic spine and cervicothoracic junction (Fig. 150.4).

![Figure 150.4. Lateral tomogram illustrates endplate destruction in this thoracic infection. Without special studies such as tomography, these lesions can be difficult to visualize.](image)

Computed tomography also has an important role in diagnosis (195,161) and is particularly useful when used with myelography (Fig. 150.5) (18). However, in infected patients, myelography carries the risk of possible intrathecal spread of the infection. Bone density can be followed with CT and may give some clue as to whether the infection is progressing or resolving. Increasing bone density has been noted after successful treatment of vertebral body osteomyelitis with antibiotics (83).
CT-guide needle biopsy allows accurate placement within the vertebral body and disc in both pediatric and adult patients (58, 72, 111). The yield of needle biopsy in producing infectious organisms, however, has been reported to be as low as 50% (6).

Technetium bone scintigraphy is positive in most patients with active vertebral osteomyelitis, but false-positive results have been reported, particularly in the elderly population (3, 134). Gallium scan has also been used to image pyogenic vertebral osteomyelitis. Haase et al. (62) described a butterfly appearance of pyogenic vertebral osteomyelitis on gallium scan; the butterfly shape, reflecting soft-tissue uptake, appears on either side of the spine on an anteroposterior view. Bruschwein (21a), reporting on a review of 100 consecutive patients with spinal infections studied with gallium scanning, found a sensitivity of 89%, a specificity of 85%, and an accuracy of 86% (6). Indium-labeled leukocyte imaging of the spine has an accuracy of only 31% (167, 174).

Mordic et al. (114) reported a sensitivity of 96%, a specificity of 92%, and an accuracy of 94% for MRI in diagnosing spinal infections. In a study of 27 patients with pyogenic vertebral osteomyelitis, MRI accurately detected abnormalities in all patients; radiography did so only in 49%, CT in 65%, technetium bone scan in 71%, and gallium scan in 86%. The most consistent finding on MRI was increased signal intensity, particularly on T2-weighted images (Fig. 150.6).

Figure 150.6. MRI provides a means for earlier diagnosis of vertebral osteomyelitis. This T2-weighted image shows increased signal uptake in the involved vertebral bodies. In addition, it yields information about the amount of soft-tissue and spinal cord involvement.

T1-weighted MR images show characteristic findings of disc-space narrowing, low signal intensity in the marrow of at least two adjacent vertebrae, subligamentous or epidural soft-tissue masses, and erosion of cortical bone (152). T2-weighted images demonstrate narrowed discs with variable signal changes, abnormal high signal intensity in the marrow of at least two adjacent vertebrae, high-signal subligamentous or epidural masses, and cortical bony erosion. MRI demonstrates disc sparing in patients with tuberculosis spondylitis, as well as the extraosseous soft-tissue extensions.

Gadolinium enhancement of MRI is useful in distinguishing epidural abscesses from the adjacent compressed thecal sac, as well as identifying a paraspinal mass most likely to yield a positive percutaneous biopsy (125, 142). Gadolinium contrast also helps distinguish active infection from an infection that has adequately responded to antibiotic therapy (125).

BIOPSY

If the diagnosis is still in question after the above examinations, the differential diagnosis will usually include infection, primary neoplasm, and metastatic involvement of the spine. Tissue from a biopsy is required to differentiate these entities. If the diagnosis is not in question but the causative organism has not been identified, aspiration or biopsy for culture is still required. For the cervical spine, we recommend an anterior approach with a formal operative exposure to avoid the high risk of inadvertently perforating neck structures with a biopsy needle if a percutaneous technique is used. Biopsy samples of the posterior cervical elements may be obtained percutaneously, although formal open exposure facilitates visualization. In the thoracic and lumbar spine, we recommend a posterior CT-guide needle biopsy technique. If additional tissue is required, a Craig needle biopsy can be performed under regional or general anesthesia (Fig. 150.7).

Figure 150.7. A radiograph demonstrates a Craig needle in the L4-5 disc space. Usually, a needle of this size can be used percutaneously in the lumbar spine. In the cervical spine, open techniques are safer. In the thoracic spine, a CT-guided needle biopsy or an open procedure is safer.

Obviously, the chances of obtaining positive culture results are increased if a patient has not been treated with antibiotics before the biopsy. If a patient's condition permits, discontinue antibiotic therapy for 2 weeks and then proceed with biopsy and culture. Although the clinical presentation and the corroborating radiographic evidence and histology from a biopsy can confirm the presence of infection, culture results are required to prescribe a specific antibiotic regimen. Histology is adequate to diagnose tuberculosis and most fungal infections.

DISEASE-SPECIFIC TREATMENT
Pyogenic Infections

The treatment of most infections of the spine include intravenous antibiotics, rest, and spinal immobilization. In pediatric discitis, this is the treatment of choice. Generally, a regimen of 6 weeks of an intravenous antibiotic followed by 6 weeks of an oral antibiotic is suggested (Table 150.2). Some recommend continuing antibiotic treatment until 3 months after the ESR has returned to normal (163). This presumes that a patient is responding well to treatment and that the response is followed by monitoring the ESR weekly, WBC counts daily (initially) and then every third day, daily temperature reading, and complaints of pain. A Hickman catheter or other long-term indwelling intravenous catheter allows outpatient administration of intravenous antibiotics. We prefer to discontinue antibiotics when a patient is afebrile, pain has nearly resolved, and the ESR is normal. When back pain improves, we allow patients to ambulate in a custom-made thoracolumbar sacral orthosis or, occasionally, in an off-the-shelf brace.

| Table 150.2. Intravenous Antibiotics of Choice for Some of the More Common Organisms Causing Pyogenic Infections of the Spine |

Indications for Surgery

If 2–3 weeks of immobilization and an intravenous antibiotic produce no abatement of fever or decrease in the ESR or WBC count, then consider a thorough anterior debridement and strut grafting (Fig. 150.8). Other indications for surgical intervention include the following:

- Large abscess, for which an intravenous antibiotic is usually ineffective
- Neurologic compromise, particularly if it is progressive
- Progressive kyphosis with osseous involvement
- Failure to obtain bacterial cultures by needle biopsy

Neurologic deficits from mechanical failure of the anterior column, which results in kyphosis, are best treated by anterior debridement and mechanical reconstruction with strut grafting (26,46,48,100,105,110). Although several bones may be used for strut grafting, including rib and ilium, tricortical iliac crest autograft is preferred. The cortical portion provides immediate stability, and early union is enhanced by the cancellous component. Before debridement, we recommend a 2-week course of an intravenous antibiotic, if possible, to decrease purulence and surrounding inflammation (153).

Laminectomy for the treatment of spinal infection has been condemned because of its resultant complications (86). The infection decreases the mechanical strength of the anterior and middle bony columns. A laminectomy then destabilizes the remaining (bony–ligamentous) posterior column, adding to instability and increasing the potential for progressive kyphosis. Laminectomy may be appropriate in treating an isolated epidural abscess (29). In this setting, early aggressive laminectomy may be the treatment of choice, permitting decompression and evacuation of the epidural abscesses, in conjunction with appropriate antibiotic therapy (69,130).

Several investigators have reported successful anterior bone grafting in the face of infection (29,48,105,110). Safran et al. (131) reported good success with combined same-day simultaneous and sequential anterior decompression and posterior spinal instrumentation. In addition, Hopf et al. (74) recommended anterior debridement and anterior instrumentation as a single-stage procedure. Raith et al. (127) demonstrated success with posterolateral debridement of the infection and posterior instrumentation and autograft, which represents an alternative way to treat osteomyelitis and disc-space infection. Percutaneous drainage combined with percutaneous placement of pedicle screws for an external fixator has also been used by Jeanneret and Magarali (79). Fusion with bone grafting and instrumentation should be added if a large laminectomy involving multiple segments is performed. This is especially true in children, in whom spinal growth will lead to a progressive kyphotic deformity if fusion is not performed.

Conclusion

Bone grafting and instrumentation in the face of infection is usually successful when performed under the coverage of intravenous antibiotics. The decision to proceed with this major surgery in the face of infection is based on what is best for a patient in the context of a surgeon's abilities and available support services. Anterior debridement and strut grafting followed by posterior instrumentation and grafting work best in our hands and others (59). If one or more vertebral bodies are to be resected to gain adequate anterior decompression and strut grafting, we recommend subsequent posterior stabilization with instrumentation to provide immediate mechanical stability and protection for the neural elements. A spanning segmented instrumentation construct is appropriate (Fig. 150.9).
The patient requires less extended hospitalization and can return to work earlier, often within 4–6 months.

Secondary deformities occur as the disease progresses, impairing the patient's cardiopulmonary function.

In the early stages of the disease, extirpation of the infected focus is easier, and fusion without deformity is possible.

Although antibiotics can medically treat Pott's disease, most orthopaedic surgeons continue to favor surgical debridement. Hodgson et al. (71) proposed that debridement be done as soon as possible after the diagnosis is established for the following reasons:

- In the early stages of the disease, extirpation of the infected focus is easier, and fusion without deformity is possible.

Secondary deformities occur as the disease progresses, impairing the patient's cardiopulmonary function.

The patient's general condition improves markedly after evacuation of the abscess.

The patient requires less extended hospitalization and can return to work earlier, often within 4–6 months.

**GRANULOMATOUS INFECTIONS**

**Historical Background**

In the past, tuberculosis was treated by rest, by encouraging patients to spend time in the fresh air, and by relying on patients' natural recuperative powers (67,80). Abscesses were drained when necessary, and the vertebral column was debrided if the patient became paraplegic. In 1895, Menard (113) decompressed an abscess surrounding the spinal cord and was delighted to find that the patient recovered neurologically. This led him and other surgeons to decompress the spinal cord through a variety of posterolateral and anterolateral approaches (17,139). The combination of rest, fusion, and debridement allowed the paraspinal abscesses to regress spontaneously (61). Some patients, however, demonstrated progressive bony destruction, paralysis, and spread of the disease.

Antituberculous drugs changed the surgical approach to spinal tuberculosis. With drugs as the only treatment, patients could be cured not only of active disease but also of paralysis (170). Operative treatment was reserved for failure of drug therapy, recrudescence of disease, Pott's paraplegia that did not resolve after 4–6 weeks of treatment, progressive or worsening paraplegia, or the development of spinal cord involvement or other complications. In 94% of patients without neurologic compromise, clinical healing of the lesion occurred without surgery (154). However, with neurologic involvement, only 38% recovered completely with drug treatment alone, while 69% had complete recovery after surgical decompression.

Martin (109) studied the results of treatment before and after the development of antituberculous drugs and with and without surgical fusion. Of 227 adult patients treated without antibiotics or surgery, bony ankylosis occurred within an average of 5.7 years. Children treated without antibiotics or surgery took even longer to stabilize, requiring on average 9 years to bony ankylosis. Patients treated nonoperatively with antibiotics experienced fusion in 4.9 years. Martin's impression was that antibiotics and surgical fusion produced a more stable spine within a shorter time; he reported a 96.2% fusion rate.

In a later study of patients with Pott's paraplegia (120 of the 740 patients in his total series), Martin (108) found that antibiotics improved patients' general condition and made the surgery safer. It did not, in his opinion, prevent paraplegia or promote recovery from it. He found that 24 (48%) of 50 patients recovered with antibiotics alone, while 60% of patients who underwent surgical decompression recovered. He suggested that an early surgery might prevent or abort the onset of paralysis.

Guirguis (60) reported on 60 patients with Pott's paraplegia, one half of whom were operated on and the other one half treated conservatively. He found better results in the surgically treated patients, with 28 (93%) of 30 patients showing improvement and many being completely cured of any neurologic compromise. Many patients were relieved of their painful flexor spasms.

Neville and Davis (119) also studied patients treated with or without surgery, with emphasis on the fusion rate. In the nonsurgical group, 50% had autofusion at an average of 15.2 months. The surgical group had a fusion rate of 92%.

Arct (7) found that patients older than 60 years of age in Poland could tolerate and benefit from surgical fusion. Of 133 patients, 61 had conservative treatment, while 72 underwent surgical decompression with or without fusion. Only 13 of the conservatively treated patients returned to their regular lifestyle; none could return to work as a farmer or laborer. Of the surgically treated patients, 41 (57%) of 72 had complete clinical and radiographic recovery; 21 patients returned to agricultural work.

In summary, the medical treatment of tuberculosis has been highly effective in controlling bony tuberculosis and even curing it. The newer drugs have been more effective in preventing recurrence of disease due to resistant organisms. However, for at least the first 6 months of chemotherapy, further bony destruction and collapse may occur, causing increased vertebral angulation and cord compression. This is particularly true if a significant amount of kyphotic angulation is already present when drug therapy is started. Without chemotherapy, there will be progressive thinning of the intervertebral space, atrophy of osseous tissue, and decalcification, which can persist for an average of 2–3 years (61). In properly selected patients, medical treatment is adequate and can be expected to yield a relatively high rate (up to 79% in one series) of solid bony fusion (68).

**Current Medical Recommendations**

Current therapeutic regimen recommended for treating acute tuberculosis of the spine includes the following:

- **Rifampin:** adults, 600 mg daily in a single oral dose 1 hour before or 2 hours after a meal; children, 10–20 mg/kg per day (not to exceed 600 mg)
- **Isoniazid:** adults, 5 mg/kg orally (up to 300 mg per day) in a single dose
- **Ethambutol:** adults only, 15 mg/kg orally in a single dose
- **Pyrazinamide:** 20 mg/kg

Rifampin, isoniazid, and pyrazinamide are each given for 12 months. A four-drug regimen for 12 months or a three-drug regimen for 18 months is appropriate for eradicating difficult infections (115). Initiate antibiotics at least 2 weeks before surgery and, if possible, continue them postoperatively. In cases of acute paraplegia requiring emergency decompression, begin antibiotics before spinal surgery.

**Surgical Management**

Although antibiotics can medically treat Pott's disease, most orthopaedic surgeons continue to favor surgical debridement. Hodgson et al. (71) proposed that debridement be done as soon as possible after the diagnosis is established for the following reasons:

- In the early stages of the disease, extirpation of the infected focus is easier, and fusion without deformity is possible.

Secondary deformities occur as the disease progresses, impairing the patient's cardiopulmonary function.

The patient's general condition improves markedly after evacuation of the abscess.

The patient requires less extended hospitalization and can return to work earlier, often within 4–6 months.
Late recurrence of the disease is less common. Rapid progression of the abscess along the spine is prevented.

Surgical exploration of the tuberculous lesion is the only way to ensure that the disease is indeed active or healed. Hodgson et al. (69) also confirmed that tuberculosis can penetrate the covering of the spinal cord (dura), causing irreversible paraplegia; therefore, they felt an urgent need for surgical drainage to prevent this complication. In their hands, early anterior debridement and fusion offered an excellent outcome in 4% mortality, but the fusion rate was 93% and 26 of 35 patients with paraplegia recovered complete function. There was a close correlation between the duration of neurologic symptoms before operation and the time required to recover from paraplegia (69). In tuberculosis, bone grafting is safe, even in the presence of drainage (45).

While anterior decompresion and fusion of the spinal column is reliable and effective in treating neurologically compromised patients, posterior laminectomy is not effective and may lead to neurologic deterioration (15). Infectious destruction is usually anterior, causing the involved vertebral body to collapse and angulate into kyphosis. Laminectomy destabilizes the spine further and aggravates this progression into kyphosis. Hence, there is no question as to the superiority of the anterior approach (6, 45).

In children, Bailey et al. (8) noted that anterior tuberculous disease was almost always more widespread than demonstrated on radiographs. Even late decompresion, when symptoms have been present for an extended period, can produce neurologic recovery. Bone grafting leads to an acceptable risk of fusion in both children and adults (4, 79, 85).

In the immature spine, there may be progressive kyphosis despite a solid fusion (50), as continuing growth in the posterior spine may create further deformity (79). Schultz et al. (138) studied anterior fusion, anterior debridement, and combined anterior and posterior fusion in children followed for at least 10 years. Anterior fusion alone had the worst prognosis in terms of progression of kyphosis. Combined anterior and posterior fusion decreased the incidence of kyphosis. On the other hand, Upadhya et al. (158, 157, 158, 159) and (160) showed that a short anterior spinal arthrodesis done at a early age was not associated with progression of deformity during growth and development from disproportionate posterior spinal growth. Therefore, they did not recommend a posterior fusion to stop posterior growth. They also reported that patients who had reduction of kyphosis at the time of the fusion showed a difference only at the sixth month of follow-up, compared with patients who had only debrideement. At final follow-up, however, they found no difference in kyphosis between the groups and stressed the importance of achieving complete reduction and fusion to prevent kyphosis. In summary, our preferred approach to the treatment of children is a combined anterior and posterior fusion when multiple levels of radical debridement are required; we use the anterior approach only when only a short fusion is necessary.

In a long-term controlled trial comparing radical debridement and anterior fusion, simple debridement, and medical treatment alone, the Medical Research Council showed radical debridement and fusion to be superior in the following ways (31, 32, 50, 150):

- Anterior bony fusion occurs earlier and in a higher percentage of patients (70% versus 20% and 26% at 5-year follow-up).
- Kyphotic angulation was less common at 5 years.
- At 10 years, kyphotic angulation increased further in the simple-debridement group, whereas it actually decreased in the radical-debridement and fusion group.

Others have agreed with this philosophy, although none has had the experience or stated the case so eloquently as the group from Hong Kong (25, 51, 75, 71, 79, 89, 90, 144, 147, 169, 175, 178). While the surgery is technically demanding and risky, the alternative seems to be worse. Yau and Hodgson (175) reported on the penetration of the lung by vertebral abscesses and irreversible paraplegia from tuberculous infection passing through the dura and directly involving the spinal cord (81, 89).

The bony destruction, collapse, and angulation that can occur while under medical treatment are undesirable and preventable (91). Adding internal fixation to the treatment of tuberculosis of the spine diminishes the incidence of kyphosis and pain, reduces the incidence of bedsores, pulmonary infections, and recurrence rates and shortens hospital stay (73). Moon et al. (116, 117) described similar findings in which anterior debridement and posterior fixation provided early fusion, prevented progression of kyphosis, and achieved correction of kyphosis. Other authors have suggested using anterior instrumentation routinely at the time of debridement (74, 93). Therefore, if proper facilities and expertise for surgical drainage and grafting of the infected vertebral column are available, surgical fusion and stabilization are indicated (14, 25, 29, 57, 87, 101, 116, 129, 160). Nonoperative treatment with antibiotics and orthotic support continues to be an option for patients without significant destruction and kyphosis (125).

Even though anterior instrumentation has successfully been used for pyogenic and granulomatous infections, we have not routinely used it. Anterior instrumentation may be used in these situations if immediate stability is needed or posterior instrumentation cannot be performed in a timely manner.

Even late cases with severe kyphotic deformity can be candidates for surgery. Spinal osteotomy, halo–pelvic distraction, and anterior and posterior surgery have been used to correct these deformities (176). Although the complication rate associated with halo–pelvic traction and the multiple surgical procedures was high, the average amount of correction was 28.3% in 30 patients; more important, further progression of the deformity was halted. Halo–pelvic traction is still a viable technique and sometimes safer than immediate correction with anterior and posterior osteotomies. In these cases, a modest correction of the spinal deformity balanced with prevention of further progression is the goal.

In the cervical spine, Lifeso (99) refined the staging of atlantoaxial tuberculosis, describing three stages with progressive bone destruction. In stage I, there is minimal bony destruction, but anterior displacement of C-1 and C-2 is present. For this, he advised transoral biopsy and decompression followed by halo orthosis. In stage II, there is minimal bony destruction, and a transoral biopsy and decompression can be used to surgically treat the infection, followed by halo orthosis. In stage III, there is minimal bony destruction, but anterior displacement of C-1 and C-2 is present. For this, he advised transoral biopsy and decompression followed by reduction with a halo orthosis (99). Although the complication rate associated with halo–pelvic traction and the multiple surgical procedures was high, the average amount of correction was 28.3% in 30 patients; more important, further progression of the deformity was halted. Halo–pelvic traction is still a viable technique and sometimes safer than immediate correction with anterior and posterior osteotomies. In these cases, a modest correction of the spinal deformity balanced with prevention of further progression is the goal.

Halo–pelvic traction is still a viable technique and sometimes safer than immediate correction with anterior and posterior osteotomies. In these cases, a modest correction of the spinal deformity balanced with prevention of further progression is the goal.

In the lower cervical spine, Hsu and Leong (75) found a high incidence of neurologic compromise and recommended anterior decompression and fusion in all cases of tuberculosis of the cervical spine (see Chapter 151). Other authors have reported similarly on lower cervical spine tuberculosis, noting a high incidence of neurologic compromise requiring surgical treatment with bone grafting and anterior plating combined with antibiotic treatment (102, 104).

**Conclusion**

The major anatomic feature characteristic of all granulomatous diseases is destruction of the anterior column. This is the area that usually needs to be drained or, if weakened by bony destruction, supported by grafting. In most cases, posterior procedures are supplemental to the anterior operation. For Pott's paraplegia, the preferred procedure is anterolateral decompression. Arthrodesis of the spine is usually necessary to support the weakened anterior column. Strut grafting is difficult through a costotransversecsection, so anterolateral decompression, debridement, and fusion are best accomplished through this approach. Posterior decompresion further weakens the spinal column and can cause further collapse and neurologic deterioration (108). We prefer anterior decompresion and strut grafting followed by a posterior stabilization procedure (Fig. 195.10). We debride infected and weakened bone and resect the anterior column with rigid bone strut grafting, which we then augment by posterior instrumentation using a neutralization construct and fusion.
Figure 150.10. Anteroposterior (A) and lateral (B) radiographs from a 30-year-old baker who had back pain after stepping into a hole. He had an ESR of 120 mm/h, a positive PPD with 10 mm of induration, and a negative coccidioidin titer. The lateral film demonstrates loss of height of the T-11 body and endplate destruction. C: CT demonstrates destruction of the vertebral body with extension posteriorly into the neural canal. D: MRI reveals the amount of vertebral destruction and compression of the spinal cord. Because of the amount of vertebral body involvement, it was elected to debride and strut-graft this lesion anteriorly and to fuse and stabilize the spine with instrumentation posteriorly. E: An anterolateral thoracic approach through the tenth rib was used to expose the T-11 vertebra. This photograph demonstrates the abscess over the vertebral body expanding the parietal pleura. The aorta lies just anterior to the spinal column. F: The abscess is incised along the posteros lateral border of the spinal column parallel to it. G: Gross purulence exudes from the incision. H: A second incision is made perpendicular to the first from posterior to anterior, forming a T, and the corners can be elevated off the vertebral body and anchored anteriorly with skip sutures. Later, these flaps can then be used as closure over the grafted area. The segmental vessels to the vertebral bodies have been ligated. H: The necrotic bone and abscess material are removed by curettage or drilling with a high-speed burr. The involved bone, disc, and other debris are removed until good bleeding bone is located at each end of the lesion. If decompression of the spinal cord or cauda equina is needed, it is done at this time. The amount of material removed can be impressive. I: Biologic bone can be removed from the ilium. This should be done with a separate drilling and surgical setup so as not to contaminate the graft site. The graft is measured before it is cut to ensure an adequate length to strut the defect. J: The strut is impacted into the defect created by the debridement. The table, which had previously been flexed to provide access to the chest, is now straightened, locking the graft in place. If an acute kyphosis is present, additional strut grafts may be needed to bridge it completely. These are placed more anteriorly and should also be implanted into the bony portion of the vertebra. K: A postoperative lateral radiograph shows the iliac strut graft to span the infected level extending into the vertebrae above and below. Cotrel-Dubousset instrumentation extends an additional level above and below the T-11 vertebra. A posterior fusion supplements this instrumentation. The patient was ambulatory and taking tuberculosis medication when he left the hospital 2 weeks after the second surgery. He will continue his medication for 1 year after surgery.

Atypical Mycobacterial Infections

Atypical mycobacterial disease usually occurs in the extremities, but cases of spinal involvement have been reported. Diagnosis depends on identification of acid-fast bacilli, as granuloma formation is not necessarily a feature of the disease (106, 133, 137). In the presence of a persistent inflammatory process, ask about a history of contact with shellfish and other sea life, gardening, or trauma. Surgical excision of the infected focus and antibiotic administration are the mainstays of therapy (84, 133).

Fungal Infections

Coccidioidomycosis

Coccidioidomycosis is caused by Coccidioides immitis, the most infectious of all fungi capable of producing systemic disease. The localized form is usually benign, but the disseminated form is progressive and potentially lethal. Of those with disseminated disease, 20% have osseous lesions. The fungus is endemic to the southwestern United States, Central America, and parts of South America. It is particularly prevalent in central California, where it carries the name San Joaquin Valley fever (171). Although the disease occurs in all ages, it is most prevalent in individuals 25–55 years of age, and dissemination is greater in men. Disseminated disease is 10 times more common in blacks than whites and is of even greater hazard to Filipinos (171).

The organisms enter the body via the respiratory tract and are spread hematogenously. If respiratory symptoms and fever develop in a patient in an endemic region and last longer than 1 month, disseminated disease should be suspected. In an endemic area, 50% to 84% of the population will have a positive coccidioidin skin test. It takes 3–6 weeks for an exposed patient to test positive. Because of anergy, the test is unreliable when systemic disease is present. A serologic complement fixation titer of 1:64 or higher is thought to be diagnostic of disseminated disease (154).

Most bone lesions are lytic in nature and indiscernibly involve the vertebrae and other bony elements of the spine (Fig. 150.11). Often, multiple spinal lesions are found. Although the discs are spared, paraspinal masses are seen with contiguous rib involvement (35). Treatment with amphotericin B or fluconazole (Diflucan) is recommended (38, 133). Indications for surgical procedures are similar to those recommended for tuberculosis.

Blastomycosis

Blastomycosis (North American) is caused by Blastomyces dermatitidis, a fungus causing chronic systemic infection that is respiratory in origin but capable of dissemination. It is endemic in the southeastern and midwestern United States. Men are affected nine times more often than women; all ages may be affected, although there is a higher frequency in the third and fourth decades.

The disease usually begins as a mild respiratory infection, but as it disseminates hematogenously, generalized symptoms of fever, night sweats, anorexia, and weight loss develop. Skin tests are often negative early in the disease, but a culture of the skin or lesion will reveal budding yeast cells. Serologic tests may show a high titer only to Histoplasma capsulatum.

Osteomyelitis is common in disseminated blastomycosis, and it has a greater tendency than coccidioidomycosis for fistula formation and erosion into joints. The disc cartilage is usually involved early, and large paravertebral masses involving ribs may be seen. Hilar adenopathy may be noted on the chest radiograph, as in tuberculosis (56). Treatment for blastomycosis is oral ketoconazole (Nizoral) or itraconazole (Sporanox), but amphotericin B may be needed in immunocompromised patients. Indications for surgery and the procedures are similar to those for tuberculosis.

Cryptococcosis

Cryptococcosis, caused by Cryptococcus neoformans, is a chronic systemic fungal disease originating in the respiratory tract. It may affect all ages, but is most prevalent between 40 and 60 years of age and is twice as common in men. Cryptococcosis is commonly seen in patients with leukemia, Hodgkin's disease, or sarcoidosis in whom central nervous system findings develop. The pulmonary disease is rarely symptomatic. Spread is by the hematogenous route and often results in a cryptococcal meningitis, with 10% of disseminated cases involving bone. The bony lesions are heralded by pain, swelling, and progressive loss of spine motion (54).

Blood, spinal fluid culture, or cultures from bony lesions may reveal the organism. India ink capsule stain is helpful, especially in spinal fluid specimens. Cryptococcal antibodies may be measured, and some authors believe that their presence indicates a good prognosis. Radiographically, the findings are indistinguishable from coccidioidomycosis (34).

Similar to all the fungal diseases, cryptococcosis is treated medically with amphotericin B or fluconazole plus flucytosine (Ancobon) (79). Guidelines for surgery are...
similar to those for tuberculosis.

**Brucellosis**

Brucellosis is a systemic infectious disease caused by small, nonmotile, non-spore-forming, gram-negative rods of the genus Brucella. Farm animals are primary sources of infection, but many other animals may harbor the bacteria (172). Human infection occurs primarily from ingestion of improperly prepared animal tissues or products or from skin wound contamination from infected animal tissues. Infection via inoculation of the conjunctiva has been demonstrated, and there is some evidence that inhalation of aerosols containing bacteria can lead to the disease (11,12).

Brucellar infections are often asymptomatic. Initial infection leads to immunity in about 90% of cases (12,172). Men are affected more often than women, probably because of a higher rate of occupational exposure. Initial symptoms may include fever, sweats, weakness, weight loss, headache, myalgia, lymphadenopathy, and hepatosplenomegaly. Late complications are multisystemic and may include septic arthritis, central nervous system involvement, osteomyelitis, and spine involvement (172). Of patients with spinal involvement, about 12% will have spinal cord compromise.

Brucelae can be cultured from the blood during a bacteremic episode and from involved lymph nodes or granulomas later in the course of the disease. The organisms are dangerous to laboratory personnel, and any suspected materials should be clearly identified (172). The Brucella agglutination test is quite reliable, and about 97% of infected patients will become positive within 3 weeks of exposure. Brucellosis is a reportable disease.

Radiographic changes to the spine occur relatively late in the course of the disease and are similar to but less severe than those seen in tuberculosis (11,172). A paravertebral abscess usually is not present, as in tuberculosis, and the spinal involvement usually is in the lumbar area (11,172).

The mainstay of treatment for brucellosis is antibiotic therapy, usually with doxycycline and rifampin, for at least 6 weeks. Surgical intervention is usually limited to a biopsy to obtain a tissue diagnosis. Occasionally, stabilization of the spine or decompression of the cord may be necessary. The indications and techniques are identical to those proposed for treatment of the tuberculous spine. Brucellosis is a completely curable infection. The primary pitfall is a delay in diagnosis of more than 1 month, which can lead to multisystem involvement with severe sequelae (11,12,172).

**Aspergillosis**

Aspergillosis is a rare form of fungal spinal osteomyelitis (Fig. 150.12) (40,88,133,136). It is most common in immunosuppressed patients but has also been reported in cases of postoperative disc-space infection and after invasive monitoring (172). The radiographic appearance is not pathognomonic but is distinctive, generally demonstrating dense reactive new bone, a small lytic region, and the absence of sequestration. Histologic diagnosis is usually made with a tomography demonstrates the amount of destruction and angular deformity. B: Myelography reveals a blockage of the spinal cord canal created by granulation tissue and the deformity. The patient was paraplegic and required anterior debridement and posterior stabilization. There was complete recovery of neurologic function after anterior decompression.

**Figure 150.12.** Aspergillosis can infect the spine in immunocompromised patients, including those with acquired immunodeficiency syndrome (AIDS) or AIDS-related complex, intravenous drug abusers, or patients receiving cancer chemotherapy. This and other unusual organisms (e.g., Candida) are appearing with increasing frequency. This young man had aspergillosis that destroyed the T-2 and T-4 vertebral bodies with acute collapse and angulation. A: Tomography demonstrates the amount of destruction and angular deformity. B: Myelography reveals a blockage of the spinal cord canal created by granulation tissue and the deformity. The patient was paraplegic and required anterior debridement and posterior stabilization. There was complete recovery of neurologic function after anterior decompression.

**Candidiasis**

Along with aspergillosis, candidal infections are becoming increasingly common, primarily in the settings of immune compromise or secondary overgrowth following antibiotic usage (44,52,55,67,82,120,146). Systemic candidiasis may be diagnosed with positive sputum, urine, or blood cultures. Medical treatment is amphotericin B or fluconazole, and surgery is indicated within the guidelines described for tuberculosis.

**Actinomycosis**

Actinomycosis is often confused with fungal infection (33). However, the cause is an anaerobic, gram-positive, branching, filamentous bacterium. In actinomycosis, granulomatous suppurative lesions form and often develop sinus tracts, particularly in the head and neck region (75,136). The infection can be treated medically with penicillin (133). The need for surgery is determined in accordance with the previously delineated recommendations for spinal stabilization.

**POSTOPERATIVE SPINAL INFECTIONS**

Infection after spinal surgery is a significant complication. Postoperative infection following disc penetration is most likely due to direct inoculation (37,38,122,177). Therefore, the routine use of prophylactic antibiotics is recommended whenever the intervertebral disc is entered (including procedures such as minor discography) or other spinal surgery is undertaken (122). Infection rates increase with the extent or complexity of spinal surgery. The lowest rates (0.7% to 0.8%) are reported with intervertebral disc surgery without fusion (27). For patients undergoing spine fusion without instrumentation, the rates range from 0.9% to 6%. The highest rates are reported with the use of spinal instrumentation (0.5% to 15%); the average is about 6% (143).

**Postoperative Discitis**

Postoperative discitis has decreased with the use of microsurgical techniques, probably because of decreased soft-tissue injury (37). Patients with discitis will usually be pain-free for 1–2 weeks after surgery, and then progressively increasing low-back pain develops. This may be accompanied by temperature elevation, an increased ESR, elevated CRP and WBC counts, increasingly tender paravertebral musculature, increasing muscle spasm, and decreased lumbosacral range of motion. The neurologic status usually does not change from the immediate postoperative examination. Plain radiographs are rarely definitive in this period, but may demonstrate disc-space narrowing and evidence of endplate involvement by 2–3 weeks after the onset of infection. Nucleotide bone scan will be positive because of the surgery, and so are not useful in differentiating infection. If the presentation is delayed, MRI may demonstrate the characteristic findings of a spinal infection (Fig. 150.13). The definitive procedure for accurate diagnosis of postoperative discitis is CT-guide needle biopsy followed by culture of the organism from the disc space (Fig. 150.14).
Epidural abscess is a potentially devastating condition. Patients complain of local pain, tenderness over the spine, generalized malaise, and fever. The symptoms may be highly variable in immunocompromised patients. Heusner (66) described four phases of neurologic involvement from epidural abscess. In early phases I and II, there is localized pain with the development of radicular pain and early neurologic changes, such as diminished reflexes. In phase III, progressive neurologic symptoms occur, including evidence of upper motor neuron impairment such as hyperflexia. Motor weakness may eventually develop, with impaired bowel and bladder function. Finally, in phase IV, complete paralysis develops. Epidural abscesses may occur from either metastatic seeding or direct extension (20,86). Spinal cord dysfunction is probably due to a combination of mechanical compression and anterior spinal artery thrombosis, which can cause ischemia and direct infection of the cord (20,86). Multiple reports have described many conditions that can lead to an epidural abscess, including intravenous drug abuse, lumbar puncture, and urinary tract and upper respiratory tract infections (9,13,36,93). Unfortunately, the diagnosis is frequently delayed (86). The ESR will be elevated, and blood cultures may be positive. MRI is the best tool for diagnosing epidural abscess. Radionuclide studies (technetium or gallium scan) may not be helpful.

Differential diagnosis includes metastatic disease to the epidural space and abscess in the subdural space, which is rare. Only 45% of the patients with an epidural abscess are infected by S. aureus (41). Gram-negative rods, anaerobes, mycobacteria, and fungi are responsible for the remaining 55%.

Treatment should be emergent. Start intravenous antibiotics immediately. A penicillinase-resistant penicillin or vancomycin will provide coverage for S. aureus, and an aminoglycoside for other suspected organisms, until the Gram stain and culture results are available (84). Posterior compressive lesions should be treated with surgical drainage by laminectomy, with maintenance of mechanical stability by preservation of the facets. The wound may be closed over drains or packed open in cases in which there is gross purulence. If an epidural abscess occurs anteriorly, particularly with a disc-space infection with extension into the epidural space, anterior debridement and decompression of the anterior epidural space are necessary.

Although management of epidural abscess with intravenous antibiotics alone without surgery has been reported, the risk of progression of neurologic compromise is high (16,30,98). The current treatment of choice for patients with cord compromise is surgical debridement and antibiotics. In patients without neurologic involvement who are poor surgical candidates, antibiotics may be used initially, with monitoring of neurologic status. Surgery may be necessary if significant neurologic findings develop.
DRAINAGE AND DEBRIDEMENT OF SPINAL ABSCESSES

LUMBAR SPINE

Abscesses secondary to tuberculosis or fungal disease may present as masses that can be palpated externally. Pyogenic abscesses rarely reach this extent without proving lethal. In the lumbar spine, an abscess will generally follow the course of the psoas muscle, although it can also appear as a paravertebral mass. An abscess that dissects along the psoas may extend below Poupart's ligament and present on the anteromedial surface of the thigh (adductor region) or in the gluteal region.

Paravertebral Abscess

- To drain a paravertebral mass posteriorly, make an incision 4–8 cm lateral to the vertebral spinous processes in a line parallel to the spine.
- Use a Cobb elevator or even finger dissection to bluntly dissect around the erector spinae muscles until the transverse processes of the vertebrae are reached.
- Usually, the abscess is entered immediately. If not, puncture the thoracolumbar fascia that separates the quadratus lumborum muscle from the erector group.
- Locate the abscess by working under the transverse process, and then debride and drain it (173). Send purulent material and tissue for Gram stain, culture, sensitivities, and histology.
- After drainage, close the tissues in layers over a drain, or pack the wound open. This is determined by the local conditions and surgeon preference (71,85).

Psoas Abscess

Posterior Approach  Psoas abscesses are extraperitoneal and can be drained posterolaterally through Petit’s triangle or anteriorly beneath Poupart's ligament. Petit’s triangle is bordered by the lateral margin of the lattissimus dorsi muscle, the medial border of the external oblique abdominal muscle, and inferiorly by the crest of the ilium.

- Make an incision 2.5 cm above the crest of the ilium and parallel to it. Begin the incision lateral to the erector spinae muscle group.
- Bluntly dissect through the internal oblique abdominal muscle to gain access to the abscess cavity.
- The incision may be also made directly over the iliac crest, in which case detach the internal and external oblique abdominal muscles from the ilium and expose its inner surface.
- Palpate the abscess extraperitoneally, and then open and drain it.
- Manage the wound as described above.

Anterior Approach

- Make an incision from the anteroinferior iliac spine extending distally and medially for about 6 cm roughly parallel to the inguinal ligament.
- Identify the sartorius muscle, and carry the dissection medial to it to the level of the anteroinferior iliac spine. Protect the femoral nerve, artery, and vein, which lie just medial to this dissection.
- Identify the abscess on the medial surface of the wing of the ilium under Poupart's ligament (173). If the psoas abscess presents medially in the adductor region of the thigh, drain it through a Ludloff approach.
- For the Ludloff approach, make a longitudinal incision on the medial aspect of the thigh, starting 2–3 cm below the pubic tubercle. Develop the interval between the gracilis and adductor longus muscles.
- Develop a plane between the adductor longus and brevis muscles anteriorly and the gracilis and adductor magnus muscles posteriorly.
- Protect the posterior branch of the obturator nerve and the neurovascular bundle to the gracilis.
- The psoas muscle, attaching to the lesser trochanter, and the floor of the hip joint are located in the base of the wound.
- Drain the abscess through this wound (169).

THORACIC SPINE

Abscess Drainage via Costotransversectomy

In the thoracic spine, abscesses are frequently drained through a costotransversectomy approach (Fig. 150.15).

- Make a midline spinal incision extending over two or three spinous processes.
- Reflect the muscle and soft tissues away from the spinous processes and the vertebral laminae on the side of the abscess.
- Widely expose the middle transverse process, and resect it at its base.
- Reflect the periosteum from the contiguous rib, and resect the medial portion of the rib by dividing it 5 cm lateral to the tip of the transverse process. Do not enter the pleural cavity.
- Follow the rib medially, and enter the abscess by bluntly dissecting down the lateral side of the pedicle close to the vertebral body.
- Remove more than one transverse process and rib, if necessary, to completely debride the abscess.
- The neurovascular bundles between the ribs must be dissected free, ligated, and sacrificed (24). Seddon (139) described a similar approach using a semicircular incision lateral to the spine that starts superior to the kyphotic deformity and ends inferior to it.

- Elevate the skin flap and muscles medially to expose the medial 8 cm of three or more ribs and their transverse processes.
- Subperiosteally resect the rib judged to be in the center of the abscess, being careful to stay outside the pleura.
- Remove at least 7 cm of the medial rib in an adult, freeing the medial end with a periosteal elevator.
- When the rib is teased free, pus should pour out of the gap created.
- Explore and debride the abscess cavity. Remove the necrotic material and any sequestered bone, and thoroughly irrigate the cavity.

Debridement and Arthrodesis

In addition to evacuating the necrotic debris of a granulomatous infection, many authors recommend immediate arthrodesis of the spine. This requires a more
extensive approach than for simple drainage. When neurologic compromise is present, the spinal cord or cauda equina may have to be decompressed by removing additional bone or soft tissue. This is usually the result of bony collapse with the development of an acute gibbus.

Anterior surgical approaches to the thoracic and lumbar spine are described in Chapter 135. The removal of diseased tissue is the same in all areas of the spine.

- Remove the debris, pus, sequestered bone, and disc, using curets and pituitary rongeurs. Some of this material can be removed with a large sucker tip.
- Remove the tissue across the entire breadth of the vertebral body.
- Remove diseased bone or areas where graft will be inserted, using double-action rongeurs, a drill, or an osteotome.
- Expose the spinal canal for the entire length of the diseased area, decompressing the neural elements. Granulation tissue, fibrous tissue, or the posterior longitudinal ligament may require sharp incision to expose the dura mater.
- Remove the disc at each end of the cavity to expose the endplates of the vertebrae above and below.
- Scrape the cartilage off the endplates, revealing bleeding cancellous bone.
- Place the strut graft into the endplates, keying the grafts into mortises made with a drill or curet to prevent dislodgement. The strut graft should correct the deformity as much as possible and hold the vertebrae apart.
- The strut grafts should be strong yet osteogenic in nature; autologous cortical or biconical iliac crest graft is ideal, but the area to be grafted may be too large for the iliac grafts available. Longer struts can be obtained from the fibula or ribs. These should be supplemented with iliac bone because the fibula is strong but mostly cortical bone and the rib is osteogenic but relatively weak and will fail if stressed.
- The best source of bone is the patient's own ilium, but cadaver bank bone is a good second alternative, especially when a long segment of bone is needed.
- In the thoracic and lumbar spine, we usually supplement anterior struts with a second-stage posterior instrumentation and fusion. With this technique, there is less chance of graft dislodgement anteriorly. Anterior instrumentation may also be used successfully if immediate stability is needed and posterior fixation cannot be done in a timely manner.

**Anterior Decompression and Fusion**

**Thoracic Spine, C7 to T4**

- Place the patient in a left lateral position on a regular operating table with the right shoulder flexed to 120° and placed on an arm rest.
- Stand on the spinal side of the patient, tilting the table toward you to afford better visualization.
- Approach the upper thoracic spine through a right thoracotomy, using the bed of the third rib. If significant kyphosis is present, a costotransversec-tomy might be better.
- Make a curved incision around the medial and inferior aspects of the scapula. After dividing the parascapular muscles, retract the scapula forward and upward.
- Excise the third rib, and enter the pleural cavity through its bed. To improve visualization, cut the insertion of the scalenus posterior muscle and remove the second rib. The level is decided by following the rib head into the vertebral body. The third rib head articulates with the junction between the T-2 and T-3 vertebral bodies (71).

If more cervical vertebrae are involved, a sternum-splitting operation may be indicated. The procedure is an extension of the exposure for the cervicothoracic junction.

- Extend the incision in the midline down the sternum to the xiphoid process.
- Clear the anterior mediastinal tissues by blunt dissection behind the manubrium, working distally from the suprasternal notch. Work proximally from the xiphoid process in the same manner.
- Divide the sternum with an oscillating saw, and resect the two halves laterally. With this approach, the vessels and midline structures can be retracted more widely.
- Mobilize the recurrent laryngeal nerve so that it will lie obliquely across the operative field. Protect it during the procedure with a moist sponge to prevent paralysis of the vocal cords.
- Identify the vertebral artery behind the carotid sheath. The artery passes upward and laterally to enter the foramen in the C-6 vertebra.
- Approach the spine from the right because the innominate artery on that side takes off from the aorta at a lower level than the left subclavian vessels. In addition, the left innominate vein runs obliquely and distally to join the right innominate vein. The thoracic duct is also avoided.
- Anterior access to the distal cervical and proximal thoracic vertebrae is fairly good when the vessels are retracted.
- After decompression and any stabilization are complete, insert a suction drain, and close the sternum with stainless-steel wire or staples. If the pleura was opened, drain the chest with a large chest tube attached to underwater suction for at least 48 hours (85).

**Approach to Lower Thoracic Spine**

The chest may be opened from either the left or the right side. In early disease without kyphosis, the right side is best because fewer important structures are present. In more severe or chronic disease when kyphosis is present, the left side is preferable because the vena cava or aorta can become incorporated in the abscess wall. The side of the larger abscess or lung penetration may also determine the side of approach.

- Use a bean bag to hold the patient in the lateral decubitus position, and flex the table at the level of the lesion to facilitate exposure.
- Make an incision along the rib to be excised. It should be two levels higher than the lesion. Additional ribs can be removed for better exposure. Divide muscle layers in line with the incision, and resect the rib subperiosteally.
- Enter the pleural cavity and divide the adhesions (if present), freeing the lung as completely as possible. If thick adhesions between the lung and the abcess are present, portions of the lung inevitably will be left adherent to the abscess cavity in order to mobilize the lung and gain exposure. Open the lung abscesses, and remove any caseous material (60). Close the cavity with absorbable suture. A thoracic surgeon often performs this portion of the procedure.
- After the parietal pleura covering the abscess is exposed, mobilize the aorta so that an interval is developed between the two. Ligate and cut the segmental intercostal arteries traversing this segment. If severe kyphosis exists, the aorta will be acutely angled and the segmentals bunched together at the apex of the curve. Take great care in developing the plane between the vertebral body and aorta: Adhesions can compromise the integrity of the aortic wall.
- After the aorta is mobilized and protected, open the abscess with a T-shaped incision. Make the transverse portion of the T on the anterior portion of the vertebral body of the aorta. Retract the triangular flaps created by the T incision, and attach them by stay sutures to the muscles at the wound edges. Work from proximal and distal to the mid portion of the kyphosis, particularly if cord compression is present.
- Radically excise all bony sequestra, sequestered disc, granulation tissue, and avascular bone.
- The posterior longitudinal ligament forms the posterior limit of the abscess cavity and is just anterior to the spinal cord. Carefully, incise the ligament and remove it with pituitary rongeurs. Allow the dura to slide or prolapse forward into the area vacated by the debridement.
- Debride the bone until bleeding cancellous bone surfaces are exposed. Cut or drill slots into the exposed cancellous bone of the end vertebrae.
- Apply posterior pressure on the kyphosis to open the interval so that it can be measured with a caliper. Place several ribs or an iliac bicortical graft into the slots, and gently impact the graft into place.
- Release the posterior pressure on the spine, and the grafts will be firmly held in compression. It is wise to supplement the impacted bone with additional struts, although these will not be under compression. Usually, five to six ribs or two bicortical iliac crest grafts can be fitted into the thoracic spine (71, 85).
- Complete closure of the abscess cavity flaps is unnecessary. In Hong Kong, streptomycin, 1 g, and isoniazid, 200 mg, are placed in the abscess cavity before closure (Fig. 150.10 and Fig. 150.16) (71).

**Figure 150.16. A:** An anterior thoracolumbar approach is best for thoracic or lumbar involvement. With the patient in the lateral decubitus position, make an incision over the rib just superior to the apex of the kyphosis. The rib can be removed for use as a strut graft. Remove the tuberculous debris, devascularized disc, and avascular vertebral body by curettage or use of a power burr. **B:** If the cord is compressed, completely expose it anteriorly to remove any pressure. Place strut grafts of biocortical ilium and rib or fibula to bridge the angular kyphosis from good vertebrae to good vertebrae. Sometimes, correction of the kyphosis can be obtained during the grafting procedure. This anterior fusion will need posterior instrumentation to stabilize the spine and keep the anterior strut grafts from displacing.
CHAPTER REFERENCES

The following complications are specific to the treatment of infections.

INTRAOPERATIVE COMPLICATIONS

The lungs can be penetrated during thoracotomy procedures. This is usually of no special concern and can be ignored, unless there is a significant air leak. This will generally scar and seal in time. Use a chest tube if a pneumothorax develops.

The dura can be opened accidentally during the decompression. Always try to close the rent. If closure is unsuccessful, a spinal fluid fistula may result. These eventually heal but may persist for up to 3–4 months.

Injury to the sympathetic nerves in the cervical region will produce Horner's syndrome, which usually is only temporary. In the lumbar area, the extremity of the operated side will be warmer. This too will usually resolve with time.

If there is excessive retroperitoneal scarring, the ureter can be cut accidentally. If so, this must be recognized and a reanastomosis performed at once. If you suspect preoperatively that the ureter might be involved in the abscess, place a stent into the ureter on the side being operated on. This will make the ureter easier to palpate and therefore less likely to be cut. With a stent with a fibrotic light, even allow the ureter to be visualized among the debris and bleeding as the abscess is incised and cleaned out.

Occasionally, the vena cava, aorta, or a common iliac vessel is cut or torn during mobilization of the great vessels. This is most likely to occur at the lumbosacral junction, where the main structure preventing access and mobilization of the common iliac vessels is the iliolumbar vein. Locate this vessel before it is torn. If it cannot be safely moved, ligate and cut it. If the vena cava or aorta is injured, do an immediate vascular repair. Usually, a stitch or two will control the problem, but occasionally a friable vena cava will be impossible to repair and will need to be ligated.

EARLY POSTOPERATIVE COMPLICATIONS

After anterior or even posterior spinal surgery in the thoracolumbar or lumbar area, a paralytic ileus is common. Patients should not be fed until bowel sounds are actively present, and they have noticed some flatus. Even oral fluids, if given too early, can aggravate the ileus and prolong final recovery.

Chest complications are also common, particularly after a thoracotomy. The most common is atelectasis, which will respond to deep breathing, coughing, and use of the inspirmeter. However, if left untreated, this can develop into pneumonia. If a chest tube is improperly placed or if it becomes blocked, pleural effusion or hemothorax can occur with lung collapse and subsequent pneumonia.

The most catastrophic complication is deterioration of neurologic status after anterior decompression. This is probably the result of excessive trauma to the already jeopardized spinal cord, particularly if the paraparesis is of long duration and the surgical approach is difficult. It is likely to resolve because the spinal cord in Pott's paraplegia is resilient and can withstand a great deal of trauma without permanent damage. On the other hand, if worsening of paraplegia is caused by spasm of or injury to the anterior spinal artery, then the prognosis for recovery is bleak. There is no good way to know which condition is causing the problem, and treatment for either condition is not very effective. If arterial spasm is suspected, administer intravenous methylprednisolone. Image the strut-grafted area with radiography or CT, or both, to ensure that a graft has not slipped posteriorly into the spinal cord. If this is suspected, reoperate and reinsert the graft into a firm bony bed so that it will not impinge on the cord. Hematoma or abscess is unlikely to cause compression of the spinal cord, because most of the abscess has been removed and the area around the debridement cannot contain the hematoma.

LATE COMPLICATIONS

If the inserted grafts are reabsorbed, usually the infection is not being sufficiently controlled by the antibiotic. This is usually evident 6–12 weeks after surgery, and culture and sensitivity reports will help in modifying the drug regimen. Usually, the grafts need not be replaced, but if destruction is severe, reoperation should be considered.

Long grafts, particularly fibula, are subject to late fracture. Fractures occur 12–18 months after surgery, when the bone is weakened by resorption and replacement by new bone. These resemble stress fractures and will heal with immobilization and rest. Fracture of the graft is best recognized with tomography in the sagittal (lateral) plane.

In 7% to 8% of patients, the spinal fusion will fail. If this is thought to be secondary to persistent infection, it must be dealt with medically. When further spinal collapse and increase in kyphosis occur, restabilization of the vertebral column is required. If the disease is judged to be quiescent, the kyphotic angle is stable, and the patient is asymptomatic, a nonunion can be ignored. If symptoms do occur, a revision posterolateral fusion with instrumentation can be performed.

TUMORS AND INFECTIONS OF THE CERVICAL SPINE

Kamshad Raiszadeh and Behrooz A. Akbarnia

Cervical Tumors
Diagnostic Evaluation
Biopsy and Aspiration
Treatment of Cervical Tumors
Exposure, Excision, and Reconstruction of Cervical Destructive Lesions
Infection
Vertebral Osteomyelitis
Epidural Abscess
Chapter References

This chapter focuses on the surgical management of destructive lesions of the cervical spine. For cervical tumors, the indications and techniques for biopsy are reviewed, followed by the exposure and reconstruction of destructive lesions. Tumor classification and details on the various tumors are presented in Chapter 126, Chapter 127, Chapter 128, Chapter 129, and Chapter 130. Many of the general principles of spinal tumors are covered in Chapter 152. Tumors of the Thoracic and Lumbar Spine. This chapter focuses solely on the management of these tumors in the cervical spine. Similarly, the general principles of management of bone infection are covered in Chapter 152 and Chapter 153, and the details of the various types of infections are covered in Chapter 150. In this chapter, we focus on the management of cervical infections. The evaluation of osteomyelitis and epidural abscess is reviewed, followed by a discussion of the outcome of different treatments.

CEPhALIC TUMORS

DIAGNOSTIC EVALUATION

In the preoperative workup for tumors of the cervical spine, the surgeon should first determine the oncologic stage and evaluate for local and systemic disease. The Enneking system of staging for musculoskeletal neoplasms (see Chapter 126) has been adapted to neoplasms of the axial skeleton (4). As with extremity neoplasms, spinal tumors are staged according to histologic grade, compartmental location, and the presence or absence of metastases. There is a major difference between surgical staging of spinal neoplasms compared with neoplasms of long bones; the Weinstein-Boriani-Biagini (WBB) classification addresses the unique anatomy of the spine (25). In the transverse plane, the vertebra is divided into 12 zones, numbered 1 to 12 clockwise starting on the left half of the spinous process. The layers are further divided into epidural, paravertebral extraosseous, or dura, denoted as layers A through F for the vertebral artery canal (Fig. 151.1). Recording the spinal segments involved defines the longitudinal extent of tumor involvement. A simpler method of categorizing the level of involvement is to divide the vertebral body into four zones, I through IV. Tumor extension is designated as A, B, and C for intraosseous, extraosseous, and distant tumor spread, respectively (Fig. 151.2). This classification is helpful because the zones of tumor involvement correspond to the surgical approach: tumors involving zones I and II are usually resected and, if necessary, stabilized posteriorly. Zone III lesions are usually approached anteriorly. Zone IV lesions that require a complete or en bloc excision must be managed through a combined anterior and posterior approach. Zone IIIb lesions should be carefully analyzed preoperatively to anticipate possible invasion of or adherence to critical neural elements, esophagus, or trachea. The general workup of tumors of the cervical spine and the different tumor types are covered in Chapter 152.

Long-term survival and decreased recurrence rates in patients with primary spinal malignancy correlate significantly with tumor type and the extent of the initial surgical procedure. Hart et al. (25) and Boriani et al. (4) showed decreased recurrence rates of giant cell tumor and chordoma, respectively, using the WBB and the Enneking surgical staging systems with en bloc excision performed at a tertiary referral center. Although they have not been specifically studied, it is reasonable to extrapolate the results obtained in other areas of the spine to cervical tumors.

The incidence and presentation of cervical disease is different from other regions, however. The reported frequency of cervical metastatic disease is much less than
thoracic or lumbar metastases. Also, the presentation of cervical metastatic disease differs from metastatic disease at the thoracic and lumbar levels (45). A review of the natural history shows the average life expectancy to be 14.7 months after cervical metastatic disease is diagnosed (52). Pain with cervical metastatic disease is more frequent (93%), whereas neurologic deficit is less frequent than when disease is present at the thoracic or lumbar levels (5–14% cervical versus 50% thoracic co-lumbar) (52,53). The prevalence of upper cervical neurologic deficit is lower than that of the lower cervical spine, possibly related to the wider canal in the upper region.

**BIOPSY AND ASPIRATION**

Conditions such as osteoid osteoma and osteoblastoma can be diagnosed solely on the basis of the radiologic workup of plain radiographs and computed tomography (CT) scans. By recognizing the benign or inactive lesions that, by their self-limiting nature, do not require biopsy, an unnecessary procedure can be avoided. Also, in cases of spinal metastases from a known primary carcinoma, no biopsy is necessary. A similar situation involves the patient with multiple myeloma and spinal involvement with impending or actual cord compression. In patients with multiple myeloma, the laboratory tests provide the diagnosis. Because the myelomas are sensitive to radiation therapy, proceeding directly with radiation rather than performing a biopsy or other surgery is most appropriate.

If the benign or malignant nature of a spinal neoplasm is uncertain, one must make a definitive diagnosis with a complete workup and a biopsy or aspiration. It is important to realize, however, that planning the biopsy should be the last step, after appropriate staging and other workup. The benefit of performing the biopsy at the end of the staging and evaluation are

- Unnecessary biopsy can be avoided (e.g., multiple myeloma)
- Other more accessible sites may be found for biopsy (e.g., a metastatic lesion)
- Prebiopsy embolization can be performed, if necessary (e.g., renal cell metastasis or other vascular lesion).

The biopsy, although seemingly simple, is a difficult procedure with possible complications that can change the course of treatment and significantly affect the ultimate outcome (40). The orthopaedist who is responsible for the definitive treatment and subsequent care should be responsible for performing the initial biopsy. The recommendations regarding performance of biopsies, either open or percutaneous, are

- Place the biopsy tract where it will be fully removed at the time of definitive treatment. This may not be possible during anterior biopsies.
- Ensure minimal tissue contamination by avoiding excessive dissection of tissue planes.
- Obtain adequate tissue for diagnosis (may require confirmation by frozen section).
- Maintain adequate hemostasis.
- Use drains only through the wound or in proximity so that the track is removed with the definitive resection. The drain can provide a track along which malignant cells can pass, which may increase the necessity for subsequent resection.

An adequate amount of tissue must be obtained regardless of whether an aspiration, needle biopsy, or open biopsy is performed. Coexistent infection and tumor have been reported (16); therefore, we recommend routine microbiologic culture. Biopsy techniques include percutaneous (aspiration, fine-needle, or large-bore), open incisional biopsy, or excisional biopsy. When normal narrow margins are present, aspiration effectively rules out metastatic malignancy. Needle aspiration and fine-needle biopsy provide only a small sample, therefore, introduce a sampling error. Simple aspiration, or fine-needle biopsy should be used predominantly in the cervical spine to rule out infection, confirm suspected metastatic disease, or diagnose recurrence of a known lesion. Because aspiration biopsy may fail to provide definitive diagnosis in up to 20% of cases (6), large-bore or open biopsy is often necessary.

For lesions in the posterior aspect of the cervical spine, large-bore trocar biopsy is relatively easy to perform under CT guidance. If a benign lesion such as osteoid osteoma or osteoblastoma is suspected, however, open biopsy followed by excision often provides the easiest solution. We also do not favor routine needle or trocar biopsy of suspected aneurysmal bone cysts. Most of these lesions, when well-demonstrated radiologically, are typical and do not require biopsy. Some lesions can have a clinical and radiographic appearance similar to that of a malignant tumor and, in fact, may also contain malignant portions; therefore, a gross pathologic specimen may be needed for diagnosis. Additionally, the small amount of tissue obtained with needle or trocar biopsy often creates confusion in the diagnosis or may not include the pre-existing lesion (50). Open biopsy with curettage or excision, or both, on the other hand, provides the entire lesion for pathologic examination. Furthermore, there have been reports that extradural bleeding of aneurysmal bone cysts of the spine following needle biopsy cause neurologic deficit (26). Finally, because open excisional biopsy can cure the condition, there seems to be little justification for needle or trocar biopsy, which may be negative and possibly risky (1).

Bipolar biopsy of anterior lesions is performed either laterally or anterolaterally following the standard surgical approach (see the discussion of surgical approaches, later). It is often not possible to entirely excise the biopsy tract with anterolateral and lateral biopsies due to the multiple tissue planes in the anterior neck and the presence of the carotid sheath. Avoid transverse posterior skin incisions. Plan the incision so that it will not compromise subsequent surgical procedures.

For planning the management of suspected metastatic disease, divide the cervical spine into three regions: the upper cervical vertebral bodies (C1–C3), the lower cervical vertebral bodies (C4–C7), and the posterior elements and posterior epidural space. Biopsies of the C1–C3 vertebral bodies can be performed through a transoral approach with the patient under general anesthesia, or through a high lateral approach. The C4–C7 vertebral bodies can be accessed through a lateral or anterolateral approach (see the discussion of surgical approaches, later) or with open biopsy. Closed biopsy techniques of the cervical spine are technically demanding and often fraught with neurologic and vascular complications. If metastasis is suspected and the lesion is extensive enough to require surgical stabilization, we recommend an open biopsy to confirm the diagnosis by immediate frozen section, followed with a definitive surgical procedure. A fine-needle biopsy is possible under CT guidance, especially if surgical reconstruction is not deemed necessary.

**TREATMENT OF CERVICAL TUMORS**

An individualized approach is necessary, focusing on the concurrent goals of relief of pain, and the maintenance of spinal stability and neurologic integrity.

**Benign Tumors**

For benign cervical tumors, these general principles are relevant:

- Differentiate "latent" or "active" (i.e., stage 1 or 2 based on the Musculoskeletal Tumor Society surgical staging system) from "aggressive" or stage 3 lesions.
- Treat stage 1 or 2 lesions with intralesional curettage.
- Precisely localize the tumor.
- Protect structural and neurologic integrity.
- In children, perform a posterior arthrodesis if performing a laminectomy.
- Treat stage 3 lesions with marginal or en bloc excision.
- Be prepared for excessive bleeding.
- Control bony bleeding with liberal application of bone wax and Gelfoam.
- Preoperative embolization may be helpful to avoid excessive bleeding, especially in the case of aneurysmal bone cysts.
- Be prepared to ligate or bypass the vertebral artery if necessary.
- Perform preoperative angiography to assess collateral blood flow.
- Consider packing the wound and embolizing the tumor or the vertebral artery if uncontrolled bleeding is encountered.
- If the anterior part of the vertebra is severely involved, perform a posterior stabilization first to establish stability.

Certain tumors, such as osteoid osteoma and osteoblastoma, are common in children and have a predilection for the posterior elements. For characteristic osteoid osteoma and spinal osteoblastomas, excisional biopsy and intralesional curettage is sufficient treatment. The key to operative management is precise localization of the osteoid osteoma before surgery. If the lesion is located in the lamina, remove the posterior cortex of the lamina using a power drill to expose the nidus. While removing the nidus, take care not to damage the dura, because the anterior cortex is usually thin.

Larger lesions such as osteoblastomas can involve the soft tissue as well as the vertebral body and, similar to giant cell tumors and aneurysmal bone cysts (ABCs), have the potential for local recurrence. Because of the size and expansile nature of these tumors, surgical excision is more radical and often leads to spinal instability, necessitating spinal fusion. “Active” stage 2 lesions are positive on a bone scan and have a well-marginated sclerotic border. These lesions can be treated by curettage and have a low local recurrence rate (5% to 15%) (3). The “aggressive” stage 3 lesions are surrounded by a large pseudocapsule, which can be observed on a contrast-enhanced CT scan. Intralesional curettage has been associated with a 20% rate of local recurrence (56). Although en bloc excision is the treatment of choice, owing to anatomic restraints in the cervical spine, selected stage 3 benign tumors can be treated by incisional biopsy and frozen section confirmation of tumor type, followed at the same surgery with marginal excision.
En bloc excision in the cervical spine is a challenge and, owing to the increased surgical risks, should be reserved for the aggressive stage 3 lesion or recurrent tumors.

- Dissect the tumor outside its wall, leaving some of the soft tissue attached to the thin wall.
- If the tumor is next to the dura, dissect the dura from the tumor and encircle and retract the dura with a Penfield elevator, taking care not to compress the spinal cord.
- Be prepared to ligate or bypass the vertebral artery, if necessary.
- If a significant part of the esophagus is encased in tumor, an esophagectomy and gastric pull-up or colon interposition is indicated (8).

Radiation therapy may be considered as adjuvant therapy in the case of ABCs but is generally discouraged because of the potential for cord damage, induced sarcoma, and growth retardation (5). Low-dose radiotherapy may be considered for the well-circumscribed recurrent ABC lesion. Embolization may be effective for decreasing vascularity and making surgical resection and decompression less morbid, and may eliminate symptoms from expansive hemangioma.

After removing the larger posterior benign lesions, consider reconstructing the potentially destabilized spine. The extent of this destabilization depends on the age of the patient as well as the amount of posterior element resection. In children, laminectomy frequently results in secondary kyphosis that is difficult to correct. Therefore, in skeletally immature children, perform a posterior arthrodesis traversing the extent of the laminectomy (37). In the adult, when resection of any part of the lateral mass or pedicle is necessary, simultaneously arthrodesis and instrument the affected levels using the remaining posterior spinal elements. Harvest an autologous graft through a separate incision, to avoid cross-contamination of the donor site.

Primary Malignant Tumors

Surgical treatment of primary cervical malignancies is predicated on the tumor type and the extent of local and systemic spread. Avoid surgery for primary malignant spinal tumors unless there is a good chance the surgery can offer significant palliation or a cure. Marginal or intralaminar resection of the tumor, followed by radiation therapy, is an appropriate palliative approach to an intermediate-grade osteosarcoma with soft-tissue involvement. A wide resection for a low-grade chondrosarcoma in the vertebral body represents an attempt to cure by surgery alone.

The treatments for solitary plasmacytoma and multiple myeloma should necessarily be somewhat different owing to their different prognoses, although they are a continuum of the same disease and most cases of solitary plasmacytoma progress to multiple myeloma. Radiation is the initial treatment of choice in either case. Propylactic laminectomy and stabilization before radiotherapy can be used if cord compromise or spinal instability is present. In the rare instance of a cervical solitary plasmacytoma, prognosis is enhanced by surgical excision reducing the tumor burden. In such cases, perform an intrasosseal excision and stabilization, followed by radiation therapy.

Chordomas pose a difficult problem owing to their high local recurrence rates and the difficulty in accessing this lesion in the cervical spine. Unlike sacral chordomas, in which sacral nerve roots can be sacrificed, cervical chordomas often involve the clivus and upper cervical spine, in which, at best, only decompression and marginal excision is possible. Often, the only option for surgical treatment is posterior stabilization and fusion, followed by anterior intralesional or marginal excision and decompression.

Metastatic Tumors

In the adult population, metastatic tumors are the most common tumors in the cervical spine with a predilection for the anterior column. In the cervical spine, the weight-bearing axis falls at or posterior to the vertebral body, and the articular processes support the weight of the skull. For this reason, destruction of the vertebral body results in some loss of vertebral body height, but kyphotic deformity is uncommon. Instability is also uncommon. Destruction of the lateral masses as well as the vertebral body must occur to permit rotatory instability. Except for extensive lysis in one or more contiguous bodies, or the involvement of the spinous process of C-2, where the nuchal fascia inserts, metastatic involvement of the upper cervical spine rarely results in kyphosis or true flexion instability (49).

In the upper cervical spine, the prevalence of neurologic deficit is much lower owing to the space available for the cord. The development of neurologic deficit here is usually due to extension of the tumor rather than to angular kyphosis. The sudden onset or rapid progression of neurologic deficit is usually due to a vascular accident rather than vertebral collapse and usually has a poor prognosis. Reporting on all locations of spinal tumors, Harrington (23) noted 62% of initially paraplegic patients regained enough neurologic function to ambulate after surgical intervention, but patients with rapid paraplegia exhibited a poor prognosis for recovery.

Appropriate treatment is selected dependent on life expectancy, type of tumor, location of tumor (accessibility), radiosensitivity, degree of instability, and neurologic status of the patient. Because the primary goal is to improve the patient's quality of life, thoroughly consider the patient's personal preference and family situation. Metastasis of lung carcinoma has a 7- to 9-month mean survival time, whereas breast carcinoma has a survival exceeding 30 months. Consider embolization of tumors with hemorrhagic tendencies, such as renal and thyroid. Treat radiosensitive tumors such as lymphoma, myeloma, and prostate with nonoperative management: Radiate with doses up to 4,000 cGy as long as there is no instability, neurologic threat, or significant deformity. Doses in excess of 5,000 cGy may cause acute or chronic radiation myelitis. Radiation therapy is compatible with internal fixation devices and methylacrylate but may cause failure of supporting bone graft struts. Radiation therapy alone is rarely effective in relieving a well-established neural deficit, especially in the presence of a collapsed vertebral body and bony impingement.

With normal neurologic function, consider surgery when there is severe pain, instability, or impending kyphotic collapse, or when the tumor is known to be radioreistant. Tumors with greater than 50% involvement of the vertebral body and greater than 50% destruction of the ipsilateral middle and posterior columns require prophylactic surgical stabilization. Kyphotic deformity and amount of subluxation should also be considered, but the assessment of instability is still somewhat subjective. The goal of surgery is to prevent neurologic compromise, but severe neurologic deficit is not a contraindication for surgery.

Location of the tumor is a major consideration for treatment with immobilization versus early radiation therapy versus surgery.

- Treat patients with tumors in the posterior C-2 arch with early radiation therapy so that progressive kyphosis does not develop.
- For destruction of the lateral mass of C-1, perform an occiput to C-3 fusion with adjunctive radiation therapy because rotatory instability is common (49).
- For destruction of the dens with instability, perform a C1–C2 fusion. If cord compression is impending, remove the arch of C-1 and perform an occiput to C-3 fusion.
- In the lower cervical spine, consider early combined anterior and posterior stabilization owing to the difficulty of fixation and the increased stress at the cervicothoracic junction.

Plain surgery so that it is appropriate for the tumor's stage and extent. Determine what anatomic structures may need to be sacrificed to perform the resection. Sacrifice of one vertebral artery can be tolerated if cure is a reasonable goal, but obtain a preoperative angiogram to assess collateral flow. If the cervical esophagus or a significant part of the thoracic esophagus is involved by tumor, total esophagectomy and gastric pull-up or colon interposition can be performed (9).

The results of surgery for cervical spine metastasis have shown a high rate of pain relief (94% to 95%), motor recovery (64% to 92%), and ambulation (87%). The results of surgery are usually maintained until the terminal stage, with local recurrences in 30% (2,49). In an elderly population with a mean age of 73, a mortality rate of 16% was reported within 7 days after surgery (60).

EXPOSURE, EXCISION, AND RECONSTRUCTION OF CERVICAL DESTRUCTIVE LESIONS

Anterior Approaches

The different incisions for the anterior approaches are shown in Figure 151.3 and are discussed in detail in Chapter 138. The different techniques employ three separate deep paths to the cervical spine: transpharyngeal, lateral and posterior to the carotid sheath, or anterior to the carotid sheath.
such ligation produces significant edema in the upper extremity. Such ligation is extended into the neck. This allows an extensile approach to the cervicothoracic junction, and the exposure can be further enhanced by ligation of the brachiocephalic arterial system. If clearance of the clavicle and manubrium is not possible, we prefer the sternal splitting approach. This approach permits extensile exposure of the anterior cervical spine. The visualization is similar to that obtained by the transmucosal route. This approach allows for tumor resection, but the risk of sepsis makes placing implants impractical.

Exposure for Upper Cervical Anterior Lesions

The upper cervical spine can be approached through the transoral approach. Routine tracheostomy is necessary only if a tongue or mandible-splitting approach is used. See Chapter 138 for a detailed description. The standard transoral approach can be used for exposure of C1–C2 (Fig. 151.4A), and this can be enlarged by the tongue-splitting (Fig. 151.4B) or transmandibular (Fig. 151.4C) approach, for decompression from the level of the clivus to C-4 (33). If division of the soft palate becomes necessary (only during extensile approaches), it is incised on one side of the midline to avoid the uvula. This approach allows for tumor resection, but the risk of sepsis makes placing implants impractical.

Exposure for Midcervical Anterior Lesions

Corpectomy and stabilization through the standard anterior prevascular approach (see Chapter 138) is usually the surgical treatment of choice for lesions from C-3 to C-7. Rarely, if a lateral biopsy was obtained and the goal of surgery was a wide margin with excision of the biopsy tract, the exposure would need to begin from the lateral approach and proceed posterior to the neurovascular bundle (22).

Exposure for Cervicothoracic Anterior Lesions

Inferior extension of the exposure in the cervical spine may be limited by the diameter of the thoracic inlet, the height of the clavicles and manubrium anteriorly, and the extent of cervicothoracic kyphosis. Obtain a preoperative radiograph to compare the upper margin of the clavicles and manubrium with the level of the vertebral body. If clearance of the clavicle and manubrium is not possible, we prefer the sternal splitting approach to clavicular osteotomy (33). The sternal splitting approach is very familiar to cardiothoracic surgeons (only the superior portion of the sternum needs to be split) and can be easily extended into the neck. This allows an extensile approach to the cervicothoracic junction, and the exposure can be further enhanced by ligation of the brachiocephalic vein. Such ligation produces significant edema in the upper extremity.
Reconstruction of Anterior Lesions

In the cervical spine, the resultant corpectomy defect can be replaced in several ways. In patients with benign lesions, or lesions with which there is long life expectancy, we prefer to use autograft or allograft struts to replace the anterior defect, followed by anterior instrumentation. If massive resection of the vertebral bodies is necessary at multiple levels, we perform posterior stabilization before anterior resection and reconstruction. The different scenarios for upper cervical, midcervical, and lower cervical reconstructions are shown in Figure 151.6, Figure 151.7 and Figure 151.8.

Figure 151.6. Scenario for upper cervical reconstruction. For extensive destruction of C1–C2, perform a posterior stabilization first with instrumentation, with next-stage anterior resection and strut grafting as needed.

Figure 151.7. Scenario for midcervical reconstruction. A: For extensive anterior destruction and fixed kyphosis in the midcervical spine, perform anterior decompression, strut grafting, and instrumentation, followed by posterior instrumentation. Perform the posterior instrumentation can be performed first if there is no significant deformity or if there is severe instability. B: For posterior destruction of the facets, perform a posterior-only reconstruction with plating or wiring.

Figure 151.8. Scenario for cervicothoracic reconstruction. For extensive cervicothoracic destruction, perform a posterior stabilization followed by anterior reconstruction.

In the case of giant cell tumor and other aggressive stage 3 lesions, some advocate use of methylmethacrylate (PMMA) anteriorly, with or without posterior arthrodesis or plating (36). Similar to its use in the extremities, PMMA has the advantage of immediate stability, local control due to the heat of polymerization, and rapid recognition of early recurrence. Despite the advantages of PMMA, we recommend reconstruction with autograft or allograft to provide a biologic reconstruction in these patients who usually have a long life expectancy. The benefits of a biologic reconstruction must be weighed against the risk of failure if radiation is used. Use of titanium or carbon fiber cages is controversial, and recognition of early recurrence with use of titanium is more difficult. Postoperative radiation therapy may be used if resection is incomplete, and in these cases, we would recommend use of PMMA.

For metastatic disease, when survival is anticipated to be less than 6 to 12 months, we use PMMA combined with metal implants to give immediate stable fixation (25). Radiation therapy can be used with PMMA without fear of impacting the healing of bone graft. Stabilization of the spine with PMMA can be fraught with major complications, however (42). Take care to avoid spinal cord injury, which can be caused by direct mass effect or by heat generated from the exothermic reaction of cement solidification.

Posterior Approach and Stabilization

The posterior approach may be preferred in the upper cervical spine or the cervicothoracic junction owing to the difficulties inherent in anterior approach and stabilization in these areas. Laminectomy alone is contraindicated in the presence of anterior compression and kyphosis. If the posterior elements can be left intact, then standard wiring techniques can be used. In the case of a laminectomy, lateral mass plates may be used for stabilization. Special techniques are available for occipitocervical and cervicothoracic instrumentation.

Options for occipitocervical instrumentation are

- Use of a contoured rod with wires for occipital and cervical laminar fixation (Fig. 151.9).
The goals of treatment are to

- Establish diagnosis
- Relieve pain
- Prevent or reverse neurologic deficit
- Establish or maintain spinal stability
- Eradicate infection

Cervical discitis or osteomyelitis can be treated with external immobilization and appropriate antibiotics if there is no abscess formation, neurologic deficit, or vertebral collapse and instability. Associated conditions that compromise wound healing or immune response should be managed aggressively. Bring diabetes or other systemic diseases under control, and address proper nutrition and reversal of hypoxia and metabolic deficits. Compared with thoracic and lumbar spine infections, infections of
the cervical spine have a higher risk of complications and surgical treatment is often required in addition to antibiotic therapy.

- Choose the antibiotic according to culture and sensitivity results.
- Withhold antibiotics in cases in which a biopsy is done, in case a second biopsy is required.
- In patients who have systemic toxicity or neurologic deficit, start maximum-dose broad-spectrum bacteriologic antibiotics as soon as biopsy is obtained.
- If the patient does not respond clinically to antibiotics, or the sedimentation rate does not decrease to one half or two thirds by completion of treatment, perform a repeat biopsy.
- Immobilize patients for pain control and to prevent deformity or deterioration of neurologic status.

Surgical indications include the following:

- The need for tissue and bacteriologic diagnosis
- To drain an abscess that is clinically significant (fevers or seizures)
- Cases refractory to nonoperative treatment
- Presence of neurologic deficit
- Prevention or correction of spinal deformity or instability

In nearly all cases of hematogenous cervical osteomyelitis, if surgery is deemed to be necessary, a solely anterior surgical approach with discectomy and debridement of pus and strut grafting from healthy bone above to below is sufficient. Laminectomy is contraindicated except for the rare case of associated posterior epidural abscess. If there is evidence of epidural extension, excuse the posterior longitudinal ligament to ensure decompression and removal of infected tissue.

Autogenous bone grafting after vertebral body resection has been shown to be safe and effective (44). Iliac bone is preferable to that of the fibula because it has more cancellous bone. Revascularization of cortical graft may not be complete even after 1 year (57). Experience has shown that instrumentation and even allograft may also be placed anteriorly in situations of active infection, as long as adequate debridement has been performed back to healthy, bleeding bone (55,57). Dietze et al. (13) reported no recurrence of cervical infection with a 37-month follow-up after debridement and use of allograft and instrumentation, but they presented information on only five patients. In cases of significant kyphosis, or to avoid halo immobilization, the anterior strut graft can be safely followed by second-stage posterior instrumentation.

Infections involving the midcervical spine can be addressed with standard surgical approaches. The occipitocervical junction is difficult to treat owing to anatomic and mechanical considerations. Upper cervical osteomyelitis is rare but generally requires fusion because of associated instability. Stabilization of the upper cervical spine should be performed in cases of instability as defined by traction or flexion-extension radiographs, odontoid and transverse ligament resection or destruction, or clivus and odontoid resection or destruction in the presence of basilar invagination. The principle of debridement to healthy bone still applies. For high cervical infections that require drainage owing to abscess formation or cord compression, we recommend a transoral drainage and posterior stabilization. Many authors recommend posterior stabilization due to the nonenlarging space of the posterior pharynx and devitalized bone (21,39). Zigler et al. (65) described five patients with pyogenic osteomyelitis of the occipitocervical region treated by operation and antibiotics. The options used were anterior debridement and occipitocervical fusion, transoral drainage, posterior occipitocervical fusion, and posterior C1–C2 fusion; and all five patients recovered. The surgical procedure must be individualized in each case according to the degree of bony destruction and instability.

**Treatment of Posterior Infection** Most posterior infections result from previous surgery. Treat by irrigation, debridement, and administration of culture-specific intravenous antibiotics. If more than 50% of the facet joint is resected during debridement (very rare), then perform a fusion. Autogenous bone graft placed in a thoroughly debried bed will usually result in a successful arthrodesis because of the abundant blood supply. We recommend a halo brace for immobilization after debridement of posterior infection and bone grafting. Stabilization with bone screws and plate or wire techniques is possible in spite of the infection, but the use of posterior cervical instrumentation in the presence of active infection is controversial. The length of time of administration of postoperative intravenous antibiotics will depend on the causative organism, but they should be given for at least 6 weeks; however, 4-week courses have been reported with good results (12).

**Outcome of Treatment**

Cervical infections have a higher rate of spontaneous fusion compared with thoracic and lumbar infections. Almost all cases of cervical infection that can be treated nonoperatively fuse spontaneously (45), as compared with only 50% of all patients with thoracic and lumbar vertebral osteomyelitis treated nonoperatively (19). Human immunodeficiency virus (HIV) status (27) and intravenous drug abuse (69) do not appear to affect the neurologic outcome of patients with spinal infections adversely. Infants with vertebral osteomyelitis (15), elderly patients, and those with underlying disease (58) have a high recurrence rate and a poorer prognosis. Factors that predispose to paralysis include increased age, a subaxial level of infection, and a concomitant disease (diabetes or rheumatoid arthritis) (14). Relapse of infection occurs in up to 25% of cases but is much less common when antibiotics are administered for more than 4 weeks (14,58).

Eismont et al. (13) found that the prognosis for patients with paralysis from cervical spine infection is better with an anterior surgical procedure than with the posterior approach; three of seven patients deteriorated and four remained unchanged after laminectomy. Stone et al. (61) reported that all surgical patients with myelopathy and radiculopathy achieved solid fusion, and at final follow-up, they were ambulatory and neurologically intact. When doubt exists regarding the reversibility of a spinal cord lesion, perform a decompression. Recovery from paralysis has been noted in patients who underwent decompression as late as 5 months after the onset of weakness (47).

**EPIDURAL ABSCESS**

**Diagnosis**

Epidural abscess is rare but potentially devastating. In a series of 25 patients, the cervical spine was noted to be involved in 13. Three were multifocal (cervical and thoracic) (54). Cervical epidural abscess may occur via hematogeneous spread from a remote location or from a contiguous focus of vertebral osteomyelitis, or by direct inoculation at the time of operation or injection.

The peak incidence of spinal epidural abscess is in the sixth and seventh decade of life, and there is a high incidence in patients who are intravenous drug abusers, so comorbid conditions may impair immunocompetence (26). Even though most epidural abscesses are seen after invasive processes that violate the epidural space, there are reports of multifocal epidural infections when the primary infection is the cause of the abscess (7).

Anatomically, the epidural space is not a uniform space (19). Some areas are filled with fat and veins, and others are in direct contact with bone or ligament, creating individual metameric segments. In the cervical spine, except for a space dorsal to the origin of the spinal nerves, the epidural space is mostly a potential space. Individual metameres are septated, preventing free communication between the anterior and posterior epidural space (29). In cases where they do not involve the anterior epidural space or are circumferentially surround the thecal sac. Conversely, postsurgical cases or cases associated with discitis or vertebral osteomyelitis not only involve the anterior epidural space but may be circumferential because of the common postsurgical disruption of normal anatomic septations (41).

To diagnose epidural abscess, MRI with contrast is the modality of choice. False-negative results may occur with nonenhanced MRI, especially with extensive abscesses that do not have a discrete proximal or distal extent (20). Comitant meningitis may also cause signal changes in the abscess that may be similar to infected cerebrospinal fluid, resulting in a false-negative magnetic resonance imaging MRI scan (51). Myelography and CT are sensitive for confirming the presence and extent of an extradural compressive lesion but should be avoided if epidural abscess is suspected because dural puncture risks spreading the infection to the intrathecal compartment. There is also a small but real risk of causing an acute neurologic deterioration owing to resultant spinal coning if lumbar puncture is performed caudal to a spinal block (41). Owing to the frequently rapid evolution of the disease process and associated illnesses, the mortality rate is as high as 20% (26). In cases in which MRI is not readily available, CT with myelography should be performed because, despite the increased risk, confirmation of the diagnosis should not be delayed.

**Treatment**

Management of spinal epidural abscess is based on the clinical condition of the patient. Medical management is often successful in the treatment of lumbar epidural abscess, but cervical epidural abscess presents an increased risk to the spinal cord. Indications for nonoperative treatment of spinal epidural abscess are

Outcomes of Treatment of Epidural Infection

As previously stated, the prognosis for patients with cervical epidural abscess is not as favorable as that for thoracic and lumbar infections. The mortality rate with cervical abscesses was reported to be as high as 38% despite aggressive treatment, and the neurologic deficits were more severe and refractory to treatment (22). Diabetes, HIV infection (20,33), and vertebral osteomyelitis (28) are associated conditions that carry a poor prognosis. Reporting on predominantly cervical and cervicothoracic epidural abscesses, Redeker and Del Maestro (54) reported a 20% mortality rate, and only 56% retained or recovered ambulation. They attribute the high morbidity and mortality rates to delay in diagnosis and treatment, which has been shown to be a factor in all epidural abscesses. Reporting on all locations of epidural abscesses, no patients with paralysis for longer than 36 hours recovered significant neurologic function (65). In chronic infection, dense granulation tissue is present; decompress the full extent of the abscess. Stabilization is usually not necessary.

Anterior epidural infections are usually associated with discitis or osteomyelitis and should be approached anteriorly (29). If the patient has discitis, osteomyelitis, and instability, anterior debridement and reconstruction can be carried out without formal excision of the granulation tissue formed by the abscess. Incline the posterior longitudinal ligament to allow evacuation of purulent material. If cord compression is symptomatic, complete exposure of the granulating abscess is necessary to allow excision of this dense, tenacious material from the thecal sack. Extreme caution is advised.

- Remove necrotic disc and endplate material, and resect diseased bone back to healthy, bleeding vertebral bone. If only the endplate and less than half of the body remain at any level, resect the remnant and extend to the next disc space.
- Use a micropituitary and small curet to fenestrate the posterior longitudinal ligament (PLL) laterally. Use small Kerrison rongeur to expand the window, and resect a portion of posterior vertebral rim.
- If there are no signs of cord compression, drain any purulent material, gently irrigate, and proceed with stabilization. If there are signs of cord compromise, carefully resect the posterior vertebral cortex and PLL over the length of the lesion to provide full decompression.
- If the thickened granulation tissue is to be removed from the surface of the cord, magnification is necessary.
- Carefully develop the interval between the abscess and thecal sack with Roton dissectors and a nerve hook.
- Monitor spinal cord function constantly.
- Once the mass is debulked and cultures obtained, irrigate with antibiotic solution and stabilize the resected segment with an autograft strut.
- Stabilize in a halo. Do not use implants in the presence of deep infection.

Figure 151.11. A case of epidural abscess formation leading to severe cervical spinal cord impingement. A 45-year-old homeless patient with increasing low back pain for months, fevers, and chills. The patient failed to seek treatment and finally presented with severe progressive neurologic deficit and respiratory difficulties. A: Lumbar CT scan showing anterior abscess. B: Lumbar MRI showing vertebral osteomyelitis and massive epidural abscess. C: Thoracic MRI showing massive posterior epidural abscess involving at least 50% of spinal canal. D: Cervical MRI showing massive posterior epidural abscess with almost 75% involvement of the spinal canal at the level of C-2. The probable start of the infection was lumbar discitis and vertebral osteomyelitis that progressed to epidural extension and eventual marked spinal cord compression. Treatment was limited cervical laminectomy. After the cervical laminectomy, the patient was placed in Trendelenberg position, with massive drainage of the thoracic and lumbar pus. Postoperatively, the patient had significant but partial neurologic recovery. The patient was lost to follow-up.

Patients with complete paralysis for more than 3 days (65). Medical treatment involves 8 to 12 weeks of intravenous antibiotics. Close monitoring with hospitalization and numerous MRIs is needed. The disadvantages of medical treatment are that neurologic deterioration can be precipitous, and once present, the deficits may be irreversible. We recommend aggressive surgical management of cervical epidural abscesses. When surgical drainage is performed and osteomyelitis is not present, shorter courses of intravenous antibiotics (less than 4 weeks) have been successful (11).

When epidural abscesses are located posteriorly, laminectomy is the most effective approach for decompression. The extent of the exposure is determined by the operative findings. If purulent material is found (acute infection), a limited approach can be used (see case example, Fig. 151.11). In chronic infection, dense granulation tissue is present; decompress the full extent of the abscess. Stabilization is usually not necessary.

Appropriate, timely surgical treatment can increase survival and improve the quality of life for many patients with spinal column tumors. The goals of treatment are pain relief, improved function, and the best possible chance of local control and cure of the disease. Aggressive surgical approaches, combined with improved adjuvant therapy, now offer good short-term and long-term outcomes for many lesions previously thought untreatable or unresectable.

**DIAGNOSIS**

**INCIDENCE AND PRESENTATION**

Spinal column tumors, malignant and benign, occur in all age groups and at all levels of the spine. Primary tumors can arise from any of the hard or soft tissues of the spinal column, or they can extend directly to the spinal column from contiguous paraspinal lesions. Metastatic tumors, which migrate from distant sites by either lymphatic or hematogenous routes, account for 97% of all spinal column tumors. Spinal metastases are common among patients with adenocarcinoma. Between 50% and 70% of all patients with carcinoma develop skeletal metastases during the course of their disease, as do 85% of women with breast cancer. The spine is the most common site for these metastases. The most common metastatic lesions are adenocarcinomas from the following:

- Lung
- Breast
- Prostate
- Kidney
- Gastrointestinal tract
- Thyroid

Certain primary tumors, such as chordoma, osteoblastoma, and plasmacytoma, show a preference for the spinal column, but they represent a small proportion of all spinal lesions.

Because of the preponderance of metastatic disease, spinal lesions in all age groups are more likely to be malignant than benign. This is particularly true in adult patients, where an increasing incidence of metastatic disease, an increased risk of systemic diseases such as myeloma and lymphoma, and a greater likelihood of having a malignant primary tumor combine to present a particularly grim prognosis. Seventy percent of primary spine tumors in patients over 25 are malignant, compared with only 30% in patients under 21 years of age.

Both primary and metastatic malignancies tend to originate in the vertebral body, involving one or both pedicles. The vertebral body contains most of the bone, hematogenous marrow, and cartilage from which primary lesions arise, and the notochordal rests that give rise to chordoma. Most of the hematogenous marrow is also contained in the bodies. Finally, retrograde flow through the venous drainage of the spinal column (Batson's plexus) permits tumor cells from the abdominal cavity to seed the vertebral bodies directly. Lesions of the posterior elements are more commonly benign.

**PRESENTING SYMPTOMS**

Back pain is common and nonspecific, and it is ubiquitous in the age group most at risk for spinal tumors. Whereas idiopathic back pain is typically mechanical, activity related, and self-limiting, neoplastic pain is more often

- progressive and unrelenting,
- unrelated to activity and unresponsive to rest,
- well localized to the spinal segment involved,
- reproduced by palpation or percussion over the involved area,
- and more severe or disturbing at night.

Pain and neurologic dysfunction are the most common presenting symptoms and usually arise from one of the following causes:

- Pathologic fracture
- Expansion of the vertebral cortex and surrounding tissues by tumor
- Compression or invasion of nerve roots
- Segmental instability
- Spinal cord compression

Rapid progression of pain or neurologic symptoms occurs with more aggressive, malignant tumors, whereas symptoms that progress over years are typical of slow-growing and often benign processes. Spine tumor patients most often present with pain. Common presenting symptoms occur as follows:

- Eighty-five percent of spine tumor patients present with pain.
- Back pain is the only symptom in 30%.
Percutaneous needle or trocar biopsy allows aspiration and removal of fine tissue fragments; the advantages are that needle biopsy is minimally invasive and does not require a surgical incision. Although radicular symptoms may simulate herniated nucleus pulposus, symptoms from lumbar and sacral neoplasms do not respond to rest and recumbency, and they tend to progress relentlessly.

Spinal deformity is rarely associated with spinal neoplasm, except when vertebral collapse results in severe kyphosis. Osteoid osteoma and osteoblastoma may produce a sclerosis that is typically painful, with localized pain, muscle spasm, and limited motion. Deformities associated with tumors may come on suddenly and progress rapidly. Unless addressed early on, these curves will become structural and difficult to manage. If the primary lesion is addressed in a timely manner, the curve will often resolve with observation or bracing. However, if the deformity is allowed to persist, surgical correction may be necessary.

To make the diagnosis before neurologic symptoms arise, the physician must be alert to any patient with persistent, nonmechanical back pain, age- or activity-related risk factors, or, particularly, a previous history of malignancy. Although neurologic injury is rarely the first sign of a spinal neoplasm, it may be present in as many as half of patients by the time they seek medical attention, and they may be recognized in more than 70% by the time a diagnosis is made.

The basic workup of any spine tumor includes the following:

- Complete blood cell count (CBC), differential, sedimentation rate, urinalysis, electrolytes, calcium, and basic chemistry panel
- Serum and urine protein electrophoresis; if positive, bone survey and bone marrow aspirate
- Renal ultrasound or abdominal computed tomography (CT)
- Chest CT
- Bone scan
- Physical exam: breasts, prostate, rectal, stool guaiac, thyroid

**EVALUATION**

**IMAGING**

**Plain Roentgenograms**

Standard anteroposterior and lateral roentgenograms of the spine still represent the most practical first study for patients with suspected spinal tumor. Good-quality studies of the symptomatic spinal segment may be sufficient to define the characteristic changes of bone destruction and tumor expansion, and they may establish a specific diagnosis in some tumor types. Plain roentgenograms will demonstrate abnormalities in 80% to 90% of patients with a spinal neoplasm. Even when the precise tumor type cannot be identified, the benign or malignant nature of the lesion can often be implied from the pattern of bone destruction.

**Nuclear Scans**

Technetium bone scans screen for bony turnover that can detect the presence of tumors before they become apparent on plain films. Because roentgenographic evidence of bony destruction is not apparent until after 30% to 50% of the trabecular bone has been demineralized or destroyed, bone scans are far more sensitive for picking up early involvement.

**Computed Tomography**

Computed tomography may provide diagnostic information on small tumor foci early in their development, before extensive bony destruction or intramedullary extension has occurred, and before cortical erosion has advanced to the point of impending fracture. CT is time consuming and not suitable for screening large segments of the spine. Once the suspected lesion is identified on plain films or bone scan, however, CT provides unsurpassed imaging of the bony architecture and bony replacement. In a patient with metastatic renal carcinoma, CT demonstrates bony destruction and expansion of the anterior vertebral cortex. Sagittal (D) and transverse (E) MRIs showing vertebral destruction, collapse, and cord compression caused by a breast metastasis to the T-3 vertebral body.

**Magnetic Resonance Imaging**

Magnetic resonance imaging (MRI) is noninvasive, safe, and readily available to most patients. It provides multiplanar images of large segments of the spine and surrounding tissues and can be used to screen for disseminated disease. MRI delineates soft-tissue extension from other processes, and newer techniques can accurately differentiate tumor from herniation, edema, and inflammation. MRI directly images the spinal cord, cauda equina, and nerve roots without the aid of intrathecal contrast. It can reveal invasion of paravertebral structures better than either CT or myelography, and with gadolinium enhancement it can differentiate osteoporotic compression fractures from metastatic disease. Characteristics of tumors on MRI are (a) convex posterior cortex, (b) epidural mass, (c) low-intensity T1 signal, (d) high or inhomogenous T2 signal intensity, (e) high-intensity signal after gadolinium injection.

**Myelography**

Previously the gold standard for spinal imaging, this test has been largely replaced by MRI. When MRI cannot be done, myelography with postmyelogram CT may provide the same information.

**BIOPSY**

There are three basic approaches to biopsy, each with advantages and disadvantages:

1. Percutaneous needle or trocar biopsy allows aspiration and removal of fine tissue fragments; the advantages are that needle biopsy is minimally invasive and uses local anesthetic. It is most suitable for lesions that are easily differentiated. Because samples are small, they are difficult to read, and they are frequently not diagnostic. When the differential diagnosis is limited to lesions that are easily distinguished histologically, needle biopsy is ideal.
Open, incisional biopsy provides moderate-size specimens showing cellular architecture and marginal tissue. It provides diagnostic tissue and may be done just prior to formal excision when used with frozen section. Place the incision so it can be excised with the definitive procedure. Carry out the incisional biopsy as the last step in tumor staging, just before or at the time of definitive resection. The incision must be longitudinal, never transverse. Handle the tissues gently, and provide meticulous hemostasis to prevent tumor spread. Take a section of tissue large enough to allow histologic and ultrastructural analysis as well as immunologic staining from the margin of the lesion (central sections may be necrotic). Take the specimen with a sharp scalpel and be careful not to crush or distort the tissue during harvest. Avoid using electrocautery on the biopsy specimen itself.

2. Open, incisional biopsy provides moderate-size specimens showing cellular architecture and marginal tissue. It provides diagnostic tissue and may be done just prior to formal excision when used with frozen section. Place the incision so it can be excised with the definitive procedure. Carry out the incisional biopsy as the last step in tumor staging, just before or at the time of definitive resection. The incision must be longitudinal, never transverse. Handle the tissues gently, and provide meticulous hemostasis to prevent tumor spread. Take a section of tissue large enough to allow histologic and ultrastructural analysis as well as immunologic staining from the margin of the lesion (central sections may be necrotic). Take the specimen with a sharp scalpel and be careful not to crush or distort the tissue during harvest. Avoid using electrocautery on the biopsy specimen itself.

3. Open, excisional biopsy includes removal of all tumor tissue at the time of biopsy. It provides complete treatment of local disease. Few tumors are suitable, however; the surgeon must already have a good idea of the diagnosis to plan appropriate excision.

**Hint and Tricks**

Because of the possibility of catastrophic hemorrhage, renal cell metastases must be approached more cautiously than most other tumors, although metastatic thyroid, melanoma, and some breast lesions may also be highly vascular. An abdominal ultrasound or CT will reveal the primary renal lesion before the surgeon performs a biopsy that may lead to uncontrollable bleeding. Preoperative angiography will reveal the extensive neovasculature often associated with these tumors, allowing embolization of abnormal vessels and nonessential segmental arteries.

**Tumor Types**

**Primary Tumors**

Primary tumors make up less than 3% of all spinal lesions. Survival rates are most directly, but not entirely, related to tumor type; some low-grade lesions may permit a long survival despite their malignant nature, whereas some histologically benign lesions may prove lethal because of their location in the spine.

**Benign Primary Tumors**

**Osteochondroma**

Vertebral involvement occurs in approximately 7% of osteochondromas, but symptomatic lesions are rare. Eighty percent of symptomatic osteochondromas occur in the cervicothoracic spine, above T-6. MRI demonstrates the radiolucent cartilage cap, which usually causes spinal cord compression. Excision of the tumor, en bloc or piecemeal, provides reliable neurologic recovery with little risk of recurrence. Enchondromas rarely produce any symptoms but may prove a diagnostic dilemma when encountered incidentally. Enchondromas develop a well-defined, benign-appearing cortical margin, but calcific stippling of the lesion may suggest chondrosarcoma, prompting an excisional biopsy.

**Osteoid Osteoma and Osteoblastoma**

Osteoid osteoma and osteoblastoma are benign neoplastic lesions frequently found in the spine, originating in or from the posterior vertebral elements. Symptoms in the spine are similar to extremity lesions (see Chapter 127), except for the occasional development of a painful scoliosis.

Because osteoid osteoma is often obscured by the overlying shadows of the vertebral body, it is most readily localized by bone scan. Excision of the lesion reliably and immediately relieves the patient's pain. The key to successful treatment is accurate localization of the tumor nidus, confirmed by directed CT of the area.

Osteoblastoma is considerably larger than the 2 cm osteoid osteoma; it is characterized by the expansion of the overlying cortical bone and a thin rim of reactive bone among the trabeculae. When complete excision of the osteoblastoma is not feasible, curettage and bone grafting may provide an acceptable long-term result.

Scoliosis related to these lesions is often flexible and will usually improve or resolve after the lesion is removed. Instrumentation and fusion of the curve may be required if the scoliosis has been present for a long period and has become structural. Corrective surgery may be planned after the patient has recovered from the tumor surgery and has had a chance to improve spontaneously.

**Hemangiomas**

Magnetic resonance imaging shows that vertebral hemangiomas are common, occurring in approximately 10% of all adults. Fortunately, only a small proportion are ever symptomatic. Reports of deformity or pain associated with hemangioma are rare, and surgeons should hesitate before attributing mechanical or chronic pain symptoms to these lesions. Asymptomatic hemangiomas rarely develop into symptomatic ones, and follow-up is unnecessary. Plain radiographs typically show vertical striations indicative of thickened trabeculae within the involved vertebral body, and CT usually demonstrates these same trabeculae dotting the region of the lesion. These lesions often respond to radiotherapy or vascular embolization alone. If vertebral collapse or neural compression occurs, surgical decompression and reconstruction through an anterior approach are indicated.

**Giant Cell Tumor**

Because of the tendency of giant cell tumors to recur, these histologically benign lesions may behave in a far more malignant fashion in the spinal column, resulting in significant mortality as well as morbidity. Usually seen in the third or fourth decade of life, the tumors appear lucent on plain radiographs, with marginal sclerosis and a geographic pattern of bone destruction. These slow-growing tumors are usually anterior and may expand the surrounding cortical bone as they grow. Some authors have suggested that spinal tumors are less aggressive than extremity lesions, whereas others have acknowledged the aggressive nature of the tumor in this vulnerable region and have recommended adjuvant irradiation or cryotherapy for local control.

Because of the tendency of giant cell tumors to recur locally, CT and MR imaging are particularly important in planning an operation that will provide as wide a margin as possible. Complete excision is the key to eradicating these tumors. Anterior/posterior vertebral curet with an en bloc excision, followed by a combined reconstruction, limits the likelihood of recurrence and allows the most rapid return to function.
Solitary plasmacytoma and multiple myeloma represent two ends to the continuum of B-cell lymphoproliferative diseases. Multiple myeloma is rapidly progressive and

eosinophilic granuloma is a benign, self-limiting lesion commonly seen in children under the age of 10 years. Vertebral involvement occurs in approximately 15% of all cases and can be associated with any of three syndromes: isolated eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease. The classic radiographic presentation is caused by near-complete collapse of the vertebral body, resulting in a vertebra plana, or “coin” lesion (57). Although classic, this appearance is not pathognomonic, and a similar picture can result from either infection or Ewing’s sarcoma (51). Once a definitive diagnosis is established, usually by trocar biopsy, the patient may be effectively treated by bracing and observation. Although radiotherapy has been advocated in the past, it can be avoided in most patients.

When neurologic symptoms of eosinophilic granuloma are present, either with or without vertebral collapse, the established course of biopsy followed by irradiation and immobilization remains the most widely accepted (26). Recovery of neurologic function is usually excellent, and some reconstitution of vertebral height is seen in most young patients.

An aneurysmal bone cyst (ABC) rarely involves the spinal column. When they do, they usually involve the posterior elements and are most commonly seen in the lumbar spine. Radiographs demonstrate an expansile lesion with an osteolytic cavity that may extend across segmental levels to involve two or even three adjacent vertebral levels. The cortex is often eggshell thin and blown out, and the cyst contains numerous strands of bone which give the “bubbly” appearance typical of ABCs. Curettage usually eradicates the lesion, and recurrences, which do not tend to invade vital structures, may be successfully treated by repeated curettage or excision (32).

MALIGNANT PRIMARY TUMORS

Chordoma

Chordoma is a relatively rare lesion arising exclusively in the axial skeleton, most often in the spine and sacrum. The tumor is derived from rests of notochordal tissue residing in the skull base, sacrococcygeal region, and the vertebral segments in between (49). The tumor is characterized by slow but relentless local progression. It metastasizes late, but it has an aggressive tendency to recur at the surgical site, which makes it highly lethal. Although uncommon in children, chordomas are more histologically variable and more clinically aggressive in this age group than in adults (11). Because of their insidious development, chordomas can reach remarkable size before they are recognized. Patients may present after months or even years of progressive pain, sitting intolerance, urinary obstruction, and constipation. Sacrococcygeal tumors are easily detected on rectal examination as firm, fixed lesions displacing the posterior rectal wall.

Surgical resection is the only curative procedure for chordomas. A wide margin is crucial to local control because these lesions are generally unresponsive to radiotherapy and chemotherapy. Whereas only 5% of patients with spinal chordoma develop metastases, nearly 70% will die of their disease, reflecting the seriousness of local tumor extension (3). Intraspinal extension is associated with a high rate of local recurrence (82%) and a high mortality (71%) (71). Carry out biopsy of a suspected chordoma through a posterior approach, after all other staging studies are done. Never biopsy a sacral lesion through the rectal vault; violation of the rectal wall necessitates colectomy.

Osteosarcoma

Osteosarcoma of the spine remains an ominous disease—the median survival following diagnosis has ranged from 6 to 18 months, irrespective of surgical approach (1,58,65). When effective local control can be obtained surgically, survival is comparable to that of extremity lesions, fewer than half of all spine patients achieve complete local excision, however (2). Spinal osteosarcoma usually arises in the vertebral body. Radiographs reveal cortical destruction, soft-tissue calcification, and periosteal reaction. The paraspinal soft-tissue mass may be extensive and may encase or invade the great vessels or other contiguous structures. Intraspinal extension of the soft-tissue mass may result in either cord or cauda equina compression.

Even though cure of osteosarcoma remains elusive, more aggressive treatment protocols have improved overall survival. By combining current adjuvant therapy with extensive anterior/posterior resections, surgeons have provided patients with improved local control, neurologic function, and improved survivals (65,73).

Chondrosarcoma

Approximately 10% of chondrosarcomas arise in the spinal column or sacrum. Resistant to both radiotherapy and chemotherapy, these tumors are slow growing, locally invasive, and difficult to eradicate from the spinal column. Although survival may be prolonged in spite of residual disease, the final prognosis for patients with spinal chondrosarcoma is poor.

Radiographically, chondrosarcoma is characterized by a prominent soft-tissue mass stippled with flocculent calcifications (33). CT and MR imaging are crucial to determining soft-tissue extensions and the potential for surgical resection. Although long-term survivals are occasionally associated with intralesional resection, a wide margin is the most reliable means of local control and cure (59,63).

Ewing’s Sarcoma

Ewing’s sarcoma may arise in the spine as a primary or a metastatic lesion. Approximately 3.5% of Ewing’s lesions are thought to arise in the spinal column primarily. These tumors produce a permeative destructive pattern that can be difficult to discern on plain radiographs, so that the first radiographic finding may be vertebral collapse and vertebra planum (21). Intraspinal extension may produce neurologic symptoms before bony involvement becomes apparent on plain radiographs. MRI will demonstrate the lesion and its extension, as well as showing occasional epidural metastasis that do not involve bone.

Effective therapy for Ewing’s sarcoma revolves around a program of multimodal chemotherapy and high-dose radiotherapy. Surgical treatment is indicated to decompress neurologic structures and stabilize the spinal column. Thoracic and thoracoolumbar laminectomies should be instrumented to prevent kyphosis (28).

Although the prognosis is generally worse than for extremity lesions, encouraging disease-free survival rates have been obtained using current multimodality regimens (23,26).

Solitary Plasmacytoma

Solitary plasmacytoma and multiple myeloma represent two ends to the continuum of B-cell lymphoproliferative diseases. Multiple myeloma is rapidly progressive and...
highly lethal, requiring little more than supportive care for spinal involvement. Solitary plasmacytoma may remain localized for years before eventually disseminating. Prolonged survival is possible if local control can be obtained (44).

Solitary plasmacytomas make up only 3% of all plasma cell neoplasms. Whereas spinal involvement in multiple myeloma is associated with a poor 1-year survival rate, patients with solitary plasmacytoma of the spine have a 60% 5-year survival rate (44,71). Although most, if not all, of these lesions will eventually degenerate into disseminated multiple myeloma with a rapidly lethal course, survivals of 20 years or more have been reported.

Plasmacytoma and myeloma are radiosensitive tumors. Surgical treatment is indicated to stabilize the spine and reduce mechanical pain and to decompress neurologic elements in patients with rapidly progressive symptoms. Surgery is also warranted for those patients with recurrent disease or tumors that have not responded to radiotherapy (Fig. 152.4). Follow-up with MRI and serum protein electrophoresis provides the earliest indication of recurrence or dissemination.

**Lymphoma**

Lymphoma may occur as an isolated lesion or as a focal manifestation of a disseminated disease. As with plasmacytoma, surgical treatment is an adjuvant to systemic therapy and radiotherapy. Surgical decompression is indicated to decompress cord, cauda equina, or nerve root injured by tumor extension or pathologic fracture, and to stabilize damaged spinal segments.

**METASTATIC DISEASE**

The vertebral column is predisposed to metastatic disease by its vascular anatomy, its architecture, and its proximity to common sources of disease. The venous drainage of the spine is contiguous with that of the thoracic and abdominal viscera. Retrograde venous flow provides a variety of tumors access to the vertebral body. There, metastatic emboli settle and implant in the capillary end-loops adjacent to the vertebral endplates. The red marrow of the vertebral body provides a physiologically favorable environment for tumor cell proliferation. The vertebral trabecular bone has a rich blood supply, with few barriers to tumor extension; once established, the tumor can grow for some time before it becomes clinically apparent.

Almost any neoplastic process can establish skeletal metastases; however, certain tumors are particularly adept at reaching and surviving in the trabecular environment (Table 152.1). Breast, lung, prostate, and lymphohemopoietic disease account for approximately 60% of all spinal column metastases requiring treatment. Whether a tumor requires surgical treatment is determined by the behavior of the primary lesion and the metastasis. Patients with breast, prostate, renal, thyroid, or gastrointestinal carcinoma may experience extended survivals with current adjuvant protocols, despite established metastases. Patients with multiple myeloma or pulmonary carcinoma typically deteriorate and die soon after metastasis. Breast, prostate, and renal carcinomas tend to establish spinal metastases early in the disease process, whereas gastrointestinal carcinomas typically seed the liver and lungs first. Hence, patients with breast, prostate, and renal carcinoma tend to live long enough for their spinal metastases to become a specific threat to function and quality of life, while patients with lung carcinoma and myeloma will often die before the spinal metastasis needs more than palliation, and patients with gastrointestinal carcinoma are often more directly affected by their visceral metastases than their skeletal disease.

Table 152.1. Trabecular Carcinomas

**PEDIATRIC TUMORS**

Metastatic disease is the most common malignancy of the spine in children; neuroblastoma accounts for nearly one third of all pediatric spinal tumors (20,39). Ewing's sarcoma is the most common primary malignancy, but it is still more often a metastasis than a primary lesion (73). However, 70% of primary pediatric tumors are benign.

**Neuroblastoma**

Neuroblastoma is an aggressive malignancy that may spread to the spine either by vascular dissemination or by contiguous spread from the primary lesion. Treated with a combination of chemotherapy, radiotherapy, and surgical excision, patients with these tumors have a poor prognosis overall. Those patients that do survive are at high risk of developing a progressive spinal deformity as a result of either rib resection or hemibody irradiation (21,52).

**Leukemia**

Leukemic infiltrates may occasionally present as the initial finding in a patient with systemic disease. Most of these patients will have back pain, and some may have vertebral collapse at the time of presentation (53). Nonspecific complaints of muscular aches and pains, lethargy, fatigue, and fever, as well as findings of anemia, should prompt a search for the underlying disease. Radiographs are not characteristic: They may show vertebral collapse, focal lytic changes, or sclerotic, geographic lesions, or they may be entirely normal. Bone scan may also be equivocal, but MRI will reliably demonstrate the infiltrate (10).

**TREATMENT**
The correct treatment of any tumor depends on a number of factors unique to the individual patient:

- Is the tumor benign or malignant? Primary or metastatic?
- Is the patient systemically ill, or fit?
- Is the tumor slow growing, locally aggressive, or widely disseminated?
- Is there any neurologic compromise?
- Is there a fracture or instability?

The surgeon cannot reliably offer the patient the best treatment until these questions have been answered. See the algorithms for diagnostic workup (Fig. 152.5) and treatment and reconstruction (Fig. 152.6).

**Figure 152.5.** Diagnostic workup algorithm for spinal tumor. SCC, spinal cord compression; SPEP, serum protein electrophoresis; UPEP, urine protein electrophoresis; TX, treatment; Zones, see Figure 152.7.

**Figure 152.6.** Treatment and reconstruction algorithm for spinal tumor. Met, metastasis.

There is a broad spectrum of medical therapies available to treat spinal tumors, ranging from observation to total spondylectomy (Table 152.2). Both undertreatment and overtreatment can lead to trouble.

**Table 152.2. Medical Therapies to Treat Spinal Tumors**

A radical margin cannot be achieved in the spinal column because any break in the vertebral ring violates the osseous “compartment.” The necessary cuts through the bony ring could expose normal tissues to contamination even in well-circumscribed tumors. Hemorrhage from the cut bone can carry tumor cells throughout the field, reducing the chance for local control. Once the tumor has extended beyond the vertebral cortex, even a marginal excision may be difficult to obtain. A tumor that adheres to or invades the dura or aorta may prove difficult or impossible to resect, and a tumor that involves the vena cava is usually unresectable. In these cases, the risks of attempting a wide resection with vascular or dural grafting must be weighed against those of following up a marginal excision with adjuvant radiation.

**INDICATIONS FOR SURGERY**

Patients with extensive metastases from a previously documented primary, or with peripheral metastases that can be easily biopsied, may not require any spinal...
surgery. Unless there is neurologic impingement or mechanical instability, radiation or chemotherapy can retard tumor progression and control the spinal lesion.

Principal indications for surgical treatment include the following:

- Inability to obtain a tissue diagnosis by other methods
- Neurologic compression due to pathologic fracture or bony impingement
- Mechanical instability, with severe pain or impending neurologic injury
- Tumor progression despite, or following, radiotherapy
- Known radioresistant tumor
- Primary malignant tumor
- Resectable solitary metastasis in patient with potential long-term survival

If the tumor is resistant to radiation therapy, or if the patient suffers from neurologic compromise, spinal in-stability, or collapse, surgical treatment will be needed following biopsy. Three issues must be considered in developing a surgical plan—first, the proper margin of resection (of primary concern in locally aggressive and malignant primary tumors); second, the need for neurologic decompression; and third, the means of reconstruction.

Resection

Numerous studies show that the ability to completely resect the primary lesion significantly improves patient survival (4,5,64,73). Even in metastatic lesions, a complete resection can confer improved survival and quality of life (56). In locally aggressive tumors, resect the anterior and posterior longitudinal ligaments, vertebral body, adjacent discs, and the overlying dura, if necessary, to avoid leaving residual tumor behind. It is sometimes necessary to sacrifice one or more nerve roots to provide a suitable margin of excision.

Plan the surgical approach and resection margins using Weinstein's staging system (72), which divides the vertebral body into four zones and three grades of tumor extension (Fig. 152.7).

- Tumors in zones 1, 2, and 3 involve the posterior elements, pedicle and transverse process, and anterior vertebral body, respectively.
- Zone 4 lesions involve the posterior portion of the vertebral body and that portion of the cortex just anterior to the spinal cord or neural elements.
- To address any lesion involving zone 4, the surgeon must cross zone 3 and must release the vertebra from the pedicles, resecting zones 1 and 2 as well.
- Zone 4 lesions frequently require a subtotal or total vertebrectomy to obtain a clean margin. This assumes that the tumor is still intraosseous (grade A), without extraspinal spread (grade B), or distant metastases (grade C).

Computed tomography and MRI provide most of the information needed for staging, with bone scan and serologies added to determine metastatic status. Pay particular attention to the possibility of extraspinal extension—Grade B lesions may prove unresectable if vital structures are directly invested by tumor. The decision to attempt a wide resection in these lesions must be weighed against the risks of vascular or neurologic injury. In some cases, the most prudent approach may be to accept a marginal or intralesional margin, supplementing local treatment with adjuvant radiotherapy or cryotherapy.

Choose the proper surgical approach for the tumor type and location:

- Zone 1 lesions are best approached through a standard posterior incision, with the extent of the incision based on the extent of the soft-tissue mass, if any.
- Zone 2 lesions require a posterolateral approach (Fig. 152.8). The laminectomy and bone resection necessary for tumor excision generally results in some degree of segmental instability, and posterior instrumentation and fusion is usually necessary.
- Zone 3 lesions can often be addressed through an anterior approach alone.
- Zone 3 lesions can be adequately resected at any level of the spine, but 3B lesions may present different challenges at different levels. Depending on the extent of resection, a formal reconstruction may or may not be necessary.
- Complete resection of the vertebral body requires a combined surgical approach if a marginal or wide margin is to be obtained. Zones 1, 2, and/or 3 must be crossed to gain access to the zone 4 lesion, and more than one zone is usually involved with the tumor.
- Complete resection of the vertebral body requires separating the posterior structures (zones 1 and 2) from the anterior structures (zones 3 and 4), at the junction between the pedicles and the vertebral body (Fig. 152.9).

The standard approach to vertebrectomy combines a midline posterior incision with either a retroperitoneal, a thoracoabdominal, or a transthoracic approach to the anterior vertebral body. An alternative approach is to extend the posterior dissection around the side of the vertebral body, completing the vertebrectomy through a posterolateral resection (18). If at least one pedicle is uninvolved, a wide margin is possible (64). Complete vertebrectomy requires both anterior and posterior stabilization, but experience has shown that this aggressive surgical approach does improve patient survival and neurologic function even when cure cannot be obtained (66).

For sacral lesions, a high sacral amputation is the procedure of choice (64). This combined anterior/posterior sacral approach provides improved outcome with surprisingly little long-term morbidity; as long as the S-2 nerve roots are spared bilaterally, or S-2 and S-3 are retained unilaterally, bowel and bladder function are usually unharmed (22,54). In more proximal tumors, these roots must be sacrificed to obtain local control and a reasonable likelihood of survival.
Decompression

As many as 20% of all patients with disseminated carcinoma develop symptomatic spinal cord compression (12,60). To prevent permanent neurologic injury, the surgeon must recognize and treat spinal cord compression early in its development. Compression may result when an enlarging soft-tissue mass encroaches on cord or nerve roots, or when a pathologic fracture results in retropulsion of bone fragments into the canal, vertebral collapse, or kyphosis. Soft-tissue metastasis to the meninges or epidural space may directly compress neural elements (5,30).

Patients often complain of persistent and progressive back pain, radicular symptoms or “girdle” pain, lower extremity weakness, sensory loss, and bowel or bladder dysfunction. Acute spinal cord compression typically results from rapid tumor growth or pathologic fracture caused by extensive bony destruction. Early treatment is crucial:

- Patients with rapidly progressive paralysis have a poor prognosis for recovery compared to those who develop symptoms over a prolonged period.
- In ambulatory patients, 60% to 95% will retain that function after treatment.
- Only 30% to 65% of paraplegic patients will walk independently after treatment.
- Less than 30% of paraplegic patients will regain ambulation after either surgical or medical treatment (31,38).

Radiotherapy remains the most appropriate treatment for most patients with spinal column metastases. Different tumor types exhibit different levels of radiosensitivity, however, and different clones of the same primary tumor may behave differently as well:

- Prostatic and lymphoreticular neoplasms are typically radiosensitive, and satisfactory local control can be gained through postoperative radiotherapy, even after an intralesional resection (63).
- Gastrointestinal and renal neoplasms, on the other hand, are often unresponsive to irradiation.
- A number of primary tumors (e.g., chondrosarcoma, chordoma) are not radiosensitive, and, consequently, neurologic compromise resulting from these lesions is best treated by operative methods.

The best results are obtained when the surgical approach is properly matched to the compressive lesion: anterior decompression for anterior tumors and posterior decompression for posterior lesions. Using the wrong approach (e.g., laminectomy for anterior compression) provides little benefit and increases complications. For example, laminectomy has shown no added benefit relative to radiation alone in treating anterior spinal lesions, and it can compound problems by introducing or increasing segmental instability in the compromised segment (23,30). Overall, decompressive laminectomy provides neurologic improvement in only 33% of cases, and among the most satisfactory outcomes (maintenance of ambulation and sphincter control) in 37% (45). By comparison, anterior decompression results in 78% improvement and 80% satisfactory outcome in similar patients (Fig. 152.10).

Figure 152.10. Anterior vertebrectomy for metastatic disease. Sagittal (A) and axial (B) MRIs demonstrating extent of an isolated renal cell metastasis involving both L-3 and L-4 vertebral bodies. The lesion probably seeded in one vertebral body, then spread contiguously to the adjacent level. C: Angiography prior to surgery shows blush of neovascularity in the tumor mass just prior to embolization. D: Anterior decompression of radiosensitive tumors begins by resecting the normal bone exposed during the anterior approach, then excising the tumor tissue in as few pieces as can be managed, moving quickly to limit blood loss. E: After removal of the bulk of involved vertebra, meticulous dissection is carried out to remove retropulsed fragments and extruded tumor from in front of the thecal sac, and to curet away all gross tumor from the resection margins. AP (F) and lateral (G) radiographic views, 2 years postoperative. After resection, the anterior column is reconstructed with a strut or cage. The titanium cage selected here is packed with autograft bone because successful treatment may provide this patient with several years of life. An anterior construct stabilizes the spine until the posterior reconstruction, using segmental instrumentation, can be performed.

Reconstruction

Spinal instrumentation and fusion are often needed after tumor resection to restore stability, prevent progressive deformity, and facilitate graft incorporation and fusion. The surgeon must choose an instrumentation construct that (a) can meet the mechanical demands it will face following tumor resection, (b) can compensate for loss of bony elements due to resection or laminectomy, and (c) will permit postoperative imaging with CT and MRI. Key principles to reconstruction are the following:

- Restore or augment the anterior weight-bearing column to prevent vertebral collapse and kyphosis.
- Use posterior instrumentation to provide a tension-band effect after laminectomy, to compensate for lost muscular attachments, and to prevent progressive an intraspinal reconstruction (63).
- Combine anterior and posterior constructs to restore axial, sagittal, and torsional stability after vertebrectomy.
- Anticipate disease progression—extend fixation over longer segments, maximize fixation points, and combine anterior and posterior constructs to ensure construct survival.
- Anticipate patient survival—strive for spinal fusion in patients likely to live more than 3 to 6 months.

Posterior Instrumentation

Distraction instrumentation (Harrington rods) can be combined with sublaminar or Drummond wires to provide segmental fixation in the thoracic spine, but they do not contour well to the lumbar spine and they tend to flatten the normal lumbar lordosis, resulting in a painful lumbar deformity. These systems are inexpensive and are adequate to stabilize thoracic compression fractures. They are not the best choice for cases with extensive bone destruction, however. Rod breakage and hook pullout are common, particularly when applied to patients with combined anterior and middle column insufficiency. These systems are vulnerable to fatigue failure, particularly in tumor patients where perioperative irradiation and systemic disease increase the risk of delayed union, and nonunion.

Luque rods, used in conjunction with sublaminar wires, provide better fixation than the Harrington system in soft bone (14,16). The Luque rods–sublaminar wire system has been used successfully in treating degenerative and neoplastic disease of the cervical, thoracic, and lumbar spine. The system has good stability in torsion and flexion but cannot resist pure axial loads—the sublaminar wires are free to slide down the rod, allowing the instrumented segment to collapse considerably along the axis of the rods.

Newer segmental instrumentation systems are versatile and resilient. They allow the surgeon to neutralize the overall length of the spine while either compressing or distracting the intercylindrical segments involved in the reconstruction. Hook and screw fixation at multiple levels improves fixation strength, and pedicle screws allow fixation to levels where posterior elements have been removed. These systems have superior torsional and sagittal strength and are widely available in titanium, improving postoperative imaging capabilities. These versatile systems also allow the surgeon to address multiple levels of vertebral involvement, restoring normal thoracic kyphosis and lumbar lordosis in the same construct.

Pedicle screw fixation is particularly helpful in patients who have undergone previous laminectomy. They allow the surgeon to minimize the number of segments instrumented, limiting the need to extend fusions to additional levels for support. Combined with an anterior strut, screw-and-rod and screw-and-plate constructs provide sufficient axial, torsional, and sagittal rigidity to allow the surgeon to instrument only two motion segments when treating primary and metastatic lesions of the thoracolumbar spine (47). Screw failure can be expected, however, if the anterior weight-bearing column is incompetent and is not reconstructed (48).
Pedicle screws are most useful in the thoracolumbar and lumbar regions, where pedicles are relatively large and the spinal cord is not at risk. They may prove useful for lower thoracic lesions, as well, by securely anchoring the caudal end of a longer thoracolumbar construct. Use in the thoracic spine is more limited, although some authors have found that screw fixation is an important alternative in patients with extensive laminectomies. Screw-and-plate constructs can be used in the upper thoracic spine to stabilize the cervicothoracic junction, to treat laminectomized segments, and to limit the bulk of instrumentation placed under thin, irradiated soft tissues (Fig. 152.11).

Figure 152.11. A: MRI of T2 metastasis. B,C: Lateral and AP views of screw and plate construct for upper thoracic spine. An alternative to rod-and-hook constructs, low-profile plates may be useful in patients with absent or incompetent posterior elements, or those with tenuous skin following irradiation.

Anterior column reconstruction may be necessary in addition to posterior procedures, or as the primary treatment in some patients. Posterior instrumentation alone cannot provide adequate stability in all cases. When posterior decompression is superimposed on anterior and middle column vertebral collapse, the resulting instability can be severe (15), and untreated anterior column deficiency leads to pedicle screw fatigue and breakage (47,48). Moreover, there is a significant incidence of wound complications associated with posterior surgery. These patients are often systemically ill. Many have undergone regional radiation therapy, have lost muscle mass and subcutaneous fat, and have impaired healing potential. Wound dehiscence, infection, and skin problems are common enough to prompt many surgeons to consider anterior reconstruction as their primary avenue of treatment.

If vertebrectomy is performed, the axial weight-bearing column must be reconstructed. Depending on the situation, the surgeon can choose from bone, polymethylmethacrylate, or a variety of prosthetic struts (Table 152.3).

Table 152.3. Choice of Struts or Spacers for Reconstruction of Anterior Spinal Tumors

Polymethylmethacrylate (PMMA) is frequently used to reconstruct the vertebral column in metastatic disease. It is resilient in compression, but because it has no potential for biological incorporation it has a tendency to loosen and extrude over time.

- Incorporate longitudinal Steinmann pins into the PMMA mass and drive them proximally and distally into the adjacent vertebrae to anchor the spacer and improve its bending resistance (Fig. 152.12). Alternatively, insert Harrington distraction rods or Knodt rods into the vertebrectomy site to distract the defect and anchor the PMMA mass (61).

Figure 152.12. Reconstruction of the anterior column with polymethylmethacrylate.

- Countersink the rod ends into the opposing endplates and distract to restore alignment.
- Apply PMMA in its dough phase to fill the defect.
- Place a Silastic or Gelfoam dam in front of the dura to protect the spinal cord from compression or thermal injury, and wash the PMMA mass constantly with cool saline during polymerization.

A tricortical strut graft or titanium cage with morcelized autograft is favored in the treatment of benign or slow-growing tumors in patients whose survival is likely to be measured in years, and similarly in malignant primaries, where successful treatment will result in prolonged survival.

- Cut tricortical struts from the anterior superior iliac crest, measuring 5–10 mm longer than the defect to be filled. Cut graft with a saw, not an osteotome.
- Key the graft into the vertebral endplates to prevent displacement when the patient is mobilized (Fig. 152.13).
Anterior reconstruction with tricortical graft. A: Anterior vertebrectomy provides a wide defect. Anterior superior iliac crest is harvested and contoured to fill and distract the vertebrectomy defect. B: Graft ends are contoured to articulate with a groove and pit fashioned in the vertebral endplates. C: Graft is impacted into place and locked with a single 6.5 mm cancellous screw.

- To prevent displacement, drive a single 6.5 mm cancellous interference screw into the vertebral endplate just lateral to the graft. This will keep the graft from slipping back out through the keyhole defect.

Titanium cages can be used to supplement either methylmethacrylate or autograft reconstructions.

- Impact the cage into the vertebrectomy defect.
- Sagittal compressive forces will tend to hold the cage in place until anterior or posterior instrumentation can be added.
- Do not penetrate the endplates during cage placement. Do not “key” the cage into place.
- If fusion is intended, pack the graft full of morcelized autograft bone before placing it into the defect. After inserting the cage, place more graft anteriorly to augment the fusion.
- Because the cage provides little torsional rigidity on its own, apply an anterior fixation system to stabilize the spinal construct.

**TREATMENT OF METASTATIC SPINAL TUMORS**

When conservative therapy fails to control metastatic disease, the physician must determine whether surgery is likely to improve the patient’s function, quality of life, or longevity. In cases of severe pain, segmental instability, or neurologic compromise, operative intervention may be indicated.

Patients with an asymptomatic or minimally symptomatic spinal metastasis often do not require surgery. Patients who may require surgery include those with known radioresistant tumors, solitary metastasis with potential for wide resection, unknown tumor type despite systemic workup and needle biopsy, bony compression of neural elements, and mechanical instability and bone destruction.

Patients with mechanical instability and no neurologic deficit need treatment to restore stability and function.

- Treat patients with mechanical instability and neck or back pain with bracing and irradiation, unless other factors dictate surgery.
- Consider surgical reconstruction once bony destruction is advanced.
- If the tumor is radioresistant, stabilize the spine with posterior instrumentation and control tumor growth with adjuvant radiotherapy.
- If the tumor is not radioresistant, or if bony destruction is advanced, perform an anterior/posterior or posterolateral decompression and stabilization, and mobilize the patient early.
- If the patient presents with a solitary metastasis from a tumor with potential long-term survival (breast, colon, prostate, kidney), consider a combined procedure to obtain a wide excision of the lesion. Treat the tumor in the same way as a primary malignancy.

Once the neural elements are involved, the need for direct decompression becomes the primary indication for surgery.

- If the tumor is radiosensitive and neural progression is gradual, radiotherapy is the initial treatment of choice. If progression is rapid, unresponsive to radiotherapy, or secondary to bony as opposed to soft-tissue encroachment, decompress the cord or roots through the most direct approach.
- Use the posterior surgical approach in the cervical spine, above the level of C-3.
- Below C-3, the posterior approach should be limited to lesions of the dorsal elements. Address lesions of the vertebral body successfully through the appropriate anterior approach.
- As an alternative in lesions of the thoracic spine, use a costotransversectomy or transpedicular technique to access the vertebral body and decompress the anterior aspect of the spinal cord (37,38). (Fig. 152.14).

![Image 1](https://example.com/image1)

Figure 152.14. Posterolateral decompression and reconstruction. CT (A) and MRI (B,C) images of a 65-year-old man with T-3 solitary plasmacytoma, cord compression, and incomplete paraplegia. D,E: Endoscopically assisted posterolateral approach allowed complete vertebrectomy and spinal cord decompression. Titanium cage reconstruction and posterior instrumentation through the single dorsal incision provided immediate stability as seen on AP(D) and lateral (E) radiographs. Complete neurologic recovery was facilitated by rapid mobilization and rehabilitation.

Although some authors have been dissatisfied with the decompression allowed through the posterolateral approach (8), the quality of both the decompression and the reconstruction can be improved by employing endoscopic control (Fig. 152.15).

![Image 2](https://example.com/image2)

Figure 152.15. Endoscopically assisted posterolateral vertebrectomy. A: After laminectomy and pedicle resection, the posterolateral aspect of the vertebral body and
TREATMENT OF PRIMARY MALIGNANT TUMORS

In primary malignancies, the principal goal of surgical treatment is local control of the disease. Plan the approach and resection to give the best chance of an adequate resection margin with the least disruption of vertebral stability.

- Treat locally aggressive (aggressive benign and low-grade malignant) tumors rigorously, ensuring a clear margin wherever possible. Because recurrent tumors are more difficult to eradicate than primary lesions, these locally aggressive lesions may become unresectable if not adequately addressed in the first place.
- Resect giant cell tumors en bloc when possible, and check the bone margins for residual tumor.
- Remove curetments if necessary to obtain a clean margin, and consider adjuvant cryotherapy or postoperative radiotherapy to ensure a clean tumor bed (42,55).
- As an alternative to the traditional anterior/posterior approach, consider a posterolateral dissection and vertebrectomy through a T posterior incision (18).

For anterior column tumors, combine an anterior and posterior approach to provide the widest possible margin for local control.

- Embolize the lesion preoperatively to limit blood loss during the procedure.
- Resect the posterior elements and posterior disc first to allow the vertebral body to be removed en bloc through an anterior approach.
- Use a transaxial or retroperitoneal approach to reach the tumor from the front.
- Excise the adjacent discs back to the posterior longitudinal ligament, and remove all anterior soft tissues with the body, developing a plane between the great vessels and the anterior longitudinal ligament.
- Separate adherent tumor from the dura using a Freer elevator as the body is excised. Excise any involved dura and patch the defect with a fascial graft to improve local control.
- Stabilize the spine posteriorly with a segmental system at the time of posterior release.
- Restore the anterior weight-bearing column, filling the vertebrectomy defect with tricortical or fibular graft, or with a prosthetic cage.
- Use anterior plate fixation to augment overall stability.

Once extensive collapse has occurred, as in vertebra plana, a clear surgical margin is not possible, and local control is dependent on adjuvant therapy.

- Perform an intraslesional resection of the vertebral body to debulk the tumor and prepare the vertebrectomy site for anterior reconstruction (40,44).
- Provide an adequate axial strut even when part of the involved vertebra can be retained, because progressive collapse can occur despite successful radiotherapy, leading to intractable pain and potential neural injury.
- In radioresistant tumors such as chordosarcoma or chordoma, make every effort to obtain a clear surgical margin.

Lesions of the sacrum present a particular therapeutic and reconstructive dilemma. A chordoma involving the distal sacrum requires a partial sacral amputation through a combined anterior and posterior approach, sacrificing whatever nerve roots exit the involved segment. For higher sacral lesions, more roots will need to be sacrificed. If the S-2 roots can be spared bilaterally, or if S-2 and S-3 roots are spared on one side, bowel and bladder function should be retained (22). Reconstruction following sacral amputation is most challenging when one or both of the sacroiliac joints is involved (Fig. 152,16).

Patients presenting with a primary spinal tumor and neurologic deficit generally have one of three problems: a pathologic fracture, which may either retropulse bone fragments into the spinal canal or produce kyphosis; extraspineous extension through the posterior vertebral cortex, producing direct compression of the neural elements, or direct extension of the tumor involving one or more nerve roots.

- In every case, the resection margins are likely to be contaminated, and adjuvant therapy is the key to eventual outcome.
- Resect any nerve roots directly involved by tumor along with the primary mass.
- Adherence to or investment of the dura or great vessels is an ominous finding. Consider nonoperative or palliative modalities in these cases.

Once metastasis has occurred, the patient's survival becomes dependent on systemic therapy. Local control is still important to prevent neurologic compromise and pain, but the impetus toward more aggressive and potentially dangerous procedures is reduced. Reconstruct the involved segments carefully, however, addressing both anterior and posterior columns to ensure that late collapse, kyphosis, and pain will not occur.

**Figure 152,16.** AP (A) and lateral (B) radiographs after resection and reconstruction of sacral metastasis. Patient with destructive lesion of the sacral ala, presenting with pain and weakness. Posterior intraslesional resection was followed by reconstruction of the ala with a bicortical iliac autograft contoured to fill the defect and transfixed with transiliac screws. Lumbosacral stability was provided with a short pedicle construct using Galveston-type fixation into the pelvis. This construct is suitable for limited resections such as this, or for more extensive tumors requiring sacrectomy and prosthetic reconstruction.

**AUTHOR'S PERSPECTIVE**

Improved medical and adjuvant therapies continue to enhance cancer survival in patients with both primary and metastatic disease. As patients live longer, metastatic lesions will pose a greater threat to independence and survival, and musculoskeletal lesions will require treatment that provides pain relief and protects function for years rather than months. It is no longer acceptable to assume that the patient with spinal metastasis is near death and beyond help; benign neglect is not benign, and
it is neither fiscally or ethnically conscienciable. Vertebrectomy, considered a radical procedure in the past, is coming to be seen as the conservative approach to tumor management in many situations. Advanced technologies have made aggressive surgery less invasive and dangerous, and improved instrumentation has all but eliminated the prolonged immobilization associated with spinal reconstruction. Appropriate surgical management can have an immediate and dramatic impact on patient function and survival, and it should never be dismissed without consideration.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and *, clinical results/outcome study.

Ankylosing spondylitis and rheumatoid arthritis, although commonly considered together, are two distinct diseases. Ankylosing spondylitis has often been described as “rheumatoid” spondylitis, but it is a different disease with a different serology. It is more common in men than in women and has a predilection for the spine and major joints; rheumatoid arthritis is more common in women and tends to affect smaller joints and the joints of the appendicular skeleton (10,15,16). Clinical manifestations of ankylosing spondylitis occur in 0.2% to 0.3% of the general population.

In ankylosing spondylitis, the major clinical problems of the spine are gross fixed deformities. In rheumatoid arthritis the spine is subject to local destruction and instability. Atlantoaxial subluxation and dislocation may occur in both diseases, however.

ATLANTOAXIAL INSTABILITY

Recognizing atlantoaxial instability in patients with rheumatoid arthritis and ankylosing spondylitis requires careful clinical monitoring. Rheumatoid disease is discussed in greater detail in Chapter 154. In ankylosing spondylitis, a solid column of bone below may place excessive stress at the craniocervical junction. With the attritional effects of inflammation of the transverse ligament and associated hyperemia on its bony attachments, atlantoaxial subluxation and dislocation may occur. With subluxation, the joint may subsequently stabilize in the subluxated position without significant symptoms.

Consider the possibility of significant instability when planning surgery on any patient who might undergo neck manipulation, either by the anesthesiologist or during the surgery itself. Obtain routine flexion and extension lateral radiographs of the cervical spine before performing any such procedures.

POSTERIOR ARTHRODESION OF C1–C2

Surgical stabilization is justified when there is gross symptomatic atlantoaxial instability and the patient is at risk. Stabilization can be effectively achieved by a Gallie-type posterior atlantoaxial arthrodesis (15,19,22,23,25).

- Shape a modified H graft from the iliac crest and contour it to fit over the posterior arches of C-1 and C-2, a stride the spinous process of C-2.
- Pass a single piece of 22-gauge stainless-steel wire inferior to the spinous process of C-2 and through the interspinous ligament of C2–C3. Carry the ends of the wire upward posteriorly to the graft around a notch in its upper border and under the arch of C-1 on each side of the graft.
- Tie the wire ends posteriorly over the graft, fixing it into position and pulling back the arch of C-1 into alignment with the arch of C-2 (Fig. 153.1). Some form of wire tightener is needed, such as that developed by Harris (8). The wire tightener grasps the wire, allowing tension to be applied, so that a knot can be tied firmly in the narrow confines of the wound with only gentle manual pressure (discussed in more detail in Chapter 154).

Figure 153.1: A: Skeletal model showing deep cancellous surface of Gallie modified H-graft, which is contoured from the posterior iliac crest to fit over the posterior arches of C-1 and C-2, a stride the spinous process of C-2. B: Posterior view showing the graft in position with cortical surface superficially. Pass the Gallie wire through the interspinous ligament of C2–C3 below the spinous process of C-2, upward over the graft on each side. Bring it out below the arch of C-1 laterally and tie it firmly posteriorly. C: Lateral view showing the position of the modified H-graft, with the wire pulling back the C-1 vertebra into a normal relationship with the odontoid. The inferior portion of the wire passes below the spinous process of C-2 through the interspinous ligament of C2–C3, which should be preserved during exposure and wiring because it assists in maintaining the wire in position until it is tightened. D: Posterior view of model showing the configuration of the wire without the graft in position.

TRANSORAL DECOMPRESSION

In the few instances when the odontoid is causing major anterior pressure that cannot be reduced, transoral resection of the odontoid may be required. This procedure is more hazardous than posterior decompression and stabilization; if the instability is recognized earlier, the procedure will be less frequently required. Transoral surgery is reserved for patients with significant anterior compression.

Two different types of abnormality can be differentiated: In the first, basilar invagination is present without gross instability, and in the second there is additional atlantoaxial instability and luxation. Posterior column involvement also may be evident in the second type, caused by posterior compression of the spinal cord by the posterior arch of C-1, which slides anteriorly.

Pure basilar invagination with narrowing of the anterior cerebellomedullary cistern is the primary indication for transoral decompression. Decompression may involve the removal of not only the odontoid process, but also the body of C-2 and the space-occupying portion of the clivus. In cases of pure atlantoaxial instability, a stable posterior atlantoaxial arthrodesis is preferred. Results of primary anterior decompression combined with simultaneous anterior fusion are not encouraging, and it would appear preferable to perform a posterior fusion as a secondary procedure following a primary anterior decompression.
Before surgery, identify and clear any evidence of oral infection or dental sepsis. Obtain nasal, oral, and pharyngeal swabs for bacterial culture and sensitivity, and administer the most appropriate antibiotic combination before surgery, intravenously during surgery, and in the immediate postoperative period.

Operative Technique

- Position the patient supine for surgery, with the neck extended. Lateral radiographic control is necessary. Some recommend routine tracheostomy and endotracheal anesthesia. However, the endotracheal tube is not an obstacle at surgery, and in some ways it is best to leave the airway intact.
- In patients who do not have a tracheostomy, place a gastric tube for postoperative nutrition, with normal oral nutrition beginning 7–8 days after surgery. If tracheostomy is indicated, perform it at the beginning of the operation with ventilation continued through a cuffed tracheal tube.
- After preparation of the oral cavity, introduce a Whitehead retractor and depress the tongue. Pack off the nasopharynx and hypopharynx.
- The procedure can usually be done without division of the soft palate. Fold the soft palate back on itself and suture it to the junction of the hard and soft palates to expose the lower portion of the nasopharynx. Release these sutures at the end of the procedure (Fig. 153.2).

Figure 153.2. Diagram of transoral exposure. Use two stay sutures to fold the soft palate on itself and keep it in position. Incise the posterior pharyngeal wall vertically.

- If division of the soft palate is considered necessary, incise it on one side of the midline to avoid the uvula, and retract the flaps laterally (Fig. 153.3).

Figure 153.3. Exposure showing incision of the soft palate on one side, avoiding the uvula.

- Palpate the posterior pharyngeal wall to locate the prominence of the anterior tubercle of the atlas. In atlantoaxial dislocation, it is quite evident.
- Make a 2-inch midline incision from the lower portion of the clivus to the lower portion of C-2.
- Center the incision one finger breadth below the anterior tubercle of the atlas.
- Carry the incision down to bone.
- Strip the soft tissues laterally to the outer margin of the lateral masses of the atlas and axis. The soft tissues may be anchored with retraction stay sutures.
- Expose the anterior arch of the atlas and the body of the axis.
- Remove the anterior arch of the atlas with sharp rongeurs and expose the odontoid (Fig. 153.4).

Figure 153.4. A: Anterior exposure of the atlas and axis with the soft tissues stripped laterally. B: Excision of the anterior arch of the atlas allowing exposure of the odontoid.

- Remove the odontoid process with a high-speed drill and a diamond burr.

Removal of the odontoid process, which is displaced upward and projects backward, is the most complicated part of the surgery.

- Carefully and gently free the odontoid of its soft-tissue attachments, using sharp dissection as necessary.
- If resection of the odontoid is difficult because of its elevation and the angle of approach, commence the resection in the central part of the body of the axis.
- Remove the lower portion of the clivus (anterior margin of the foramen magnum) only when necessary; when it is required, I recommend a diamond burr and upward-cutting bone forceps.
- If lateral fusion of the C1–C2 joint is to be attempted, clear the articular cartilage from the joints and wedge iliac grafts between the lateral masses.
- Close the posterior pharyngeal wall.

Some authors recommend a multilayer closure involving the anterior ligament, the buccopharyngeal fascia and constrictor muscles, and the pharyngeal mucosa. Many, however, recommend a loose, single-layer closure because it allows wound secretions to drain more easily and it has technical advantages. Defer oral feedings 6–7 days to allow adequate healing; introduce liquids before solids. See Chapter 138 and Chapter 154.

ATLANTO-OCCIPITAL DISABILITY

Occasionally in ankylosing spondylitis, severe disability may arise from destructive changes at the atlanto-occipital joint. Destructive changes may produce intractable pain associated with minimal persisting motion, justifying surgical stabilization. On occasion, subluxation or even rotatory deformity can occur, which may warrant gradual reduction with halo traction followed by stabilization with occiptocervical fusion.

OCCIPITOCERVICAL FUSION

I prefer to use double-cortical and cancellous onlay iliac grafts fixed to the base of the skull and the upper cervical spine, reinforced by multiple cancellous bone grafts. The onlay grafts are contoured to fit over the posterior arches of the upper cervical vertebrae (usually down to C-4), the cancellous surface of the graft being contoured...
Figure 153.5. Occipitocervical Fusion: A: Posterior operative view showing double onlay cortical and cancellous iliac grafts. B: Operative view showing additional onlay cancellous bone grafts, which reinforce the main grafts and extend from the cervical spine to the skull. C: Postoperative lateral radiograph showing a solid fusion extending from the occiput to the cervical spine. The wiring passes through the skull. Compere wires fix onlay grafts to the posterior arches of the cervical spine. D: Postoperative anteroposterior radiograph demonstrating the configuration of the wire loop, Compere wires, and grafts.

- Postoperative immobilization in a well-fitted halo cast is essential to protect the area of fusion from abnormal stress.

SPONDYLODISCITIS

Erosion and sclerosis of bone adjacent to the sacroiliac joints is a typical radiographic feature of ankylosing spondylitis. This erosive, sclerotic process may occasionally extend into the intervertebral disc and adjacent bone, and it is then called spondylodiscitis. Such lesions were first reported by Andersson in 1937.

Two opposing views exist as to the nature of these lesions. The first view is that spondylodiscitis is an inflammatory process affecting the intervertebral disc and surrounding bone. Detailed assessment and biopsy specimens support this view. The second, less commonly held view is that spondylodiscitis is secondary to trauma with excessive forces localized at one intervertebral segment, resulting in mechanical destruction and a functional pseudarthrosis.

The radiographic appearance is fairly typical. The erosive process widens the disc space, breaking down the subchondral bony plates. The surrounding bone becomes sclerotic and radiodense. The prominence of either erosion or sclerosis varies. Spondylodiscitis has a reported incidence of 5% to 6% in ankylosing spondylitis. Most of the lesions develop in the lower thoracic spine. A little more than half the lesions are discovered on routine radiographic studies and are asymptomatic.

About half the patients with spondylodiscitis present with back pain.

The lesion generally follows a benign course and usually responds to conservative management. Surgical stabilization may occasionally be required for intractable pain, particularly when there is an associated fracture or disruption of the posterior fused spine resulting from loss of bony substance anteriorly. If the lesion presents with intractable pain and no deformity, as in the mid-thoracic spine, then anterior resection and strut grafting may be indicated. The involved disc space and adjacent eroded bone are resected, and fibular or iliac strut grafts are fixed into the defect in a keystone fashion. Supplemental rib and iliac grafts are added as necessary.

When the lesion is painful, it is most often in the lower thoracic spine—an area subject to shear stress—with increasing deformity shifting the weight-bearing line anterior to the lesion, causing further erosion and increasing pain. In my experience, successful handling of this lesion requires correction of the overall spinal deformity. In my experience with more than 20 patients with this problem, the lesion has healed following resection–extension osteotomy of the mid-lumbar spine, shifting the weight-bearing line posteriorly, and changing the direction of the area of spondylodiscitis to horizontal, thus converting the shear force to a compression force. This outcome is preferable to multiple anterior and posterior procedures, which have a higher failure rate when the overall deformity is not corrected, and which do not alleviate the shear stress.

Figure 153.6. Lateral radiograph showing the typical lesion of spondylodiscitis in the lower thoracic spine (the most frequent location). Erosive sclerotic changes involve the vertebral endplates adjacent to the disc space.

Figure 153.7. A: A 58-year-old man had severely painful spondylodiscitis at T12–L1, which resulted in an increasing flexion deformity of the thoracolumbar spine. B: A lateral radiograph of T12–L1 shows gross destructive spondylodiscitis at the apex of the deformity. C: A lateral standing 3-foot radiograph shows the weight-bearing line to be anterior to the area of spondylodiscitis, producing shear stress on the lesion. D: A standing lateral 3-foot radiograph after an extension osteotomy of the mid-lumbar spine shows that the weight-bearing line has been shifted posteriorly, converting shear force to compression force at the site of the spondylodiscitis. E: A lateral radiograph at T12–L1, 4 months after surgery, shows spontaneous healing of the area of spondylodiscitis as a result of the conversion of shear stress to compression. F: The patient following healing of the osteotomy and area of spondylodiscitis. The extension osteotomy of his lumbar spine corrected his deformity and allowed spontaneous healing of the spondylodiscitis.
The incidence of spondylodiscitis may be greater than previously suggested. In my review of 124 patients referred for surgical correction of spinal deformity for whom radiographs of the entire spine were available for study, 28 (23%) were found to have spondylodiscitis. When the lesion was in the area of the deformity and contributed to it, correction of the deformity resulted in fusion at the site of the spondylodiscitis (20-24).

FLEXION (KYPHOTIC) DEFORMITIES OF THE SPINE

Severe flexion deformities of the spine may occur in patients suffering from Marie-Strümpell spondylitis or ankylosing spondylitis associated with psoriasis. Prevention of deformity by early recognition and appropriate medical care should be the aim. Despite improvements in medical care, however, patients still present with gross disability from advanced kyphotic deformity of the trunk.

The indications for surgical correction vary with the extent of deformity, the degree of functional impairment, the general condition and age of the patient, the feasibility of correction, and, perhaps most important, the willingness of the patient to accept the risks and undergo the reconstructive and rehabilitative measures required for correction.

CLINICAL ASSESSMENT

If any major correction is to be obtained, surgery must address the area of involvement. For example, a patient with apparent spinal deformity actually may have a major deformity in the hip joints. If a hip flexion deformity is the cause of the patient's malalignment, then it should be corrected through surgery on the hip joints. Also, accurate assessment and measurement of any deformity are required to gauge the results of treatment. The most effective and reliable measure of a spine flexion deformity is the chin-brow-to-vertical angle. It is a measure of the angle formed by a line from the brow to the chin through the vertical, when the patient stands with the hips and knees fully extended, and the neck in its neutral or fixed position (Fig. 153.8).

KYPHOTIC DEFORMITY OF THE LUMBAR SPINE

Kyphotic deformity of the lumbar spine was the first type of deformity corrected surgically in arthritic disease, as reported by Smith-Peterson et al. in 1945 (26). The initial procedure was done under general anesthesia with the patient lying prone. Difficulties with the prone position were later avoided by performing the surgery with the patient on the side, as recommended by Adams (1).

Some have recommended a two-stage or double-exposure procedure with surgical division of the longitudinal ligament anteriorly. I do not find it necessary: Correction can be achieved through the posterior approach alone.

A major complication of lumbar osteotomy is gastric dilatation and abdominal ileus. As the spine is extended, the superior mesenteric artery is stretched over the third part of the duodenum, predisposing to gastric dilatation. A nasogastric tube must be in position after surgery until intestinal motility is established.

A review of the literature until 1969 indicated a mortality rate of 8% to 10% with this procedure; some degree of neurologic deficit, including paraplegia, occurred in up to 30% of patients. Two thirds of the deaths were related to the use of general anesthesia. As a result, I used my experience in cervical osteotomy, as well as the recommendations of others, to perform surgical correction of lumbar flexion deformity with a resection–extension osteotomy under local anesthesia. From the 1970s to the early 1990s, I used this method in a series now totaling 100 patients. Generally, correction under local anesthesia has proved to be a safe, reliable, and practical procedure (19,21,23). The main advantage of local anesthesia is that it allows a critical assessment of the patient's neurologic and vital functions throughout the operation.

Over the past 10 years, there have been substantial improvements in anesthesia, including fiberoptic intubation and spinal cord monitoring. The risks of surgery under general anesthesia have decreased; therefore, today I use general anesthesia following the strict guidelines that will be discussed later.

Resection–Extension Osteotomy at L3–L4

The primary deformity of patients selected for lumbar extension osteotomy is in the lumbar spine and loss of lumbar lordosis. There may be some associated increase in thoracic kyphosis, which can be balanced by overcorrecting the lumbar deformity so that the chin-brow-to-vertical angle will be normal. This angle is measured and transposed to a lateral radiograph of the lumbar spine, placing the apex of the angle at the posterior longitudinal ligament over the L3-L4 disc space. The L3-L4 level is selected for correction because it is the center of the lumbar lordosis and is below the spinal cord. The L4-L5 level is used only on rare occasions.

Do a careful preoperative evaluation, including medical assessment, pulmonary function tests, and electrocardiography. Instruct the patient in deep breathing and extremity exercises, which will be used postoperatively. Psychological preparation includes explaining to the patient the procedure and the importance of awake intubation and positioning, prior to inducing general anesthesia. Make plaster molds of the upper and lower halves of the body before surgery. The upper half extends from the waist up, supporting the chest and head; the lower half extends from the waist to the knees. These shells are used for support when the patient is turned prone after the correction is done. The molds protect the face and allow the anesthesiologist to administer oxygen by face mask through the opening in the shell (Fig. 153.9).

Figure 153.8. Technique for measuring the degree of flexion deformity of the spine in ankylosing spondylitis. The chin-brow-to-vertical angle is measured from the brow to the chin to the vertical, with the patient standing with hips and knees extended and the neck in its fixed or neutral position.

Figure 153.9. A: Cephalad and caudal anterior molds. The cephalad mold supports the head and has an opening for the face. B: Postoperative view. After correction of deformity, the patient is supported in the prone position by the anterior molds with a jack below the upper mold. Note the restoration of lordosis with correction of the
In planning the osteotomy, it is important to know whether the patient has normal spinal canal dimensions. If the patient has a canal of normal or above-average size, then less bone may be removed posteriorly with closer approximation of the laminae. However, if the canal dimensions are fairly small (less than 20 mm on the anteroposterior diameter) or in the stenotic range, then considerably more caution must be taken to ensure that the posterior decompression is generous, particularly superiority. In this situation, it is best to leave the central laminectomy area open significantly above and below to avoid any compression from postoperative edema, buckling of the dura, or minimal translation. Some indication of adequate canal size may be noted on a lateral view of the spine; patients with large foramina and long pedicles have a greater canal size than those in whom the foramina appear small and the pedicles short. If a narrow canal is suspected, make accurate computed tomography (CT) canal measurements.

My method is based on the original technique by Smith-Petersen et al. (26). They described a posterior wedge resection of the mid-lumbar spine in a V fashion. This resection was carried superiorly and laterally through the superior facet of the vertebra above and the inferior facet of the vertebra below in an oblique fashion. More bone was resected superiorly than inferiorly. The oblique plane of the osteotomy was designed to produce overlap of the posterior elements following correction, in an effort to prevent displacement. Since the deformity was corrected by manipulation of the spine after the posterior resection was completed, the anteriorly longitudinal ligament was fractured. This technique is the basis for the procedure described next.

- Have your neuromonitoring technician apply the spinal cord monitoring electrodes and confirm that the spinal cord monitoring is satisfactory.
- Have the anesthesiologist stimulate the patient while he is awake and lying on the gurney on which he was brought into the operating room. When the endotracheal tube is in position, ask the patient to stand (with assistance) and transfer to a suitable spinal OR table with his knees and hips flexed. Adjust the supports to provide comfortable positioning for his head, chest, and pelvis, avoiding any strain on his neck. Ask him to give an OK signal with his hand when he is comfortable, and then induce general anesthesia (26).
- Compared to our previous use of local anesthesia only, general anesthesia makes the posterior bony resection easier to perform. It is much easier to undercut the pedicles above and below the area of resection, and a more complete decompression of the L-3 nerve roots is possible.
- Prepare and drape the back.
- The general anesthesia can be augmented by infiltration of the skin and the paraverterbral muscles with 0.5% bupivacaine with 1:200,000 epinephrine. This will reduce somewhat the level of general anesthesia required and provides some hemostasis.
- Make a midline exposure and confirm the proposed L3–L4 osteotomy site radiographically with towel clips placed on the base of the spinous processes at the level of the laminae of L-3 and L-4.
- I now routinely use pedicle screw fixation; therefore the next step is the insertion of the pedicle screws prior to the performance of the osteotomy. The number of levels of fixation required depends on bony quality, but usually I place screws in the pedicles of L-1, L-2, L-3, as well as L5 and S-1 (Fig. 153.10A).

![Figure 153.10](image1)

**Figure 153.10.** Resection-Extension Osteotomy, L3–4: A: The osteotomy is planned to completely decompress the thecal sack in the midline, with symmetrical lateral resections extending cranially and laterally. Pedicle screw insertion sites are identified, and screws may be placed prior to osteotomy. B: Following decompression, the Smith-Peterson osteotomy provides two wedges of posterior bone that will lock together when the spine is placed in extension. Relieve the undersurface of the laminae to prevent impingement as the spine is extended into its reduced position. C: Closure of the osteotomy by extension of the spine. Pack resected bone and autograft posterolaterally over the transverse processes and dorsal cortex of the osteotomy. Place the fixation rods into the screws and compress the osteotomy site, locking the wedges together to ensure stability and reliable arthrodesis.

- Next, perform a V-shaped wedge resection osteotomy at the interlaminar space, as recommended by Smith-Petersen et al. (26), resecting the ossified ligamentum flavum and adjacent laminae.
- Extend the resection upward and laterally on each side through the fused posterior joints at L3–L4. The amount of bone to be removed posteriorly is measured from the radiograph at the level of the tips of the spinous processes, the laminae, the posterior aspect of the posterior joints, and inside the canal at the level of the pedicles. The obliquity of this resection allows locking of the vertebrae following correction.
- Remove the spinous processes in small strips to be used for grafting. Remove the bone with bone cutters and rongeurs.
- A power burr may be a useful tool for cutting slowly through the fused posterior elements toward the spinal canal, which is opened. The ossified ligamentum flavum is harder and denser than the vertebral elements.
- Protect the dura with cotton paddles. In many instances, the dura is atrophic and occasionally it may adhere to the laminae, making separation difficult.
- Completely expose the dural sac laterally on each side to the level of the pedicles.
- Undercut the laminae above and below to avoid impingement on the dura following extension. Undercut the pedicles to avoid any impingement on the third lumbar nerve roots following extension.
- Remove bone from each side symmetrically, to allow symmetrical closure of the defect (Fig. 153.10B).
- When the osteotomy is completed, correct the kyphotic deformity by extending the hips with the adjustments of the spine table. This will produce an anterior osteotomy wedge and allow correction with closure of the posterior osteotomy. Perform this maneuver gently and carefully, constantly watching the neuromonitoring for any evidence of compromise of neurologic function, and close the osteotomy down to obtain good posterior bone apposition (Fig. 153.10C).
- Full correction must be obtained with the weight-bearing line shifted posterior to the osteotomy site, so that gravity will maintain and increase the correction as it heals; it will also stimulate bone formation across the osteotomy sites of the resected posterior fusion masses (Fig. 153.11).
- Complete the stabilization by fixing the rods to the pedicle screws using TSRH instrumentation (Sofamor-Danek, Memphis, TN).

![Figure 153.11](image2)

**Figure 153.11.** A: Lateral view of a patient standing with hips and knees extended. This patient still had mobility of his cervical spine and was compensating with the neck hyperextended. When the neck was in the neutral or comfortable position, he had a chin-brow-to-vertical angle of 45°. B: Lateral radiograph of lumbar spine showing the chin-brow-to-vertical angle superimposed with the apex at the L3-4 disc space. The amount of bone to be resected is indicated at each depth posteriorly. C: Postoperative lateral radiograph following correction under local anesthesia showing the angle of correction obtained after closure of the resected defect posteriorly with an opening osteoplastis at L3-4 of 48°. The weight-bearing line has been shifted posterior to the osteotomy site. D: Postoperative standing lateral radiograph showing complete correction of the deformity after removal of a calculated wedge of bone based on preoperative assessment.
segmental instrumentation and Drummond buttons and wires. The advantage of internal fixation with segmental instrumentation was that it decreased the risk of translation and allowed earlier postoperative mobilization (Fig. 153.12). I now prefer pedicle screw and rod fixation with the decompression technique just described, as it allows easier and more liberal decompression; the rigid internal fixation decreases the risk of displacement and allows easier and quicker mobilization of the patients, who seem to have less postoperative pain. The disadvantages of pedicle screw and rod fixation are increased operating time, and increased risk of neurologic injury from improper insertion of bone screws because of the altered anatomy of the pedicles. Overall, however, I feel that the advantages outweigh the disadvantages, as illustrated by the patient in Figure 153.13.

![Image](72x888 to 272x1029)

Figure 153.12. Postoperative lateral radiograph showing Luque instrumentation in position using Drummond buttons and wires, which add stability to the osteotomy. A rectangle is usually used and is bent to the desired angle of correction at the time of insertion. The use of Drummond buttons avoids the necessity to invade the spinal canal, the insertion being done under local anesthesia.

![Image](72x1140 to 272x1281)

Figure 153.13. A: This 41-year-old man with a 21-year history of ankylosing spondylitis has had a major kyphotic deformity for 10 years, with a chin-brow-to-vertical angle measuring 55°. He has been unable to work for about 6 years. B: Lateral standing 3-foot radiograph of the spine shows a thoracic kyphosis of 75° and a decreased lumbar lordosis of 16°. The weight-bearing line is well anterior to the mid-lumbar spine. C: Preoperative lateral radiograph of the lumbar spine shows the planned resection/osteotomy of 50° to 55° located at L3–L4. D: This lateral standing 3-foot radiograph, taken 16 months postoperatively, shows the healed lumbar osteotomy with pedicle screw fixation and rods in place. The lumbar lordosis now measures 74°; the thoracic kyphosis is approximately 70° and the spine is in balance. The weight-bearing line is posterior to the osteotomy site. E: The patient 16 months after surgery. He returned to a normal lifestyle. (From White AH, Schofferman JA. Spine Care: Operative Treatment, vol.2. Philadelphia: Mosby, 1995:1678, with permission.)

- Strip the spine further lateral to the osteotomy site, exposing the transverse processes of L-3 and L-4. Divide the autogenous bone removed during the resection into equal portions and place it posterolaterally on both sides, creating an adequate fusion mass.
- Close the wound with suction drainage.
- When the patient is still prone after wound closure, apply a well-molded posterior plastic shell, before transfer to a Roto-rest bed. The shell must be rigid and the contour of the spine must be maintained with adequate support under the pelvis, so that the rounded hump of the thoracic spine is not pushed forward in relation to the lumbar spine as the patient rests in the supine position (Fig. 153.14). The posterior shell is necessary to support the patient adequately when the Roto-rest trap door is removed for use of a bedpan.
- Continue nasogastric suction until the patient is expelling flatus. About 7–10 days after surgery, when the patient is comfortable, he is lifted to an orthopaedic table in the posterior shell. Partly suspend the patient by the lower portion of the shell while the upper portion and sides are trimmed away, and then immobilize him in a well-molded plaster jacket. Take care in transferring and supporting him during application of the jacket, to avoid any loss of position.

Postoperative Care

Results and Complications This technique, with Luque instrumentation and performed under local anesthesia, was used in 100 patients between 1969 and 1993 without major intraoperative difficulty. Satisfactory correction was achieved, with restoration of normal functional alignment. There were no major respiratory complications and there was no pneumonitis in the series. Three nonunions occurred, one in a patient without internal fixation who subsequently responded to posterior instrumentation and fusion. In one patient, the fusion site appeared to be united, but a fracture of the osteotomy site was sustained in an automobile accident, requiring anterior strut-grafting. In a third patient who had severe osteopenia, union was not achieved and subsequent anterior strut-grafting with allograft and autogenous bone was performed.

One female patient who was on oral contraceptives suffered a sudden fatal pulmonary embolism 15 days after surgery, at which time she had been ambulatory in a plaster jacket. Eight patients developed L-3 root or cauda equina compression within 2 to 14 days after surgery; all except two compressions occurred in patients in whom internal fixation with segmental instrumentation was not used. In one of these, the compression was thought to be vascular in nature—he was an obese patient (about 300 pounds) who developed vena caval compression from thrombosis with neural venous stasis.

Management problems contributing to other cases of compression included patients slipping during the course of turning on a Circoelectric frame, the removal of the trap door on a Roto-rest bed with the patient not supported in a posterior shell, and in one patient, manipulation on a table for cast application. In most of these, estimates of canal dimension had not been done and in retrospect were probably on the low side. In most of these patients, the osteoclasis occurred through the body.
of L-2 rather than through the disc space, and this would appear to be a risk factor.

In certain instances when the ossification at the disc is considerably greater than at the vertebral body, selected preliminary anterior L3–L4 disc division might be considered, but I have not done this. Patients who presented with these problems were promptly reexplored and further decompression was carried out (usually superiority), with the spine stabilized by internal fixation in the form of Luque instrumentation and Drummond buttons. On the whole, this prompt treatment allowed satisfactory recovery.

In my experience, if the correction is complete and the weight-bearing line is shifted posterior to the osteotomy site, fusion will occur with a 97% success rate and the correction will be maintained. Our results using pedicle screw fixation under general anesthesia are equally good.

Resection–extension osteotomy of the lumbar spine is a reasonably safe, practical, and reliable procedure in this high-risk type of patient. This technique allows a greater degree of correction of purely lumbar spinal deformity, in that it produces more hyperextension at the osteotomy site than can be obtained with multiple anterior and posterior osteotomies using compression instrumentation (either Harrington or Ziete) of the thoracolumbar spine. The range of osteotomy correction in our patients was from 40° to 104° (average, 56°). The preoperative chin-brow-to-vertical angle varied from 35° to 134° (the latter was in a patient with associated hip deformity), with an average of 60°. The postoperative chin-brow-to-vertical angle ranged from –5° to +15°, with an average of +15° (Fig. 153.15).

**Alternative Approach to Lumbar Osteotomy and Stabilization**

The technique presented in this section was contributed by Dr. Isadore Lieberman.

The “eggshell” closing wedge osteotomy is an alternative to the opening wedge technique just described. In this approach, carry out the dorsal osteotomy and decompression as described, but complete the anterior correction through the posterior approach by removing the vertebral pedicles, and by decancellating and collapsing the vertebral body to correct the sagittal alignment. Then stabilize corrected segments with a pedicle screw fixation construct.

- Position the patient prone as described, and use the routine midline longitudinal dorsal approach to the thoracic and thoracolumbar spine.
- Begin by removing the spinous processes and laminae over the L2–L3 interspace, cutting a wedge-shaped defect posteriorly.
- Isolate and remove the pedicles and transverse processes of L-2, carefully resecting the pedicles until they are flush with the back of the vertebral body.
- Working through the pedicles, use curets and pituitary rongeurs to break up and remove the cancellous bone from within the vertebral body.
- Use curved curets or a burr to remove cancellous bone from between the pedicles and along the dorsal cortex of the body.
- Take care not to breach the anterior cortical wall.
- Place pedicle screws at adjacent levels before attempting the final correction.
- Use a blunt impactor to fracture the posterolateral cortex of the body, then score the dorsal cortex with an osteotome and implode it into the vertebral body cavity, away from the thecal sack.
- Slowly hyperextend the operating table, or bring the patient’s legs into extension to collapse the dorsal aspect of the vertebral body and close the dorsal osteotomy.
- Instrument the spine from L-4 to the thoracic spine and graft for fusion (Fig. 153.15).

![Figure 153.15](image)

**KYPHOTIC DEFORMITY OF THE THORACIC SPINE**

A degree of thoracic kyphosis is common in spinal deformity associated with ankylosing spondylitis. It is much less common for the only deformity or primary deformity to be in the thoracic region, requiring the correction to be confined to that area.

Patients with thoracic kyphosis can be classified into two groups (19, 21, 23). In the first group, the main or primary deformity is in the thoracic spine, but in addition there is a loss of lumbar lordosis. If the thoracic kyphosis is mild or moderate and the lumbar spine rigid and flattened, the overall deformity can be satisfactorily corrected by a compensatory osteotomy in the midlumbar spine. With sufficient extension of the lumbar spine, the thoracic kyphosis can be compensated for with restoration of spinal balance and a normal chin-brow-to-vertical angle.

Patients in the second group have thoracic kyphosis with normal or exaggerated cervical and lumbar lordosis. These patients require correction of the primary thoracic deformity. It is impossible to do this safely with a single major angular correction. Correction of purely thoracic deformity requires multiple anterior and posterior intervertebral osteotomies, instrumentation, and grafting.

Patients who have thoracic kyphosis with normal cervical and lumbar lordosis can be further subdivided into two subgroups, depending on the rigidity of the thoracic spine. In the first subgroup, with incomplete ossification of the thoracic spine or extensive areas of destructive spondyloidesis, preliminary correction can be obtained by halo-dependent traction; this is followed by multiple posterior resection osteotomies and compression instrumentation with second-stage anterior resection of the areas of spondyloidesis and the disc spaces, with supportive strut-grafting (Fig. 153.16).

![Figure 153.16](image)
Approach the thoracic spine through a right-sided thoracotomy with removal of the rib at the level of the apex of the deformity in the midaxillary line.

Reflect the pleura and resect the ossified disc spaces completely from right to left, anterior to the posterior longitudinal ligament. Thoroughly cure the disc spaces and pack them with autogenous bone, using portions of the removed rib supplemented by iliac crest bone where necessary.

Apply halo-dependent traction after surgery.

Perform the second-stage procedure about 7–10 days later using a posterior approach. Perform multiple V-shaped resection osteotomies at each level, resecting the ossified ligamentum flavum and adjacent portions of the laminae upward and outward on each side through the intervertebral foramen, removing enough bone to allow adequate correction following closure.

Apply bilateral segmental compression instrumentation, gradually closing the osteotomy sites and correcting the deformity (Fig. 153.17).

Figure 153.17. A: Lateral view of a 34-year-old woman with rigid thoracic kyphosis and normal lordosis of the cervical and lumbar spines. The patient had lost 5 inches in height. B: Anterior view of the patient showing restricted field of vision with rib impingement on the pelvis. Pulmonary function was reduced to 54% of predicted normal. C: Preoperative standing lateral 3-foot radiograph of the spine showing thoracic kyphosis of 110° with normal lumbar lordosis. D: Lateral radiograph of the cervical spine showing normal or increased cervical lordosis. E: Operative view showing anterior transverse resection of the ossified disc spaces completely through, from one side to the other. F: Operative view showing rib grafting of resected ossified disc spaces. G: Operative view showing multiple posterior V-shaped osteotomies, which were followed by bilateral posterior Harrington compression instrumentation with fusion. The ossified ligamentum flavum has been resected at each level, passing upward and laterally through the fused posterior joints. The margins are undercut before the compression instrumentation was performed. H: Postoperative standing 3-foot radiograph showing correction of major deformity with restoration of normal spinal alignment. I: Postoperative lateral view of patient showing correction of the thoracic kyphosis with the ribs being lifted out of the pelvis. J: Postoperative anterior view of the patient showing restoration of normal field of vision.

**HINTS AND TRICKS**

- Perform multiple osteotomies in the thoracic region so that correction at any one level is minimal, yet the cumulative effect allows substantial improvement.
- Anterior and posterior osteotomies with interval traction produce some of the correction while the patient is awake, reducing neurologic risk.
- Place the posterior instrumentation using spinal cord monitoring to allow reasonable correction in a critical area with greater safety.
- The technique of multiple, two-stage anterior and posterior osteotomies with posterior instrumentation is the obvious choice for primary thoracic deformity with a normal cervical and lumbar lordosis.
- Resection-extension osteotomy of the mid-lumbar spine is ideal for purely lumbar kyphosis with a normal or reduced thoracic kyphosis.

Despite the feasibility, multiple anterior and posterior osteotomies under general anesthesia in two procedures are more hazardous than a single-stage extension correction of the lumbar spine under local anesthesia. Tracheostomy, with its attendant problems, may be required in the management of patients with kyphotic deformity. However, where the primary deformity is thoracic with a normal lordosis above and below, these risks must be accepted if the deformity is to be corrected.

Although Harrington, Zielke, and Cotrel-Dubousset instrumentation systems have been used in the past, current segmental instrumentation systems offer more reliable correction and fixation. I favor the TSRH system, which provides a variety of pedicle-screw fixation options that allow the surgeon to tailor the instrumentation construct to the individual. Other systems are available that provide similar features. The surgeon should be well versed in the technical features of any selected instrumentation before undertaking this sort of reconstruction.

- In kyphosis procedures, place pedicle screws above and below the selected level before performing the osteotomy.
- Use fluoroscopy or plain radiography to confirm position and alignment during placement. I use spinal cord monitoring in all patients done under general anesthesia, and I stimulate the screws to confirm safe placement during instrumentation.
- After the osteotomy is completed, extend the patient's hips until the osteoclasis occurs, then place contoured fixation rods into the screws and fix them in place.
- Pack milled bone graft along the lateral gutters and across the osteotomy site. Place a well-molded plaster shell over the patient's back before rolling him off the operating table. This will prevent excessive pressure over the dorsal kyphosis in the immediate postoperative period, and it will be converted to a plaster cast when abdominal distension resolves.

**KYPHOTIC DEFORMITY OF THE CERVICAL SPINE**

In a few patients with ankylosing spondylitis, flexion deformity of the spine occurs primarily in the cervical region. This deformity can be severely disabling, with restriction of the field of vision, and it may progress to the point where it interferes with opening of the mouth. Surgical correction is fraught with hazard. Anecdotal reports of isolated attempts to correct this deformity under general anesthesia indicate a high rate of disastrous complications including death.

For the few severely afflicted patients with this type of deformity, it is important that the surgeon clearly understand the principles related to its possible correction and its indications. Over the past 30 years, I have routinely used a technique of correction under local anesthesia that has allowed a consistent, satisfactory, and somewhat dramatic correction with relative safety (5, 6, and 7).

**Diagnosis of Fracture**

Not all patients with a "chin-on-chest" deformity in ankylosing spondylitis require cervical osteotomy, as the underlying problem is fracture. Those who present with a recent onset of a painful flexion deformity often do not require osteotomy, as, again, an underlying problem is fracture. In fact, any patient with ankylosing spondylitis whose deformity has been relatively unchanged over time and who has had little pain, who then experiences painful, progressive flexion deformity after minor trauma, has a fracture of the cervical spine until proven otherwise. The fracture is usually at the base of the neck at the cervicothoracic junction. Unfortunately, the pain is often attributed to the patient's disease.

A fracture of the spine in ankylosing spondylitis resembles a fracture of an osteoporotic tubular bone, with a transverse shear pattern. The fracture is difficult to recognize radiographically, being obscured by the shoulders, and it may vary in its location from C-6 to T-2, although most commonly it is in the area of C-7 or T-1. The fracture undergoes gradual erosion, causing compression and collapse anteriorly, with the chin approaching the chest. The patient is aware that the position of the head varies during the day, being more elevated on waking in the morning and dropping more toward the chest after being ambulatory during the day. The patient may...
It is important to diagnose this fracture using lateral tomography at the cervicothoracic junction. Patients with this fracture do not require cervical osteotomy. Apply a cranial halo and initiate traction along the line of the deformed neck. Then slowly restore normal alignment under careful observation until the head is restored to its normal functional position. It is usually possible to obtain a fairly normal chin-brow-to-vertical angle, after which place the patient in a well-molded halo cast for 4 months. The halo cast is essential: A halo vest does not provide adequate immobilization.

The craniocervical junction is the other area of the cervical spine where lesions may occur that cause painful flexion deformities. Destructive arthritis at the atlanto-occipital joint may cause the patient to flex the neck at this joint with the chin held downward, while the lateral radiograph of the cervical spine shows a relatively normal lordosis. Correct this by graduated halo traction to restore a normal chin-brow-to-vertical angle, followed by posterior stabilization, usually with occipitocervical fusion and, where necessary, excision of the posterior fragmented arch of C-1.

**Cervical Osteotomy under Local Anesthesia**

Unrecognized and untreated fractures at the base of the cervical spine ultimately heal, at which time the pain disappears, leaving the patient with a painless, fixed flexion deformity. At this stage, osteotomy is required for correction.

Of those patients for whom I have performed cervical osteotomy, 36% have shown evidence of previous cervical fracture. In 31%, the fracture contributed significantly to the spinal deformity. In only 15% of those who presented with evidence of fracture had the fracture been diagnosed previously. This experience underscores the fact that early recognition of the fracture and adequate immobilization are essential if the risk of further deformity is to be avoided.

**Preoperative Considerations** Determine the amount of bone to be resected from preoperative radiographs. Measure the chin-brow-to-vertical angle and transpose it to a lateral radiograph of the cervical spine with the apex of the angle at the posterior margin of the C7–T1 disc space. A lateral tomogram probably will be necessary to show this clearly. Center the angle over the posterior arch of C-7. The amount of bone to be resected is determined from the radiograph with the angle superimposed over the spinous processes, the laminae, the posterior margin of the facet joints, and the posterior margin of the spinal canal at the level of the pedicles. The lines of resection are beveled upward at the superior margin and downward at the inferior margin. Following correction, the two surfaces will be parallel and in apposition.

One or two days before surgery, fit the patient with a rigid plaster or fiberglass body jacket incorporating the supports for the halo unit. The jacket must be rigid and made of a material that will not soften with body heat. It must be very skillfully contoured to the patient's trunk so that it cannot slide up or down. It must be molded under the rib cage and the sides of the chest to prevent it from going upward, and over the pelvis and iliac crests to prevent it from moving distally.

A commercial plastic halo jacket is inadequate for the postoperative immobilization required for these patients. In most instances, because the spine is completely solid above and below the area of osteotomy, a flexible jacket creates excessive forces that tend to cause movement at the osteotomy site with almost any activity. If the patient is not rigidly immobilized, he will have extreme distress when trying to get in or out of bed or to move about. Excessive mobility can even result in some neurologic compromise with irritation of the C-8 nerve root. Apply the jacket and test it carefully with the patient up and about to make certain that it is well contoured and secure; do this far enough before the surgery that there is time to make any necessary adjustments. Fit a halo to the skull preoperatively under local anesthesia in a stable position, below the maximum circumference of the skull.

**Operative Technique** As Urist (27) has recommended, perform the operation under local anesthesia with the patient in the sitting position. Use a dental-type chair, so that the patient can be placed in a recumbent position if necessary. Having the patient awake avoids any major anesthetic hazards, and allows accurate monitoring of neurologic and other vital functions. The patient can assist with anatomic localization of the level during the decompression by indicating at any time any paresthesias or discomfort along the distribution of a cervical nerve root. This ability is of real value in confirming the location of the C-8 nerve root canal and the level of the root.

Perform the excision posteriorly with subsequent fracturing and extension of the spine at the cervicothoracic junction. The preferred level for correction is between C-7 and T-1 (Fig. 153.18), because, as Mason et al. (11) and Urist (27) have indicated, this interspace is more receptive to surgical treatment than any other level of the cervical region. The advantages are many:

- The spinal canal is relatively wide.
- The cervical cord and C-8 nerve root have reasonable mobility in this area.
- Any weakness caused by compromise of the C-8 nerve root results in less disability than with other roots.
- The vertebral artery and veins usually pass in front of the transverse process of C-7 and enter the transverse foramen at the sixth vertebra.
- The position of these vessels above the level of T-1 protects them from injury during osteotomy at the C7–T1 level (Fig. 153.19).

![Figure 153.18](image1.png)

**Figure 153.18.** Diagrammatic posterior view of the area of resection for cervical osteotomy. Bevel the margins of the resection of the lateral fused joints slightly away from each other extending posteriorly, so that after correction the two surfaces are parallel and in apposition. Undercut the pedicles significantly to avoid impingement of the C-8 nerve root. Apply the angle and test it carefully with the patient up and about to make certain that it is well contoured and secure; do this far enough before the surgery that there is time to make any necessary adjustments. Fit a halo to the skull preoperatively under local anesthesia in a stable position, below the maximum circumference of the skull.

**Figure 153.19.** Lateral anatomic diagram showing the normal passage of the vertebral arteries and veins in front of the transverse process of the seventh vertebra, entering the transverse foramen at the sixth vertebra. (Simmons EH. Surgery of the Spine in Rheumatoid Arthritis and Ankylosing Spondylitis. In: Cruess RL, Mitchell NS, eds. Surgery of Rheumatoid Arthritis. Philadelphia: Lippincott, 1971, with permission.)
Identify the last bifid spinous process, which is usually C-6. Compare the architecture of the lower cervical spinous processes using a lateral radiograph of the cervical spine. If you encounter any difficulty in anatomic localization, obtain radiographic confirmation of the level.

- Remove the C-7 spinous process, the inferior spine of C-6, and the superior spine of T-1 in strips and preserve them for grafting. Remove the entire posterior arch of C-7 along with the inferior half of the arch of C-6 and the superior half of the arch of T-1 (Fig. 153.20).

**Figure 153.20.** Lateral diagrammatic outline of the area of posterior resection at the C7–T1 level. The shaded areas represent where the pedicles are undercut to avoid nerve root impingement after extension correction.

- Open the spinal canal. Protect the dura and spinal cord with cotton patties.
- Extend the decompression laterally on each side beyond the lateral margin of the spinal cord to the level of the pedicles. Undercut the laminae above and below the decompression to avoid impingement following extension correction.
- Identify the C-8 nerve root and pass a curved probe into its canal. The patient may be able to assist in confirmation of the level by indicating the distribution of any paresthesias associated with displacement of the root. Extend the resection through the fused area of the posterior joints of C7–T1, decompressing the C-8 nerve root completely.
- Expose the inferior aspect of the pedicles of C-7 and the superior aspect of the pedicles of T-1.
- Cut the pedicles through in a curved fashion away from the C-8 root, leaving a shell to protect the nerve root while the main bone is removed; the shell is removed at the completion of the nerve root decompression. This is done to undercut the pedicles above and below adequately, so that after the extension correction, there will be a bony recess for the eighth nerve root to avoid impingement or a pincer effect.
- Follow the nerve root laterally, and remove all bone that could impinge on it.
- Resect the lateral masses completely through from medial to lateral so that there is no remaining bridge of bone laterally that could interfere with extension correction (Fig. 153.21A).

**Figure 153.21.** A: Posterior operative view showing midline decompression with resection of lateral masses, decompression of C-8 nerve roots, and undercutting of pedicles. B: Posterior operative view of wound after anterior osteoclasis and extension correction. The lateral masses have come together posteriorly on each side. The wound has been transformed from a vertical configuration to a transverse one.

- Insert the deep closing sutures and a suction drain before the osteoclasis is done.
- Have the anesthesiologist give supplemental oxygen during the procedure, either by nasal catheter or face mask. The patient is allowed to listen to music from a radio or tape recorder. This is an important part of the anesthetic management, along with a continuing, cheerful conversation between the anesthesiologist or an attendant and the patient. When this is done well, the amount of discomfort or concern expressed by the patient can be minimized.
- Complete the decompression. The patient is given a small dose of a short-acting barbiturate, such as brevitol.
- When the anesthesiologist indicates the sedation is effective, extend the neck by grasping the halo firmly and tilting the neck backward. An audible snap may be heard and a physical sense of fracture will be appreciated.
- Extend the neck until resistance occurs. The lateral masses can be palpated as they come together posteriorly on each side (Fig. 153.21B).
- The patient is allowed to awaken almost instantly and can confirm normal neurologic function of the extremities.
- Hold the head firmly in the corrected position while an assistant stabilizes it by connecting the anterior supports for the halo unit to the cast.
- Avoid overcorrection, particularly in patients with a rigid cervical spine and no compensatory movement at the occipitocervical junction. The final position should effect a compromise for the patient between looking ahead for walking and being able to work at a desk (Fig. 153.22).

**Figure 153.22.** A: Posterior view of a male patient with a severe rigid flexion deformity of the cervical spine. His head is not visible from the posterior aspect. B: Lateral view of the patient showing marked restriction of the field of vision. His chin is rigidly fixed against his chest, interfering with his ability to open his mouth. C: Anterior view showing complete restriction of his field of vision. D: Lateral view of the cervical spine showing ossification of posterior joints with previous subluxation of C6–C7. E: Postoperative lateral radiograph of the cervical spine showing extension–resection osteotomy correction. F: Postoperative anterior view of the patient in a halo cast, showing return of his normal field of vision. G: Postoperative lateral view of the patient after union of the osteotomy, demonstrating return of normal chin-brow-to-vertical angle. H: Postoperative posterior view of the patient demonstrating return of normal head–trunk configuration.

- Place the bone that has been removed during the course of the decompression posterolaterally on both sides over the apposed lateral masses; do not place it in the midline over the exposed dura.
- Tie the deep sutures after extension correction, and complete the wound closure.

Excessive force is not required to straighten the neck if there has been an adequate and complete decompression posteriorly. If the spine does not fracture readily, check to be sure there is not a bridge of bone remaining laterally and that the correct level has been operated on.

Although full correction is usually obtained at the initial procedure, correction of a severe deformity is sometimes limited by tightness of the anterior musculature, or by the patient's apprehension that the deformity is going to be overcorrected. In this case, most of the correction can be established at the time of surgery, with further correction added 7–10 days later by adjustment of the halo-jacket. By this time, the soft tissues will have had an opportunity to stretch and the patient will have had an opportunity to assess the amount of correction that has been achieved. With the patient supine under diazepam and fentanyl sedation, the head may be supported by...
the surgeon, and the attachments for the halo released, and the neck allowed to extend to obtain full correction.

Postoperative Care Place the patient on a ciro-electric bed during the immediate postoperative period. It allows the patient to be brought to a vertical position fairly easily, to stand and walk about and then return to the recumbent position without difficulty. When sufficiently mobile to get in and out of a regular bed, the patient is transferred to a hospital bed with or without a trapeze attachment. Immobilize the patient in a halo cast for 4 months, then remove the cast and perform careful radiographic studies, including lateral tomography centered at C7–T1. When there is radiographic evidence of union and clinical evidence of stability and no pain, remove the halo. Have the patient wear a skull-occup-mandibular immobilizer (SOMI) brace for at least 2 more months or until it is certain that there is solid union, clinically and radiographically.

Results and Complications I have used this technique consistently without any major deviations over the past 20 years in a total of 130 patients. The results have been exceedingly satisfactory, with a minimum of complications, considering the nature of the deformity and the associated disease process. Nonunion occurred in four patients (3%). Three of these responded to anterior cervical fusion at the C7–T1 level with an iliac crest graft. The fourth patient required not only anterior cervical fusion, but also posterior segmental instrumentation and fusion to obtain solid union. Transient neurologic complaints occurred in 16 patients, including 13 patients with transient C-8 paresthesias, one with Horner’s syndrome, one with mild central cord syndrome 2 weeks after surgery, and one with transient paresis of the ninth and tenth cranial nerves thought to be secondary to traction. All of these cleared spontaneously without treatment. Five other patients had persistent C-8 nerve root deficits; one of these underwent further decompression, with subsequent improvement. All improved with minimal residual signs and no gross functional handicap.

There has been no major permanent injury to the spinal cord. One dramatic intraoperative experience demonstrates the necessity for surgery performed under local anesthesia. A 70-year-old man had a severe flexion deformity accentuated by an unrecognized fracture that had healed in such a way that his chin rested on his chest. On posterior decompression, dense scarring was noted about the dura related to the previous fracture. As the spine was decompressed in the midline, the patient suffered increasing weakness of his lower limbs and had difficulty with speech.

The dura was exceedingly tense with dense scarring about it. In view of this tension, it was split longitudinally down to the arachnoid. As this was done, there was an immediate, dramatic return of neurologic function in the lower extremities, and the patient’s speech returned to normal. The operation was continued and as the decompression was being completed on both sides, he again developed weakness of his lower extremities. The remaining exposed dura was split further distally, again with immediate recovery of neurologic function. The operation was completed without any further difficulty and the patient went on to a satisfactory result without neurologic deficit.

This observation is in keeping with McKenzie and Dewar’s report (13) describing the results of laminectomy for cord compression associated with kyphoscoliosis. They related the compressive effect of the dura to the kyphosis and recommended that the dura be spilt both longitudinally and transversely. Surgeons undertaking this type of surgery should be familiar with this recommendation. If this problem should occur during surgery, adequate splitting of the dura should be done longitudinally and transversely. When incising the dura, take care not to violate the arachnoid; cerebrospinal fluid leakage is thus avoided. If leakage should occur, it can be stopped with a sheet of Gelfoam or a free fat graft.

No major intraoperative problems were noted immediately following the osteoclasis. However, a sudden cardiac arrest occurred in one patient toward the end of the decompression. The chair was flattened and the patient responded to resuscitation without late sequelae. The cause of this arrest remains unknown. Air embolism is a possibility with surgery in the sitting position, and a doplar is now routinely used over the chest and care is taken to control venous bleeding.

One 79-year-old woman suffered a fatal pulmonary embolism 21 days after surgery; her lungs showed multiple previous areas of subclinical embolism. Another patient suffered a fatal pulmonary embolism before the osteotomy was done. Autopsy revealed multiple thrombi in his leg veins, with evidence of previous pulmonary infarctions. Other complications have been related to the age of the patient and associated disease processes, including one nonfatal pulmonary embolism, a perforated peptic ulcer, and myocardial infarction.

Considering the age and medical risk factors of these patients, the results and complication rates compare favorably with any other type of major reconstructive procedure in a similar group of patients with the same disease process. These patients have an increased tendency for peptic ulceration. Considering the lethal nature of any intra-abdominal catastrophe in these patients, who breathe entirely with the diaphragm, I now place all patients routinely on cimetidine.

In this series of patients the average desired angle of correction was 60°. In 15 patients, cervical osteotomy was combined with lumbar osteotomy for major deformity in both areas; the procedures were performed either on separate admissions or during the same hospitalization. When you plan to repair severe deformity in both areas during the same admission, do the cervical osteotomy first, followed by lumbar osteotomy 1–2 weeks later. Both procedures are done under local anesthesia (Fig. 153.23).

Figure 153.23. A: Anterior view of a 43-year-old woman suffering combined neck and lumbar flexion deformities with severe restriction of field of vision. She had suffered arthritic disease since her teens. B: Lateral view demonstrating severe flexion deformity of the cervical spine combined with flexion deformity of the lumbar spine. Patient had undergone total hip replacement arthroplasties with some residual hip flexion deformity. C: Composite lateral radiograph showing combined neck and lumbar flexion deformities. D: Lateral radiograph of the cervicothoracic spine showing the plan of the extension osteotomy. E: Postoperative lateral tomogram showing resection–extension osteotomy at C7–T1. F: Planned resection–extension osteotomy of the flattened lumbar spine, which was performed after cervical osteotomy. Both procedures were performed under local anesthesia. G: Standing lateral 3-foot radiograph of the spine showing cervical and lumbar extension osteotomies. The weight-bearing line is shifted posterior to the lumbar osteotomy site. H: Postoperative anterior view demonstrating normal field of vision. I: Postoperative lateral view showing complete correction of spinal deformities with restoration of normal chin-brow-to-vertical angle.

Rheumatoid involvement of the articulations of the cervical spine is extremely common among patients with rheumatoid arthritis. Estimates of frequency vary. Conlon et al. (15) documented radiographic changes in the cervical spine for 85% (283 of 333) of patients with classic rheumatoid arthritis. While the majority of such patients do not develop significant neurologic deficits, identification of those at high risk of neurologic compromise remains a difficult clinical problem.

The three primary patterns of instability due to rheumatoid involvement of the cervical spine are referred to as atlantoaxial instability, cranial settling, and subaxial instability. Clinically relevant radiographic measurements associated with the risk of neurologic compromise have been described for these instability patterns (4). In addition, advanced radiographic techniques such as magnetic resonance imaging (MRI) allow a more precise determination of spinal cord compression.

Surgical indications have historically included significant neurologic compromise, intractable pain, or both. As the concept of impending neurologic compromise has been defined, the selection of patients at risk for neurologic injury for surgical stabilization has also improved. Given the uncertainty of recovery once significant neurologic deficits are present, early stabilization of the unstable rheumatoid cervical spine appears to improve the outcome for these patients. In addition, continued developments of surgical and anesthetic techniques have facilitated their management.

PATHOPHYSIOLOGY

The involvement of synovial articulations by rheumatoid arthritis is well described. The response to immune complex (IgG and antibodies to IgG) deposits in the articular cartilage and synovium of involved joints includes proliferation of fibrovascular tissue, known as pannus. Examination of these tissues shows the presence of chronic and acute-phase inflammatory cells, including lymphocytes, plasma cells, and macrophages. The persistent inflammation leads to cartilage loss and bony erosion, as well as ligamentous laxity. In addition, the rheumatoid disease process per se leads to diffuse osteopenia. Chronic steroid use may contribute to these ligamentous and osseous changes as well.

The cervical spine is susceptible to involvement with rheumatoid arthritis because of the large number of articulations and their significant mobility. The subaxial facet joints and intervertebral discs as well as the ligaments and bursae of the cervical spine are all potential locations of involvement (10,25). The most common clinical involvement, however, includes the atlanto-occipital, the atlantoaxial, the periodontal, and the zygoapophyseal (facet) joints.

Historically, the patterns of instability described in rheumatoid patients are anterior atlantoaxial instability, cranial settling, and subaxial instability (Fig. 154.1) (16,43,54). In addition to these patterns, other observed instability types have included posterior instability of the atlas, subaxial dislocation, and rotation and lateral subluxation of the atlas (4,42,43) and (46,52,70).

Figure 154.1. Patterns of cervical spine instability due to rheumatoid arthritis. A,B: Atlantoaxial instability. C: Cranial settling. D: Subaxial instability.

The primary concern with all patterns of cervical involvement is the development of neurologic compromise due to compression of the spinal cord and nerve roots. This compression can arise as a dynamic phenomenon due to the instability, or it can be secondary to a mass effect caused by fixed vertebral subluxations or pannus formation. In addition, deficits can arise that are attributable to compromise of vascular supply at the level of either the anterior and posterior spinal arteries or the vertebral arteries themselves (19,21,56).

Patterns of neurologic involvement can include radiculopathy, myelopathy, and cranial nerve compromise. The most common radicular complaint is suboccipital headache due to irritation of the second cervical nerve root by atlantoaxial degeneration or instability (14,43). Radiculopathy can also produce motor weakness due to disc collapse or instability in the subaxial spine. The symptoms of myelopathy are hyperreflexia and spasticity, with or without motor weakness. The Ranawat classification of neurologic compromise has been widely used in published reports of rheumatoid patients. Normal patients are considered grade I, patients with paresthesias and hyperreflexia but without motor weakness are grade II, and patients who demonstrate motor weakness constitute grade III. Grade IIIA describes ambulatory patients, and grade IIIB is used for nonambulatory patients (43).

Motor compromise resulting from spinal cord involvement may be asymmetric, and it may show greater involvement of the upper extremities. Cruciate paralysis (of Bell) develops in some patients, with a striking lack of weakness in the lower extremities but profound involvement of the upper extremities due to medullary compression at the pyramidal decussation of upper extremity motor fibers (3,65). Cranial nerves, particularly the lower cranial nerves such as cranial nerve IX (involving the gag reflex), can also be compromised, especially in patients with cranial settling. Finally, respiratory paralysis may also occur with upper cervical involvement, sometimes with fatal results (16).

DIAGNOSTIC EVALUATION
Neurologic examination of patients with rheumatoid arthritis can be notoriously difficult because of the effects of extremity contracture, deformity, pain, and inflammation, as well as weakness from muscle wasting and mechanical loss of function. A high index of suspicion in patients complaining of neck and occipital pain or new extremity weakness or loss of function is therefore important. Descriptions of an electric shock sensation with head and neck motion (Lhermitte’s sign) should also arouse suspicion.

Begin diagnostic imaging with cervical spine plain radiographs, including an open-mouth odontoid view and lateral flexion–extension views. These films may disclose osteopenia, erosion of the atlantoaxial and subaxial facet joints, or erosion of the odontoid process itself. While plain radiographs do not directly demonstrate synovial pannus or spinal cord compression, much indirect information may be gained, such as the presence of bony instability.

Atlantoaxial instability is measured from lateral flexion–extension cervical spine radiographs. Historically, instability was measured as the change in the anterior atlantoaxial interval (AAI) (Fig. 154.2). Posterior displacement greater than 3 mm of the dens relative to the anterior ring of the atlas is considered abnormal. Displacement ranging from 6 to 10 mm has been considered an indication for surgery, even in patients without neurologic abnormalities (14,15,27,43,51).

A better radiographic measurement for predicting spinal cord compromise due to atlantoaxial instability is the posterior atlantoaxial interval (PAI). Also referred to as the space available to the cord, the PAI is measured from the posterior aspect of the dens to the anterior edge of the posterior ring of the atlas, along the transverse axis of the ring of the atlas (Fig. 154.2). Boden et al. (4) demonstrated that a PAI of less than 14 mm correlated with a significant risk of neurologic impairment, and that the PAI was a better predictor of not only the development of neurologic compromise but also the potential for neurologic recovery.

Numerous landmarks for measurement of cranial settling have been described (Fig. 154.3A). Chamberlain’s line runs from the posterior foramen magnum to the hard palate. Wackenheim’s line is drawn tangent to the cranial surface of the clivus. McGregor’s line runs from the lowest point of the occiput to the hard palate. McRae’s line extends between the basion and the posterior edge of the foramen magnum. For the projection of the dens above McGregor’s line, 4.5 mm is considered the upper limit of normal (12-29).

They found normative values for this distance of 17 mm in men and 15 mm in women. This measurement has the advantage that visualization of the dens and skull base is not required.

Redlund-Johnell and Patterson (46) measured the distance from the base of the axis to McGregor’s line (Fig. 154.3C). Less than 34 mm in men or 29 mm in women indicates cranial settling. The Sakaguchi-Kauppi method involves determination of the station of the medial aspect of the superior facet of the axis relative to the anterior ring of the atlas. These authors (29) felt that their method was easier to apply than the Redlund-Johnell method, and that it had the advantage of not relying on visualization of the skull base or odontoid tip.

Computerized tomography (CT) evaluation of the cervical spine provides excellent detail of the bony structures. Erosion of the dens and facet joints is much better demonstrated on CT images than on plain radiographs (6). In addition, fractures of the dens may be diagnosed with this modality.

Sagittal reconstructions based on CT scans are important not only diagnostically, but also in some cases for surgical planning. Posterior atlantoaxial arthrodesis using transarticular screws requires sufficient width of the cervical two-vertebral isthmus to allow passage of a 3.5 mm screw (33). In addition, sclerosis and erosion of the posterior ring of the atlas are requisite for arthrodesis with conventional atlantoaxial wiring techniques and thereby require atlantoaxial screw fixation or extension of the arthrodesis to the occiput (14). There can be problems even with these techniques, however, when there is significant bone loss.

Magnetic resonance imaging has become the best imaging modality for evaluation of neurologic compromise; use it to evaluate any patient who has neurologic weakness or spasticity (7,30-31). MRI provides enhanced definition of soft tissues and can demonstrate spinal cord compression from pannus at the atlantoaxial articulation. Recently, use of dynamic flexion–extension MRI views has been recommended for preoperative planning in patients with neurologic compromise (34).

Patients for whom neurologic compression is not relieved by maximal reduction of the atlantoaxial articulation may be candidates for posterior decompression either by removal of the posterior rim of the foramen magnum and laminectomy of the atlas, or by anterior resection of the odontoid.

Sensory impairment in patients with rheumatoid arthritis has been demonstrated with somatosensory evoked potentials and cutaneous electric stimulation, both peripherally and in the trigeminal nerve distribution (52). While such techniques may confirm neurologic impairment, they are not widely used by orthopaedic surgeons or neurosurgeons for diagnosis or treatment planning, although they may have expanded roles in the future.

**NATURAL HISTORY**

It is clear that as a direct result of cervical spinal instability, some patients with rheumatoid arthritis develop severe neurologic impairment with profound motor deficits,
occasionally leading to respiratory paralysis and death. It is also clear that once neurologic deficits develop, there is no universally successful means of regaining lost function. Unfortunately, our understanding of which factors predict neurologic progression remains incomplete (12).

Several investigations of the natural history of rheumatoid involvement of the cervical spine have been reported (16,40,43,51,52,55,62,63). Conlon et al. (16) provided an early estimate of the incidence of cervical instability in an unselected group of 333 rheumatoid patients. Plain radiographs disclosed atlantoaxial subluxation in 84 (25%) of their patients, while an additional 23 (7%) demonstrated subaxial subluxation. Although cervical instability was statistically correlated with the severity of peripheral disease, no correlation was found with duration of disease or use of steroid medications. Although 23 patients (7%) demonstrated symptoms of spasticity, the authors did not feel that these findings correlated with the presence of cervical instability.

Smith et al. (55) reviewed 130 rheumatoid arthritis patients with significant atlantoaxial instability but without neurologic compromise at the time of initial radiographs. They reevaluated 84 surviving patients an average of 7.8 years after the initial examination. Four patients (3%) had developed spinal cord compromise, while an additional six (5%) described symptoms of transient weakness. Of the 84 (74%) surviving patients, 62 had been maintained on chronic oral steroid medication, which appeared to correlate with radiographic progression of instability. No effect of cervical instability on long-term survival could be demonstrated.

Winfield et al. (62,63) followed 100 patients prospectively with annual flexion-extension radiographs. Over an average of 7 years' follow-up, they documented that 12 patients (12%) developed atlantoaxial instability, 8% developed subaxial instability, and 3% developed cranial settling. All the patients who developed instability demonstrated onset of subluxations within 2 years of diagnosis with rheumatoid arthritis. By an average of 9 years and 5 months' follow-up, one patient had developed myelopathy and two had undergone posterior cervical fusion for severe occipital headache (3%). These authors also demonstrated a significant correlation between the presence of severe peripheral erosive disease and cervical spine involvement.

Santavirta et al. (51) described the progression of symptoms in 16 patients with 8 mm or greater atlantoaxial instability or cranial settling. They compared disease progression in these patients with a group of 18 surgically treated patients with a comparable degree of radiographic instability but more significant neurologic symptoms. Although this was not a randomized study, they found that none of the operatively treated group had worsening of their neurologic status, and 8 of 14 (57%) who had had preoperative neurologic deficits showed improvement. Postoperative complications were relatively minor. In the nonoperatively treated group, however, 7 of 14 surviving patients (50%) suffered neurologic worsening. A further report on this patient group documented progression of cranial settling in 12 untreated patients, three of whom developed neurologic progression (52).

Pellici et al. reported prospective data on 106 rheumatoid arthritis patients with initial complaints of cervical pain over a 5-year period (60). They noted neurologic progression in 27 of 85 surviving patients (36%) and radiographic progression in 60 (80%). Seven patients had undergone surgical intervention by the end of the study secondary to severe neurologic involvement. Only two patients underwent spontaneous fusion of the atlantoaxial articulation, one of whom subsequently developed subaxial subluxations (Fig. 154.4). They also found that patients without radiographic changes at the time of their initial complaints did not develop significant instability over the 5 years of the study.

Figure 154.4. An adverse natural history. A,B: Flexion-extension lateral radiographs obtained in 1991 demonstrate significant atlantoaxial instability, although the patient was neurologically normal. Significant erosion of the dens was already present, allowing posterior displacement of the ring of C-1 in extension. C,D: Six years later, a fixed posterior subluxation of C-1 has developed. Subaxial subluxation is also present. The patient at this time was quadriparalytic and unable to ambulate (Ranawat IIIIB). E: A sagittal view from an MRI scan demonstrates cord compression at both the atlantoaxial and subaxial levels. This patient would likely have benefited from an atlantoaxial arthrodesis at an earlier stage.

Boden et al. (4) described 73 patients followed for an average of 7 years, 42 of whom (58%) developed neurologic compromise. These authors demonstrated the importance of the PADI as a predictor for neurologic injury (Fig. 154.2). They noted that a reduction of the PADI below 14 mm, or a reduction of the spinal canal diameter below 14 mm in the subaxial cervical spine, was correlated with an increased prevalence of nonreversible neurologic deficit. They also demonstrated an increased risk of neurologic deficit in patients with atlantoaxial subluxation combined with cranial projection of the odontoid of 5 mm or greater above McGregor's line.

PERIOPERATIVE MANAGEMENT

Medical management of rheumatoid arthritis continues to improve. Many patients are now maintained on methotrexate or other nonsteroid medical regimens, with steroid use limited to short-duration bursts for flares of the rheumatoid disease. The effect of this shift in treatment patterns on the progression of cervical instability is not known.

Patients with rheumatoid arthritis who are scheduled for other operative procedures requiring general anesthetic should undergo cervical radiographic evaluation with dynamic flexion-extension lateral views. Patients with neck pain but without significant instability can be treated with pain medication and a cervical orthosis. While orthotics may provide symptomatic relief, they neither slow the disease process nor provide significant additional stability, and these patients should be followed for possible progression of their disease (1).

Airway and pulmonary management is a significant concern in surgical patients with rheumatoid arthritis. Patients undergoing multiple-level anterior cervical spine procedures and those with severe neurologic compromise should be considered for elective tracheostomy (27). If a tracheostomy is not likely to be necessary, patients may need to remain intubated postoperatively for an additional period of time. All other rheumatoid patients should be considered for fiberoptic intubation (14). This has been demonstrated for all neurologically vulnerable patients, and a reduction in postoperative airway complications in rheumatoid patients undergoing fiberoptic intubation has been demonstrated (59).

Preoperative skull traction has been recommended for patients with cranial settling or subluxations that do not reduce on voluntary flexion-extension lateral radiographs. Traction for 24–48 hours has proven useful, with most reductions occurring within this time (38). Extended periods of traction probably do not improve reduction and should generally be avoided because of the preexisting physical weakness of many patients with rheumatoid arthritis and the rapid physical deterioration that occurs with extended bed rest. Halo-wheelchair traction provides traction while allowing the patient to be upright.

Postoperative immobilization must be tailored to the individual patient's needs. Historically, several means of immobilization have been used ranging from skull traction or a halo cast to a cervicothoracic or hard cervical orthosis (14,16,27,43,65). Halo-bracing is generally well tolerated by rheumatoid patients, perhaps because of their lower physical demands. The advantages of reducing the risks of hardware failure and nonunion in this patient population probably outweigh the easier mobility afforded by less aggressive bracing.

Evaluate the patient's suitability for cervical spine surgery before deciding on a specific surgical plan; pay attention to the patient's activity level, expectations, and overall health status. Preoperative evaluation should include pulmonary, cardiac, and renal testing. Patients with longstanding, severe neurologic injury and patients with limited pulmonary or cardiac reserve should be considered for nonoperative management.

OPERATIVE TREATMENT AND RESULTS

ATLANTOAXIAL ARTHRODESIS

Indications for atlantoaxial arthrodesis include neurologic compromise demonstrated by spasticity or motor weakness (Ranawat II or III), impending neurologic instability (Ranawat I), and/or atlantoaxial instability (Fig. 154.4) occurring with extended bed rest. Halo-wheelchair traction provides traction while allowing the patient to be upright. Although the neurologic deficit may have improved, these patients may still have atlantoaxial instability (Fig. 154.4). This a
compromise as demonstrated by spinal cord compression on MRI or a PADI of 14 mm or less on plain films, and intractable occipital headache with demonstrated atlantoaxial degeneration or instability. If preoperative reduction in cranial traction is insufficient to allow spinal cord decompression, consider a laminectomy of the atlas, and enlargement of the foramen magnum as well, which usually requires extension of the arthrodesis to the occiput.

A number of methods of posterior atlantoaxial arthrodesis have been described. Historically, posterior wiring techniques have been very successful in other patient populations but have had significant nonunion rates in patients with rheumatoid arthritis. In addition, atlantoaxial wiring techniques require availability of the posterior ring of the atlas. Recently, the technique of transarticular screw fixation has improved fusion rates and can be performed with laminectomy of the posterior ring of the atlas. However, risks of neurologic and vascular injury with this technique are still being evaluated, even if it should not be used when reduction of the atlantoaxial facets cannot be achieved. A CT scan with sagittal reconstructions to evaluate the position of the vertebral arteries is a prerequisite for this technique.

Brooks and Jenkins (8) described their wedge compression method of bone grafting and sublaminar wiring as an alternative to Gallie’s (22) midline wiring and demonstrated fusion in 12 of 13 patients (Fig. 154.5A, Fig. 154.5B). They had less success in patients with rheumatoid arthritis, however, describing one patient who developed nonunion and a second who suffered an intraoperative fracture and required extension of the arthrodesis to the occiput. Clark et al. (14) modified this technique by using a single, larger piece of corticocancellous bone graft (Fig. 154.5C). They reported a bony fusion rate of 75% in a series of 20 patients with rheumatoid arthritis, with an additional two patients achieving stable fibrous union (Fig. 154.6).

Bryant et al. (9) described the use of polymethylmethacrylate (PMMA) as part of a longer arthrodesis construct from the atlas to the subaxial spine in a series of five patients with either prior nonunions (two patients) or combined atlantoaxial and subaxial subluxations (three patients). Two of these patients progressed to nonunion, and a third patient developed a wound infection and fistula. Because of this higher incidence of wound problems, as well as reports of bone lysis, PMMA is not longer recommended as a supplement to cervical fixation (37).

Moskovich and Crockard (39) described results with an interlaminar clamp in a series of 25 patients (Fig. 154.5D). While the overall fusion rate in this series was 80% (20 of 25), the rate for rheumatoid arthritis patients was only 73% (11 of 15). This technique thus seems to offer little improvement over wiring techniques with respect to fusion rate, although it may be neurologically safer than sublaminar wires for patients with severe stenosis.

Since Magel and Seemann (30) described posterior transarticular screw placement for atlantoaxial stabilization and arthrodesis, this technique has been given increasing attention (Fig. 154.5E). Grob et al. (42) described their experience with transarticular 3.5 mm screws supplemented with midline wiring in a series of 161 patients, including 51 with rheumatoid arthritis. They achieved a 99.4% fusion rate at an average of 24 months. Although no symptomatic vertebral artery injuries were reported, there were five postoperative deaths, three in patients undergoing simultaneous transoral odontoid resection.

The case of injury to the vertebral artery or other structures due to screw malposition continues to be evaluated. Madawi et al. (35) reported an 87% fusion rate in 61 patients (37 rheumatoid patients) using transarticular screw fixation. They reported that 14% of screws were malpositioned with an 8% (5 of 61) rate of vertebral artery injury, although only one patient was symptomatic. These authors also described anatomic measurements on 25 cadaveric C-2 vertebrae, demonstrating an insufficient diameter of the pars interarticularis to accommodate a 3.5 mm screw in 20% of individuals. Recently published survey data from 847 neurosurgeons regarding 1,318 patients treated with transarticular screws revealed a rate of vertebral artery injury of 4.1%. Most arterial injuries were asymptomatic, however, with only 0.2% of all patients suffering a neurologic deficit (64).

While some surgeons have gained substantial experience with the transarticular atlantoaxial screw technique (64), the risk of vertebral artery injury in rheumatoid patients has not been fully evaluated. This risk is probably somewhat higher than in the nonrheumatoid population because of the tortuous anatomy of the vertebral artery that can develop with rheumatoid arthritis, as well as the difficulty of reducing the atlantoaxial facets in some patients, complicating appropriate screw trajectory.

While transarticular screw fixation seems to offer a higher rate of arthrodesis, further documentation of outcome in rheumatoid patients is needed. Despite a lower mechanical rigidity compared with transarticular screw fixation, wiring techniques are still appropriate in many patients because they offer a reduced risk of neurologic and vascular complications, particularly when reduction of the atlantoaxial articulation cannot be obtained, or when the isthmus is smaller than 3.5 mm in diameter (53).

**OCCIPITOCERVICAL ARTHRODESIS**

Indications for including the occiput in a posterior cervical arthrodesis include cranial settling with current or impending neurologic compromise, inability to obtain fusion to the posterior ring of the atlas due either to insufficient bone stock or to the need for a laminectomy, nonunion from a prior atlantoaxial arthrodesis, and severe involvement in patients with combined atlantoaxial and subaxial instability. While inclusion of the occiput in the arthrodesis further reduces neck motion over an isolated atlantoaxial fusion, incorporating the occiput affords strong fixation, allowing a variety of constructs for stabilization.

As with atlantoaxial arthrodesis, wiring techniques have historically provided acceptable results in a large number of patients. De Groot et al. (18) described results in 14 rheumatoid arthritis patients using an H-graft and a wiring technique based on the method of Robinson and Southwick (47). They obtained fusion in 11 patients, and none of the three patients with nonunion required revision surgery during the follow-up period.

Wertheim and Bohlin (61) described a three-wire technique [also derived from Robinson and Southwick (47)] using a spino-cranial wire at C-2, a looped sublaminar wire at C-1, and a wire through the inion along with structural corticocancellous bone grafting posteriorly. In a series of 13 patients, eight of whom had rheumatoid arthritis, they achieved a 100% fusion rate with all patients with preoperative neurologic deficits showing improvement. Clark et al. (11,54) described a
six-wire technique using paired lateral sublaminar wires at the atlas and axis (Fig. 154.74). This method can still be used when a laminectomy of the atlas has been performed.

McAfee et al. reported on 37 patients, 20 of whom had rheumatoid arthritis. They had an 85% fusion rate (33 of 37 patients). They noted that when reduction of cranial settling was achieved and maintained, patients had a significantly better prognosis for neurologic recovery than when reduction was not possible (93% versus 40%). Only two patients underwent a late anterior odontoid resection due to persistent compression and neurologic deficits; both eventually recovered normal neurologic function.

Ransford et al. (44) described occipitocervical fixation with a contoured, threaded Steinmann pin and sublaminar wiring along with laminectomy of the atlas and foramen magnum enlargement in a series of three patients (Fig. 154,7B). Although none of the patients had rheumatoid arthritis, the authors recognized the potential application to this population. Itoh et al. (28) described 13 rheumatoid patients treated with this technique, fusing an average of 5.9 cervical levels. Ten of these patients had cranial settling, and 12 had subaxial involvement. Of 8 patients with moderate or severe myelopathy, 7 (88%) had significant postoperative neurologic improvement. Twelve of 13 patients (92%) went on to solid arthrodesis. All patients had relief of occipital pain.

Apostolides et al. (3) reported results in this technique in 39 patients, 12 of whom had rheumatoid arthritis. Five of the 12 rheumatoid patients (42%) had cranial settling, while 4 (33%) had prior nonunions. Four patients (33%) underwent foramen magnum enlargement and laminectomy of the atlas, while 5 (42%) underwent transoral resection of the odontoid. Ten of these patients (83%) went on to solid arthrodesis, with 2 developing stable fibrous union. None of these patients suffered hardware failure. All 10 patients with preoperative myelopathy showed improvement, although 9 (90%) demonstrated persistent deficits to varying degrees.

Occipitocervical plating has gained popularity in recent years (Fig. 154.7C). Like transarticular screw fixation for atlantoaxial arthrodesis, this technique was developed in Europe but is increasingly used in the United States as well. The advantages claimed for occipitocervical plating include avoiding entry into the spinal canal and reducing the number of caudal segments required to obtain rigid fixation. An early report by Grob et al. (23) described this technique in 14 patients, seven of whom had rheumatoid arthritis. Using a Y-shaped plate with a single arm for cranial fixation and including transarticular atlantoaxial screws as part of their construct, they reported fusion in all patients.

Smith et al. (54) described preliminary results in 14 patients using bilateral, contoured steel pelvic 3.5 mm reconstruction plates. They used a pedicle screw at the C-2 vertebra in place of transarticular screws. Five of these patients had rheumatoid arthritis, and the arthrodesis extended an average of 4.6 cervical levels. Fusion was reportedly obtained in all patients. While these early results are promising, long-term follow-up of these patients to evaluate for instability caudal to the arthrodesis is needed.

As in instrumentation for atlantoaxial arthrodesis, these techniques require training and experience prior to routine use. The specific risks of neurologic or vertebral artery injury during lateral mass or atlas pedicle screw placement have not been documented in rheumatoid arthritis patients, where marked distortion of the anatomy can occur. A CT scan to determine the course of the vertebral arteries is advised. While these techniques offer the potential to improve fusion rates and reduce postoperative immobilization, the long-term effects of these constructs on adjacent motion segments is also unknown.

**SUBAXIAL ARTHRODESIS**

Posterior arthrodesis with or without laminectomy is indicated for patients with subaxial instability or fixed subluxation with impending or actual neurologic compromise. As with atlantoaxial instability, a measurement of the space available to the cord on a lateral radiograph of 14 mm or less indicates that the spinal cord is at risk of compromise. Patients with subaxial instability who also have atlantoaxial instability or cranial settling often require treatment of these combined instability patterns by a single operation (4).

Less has been reported about treatment of isolated subaxial rheumatoid spine problems than of upper cervical spine involvement. Ranawat et al. (43) discussed posterior arthrodesis in six patients with subaxial subluxations. Three of these patients underwent arthrodesis to the occiput due to coexisting atlantoaxial instability or cranial settling. All patients had significant pain relief and three (50%) had improvement of myelopathic symptoms.

Less-satisfactory results occurred in five patients treated with anterior surgery; one patient achieved neurologic improvement, because of graft collapse and dislodgement. These authors felt that anterior surgery was contraindicated in patients with rheumatoid arthritis due to the mechanically insufficient, osteopenic bone of the vertebral bodies (43). In addition, the anterior longitudinal ligament may be one of the last remaining stabilizers in rheumatoid patients, and this ligament is necessarily disrupted during an anterior procedure.

Conaty et al. (15) reported results in seven patients with isolated subaxial involvement treated by posterior fusion without wiring. Two patients underwent laminectomy due to severe neurologic compromise, but neither recovered significant function. Patients were managed postoperatively either in cranial traction or a halo. All six surviving patients went on to solid arthrodesis, with satisfactory results reported in 4 of 7 patients (57%).

Heywood et al. (27) treated seven patients with subaxial instability, four of whom had had preoperative myelopathy. Five patients treated with posterior subaxial bone grafting and wiring went on to solid fusion, with all neurologically compromised patients experiencing significant recovery. No laminectomies were performed in this series. Two patients treated with anterior procedures died postoperatively of pulmonary complications. These authors argued against the need for a laminectomy to obtain neurologic recovery, and they argued for posterior rather than anterior procedures.

Clark et al. (14) reported on 41 rheumatoid patients, seven of whom had posterior subaxial arthrodesis for subaxial instability. They reported no subaxial nonunions with spinous process wiring and bone grafting. Four patients (67%) had clinical improvement of pain complaints, and no patient suffered neurologic worsening. One patient who had undergone an anterior decompression and attempted arthrodesis had developed graft subluxation, which necessitated the posterior procedure.

Santavirta et al. (49) reported results in 16 patients with subaxial instability treated with a posterior procedure. Ten patients had myelopathy and seven had severe neck and shoulder pain. All patients underwent posterior wiring and arthrodesis, and patients with myelopathy also underwent laminectomy. Eight patients were treated in postoperative skull traction. All achieved solid fusion, and 90% (9 of 10) with myelopathy recovered. Two perioperative deaths occurred. Three patients developed adjacent segment instability during an average follow-up period of 4.4 years.

Several authors have reported disappointing results for subaxial anterior decompression procedures in patients with rheumatoid arthritis (14,27,43). The reasons for failure seem to be the tendency of the osteoporotic vertebral bodies to collapse around the bone graft, resulting with nonunion, kyphosis, and graft extrusion. In most cases, rheumatoid patients with subaxial instability and osteopenia or combined subaxial and upper cervical involvement should be treated with posterior surgery.

Patients with persistent neurologic deficits and anterior spinal cord compression following posterior fusion may be candidates for anterior decompression and structural bone grafting. In addition, there appears to be a subclass of rheumatoid patients with less severe involvement that can be effectively treated with anterior decompression and arthrodesis procedures. These patients may have fewer peripheral joint deformities, less corticosteroid exposure, greater bone density, and a shorter duration of rheumatoid disease. The radiographic appearance of these patients is similar to that of patients with cervical spondylosis, without significant
Subaxial or atlantoaxial instability (Fig. 154.8).

Figure 154.8. Subaxial cervical degeneration treated by anterior corpectomy and fusion. A: Lateral cervical spine radiograph demonstrates subaxial spondylosis in this 66-year-old man. He had a 20-year history of seronegative rheumatoid arthritis but displayed limited peripheral joint deformity. He was maintained on a combination of methotrexate and a daily dose of 5 mm prednisone. Despite the long history of rheumatoid arthritis, his clinical appearance is more consistent with cervical spondylosis without significant instability. B: Postmyelogram CT image through the C-5/C-6 disc level demonstrates significant spinal cord compression. Spasticity without motor weakness was present. The patient had undergone a laminoplasty with subsequent redosure of the laminae. C: Sagittal MRI demonstrates spinal cord compression at the C-3/C-4, C-4/C-5, C-5/C-6, and C-6/C-7 discs. D: This patient underwent anterior corpectomy of C-4, C-5, and C-6 with autologous fibular strut grafting with successful fusion and resolution of his myelopathic symptoms.

ODONTOID RESECTION

Anterior decompensation at the level of the odontoid process is sometimes required because of severe cranial settling with persistent neurologic compression despite maximal reduction in skeletal traction. For many patients, decompression can be accomplished at the time of occipitocervical arthrodesis via traction reduction with foramen magnum enlargement and laminectomy of the atlas. For patients who fail to improve despite this treatment or whose compression is so severe that posterior decompensation is likely to be inadequate, anterior resection of the odontoid is indicated.

Resection of the odontoid is usually performed through a transoral approach. Crockard et al. (17) performed simultaneous odontoid resection and posterior occipitocervical arthrodesis in 14 patients with rheumatoid arthritis, all of whom had myelopathy with significant weakness. One patient suffered a vertebral artery injury requiring abortion of the procedure. No patient developed a wound infection. These authors argue that this procedure results in faster neurologic recovery and avoids the need to obtain intraoperatorively and hold postoperatively an anatomic reduction.

Many authors, however, report good results with only limited use of this procedure (4, 14, 28, 37, 43). Postoperative MRI imaging has documented reduction in the periodontal pannus following solid arthrodesis. In addition, significant numbers of patients have demonstrated good neurologic recovery with solid posterior arthrodesis in a reduced position (14, 37). Be aware of the fact that the physiologic stress and difficulties of airway management during combined anterior/posterior cervical spine surgery in this population are considerable. Finally, patients who do not fully recover from neurologic deficits following arthrodesis may obtain further neurologic recovery after a delayed anterior odontoid resection (47).

SURGICAL TECHNIQUES

ATLANTOAXIAL WIRING

After fibrocartilaginous intubation and placement of spinal cord monitoring leads, position the patient prone using tongs or halo traction on a head rest to control the head position. Position the head in sufficient extension to reduce the atlantoaxial articulation, and verify the reduction fluoroscopically prior to preparing and draping. Recheck neurologic status after positioning, either via spinal cord monitoring or a brief wake-up test. Alternately, position patients while awake to allow continuous neurologic monitoring prior to the induction of general anesthesia.

Following a midline posterior approach, expose the ring of the atlas; strip only 1.5 cm laterally on either side of the midline to avoid injuring the vertebral arteries. Expose the C-2 and C-3 vertebral to the lateral edge of the C-2 and C-3 facets, avoiding injury to the joint capsules. Gently strip the attachments of ligamentum flavum from the cranial and caudal edges of the laminae of both the atlas and the axis vertebrae with a 4-0 curved Penfield 4 elevator gently along the medial wall of the C-2 pedicle and into the C-1/C-2 facet joint. Be careful to remain subperiosteal and to perform the dissection bluntly to avoid injury to the C-2 nerve roots exiting posterior to the C-1/C-2 facets. Place a Penfield 4 elevator gently along the medial wall of the C-2 pedicle and into the C-1/C-2 facet joint to verify orientation. Obtain a sufficiently steep trajectory for screw placement can be very difficult. Start the screw on the medial side of the inferior facet of the axis, aiming for the visible on the anteroposterior (AP) view. Reassess neurologic function after positioning, either by a brief wake-up test or by verification of maintenance of baseline somatosensory evoked potentials. Position patients with marked instability while they are awake to allow continuous neurologic monitoring prior to inducing general anesthesia.

Using a midline posterior cervical approach. Take care not to expose the occiput, as the fusion mass can unexpectedly extend to areas of exposed bone.

Achieve the exposure described for the atlantoaxial wiring and extend it cranially from the C-2/C-3 facets along the isthmus of C-2 to expose the C-1/C-2 facet joint. Be careful to remain subperiosteal and to perform the dissection bluntly to avoid injury to the C-2 nerve roots exiting posterior to the C-1/C-2 facets. Place a Penfield 4 elevator gently along the medial wall of the C-2 pedicle and into the C-1/C-2 facet joint to verify orientation.

Obtaining a sufficiently steep trajectory for screw placement can be very difficult. Start the screw on the medial side of the inferior facet of the axis, aiming for the

HINTS AND TRICKS

POSTERIOR ATLANTOAXIAL TRANSARTICULAR SCREWS

Place the patient in three-point tongs prior to positioning. Radiolucent tongs with a radiolucent operating table improve fluoroscopic visualization of the atlantoaxial facet joints. Position the patient prone, with the upper cervical spine in slight flexion and the lower cervical spine in extension. This position allows better access to the starting points and better trajectory for screw placement. Check fluoroscopically that the atlantoaxial articulation is reduced and that both facet joints are visible on the anteroposterior (AP) view. Reassess neurologic function after positioning, either by a brief wake-up test or by verification of maintenance of baseline somatosensory evoked potentials. Position patients with marked instability while they are awake to allow continuous neurologic monitoring prior to inducing general anesthesia.

Use a midline posterior cervical approach. Take care not to expose the occiput, as the fusion mass can unexpectedly extend to areas of exposed bone.

Achieve the exposure described for the atlantoaxial wiring and extend it cranially from the C-2/C-3 facets along the isthmus of C-2 to expose the C-1/C-2 facet joint. Be careful to remain subperiosteal and to perform the dissection bluntly to avoid injury to the C-2 nerve roots exiting posterior to the C-1/C-2 facets. Place a Penfield 4 elevator gently along the medial wall of the C-2 pedicle and into the C-1/C-2 facet joint to verify orientation.

Obtaining a sufficiently steep trajectory for screw placement can be very difficult. Start the screw on the medial side of the inferior facet of the axis, aiming for the

exposed isthmus cranially.

- Under fluoroscopic or stereotactic guidance, aim for the middle of the C-1/C-2 facet joint on the AP view, and for the anterior ring of the atlas on the lateral view.
- Use a cannulated drill system to allow repositioning of the guide wire until you are satisfied with the orientation and location.
- The thoracic cage can obstruct hand position and block the appropriate trajectory. If it does, a percutaneous incision distally on the back can improve orientation.
- Use a flexible, cannulated 2.5 mm drill and articulated screwdriver to improve the inclination.
- Place both guide wires prior to drilling and screw placement, to stabilize the articulation during passage of the first screw.
- Tap past the facet joint to improve ease of screw insertion. After cannulated drilling and tapping, place either a solid 3.5 mm or cannulated 4.0 mm screw. Use fully threaded narrow-pitch screws for the best purchase. Screw length should come just to the inferior edge of the anterior C-1 ring on the lateral view.
- If entry into the vertebral artery is suspected, abandon the procedure on the opposite side to avoid the potential of a bilateral injury.
- Once screws have been placed, augment the construct with a corticocancellous bone graft and wiring following the previous guidelines (Fig. 154.5E, Fig. 154.9).

**Figure 154.9**. This 66-year-old woman had hyperreflexia in upper and lower extremities without weakness or pathologic reflexes. **A,B:** Flexion–extension lateral radiographs demonstrate reduction of the posterior atlantodental interval to 15 mm in flexion. Full reduction occurs with extension. **C,D:** Because of the limited space available to the spinal cord, this patient underwent posterior atlantoaxial arthrodesis with transarticular screw fixation and supplementary wiring. She obtained a solid fusion with no neurologic deterioration.

See [Hints and Tricks](#) on the next page.

### OCCIPITOCERVICAL WIRING

- Prepare and position the patient as in previous descriptions. Check atlantoaxial reduction radiographically and verify neurologic status once positioning is complete. Prepare and drape well the back of the head, approximately 5 cm cranial to the inion. Use a posterior cervical approach, extending the cranial exposure approximately 1 cm cranial to the inion. Exposure of the posterior ring of the atlas should extend no more than 1.5 cm lateral on either side.

### HINTS AND TRICKS

- Do not begin the procedure until fully satisfied with the head position, visualization of necessary anatomy on both AP and lateral fluoroscopic views, and reduction of the atlantoaxial articulation.
- Verify on preparative CT sagittal reconstructions that the C-2 isthmus is sufficiently large to accommodate at least a 3.5 mm screw.
- Extend preparation and drilling distal to the scapulae to allow percutaneous incisions for drilling and screw placement if needed.
- A looped sublaminar wire at C-1 can improve reduction and allow stabilization of the C-1 ring during passage of the guide wires and screws. An alternative procedure such as C-1 laminectomy and occipitocervical arthrodesis should be performed in patients whose C-1/C-2 articulation cannot be anatomically reduced.
- Accurate assessment of screw orientation in the coronal plane is critical. Lateral screw position can produce injury to the vertebral artery, while medial positioning threatens neurologic structures.

- If a laminectomy of C-1 and foramen magnum enlargement are necessary, do these before preparing for wiring.
- Free the ring of C-1 of ligamentous attachments cranially and caudally with a sharp 4-0 angled curet. If the ring is too thick to remove with a 1 mm Kerrison rongeur, it may be thinned with a burr.
- Start the resection at the lateral limits of the exposure of the laminae first, leaving a floating central fragment to be resected last. This technique reduces the potential pressure against the cord during the laminectomy.
- Enlarge the foramen magnum by thinning the occiput with a burr in a semicircle measuring approximately 5–7 mm. Then resect the remaining inner table piecemeal with a 2 mm Kerrison rongeur to remove the posterior lip of the foramen magnum; always do this to allow safe passage of occipital wires.
- Create two occipital burr holes with a 4 mm carbide burr approximately 1 cm lateral to the inion and approximately 7 mm cranial to the foramen magnum.
- Complete the holes through the inner table with a diamond burr. Elevate the dura off the inner table toward the burr holes and from the foramen magnum with a 4-5 curved curet.
- Pass a looped, double-twisted 24-gauge wire through the holes on both sides using the suture-passing technique previously described.
- If a laminectomy of C-1 has been performed, drill a small hole through the remnant of the lamina on either side, if there is sufficient remaining bone, and pass a single 24-gauge wire through this hole. Otherwise, pass bilateral sublaminar wires at both C-1 and C-2 using a technique similar to that described for atlantoaxial wiring.
- Alternatively, if neurologic compression is present, pass a wire through the spinous process of C-2 by drilling transversely approximately a third of the length up the spinous process from the lamina. Use a 2 mm burr to perforate the cortex on either side of the spinous process and connect those holes with a towel clip. Then pass a 20-gauge wire through the hole, loop it under the spinous process, and pass it a second time. Use a similar method if the fusion is to be extended caudally; we do not use sublaminar wires caudal to C-2.
- As in atlantoaxial arthrodesis, obtain a thick corticocancellous bone graft from the posterior iliac crest. For occipitocervical arthrodesis, harvest a graft measuring approximately 3 by 5 cm.
- Divide the graft lengthwise and place three evenly spaced drill holes in both grafts.
- Lightly decorticate the occiput, C-1 ring (if still present), and C-2 laminae using a carbide burr.
- Thread the more lateral arm of the wire at each level through the corresponding holes, and maneuver the graft down the wires until it is in apposition to the decorticated bone. Bring the second arm of each wire medially around the graft and tighten the wires sequentially as described previously.
- When the bone on the back side of the occiput is almost free, use a drill to thin the bone from the bone graft, and if it is thinned to the correct thickness, pass a wire through the hole, loop it under the spinous process, and pass it a second time. Alternatively, if the bone quality is poor, use a drill to decorticate and thin the bone. If fixation is secure and bone quality is good, use a skull–occiput–mandibular immobilization (SOMI) or Minerva brace postoperatively. If fixation is compromised because of osteopenic bone, maintain the patient in a halo vest for 6–12 weeks after surgery (Fig. 154.7A, Fig. 154.10).

**Figure 154.10**. This patient had hyperreflexia and bilateral Babinski and Hoffmann’s signs without motor weakness (Ranawat II). **A,B:** Flexion–extension lateral radiographs demonstrate atlantoaxial subluxation with incomplete reduction in extension. Posterior atlantodental interval (PADI) is 11 mm. Mild cranial settling is also present. **C:** MRI demonstrates persistence of spinal cord compression by the posterior ring of the atlas despite maximal reduction in extension. **D,E:** This patient underwent occipitocervical arthrodesis with laminectomy of the atlas and foramen magnum enlargement. Spinous process wires were used at C-2 and C-3. The patient obtained solid arthrodesis with resolution of spasticity.
SUBAXIAL ARTHRODESIS

The subaxial arthrodesis in the patient with rheumatoid arthritis is essentially the same as that in cervical trauma and is discussed in Chapter 140.

- Approach the appropriate cervical vertebrae through a midline posterior approach. Place a Gelphy retractor longitudinally in the incision to remove skin folds. For subaxial approaches, obtain a lateral radiograph with a Kocher clamp placed on an exposed spinous process to determine the appropriate spinal level. A triple-wire fixation technique is most widely applicable. If the spinous processes are deficient, use lateral mass plates.
- Postoperatively, immobilize the patient in a Philadelphia collar for 12 weeks.

HINTS AND TRICKS

- Pay careful attention to staying in the midline during initial dissection. If you can see muscle fibers, the dissection has strayed to one side. Maintaining a midline position will limit bleeding.
- Stabilize the C-2 vertebra with a towel clip or Kocher clamp during dissection of soft tissues to prevent gross movements of the vertebra.
- Do not use sublaminar wires at C-1 or C-2 if neurologic compression is present. In these cases, perform a careful laminectomy of C-1 and use a spinous process wire at C-2.
- If a spinous process wire is used, gently work the towel clip from side to side until it moves readily through the hole. This technique will allow passage of the transverse wire with relative ease.

PITFALLS AND COMPLICATIONS

Early complications from these procedures include perioperative mortality due to airway compromise, neurologic deterioration, infection and wound problems, hardware and graft failure, and surgical complications such as myocardial infarction, pulmonary embolus, and pulmonary or urinary tract infection. Late complications include nonunion and adjacent segment instability with recurrent neurologic compromise.

Airway and pulmonary complications are always a significant concern after cervical spine surgery. These concerns are magnified in the case of rheumatoid arthritis, because these patients often have decreased pulmonary reserve and difficulties with postoperative mobilization. For these reasons, consider preoperative tracheostomy in patients undergoing anterior corpectomies or dens resection and patients with severe neurologic compromise (14,27). Alternatively, maintain these patients on a ventilator for several days postoperatively to allow resolution of airway edema. All other patients with rheumatoid arthritis should undergo fiberoptic intubation to reduce postoperative airway complications (59).

Infection and wound healing problems are a significant concern in rheumatoid patients because of the atrophy of their skin and soft tissues, as well as the immunosuppressive effects of their medication regimens. Administer intravenous antibiotics preoperatively, and maintain patients on antibiotics until postoperative drains have been removed. Reduction of foreign material in the wound is also important in obtaining wound healing. While supplementary PMMA was recommended in the past, it has been associated with wound healing problems and is no longer used (6,13,14).

Intraoperative or acute postoperative neurologic deterioration should be a rare occurrence. Interoperative spinal cord monitoring should be used routinely to allow the earliest possible detection of potential spinal cord injury and immediate institution of measures with the potential to reverse neurologic compromise, such as removal of hardware or wires. Obtain a CT scan or MRI on patients in whom deficits develop or worsen postoperatively to rule out an epidural hematoma and bone graft orhardware malposition. Patients with new deficits and radiographic evidence of spinal cord compromise should undergo an emergent wound exploration, and appropriate steps should be taken to reverse the source of the neurologic compression.

The majority of patients with preoperative neurologic deficits experience improvement in function with surgical decompression and solid fusion. The long-term stability of these results, however, has been a concern because of the potential for new subluxations caudal to the original arthrodesis (41). While new subluxations may partly reflect disease progression, they also may be accelerated by the mechanical effect of the adjacent fusion.

Santavirta et al. (49) reported a minimum 10-year follow-up of a series of 38 patients treated with posterior arthrodesis. Nineteen patients died during the follow-up period. Four patients (11%) underwent further arthrodesis for subluxations caudal to the original procedure. Although 12 of 24 patients (50%) undergoing a Gallie (22) atlantoaxial arthrodesis developed nonunion, it did not appear to adversely affect their clinical outcome.

Kraus et al. (32) reported the incidence of caudal subluxations of 79 patients treated with either occipitocervical (24 patients) or atlantoaxial (55 patients) arthrodesis. They found that patients undergoing occipitocervical arthrodesis experienced a higher and more rapid rate of caudal subluxation requiring revision surgery. Of the patients with occipital arthrodesis, 36% developed subaxial subluxation in an average of 2.6 years, compared with 5.5% of the patients undergoing atlantoaxial arthrodesis in an average of 9 years postoperatively.

Krieg et al. (33) performed a minimum 7-year follow-up of the 41 patients originally studied by Clark et al. (12,14). Thirteen patients (32%) had died by the time of the latest follow-up. Eighteen patients underwent clinical and radiographic evaluation, and nine were interviewed. None of these 27 patients had had clinical or radiographic deterioration over the length of the follow-up.

Nonunion has also been a significant problem for rheumatoid patients following arthrodesis. Overall rates of nonunion have ranged from 8% to 50% in various series of posterior cervical arthrodesis in patients who have rheumatoid arthritis (8,14,27,28,41,43,48,49). In series of patients with mixed diagnoses treated with uniform surgical procedures, rates of nonunion are somewhat higher for rheumatoid patients than for patients with other diagnoses (2,8,35,37,39,61). While new technology may ultimately improve patient outcomes, adherence to proven surgical techniques such as use of structural corticocancellous autograft, good apposition of graft to bony surfaces, and appropriate postoperative bracing lead to good results for the majority of patients.

AUTHORS’ PERSPECTIVE

It is worthwhile to identify patients with rheumatoid arthritis who are at risk of developing neurologic injury, as recovery of neurologic function once deficits develop is uncertain and often incomplete. New imaging modalities, as well as means of interpretation of plain radiographs, allow more accurate selection of patients at risk for neurologic injury. While new techniques of internal stabilization should improve rates of achieving solid arthrodesis, an assessment of the risks of these techniques in rheumatoid patients is needed. The long-term effect of such fixation on adjacent motion segments is not known. The primary determinants of satisfactory outcomes remain careful patient selection, appropriate choice of surgical procedures, and adherence to the principles and techniques of neurologic decompression and spinal arthrodesis.

CHAPTER 155

ANTERIOR APPROACH TO SCOLIOSIS

Jesse Butler and Michael F. Schafer

Historical Background

Scoliosis is a complex three-dimensional deformity characterized by coronal, sagittal, and horizontal plane deviation. Although posterior spinal fusion and instrumentation can be used for most patients, there are many situations in which the anterior approach is necessary. With recent advances in thoracoscopic techniques, the indications for anterior surgery may be expanded (40). The deformity surgeon must, therefore, be aware of the anterior surgical options available.

Although Compere reported the resection of a hemivertebra by the anterior approach in 1932 (4), anterior surgery for the treatment of spinal conditions started with Hodgson, who reported the results of anterior spinal decompression and fusion for tuberculosis of the spine in 1956 (13,14). Dwyer expanded the technique developed by Hodgson to approach the convex side of a scoliosis curve (8,39). During the past 30 years, spinal surgeons have become facile with the anterior or combined anterior and posterior approaches.

INDICATIONS

Indications for an anterior approach include certain cases of idiopathic, congenital, neuromuscular, and adolescent scoliosis. The neuromuscular curves include those caused by cerebral palsy, myelomeningocoele (MM), muscular dystrophy, polio, trauma, Friedrich's ataxia, and syringomyelia. The combination of curve magnitude, rigidity, spasticity, and paralysis frequently necessitates combined anterior and posterior spinal fusion.

The spinal deformities associated with neuromuscular disease are often progressive and disabling. The indications for surgery are at times controversial in severely involved children, and complications are frequent. Patients with impending skin compromise due to pelvic obliquity or kyphosis, poor sitting balance with muscular fatique and pain, loss of upper extremity function due to using their arms to support and elevate the trunk, and progressive deterioration of pulmonary function are strong indications for surgery (39). Attempts to delay surgery with bracing until adequate trunk height is obtained are a common dilemma in the preadolescents with significant deformity. Absolute Cobb angular measurements for which surgery is indicated range from 40° to 60°. Issues regarding age, medical comorbidity, and family acceptance make rigid guidelines difficult to implement.

When combined anterior and posterior fusion is indicated, same-day sequential surgery usually is performed. The anterior approach allows more correction by excising the discs and ligaments (3), increases fusion rates, prevents crankshaping in immature spines (8,20-21), decompresses the spinal cord, and provides exposure for internal thoracoplasty (40). This is followed by posterior instrumentation and fusion. Powell et al. (38) compared the results between staged and same-day surgery. They found less blood loss, shorter hospital stays, and reduced cost with same-day surgery. Ferguson et al. (11) reviewed the results of same-day surgery in patients with neuromuscular scoliosis. The overall complication rate was reduced from 124% to 88%. The number of patients without any complications in this high-risk group increased from 35% to 63%.

The indications for anterior instrumentation have changed since the second edition of this book. The Dwyer and Zielke instrumentations are no longer used in our practice. Anterior instrumentation is used now for structural support as well as for deformity correction. In select cases of idiopathic scoliosis, anterior instrumentation may be all that is necessary. Valuable motion segments may be preserved in the lumbar spine when fusing with anterior instrumentation.

PREOPERATIVE PLANNING

The initial step in preparing the patient for an anterior procedure is a thorough history and physical examination. For all cases, obtain an appropriate medical consultation prior to surgical intervention. A complete examination of the chest, abdomen, back, and lower extremities is important. Assess spinal balance, as this aids in determining fusion level. For example, a lumbar scoliosis with an associated rigid thoracic kyphosis must be fused across both curves to prevent decompensation and progression of the thoracic deformity.

Carefully evaluate neuromuscular patients for asymmetric muscle strength, rapid curve progression, increasing motor weakness, or cavus foot deformity. Evaluate with magnetic resonance imaging (MRI) to look for an intraspinal lesion or tethered cord (37). Do a myelogram only in cases that are difficult to interpret. An assessment of pelvic obliquity and hip joint contracture is vital if the fusion is to be carried into the lumbosacral region. At times, a release of hip flexion contracture may be required to increase excessive lumbar lordosis prior to spine surgery.

A complete radiographic assessment includes standing or sitting 14×36 films in the posteroanterior and lateral planes. Supine side bending films determine the curve flexibility and assist in determining the fusion endpoint. Image the lumbosacral junction to detect an occult spondylolisthesis. Preoperative MRI is not necessary for idiopathic adolescent (48) and adult deformity.

Pulmonary function studies are mandatory. This helps determine which group of patients will require respiratory assistance in the perioperative period. Forced vital capacity (FVC) values less than 40% of predicted values, and small children with recurrent upper respiratory infections should be evaluated closely (18). In idiopathic scoliosis, little effect on the FVC occurs until curves approach 60° to 100°. However, patients with spinal muscular atrophy or muscular dystrophy have marked reductions in FVC to less than 50% with curves of only 30° (39).

We obtain preoperative lower extremity somatosensory evoked potential exams to establish a baseline with which comparison can be made intraoperatively. Theoretically, detecting early subtle changes in evoked potential can enhance the safety of the procedure.

Congenital curves require a detailed evaluation by multiple disciplines. A careful history should elicit any urologic, cardiac, musculoskeletal, or neurologic anomalies. Approximately one third of these patients have urologic abnormalities, and 10% possess cardiac malformations (24). Evaluation of the genitourinary system with an
intravenous pyelogram or ultrasound can detect anomalies, which may need treatment prior to spinal surgery.

Perioperative nutritional assessment is important to minimize infection and wound healing problems (1). Mandelbaum's review (28) of staged anterior and posterior surgery noted that all infectious complications but one occurred in malnourished patients. A serum albumin over 3.5 g/dl and total lymphocyte count of more than 1,500/µl are acceptable. The normalization of nutritional parameters following combined spinal surgery correlates with the length of fusion according to Lenke et al. (22). Shorter fusions required approximately 6 weeks, and longer fusions about 12 weeks before nutritional parameters normalized when perioperative hyperalimentation was not used.

We use intravenous hyperalimentation in all of our patients undergoing combined anterior and posterior procedures. We place a central line at surgery and continue hyperalimentation until the postoperative ileus resolves and the patient's appetite returns. We have found a decrease in hospital stay and perioperative morbidity with this regimen.

We encourage the preoperative donation of autologous blood (6,31). Autologous donation does not compromise nutritional status, nor does it increase complication rates or the need for postoperative transfusions. The blood lost during surgery in these patients is more dilute, since their hematocrit at the time of surgery is lower. Homologous blood donation causes immunosuppression and places the patient at risk for transmission of viral diseases.

While intraoperative autologous transfusion (IAT) is used in our institution, there are recent studies that question its utility (41,42 and 43) in selected populations. There are significant costs for equipment and technicians, and the salvaged blood has a low hematocrit. There is no definitive evidence that IAT reduces the need for postoperative transfusion in select populations. However, for our combined procedures to correct scoliosis and kyphosis, IAT is used. We feel that this decreases the amount of homologous blood required for the surgery.

**SELECTION OF LEVELS TO BE FUSED**

**IDIOPATHIC SCOLIOSIS**

The majority of cases will be approached posteriorly, but for certain lumbar and thoracolumbar curves we use the anterior approach. Anterior instrumentation systems provide better correction of rotation, as forces are exerted directly through the vertebral body and disc spaces. When an anterior approach is selected, fewer levels are fused, which may prevent the future development of low-back pain. The Dwyer system was one of the first used this way (6,10). The lower pseudarthrosis rates and improved sagittal contour fueled the transition to solid rod systems such as Isola, the Texas Scottish Rite Hospital system (TSRH), and Kaneda.

The patients selected should have a lumbar or thoracolumbar curve of 60° or less, with a flexible deformity that reduces to less than 20° on supine bending films. The number of levels to be fused depends on whether the curve apex is at the disc or the vertebral body level. When the apex lies at the disc, two levels above and below are fused. If the apex is at the body, then one body above and below the apical vertebra is fused.

Hall et al. (12) noted similar correction of coronal deformity when comparing their results using the Dwyer, Zielke, and TSRH systems. The TSRH system produced less segmental kyphosis. There was only one pseudarthrosis in their series of 18 cases with TSRH. This was successfully salvaged with a posterior fusion.

**PARALYTIC SCOLIOSIS**

While the etiologies of paralytic scoliosis are diverse, there are many common features. The curves tend to occur early, progress rapidly, involve the entire spine, and result in pelvic obliquity, and they progress in adulthood (39). A combined anterior and posterior procedure is often utilized with fusion from T2 to the pelvis.

The criteria for anterior release are based on curve flexibility and leveling of the pelvis on side-bending films. When the pelvis becomes level on side-bending films, an anterior release is not necessary. However, when lumbar rigidity precludes correction to less than 30°, the anterior discectomy and bone grafting is performed prior to the posterior procedure.

We have modified our technique from combined anterior and posterior instrumentation (Dwyer anterior and Luque-Galveston posterior) to anterior release with segmental fixation posteriorly with either Isola (DePuy Acromed, Warsaw, IN) or CD Horizon (Sofamor Danek, Memphis, TN) instrumentation. This change emphasizes the role of the anterior procedure in mobilizing a rigid deformity, establishing lumbar lordosis, and improving fusion rates and overall sagittal balance. Recently, we have utilized titanium cages anteriorly to improve sagittal contour prior to the posterior procedure. This prevents loss of lordosis from graft settling that may be seen with the use of autograft or allograft alone. Pelvic fixation varies with the patients' anatomy, but an iliac post is most commonly used. The iliac post, placed between the inner and outer tables of the ilium, increases the rigidity of the fixation.

**MELOMENINGOCOELE**

The treatment of scoliosis in the MM population is complex and complications are frequent (see Chapter 157). As the level of neurologic compromise rises, so does the incidence of spinal deformity (25,37), approaching 100% in thoracic-level patients. Nearly 60% of L4 level patients have scoliosis. The overall goal of surgery is to achieve a vertical torso centered over a level pelvis. Therefore, most patients require a fusion from T2 to the sacrum (Figs. 155.1).

![Figure 155.1](image)

From 1980 to the early 1990s, we followed all anterior instrumentation and fusions with the Dwyer technique with a supplemental posterior fusion to the sacrum with Luque instrumentation. This technique allowed excellent coronal and sagittal correction. We had only one pseudarthrosis with this technique and it was associated with persistent infection necessitating early removal of the posterior hardware.

Currently, we perform anterior discectomy and fusion followed by posterior Isola instrumentation with iliac post fixation in the pelvis. The fusion rates have remained acceptable with this modification. The real benefit has been the improved sagittal balance obtained from the anterior mobilization followed by posterior deformity correction and fusion. Segmental fixation posteriorly combines hooks, sublaminar wires, and pedicle screws.

We have not used isolated anterior instrumentation for MM patients because of reported high complication and revision rates (25,44). The kyphosis caused by some anterior instrumentation is only exacerbated in this population. Anterior instrumentation also reduces the sagittal correction obtained by posterior techniques.

**CEREBRAL PALSY**

There is controversy over the treatment of scoliosis in cerebral palsy (CP) patients. As the magnitude of neurologic involvement increases, the severity of the curve increases (27,38,39). Ambulatory patients with CP have approximately half the rate of significant deformity that nonambulators have. Curve progression into adulthood...
is known to occur; therefore, maintenance of ambulation through aggressive physical therapy and close follow-up is necessary.

There is often not one right answer for the CP patient. The risks and benefits of surgery should be thoroughly discussed with the parents. When there is any prospect of functional benefit to the patient, surgery is recommended. It is difficult to judge the true benefit for those with severe cognitive impairment, seizure disorder, and malnutrition.

The curves frequently are quite large and rigid. Therefore, fusion is required from the upper thoracic spine to the pelvis. The anterior procedure releases the rigid structures, which enhances posterior correction and fusion. If pelvic obliquity is not significant (i.e., it corrects on side-bending films), then fusion may be carried down to L4 or L5.

**CONGENITAL HEMIVERTEBRA**

Treatment of a congenital hemivertebra depends on whether the hemivertebra is segmented, semisegmented, or incarcerated. The fully segmented variety is the most common and produces the greatest deformity. In growing patients, use an anterior and posterior approach to perform a hemiepiphysiodectomy, where obliteration of the convex endplates will halt spinal growth on the convexity and allow concave growth to correct the deformity (47). Thompson et al. (45) reported their results of convex epiphysiodectomy for hemivertebra. The operative objectives were to prevent the development of severe deformity and allow growth of the remaining concave epiphysis to correct scoliosis. They found the procedure to be safe, and it yielded some correction in 76% of their patients and slowed progression in the remaining patients. The greatest correction was obtained in the lumbar spine of the youngest patients in their series.

Hemivertebrectomy is an alternative treatment. The technique has been described for lumbosacral hemivertebra with severe coronal plane imbalance. Callahan et al. (3) reported the results of hemivertebrectomy excision on 10 patients. Nine of 10 were excised in a single stage from T12 to L3. The procedure was safe and effective with a curve correction of 67% obtained. Greatest correction was obtained in the younger patients (under 4 years old).

**ADULT SCOLIOSIS**

One of the major concerns in the treatment of adult scoliosis is the high rate of complications, particularly pseudarthrosis. In a review of 62 adult cases, a 16.7% incidence of pseudarthrosis was present among patients undergoing posterior spinal fusion with Harrington rod instrumentation (34).

To minimize pseudarthrosis and improve correction, we treat all thoracolumbar or lumbar structural curves greater than 65° by combined anterior discectomy and fusion, followed by posterior spinal fusion with Cotrel-Dubousset (CD) instrumentation. This aggressive approach is indicated because these curves are stiff and there is little correction with posterior instrumentation and fusion alone. The anterior discectomy and fusion, followed by posterior instrumentation and fusion, results in a better correction of the curve and a more balanced spine, and it enhances the fusion rate (Fig. 155.2).

![Figure 155.2](image)

**Figure 155.2.** A: A 26-year-old woman with an increasing thoracolumbar curve and low back pain. B: A lateral x-ray reveals a junctional kyphosis from T11 to L1. C: The postoperative AP x-ray shows correction of the curve to 20° with titanium cages filled with autogenous bone placed between T11 and L3. D: The lateral x-ray demonstrates the restoration of the normal lordosis between T11 and L3.

In adult curves of less than 65° that are located in either the thoracolumbar or the lumbar area, an anterior approach using anterior CD instrumentation is performed. If a curve has an associated kyphosis of the thoracolumbar or lumbar spine, we have used titanium cages to correct sagittal alignment. The cage size is selected to restore each disc space to a more lordotic posture.

**SURGICAL TECHNIQUE**

- Place the patient in the lateral decubitus position with the table in a flexed position. Move the upper arm forward to rotate the scapula away from the posterior portion of the vertebral column. Place an axillary roll between the patient and the table to minimize pressure on the brachial plexus during the procedure (Fig. 155.3).

![Figure 155.3](image)

**Figure 155.3.** A: Anterior view of a patient in the lateral decubitus position. A roll is placed under the axilla to minimize the compression of the axillary artery. The dotted line represents the skin incision for exposure of T5 to T12. For both exposures, the table is flexed to accentuate the spinal curvature. B: The posterior view of the patient showing the position of the arms and the posterior extent of the incisions.

- Expose the anterior spine by one of two standard approaches: Approach the thoracic spine through the bed of the convex fifth rib, which provides good visualization of T5 to T12 (Fig. 155.3); or approach the thoracolumbar spine through the bed of the tenth rib. Extend this incision anteriorly to the lateral border of the rectus sheath. The incisional length varies, depending on the number of levels exposed.

The rib to be removed by either the thoracic or thoracolumbar approach is the rib cephalad to the upper-end vertebra in the fusion. For example, if the upper vertebra to be instrumented or fused is T10, then the ninth rib is resected. Once the rib is excised, the pleura is incised to expose the thoracic column. A double lumen endotracheal tube combined with moist laparotomy sponges and a well-contoured malleable retractor allows excellent retraction of the thoracic contents.

- The thoracolumbar approach enters the retroperitoneal space on the convex side of the curve.
- After removing the appropriate rib, split the costal cartilage along the longitudinal axis. Identify the yellow fatty tissue of the retroperitoneal space immediately beneath the split costal cartilage. Enter the plane by blunt, finger dissection.
- Sweep the peritoneum off the undersurface of the diaphragm and the anterior surface of the psoas muscle to expose the spine. Incise the diaphragm along its peripheral margin from anterior to posterior (Fig. 155.4). Leave 1.5 cm of diaphragm as an edge for reattachment at the conclusion of the procedure. Place stay sutures at 3 cm intervals. If the diaphragm is cut too close to the periphery, muscular contraction may make closure difficult.
Reflect the pleura and ligate the intercostal vessels in the midportion of the vertebral body to complete the thoracic exposure (Fig. 155.5). Carefully elevate the vessels off of the vertebral body, and double-ligate with suture, then retract the vascular elements from the working field.

The segmental vessels usually join the anterior median longitudinal arterial trunk of the spinal cord and also the posterior lateral longitudinal arterial trunks of the cord. Spinal cord blood supply is not compromised by ligating multiple intercostal vessels as long as this anastomosis is preserved (7).

Detach the crura of the diaphragm to expose the thoracolumbar spine at L1-2. Detach the origin of the psoas at the L1 vertebral body or reflect it anteriorly. For patients with large psoas muscles, the muscle may be split along its longitudinal axis to expose the spine.

When exposure of the L4 level is required, it is critical that the lumbar segmental vessels arising from the iliac artery and vein be ligated in the middle of the vertebral body. There is also a lumbar segmental vessel from the iliac artery and vein that passes into the pelvis. Identify this vessel carefully so that the iliac artery and vein can be mobilized away from the spine. Inadvertent transection of this vessel is difficult to manage because the vessel retracts into the pelvis. This can lead to extensive hemorrhage.

Once the spine is completely exposed, place retractors to protect the vascular structures. Place a Chandler elevator on the opposite side of the disc space to be resected.

Resect the disc back to the posterior longitudinal ligament with a knife and rongeurs (Fig. 155.6). Use a headlight and loupes during this phase of the procedure. Meticulous technique is needed to avoid inadvertently penetrating the ligament, which is closely adherent to the dura and spinal cord. Exposing a broader surface area improves the fusion rate.

**HINTS AND TRICKS**

- If the posterior longitudinal ligament is inadvertently transected, brisk bleeding may be encountered from the epidural venous plexus. Obtain control by gently packing with thrombin-soaked Gelfoam pledgets. Small dural tears may be sealed in a similar fashion. It is the second-listed author’s experience that this local treatment plus curve correction will cause the tear to seal off. Larger tears require closure. Facilitate exposure of the tear by removal of a portion of the vertebral body, and use 6-0 nylon sutures to repair the dural tear.
- On completion of the discectomy, excise the vertebral endplates using a fine osteotome. Take care to remove only the endplate. If too much of the body is removed, the purchase of any form of instrumentation on the vertebra will be compromised.

**SELECTION OF INSTRUMENTATION**

Recent technical advances in instrumentation have given the surgeon multiple options for anterior fixation. The anterior surgical options include discectomy and fusion with autograft or threaded/solid rod systems. Personal experience, anatomy and location of the curve, number of levels, patient age, and cost will dictate the specific approach. The indications and contraindications for anterior instrumentation are outlined in Table 155.1. Additional consideration should be given for anterior instrumentation when prominent posterior hardware and crankshaft phenomena are a concern.

The number of levels to be instrumented anteriorly is determined the same way regardless of the instrumentation used. The apex of the curve of concern is determined from the standing radiograph. It is the most laterally displaced portion of the Cobb curve from a line joining the center of the end vertebral bodies as measured by the Cobb method. If the regional apex is a vertebra, further apparent as the single most rotated vertebra, the apex vertebra plus one vertebra above and one below are included in this instrumentation construct. As the scoliosis reaches 55° or greater, it is generally necessary to add two vertebrae above and two vertebrae below the end vertebra. If the regional apex is a disc, further apparent because of similar adjacent vertebral rotation, then two vertebrae above and two vertebrae below are added. In addition, the first caudal disc space that shows reversal of coronal plane angulation on a convex bending radiograph can usually be excluded.

The following sections describe the specific surgical techniques for insertion of a threaded rod system [Zielke (Osteotech, Inc., Eatontown, NJ)] and two solid rod systems (DePuy Motech and Isola).

ZIELKE INSTRUMENTATION

Zielke instrumentation utilizes a threaded rod and vertebral body screws to correct deformity (Fig. 155.7).

![Figure 155.7. The threaded Zielke rod with associated locking nuts. (Courtesy of Daniel Benson, M.D.)](image)

- Insert the instrumentation after exposure of the anterior spine has been completed. Place appropriate-size screws across the vertebral bodies (Fig. 155.8) by measuring the width of the vertebral body, and selecting the appropriate-length screw to allow several threads to protrude from the opposite cortex. Place the screw as posterior as possible in the vertebral body.

![Figure 155.8. The slotted screw head for the insertion of the Zielke rod. (Courtesy of Daniel Benson, M.D.)](image)

- Following appropriate placement of the screws (Fig. 155.9), place a threaded rod in the screw heads, beginning at the apex; working proximally and distally, compress the convexity (Fig. 155.10).

![Figure 155.9. The spine has been exposed and all the Zielke screws are in place. (Courtesy of Daniel Benson, M.D.)](image)
Figure 155.10. The compression force has been applied to the convex side of the curve, and resected rib for the graft is placed into the intervertebral disc space. (Courtesy of Daniel Benson, M.D.)

Prior to any significant compression across the apex, place the derotator bar (Fig. 155.11). This consists of a metal bar that is fitted to the ends of the rod, and a tension screw that is placed between the apex of the rod and the bar. Tightening the tension screw affords some increase in lordosis of the spine, which may be further increased by rotating the bar (Fig. 155.12). This is seen intraoperatively by an opening anteriorly of the disc spaces.

Figure 155.11. The derotation bar has been applied to the Zielke rod. (Courtesy of Daniel Benson, M.D.)

Figure 155.12. The Zielke rod has been inserted and all hex nuts tightened. This provides the curve correction. (Courtesy of Daniel Benson, M.D.)

Place rib graft anteriorly to facilitate fusion and maintain adequate lumbar lordosis. Then achieve compression by tightening the hex nuts.

Results

The Zielke procedure is an accepted treatment for coronal correction of scoliosis. The rate of curve correction varies between 60% and 80%, with adolescents achieving the higher rate of correction. In an early report that looked at the correction of this instrumentation, 19 patients were evaluated with an average success rate of 77% for the thoracolumbar curve and 92% correction in the lumbar curve (49). These results have been duplicated in many studies (55,30,35). In a report that stratified results obtained by Zielke, Dwyer, and Harrington rod instrumentation, the Zielke appeared to have the highest rate of correction (26).

The adult population does not fare as well as the adolescents. Kaneda reported a correction rate of 59%, with all developing a pseudarthrosis. The literature suggests that loss of correction occurs between surgical intervention and later follow-up. In one report, 18 patients who had an initial mean correction of 82% in the lower curve found the rate dropped to 63% at follow-up. The same trend was found in the correction rates associated with the upper curve, with a loss from 33% to 18% at follow-up. Rotational correction was also reduced from 66% to 56%. This loss of correction is likely the result of a lack of stiffness of the threaded rod.

The Zielke instrumentation tends to produce kyphosis with an average loss of lordosis of 8° to 10° over the instrumented segments. Many studies (17,23,32) have documented the occurrence of this increased kyphosis, but none have shown it to affect the surgical outcome. This, however, can be reduced with appropriate anterior column support by structural grafts such as femoral rings, and threaded or titanium cages.

DEPUY MOTECH

The anterior instrumentation developed by DePuy Motech uses a solid rod connected to vertebral screws.

Place the patient in the lateral decubitus position and make a single skin incision paralleling the eighth rib. Mobilize and detach the serratus anterior muscle. Make an incision in the intercostal space at T4 or T5 for instrumentation of the T5 vertebra. Make a second incision between the intercostal space three or four ribs distally (i.e., to T8 or T9) for instrumentation of T12 (Fig. 155.13).

Figure 155.13. Incisions made at the intercostal space at T4 or T5, and between the intercostal spaces at approximately three to four ribs distally. (Redrawn from Moss Miami 4.0 mm Anterior System Surgical Technique: Anterior Treatment of Thoracic Idiopathic Scoliosis. DePuy Motech, Warsaw, Indiana, 1997.)

If the preoperative analysis suggests that a thoracoplasty is necessary for cosmetic reasons, perform it at this stage. A rib approximately 2 cm in length is removed as far posteriorly as possible between the two intercostal space entrances. If there is a very significant rib hump, then the entire posterior 2 cm of rib is removed from each of the vertebrae to be instrumented. Rib resections better mobilize the chest wall, making the disectomies and instrumentation less difficult to perform.

Facilitate exposure of the disc space, especially near the proximal vertebrae, by removing the rib head covering the disc space. Insert the vertebral body staples in approximately the same anatomic position in each vertebral body. Position these as far posteriorly as possible to prevent penetration of the spinal canal with the staple prongs.

In the most proximal vertebrae, insert the most proximal staple so that the screw can be placed eccentrically into the vertebral body. Insert the screw from posterior to anterior, as with the other screws. This superior eccentric placement adds strength by putting the screw threads against the superior endplate of the vertebral body. Place an identical staple in the most inferior vertebral body so that the screw is in the inferior aspect of that vertebral body (Fig. 155.14).
Use an awl to make a hole for the insertion of the screws. When the screws are positioned, it is important that they penetrate the concave side of the vertebral body.

Perform bone grafting before rod insertion. Begin distally, and wedge the disc space open and pack the interspaces. It is important to pack the discs between T10 and L2 firmly with bone graft. A structural type of anterior support may be needed to help ensure maintenance of the sagittal correction. When grafting the apical vertebrae, consider the original sagittal contour. If the starting sagittal profile is lordotic or hypokyphotic, only a small amount of graft can be inserted into the disc at the apex of the curve, to allow kyphosis to occur during compression with instrumentation.

Measure the appropriate length of the rod from the proximal to the distal screw. Add ¼ inch (i.e., 1/8 inch for each end), and cut the rod. Bend the rod to parallel the anatomically correct kyphosis–lordosis of the area of the spine needing instrumentation. Insert the rod so that the kyphosis is used to accommodate the scoliosis that is still present. It is important to remember to straighten out the table if it has been bent to facilitate the thoracotomy and disc exposure. When applying the nuts, it is easier to start at the top three nuts and then work toward the distal end.

After inserting the inner setscrews and outer nuts, the rods should be loose. The spine can be corrected by rotating the rod into a normal sagittal plane (Fig. 155.15). Correction can be facilitated by the anesthesiologist pulling on the lower arm and by the surgeon pressing on the apex of the curvature. With the rod rotated into an anatomically correct position, tighten both the inner setscrews and outer apical nuts. At this point, a decision has to be made about the anticipated coronal correction that is needed. If there is a structural upper thoracic curve, only a modest correction can be obtained in the main thoracic curve equal to the correction seen on the bending films of the upper thoracic curve. If there is no residual structural curve, then near-complete reduction of the curve can be obtained.

Obtain correction by using a compressor on each screw. Gradually compress each screw toward the apex. This needs to be done slowly and sequentially. After it has been completed, perform the final tightening in both the inner setscrews and the outer nuts. It is important to be cautious during this final tightening, especially in the end vertebrae. Torquing the screw could translate the screw out of the vertebral body. It is recommended that you use the rod stabilizer device that goes over the rod and provides neutralizing forces while tightening the inner setscrews and outer nuts (Fig. 155.16).

Figure 155.15. Rotating the rod into a normal sagittal plane. (Redrawn from Moss Miami 4.0 mm Anterior System Surgical Technique: Anterior Treatment of Thoracic Idiopathic Scoliosis. DePuy Motech, Warsaw, Indiana, 1997.)

Figure 155.16. Screws are gradually compressed toward the apex. (Redrawn from Moss Miami 4.0 mm Anterior System Surgical Technique: Anterior Treatment of Thoracic Idiopathic Scoliosis. DePuy Motech, Warsaw, Indiana, 1997.)

Figure 155.17 shows the results obtained with this instrumentation. Preoperative side-bending films of a thoracic curve show excellent flexibility. The postoperative anteroposterior (AP) and lateral films show near-complete correction.

Figure 155.17. The preoperative AP (A) and lateral (B) views of a child with a thoracic scoliosis. The postoperative films (C,D) show near complete correction of the coronal and sagittal deformities. The cage is used to prevent kyphosis at the thoracolumbar junction.

ANTERIOR ISOLA INSTRUMENTATION

Expose the anterior spine as previously described.

Place the end screws first from posterior to anterior, horizontal to the frontal plane of the vertebral body and paralleling the apex. Start the hole with an awl and continue with the 5.5 mm tap. Tap the vertebra until the tip just exits the far side of the cortex (Fig. 155.18). Insert a ballpoint probe to make sure that the far side...
of the cortex has been exited. Tap the first third of the hole with a 7 mm tap and insert a 7 mm closed-top screw with washer (Fig. 155.19).

Figure 155.18. Following a thorough 360° discectomy in which the posterior longitudinal ligament is exposed, placement of the upper vertebral screw site is begun with an awl, which is positioned at the furthest lateral waist of the vertebral body. (Redrawn from Asher MA. Surgical Technique for Anterior Segmental Instrumentation of Thoracolumbar and Lumbar Scoliosis Using the Anterior Isola Spinal System. AcroMed Corp., Cleveland, OH, 1996.)

Use a staple, and place it prior to the insertion of the screw. Insert the screw to maximum torque. The screw should protrude through the far cortex by at least one to two threads.

Repeat the same process at the lower-end vertebra. After the superior and inferior vertebrae have been instrumented with the staple and screws, cut the rod and contour it so that it fits through both the superior and inferior screws (Fig. 155.20). Add about 1 cm to each side of the rod to ensure that the rod passes completely through the end screws. After the rod has been cut to length and contoured, it is used as a guide for placement of the intermediate screws.

Figure 155.20. Rod is cut and contoured. Intermediate screws should be placed very slightly posterior on the waist of the body. (Redrawn from Asher MA. Surgical Technique for Anterior Segmental Instrumentation of Thoracolumbar and Lumbar Scoliosis Using the Anterior Isola Spinal System. AcroMed Corp., Cleveland, OH, 1996.)

Insert open-ended screws and staples at the intervening levels. Insert the rod into the superior and inferior screws and drop into the intermediate screws (Fig. 155.21). Place caps on the intermediate screws. After placing the caps, rotate the rod approximately 180° to obtain both a coronal and a sagittal correction (Fig. 155.22).

Figure 155.21. The middle screws are 7.0 mm in diameter and should protrude through the far cortex of the body by one to three turns. (Redrawn from Asher MA. Surgical Technique for Anterior Segmental Instrumentation of Thoracolumbar and Lumbar Scoliosis Using the Anterior Isola Spinal System. AcroMed Corp., Cleveland, OH, 1996.)

Figure 155.22. A: The rod is rotated to place the sagittal plane contour of the rod (B) in the true sagittal plane. (Redrawn from Asher MA. Surgical Technique for Anterior Segmental Instrumentation of Thoracolumbar and Lumbar Scoliosis Using the Anterior Isola Spinal System. AcroMed Corp., Cleveland, OH, 1996.)
Secure the rod by tightening one of the intermediate setscrews. After the rod has been rotated, a Cobb elevator can be placed into the vertebral space to pry open the previously concave side of the curve (Fig. 155.23). At this point, some distraction may actually be applied between the screw connector bodies to further open the space. Completely fill the disc spaces with bone graft.

Figure 155.23. Disc space is restored utilizing a Cobb elevator. (Redrawn from Asher MA. Surgical Technique for Anterior Segmental Instrumentation of Thoracolumbar and Lumbar Scoliosis Using the Anterior Isola Spinal System. AcroMed Corp., Cleveland, OH, 1996.)

Compress the vertebral screws in order to compress the disc spaces. This is done sequentially, starting from the top to the second screw (Fig. 155.24). The second compression occurs between the bottom and the next upper screw. The final compression is applied across the apical vertebra.

Figure 155.24. Disc spaces are compressed to provide anterior column load sharing. (Redrawn from Asher MA. Surgical Technique for Anterior Segmental Instrumentation of Thoracolumbar and Lumbar Scoliosis Using the Anterior Isola Spinal System. AcroMed Corp., Cleveland, OH, 1996.)

Close the wound over a chest tube as previously described. A sample case is illustrated in Fig. 155.25.

Figure 155.25. This 14-year-old girl has left thoracolumbar major and right thoracic compensatory scoliosis. Standing frontal plane (A) and sagittal plane (B) radiographs show imbalance to the left in the coronal plane, and in the sagittal plane flattening of the upper lumbar spine. On the left bend x-ray, there is not a clear opening of the disc space above the lower Cobb (C). On the right bend (D), the upper scoliosis corrects from 44° to 15°. Two-year postoperative radiographs (E,F) show restoration of coronal balance and a well-healed fusion with normal sagittal plane alignment. The standing postoperative posteroanterior radiograph (E) shows instrumentation from T12 to L3, the upper end vertebra level having been left out to allow for compensation. The sagittal plane angulation has been restored (F).

POSTOPERATIVE CARE

Monitor all patients in an intensive care unit postoperatively. Carefully monitor hemodynamic parameters such as hemoglobin and hematocrit, platelets, blood coagulation, electrolytes including calcium and magnesium, and urinary output. Record chest tube and drain outputs. Obtain daily chest radiographs until the chest tube is discontinued, usually by the third postoperative day. The goal of respiratory care is to prevent atelectasis and wean the patient from the ventilator safely and as soon as possible.

Mobilize the patient to a chair once extubated. The patient may ambulate when the chest tube is removed. Apply a custom-molded underarm thoracolumbar spine orthosis (TLSO) to all patients; this is worn full time for 6 months. Strongly stress walking to improve aerobic conditioning and an overall sense of well-being. Formal physical therapy is not required except for gait training.

PITFALLS AND COMPLICATIONS

INSTRUMENTATION

Significant compressive forces are generated by all instrumentation systems, and vertebral fracture can occur. Apply corrective force slowly over time to allow the viscoelastic characteristics of the spine to work. Patients with osteoporosis require even more care while tensioning instrumentation. Advanced osteoporosis is a contraindication to anterior instrumentation.

Hardware pullout is another potential complication. Bicortical fixation significantly improves fixation strength and should be attempted at each level. Many systems utilize screw–staple or screw–washer combinations that maximize stability. When pullout does occur, it is usually at the proximal or distal end of the instrumented levels. Augmentation with methylmethacrylate can be utilized, or the level may need to be bypassed.

MEDICAL

Perioperative medical complications are classified as major when they significantly alter the expected course of recovery, or minor when there is no delay in expected recovery. McDonnell et al. (29) reviewed complications of anterior spine procedures. They noted that pulmonary (37%) and thoracostomy tube (14%) complications were the most common of the major complications. Genitourinary complications were present in 11.6% of all patients and made up 42% of the minor complications.

Certain diagnostic groups are at higher risk for complications. The neuromuscular, adult, and congenital scoliosis groups had overall complication rates of 52%, 41%, and 36%, respectively (29). Patient age is also a significant factor contributing to perioperative morbidity. McDonnell et al. (29) found that the complications increased with patient age and were highest in the 61- to 85-year age group.
Prolonged operative time, dilutional anemia, and hyperthermia can produce a severe coagulopathy. Careful monitoring of only the hemoglobin during surgery is not adequate. The prothrombin and partial thromboplastin times and platelet counts must also be monitored in these procedures. The administration of fresh frozen plasma and platelets may at times be required. Arrangements with the hematology lab to provide a quick turnaround on coagulation profiles can be critically important.

NEUROVASCULAR

Vascular compromise of the spinal cord after the ligation of multiple segmental vessels is rare. Take care to avoid the foraminial region where the vascular anastomosis of the cord lies. The aorta and vena cava need to be carefully protected. Reported rates of injury in 447 cases of anterior spine procedures are low, with McDonnell et al. (29) reporting no great vessel injuries in 447 cases.

Spinal cord injury may result from overcorrection of deformity. Animal studies have confirmed that spinal cord injury can result from distraction or compression of the spine. While mechanical disruption does not typically occur, infarcts or hemorrhages can result from aggressive deformity correction. Bridwell et al. (2) reported their incidence of major neurologic deficits after adult and pediatric deformity surgery: Four cases were identified in 1,153 patients. All these cases were similar in that anterior and posterior procedures were performed on the same day for large deformity with the ligation of segmental vessels on one side, and intraoperative or perioperative hypotension placing the mean arterial pressure below 50 mm Hg for at least 15 minutes.

Mechanical damage to the cord may be the result of misdirected vertebral body screws. Taking care to place the screws parallel to the posterior longitudinal ligament can avoid canal penetration. If misdirection occurs, revise the screw or bypass the level.

Postoperative blindness is a rare but devastating complication after spine surgery. Myers et al. (33) reviewed 37 cases of postoperative visual loss. Significant risk factors were intraoperative hypotension, prone positioning, anemia, and prolonged operative time. They noted that "the lowest intraoperative blood pressure averaged 77 mm Hg, with an average of 260 minutes spent below 75% of the baseline preoperative pressure." The cause of blindness was ischemic optic neuropathy in 19 and retinal artery occlusion in seven. Improvement was obtained in only five patients who had partial loss of vision initially. Mayfield tongs may be of benefit in reducing facial pressure when the patient is placed prone for posterior surgery.

PRINCIPLES OF POSTERIOR TECHNIQUES

The principles of achieving a solid arthrodesis and a stable, balanced spine tend to be overshadowed by the marketing of new implant systems. With the development of each new system comes the promise of “perfect results with no complications.” The belief that more hardware is better has shifted our focus away from the concepts of precise planning and selection of fusion levels, meticulous operative technique, and careful postoperative management. New implant systems can and should be added to our armamentarium of scoliosis management, but scientific study is mandatory, and the tried and proven principles must not be forgotten.

Posterior techniques are effective for managing scoliosis associated with a wide variety of disease processes (Table 156.1). Establish the exact diagnosis in each patient whenever possible. An understanding of the natural history and the type of curve pattern that might develop is necessary to determine the appropriate approach for the treatment of idiopathic scoliosis; a patient with congenital scoliosis requires still another approach during evaluation and treatment.

Table 156.1. Etiology of Scoliosis: Conditions for Which Posterior Techniques Are Useful

INDICATIONS FOR SURGERY

The indications for surgical treatment vary, depending on the underlying diagnosis, curve magnitude and progression, the patient’s age and health, and the surgeon’s skill and judgment. All variables must be carefully considered before rendering a surgical decision. In general, there are four indications for surgical treatment in idiopathic or congenital scoliosis: severe curves, unacceptable curve progression, pain, and unacceptable cosmesis (Table 156.2).

Table 156.2. Indications for Surgery for Idiopathic Scoliosis

Curves of greater than 65° reduce total lung capacity (8, 14, 39, 55). Therefore, large or progressive curves should be corrected and stabilized. Winter et al. (61, 62) reported on the role that thoracic lordosis plays in decreasing pulmonary function and recommended screening and treatment in severe cases. In patients with thoracic lordosis, surgery may be necessary even though the coronal curve may not appear large enough to warrant it.

Collis and Ponsel (14) have shown that curves greater than 50° tend to progress even after skeletal maturity. There is a correlation between age, Risser sign, and curve magnitude as prognostic indications for progression (34, 54). In young patients without evidence of menarche, a Risser sign of 1 or less, and a curve of 40° or more, orthotics management is less effective and surgery might be indicated. On the other hand, there are times when combined thoracic and lumbar curves exceed 45° to 50° in magnitude but show no loss of pulmonary function, are cosmetically acceptable, and remain stable. These curves might be best managed by observation.
All patients are different, so determine treatment on an individual basis.

Pain is rarely associated with idiopathic scoliosis in the adolescent group. If a patient complains of pain, a thorough investigation to rule out organic causes must be undertaken. Adults with untreated curves, especially large curves, may have disabling pain that can be relieved by surgical treatment (30,43,46,51,57).

An unacceptable cosmetic appearance may be an indication for surgical treatment. Severe trunk decompensation or rotation may be a reason for surgery, but that decision must be made by the patient and family. Scoliosis surgery is a major undertaking: Careful thought must be given if the only indication is cosmesis. Rib deformity may not be corrected by correcting the curve, and improving the deformity always leaves a surgical scar.

In neuromuscular conditions, the indications for surgery are similar to those for idiopathic or congenital problems (Table 156.3). In patients who are marginal ambulators or wheelchair bound, progressive spinal curvatures may compromise ambulation or sitting balance. In wheelchair-bound patients, listing to the side because of a decompensated spine necessitates increased use of the upper extremities to achieve support and balance, which severely impairs overall function. In patients with poor sensation, progressive scoliosis tends to create pelvic obliquity, with subsequent asymmetric pressure-loading on the buttocks and eventual skin breakdown.

### PREOPERATIVE PLANNING

Careful preoperative evaluation and planning are integral to the overall success of spinal surgery. Attention to detail at this phase is essential for a smooth perioperative course. Document a careful history and physical examination of the patient. The neurologic evaluation is especially important in patients with congenital or neurologic conditions. Any abnormal findings will necessitate further evaluation with electromyography, myelogram, computed tomography (CT), or magnetic resonance imaging (MRI). In the physical examination of the spine, note rotational prominences, the amount of decompensation of the spine, and any evidence of defects or cutaneous abnormalities along the midline. Cutaneous abnormalities such as hair patches, nevi, dermal sinuses, and lipomas are frequently associated with intraspinal pathology (19,27,61). Myelography or MRI may be indicated to rule out disease in in or about the spinal cord.

### RADIOLOGIC EVALUATION

Magnetic resonance imaging is a relatively recent advance for evaluating the spinal column and its contents. This noninvasive tool has been valuable in diagnosing syringomyelia and other spinal cord anomalies. However, the three-dimensional nature of scoliosis can make clear imaging difficult. A close working relationship with the radiologist is necessary so that specific problems may be more carefully evaluated. (See Chapter 4 on imaging modalities.)

Myelography is indicated when abnormal neurologic findings are present on the physical examination, when spinal dysraphism is expected, and when MRI has proven inadequate or equivocal. Water-soluble dyes are preferred whenever, possible because they can be used in conjunction with CT and are useful in conditions in which the neurologic deficits are not consistent with the known diagnosis.

Begin preoperative radiographic evaluation with upright posteroanterior and lateral radiographs of the spine. Measure the curve by the Cobb method (12). Look for rotation and any evidence of congenital anomalies, tumors, or bony abnormalities. The Nash and Moe classification of rotation is useful in determining structural curvatures and selecting fusion levels (29). The lateral radiograph shows curvatures in the sagittal plane and the possible coexistence of lumbosacral spondylolisthesis. Supine right and left side-bending films demonstrate curve flexibility and give a good indication of the amount of correction that can be anticipated from surgery (29).

In severe deformities, bending films help in deciding whether to perform anterior procedures. For patients with severe rigid curves, it may be desirable to consider anterior releases or wedge resection before the posterior procedure. (See Chapter 155 for the anterior approach to scoliosis.) This allows better mobility of the spine and may decrease the pseudarthrosis rate. When excessive kyphosis or lordosis is noted, take lateral flexion and extension views. In patients with paralytic scoliosis, a supine view in maximum traction including the pelvis is useful to determine the amount of curve flexibility and what type of correction of pelvic obliquity might be expected.

Other diagnostic modalities may be necessary, depending on the clinical setting. In adolescent patients with scoliosis and back pain, perform technetium polyphosphate bone imaging to rule out tumor or inflammatory causes. Keim and Reina (28) have reported osteoid osteoma as a cause of painful scoliosis.

### LABORATORY STUDIES

Preoperatively, obtain a complete blood count, urinalysis, and electrolyte values in patients who are otherwise healthy. Any major medical problem might necessitate further studies. In patients with neuromuscular conditions or with severe scoliosis, obtain a preoperative electrocardiogram. Electrocardiography is also indicated in adults undergoing corrective spinal surgery. In patients with known cardiomyopathy, congenital heart disease, or cor pulmonale, obtain anesthiesia, pulmonary, and cardiology consultations before surgery. For patients with severe debilitating health problems, careful preoperative evaluation and management by an appropriate team of physicians, surgeons, and paraprofessionals ensures an easier and smoother postoperative course.

### PULMONARY EVALUATION

Vital capacity and total lung capacity are decreased in patients with scoliosis (6,18,38,60). The amount of decrease seems to correlate with the degree of curvature (38,60). Neuromuscular conditions tend to compound the loss of vital capacity from the scoliosis (17). For most patients, however, the decreased pulmonary function does not play a major role in the perioperative course. Therefore, routine preoperative pulmonary function studies are unnecessary.

Pulmonary function studies and arterial blood gases are indicated in patients with cor pulmonale, severe curves, thoracic lordosis, neuromuscular conditions, or a history of pulmonary problems. A 40% or greater loss of vital capacity and maximum breathing capacity increases the risk of postoperative complications (52). In patients with recurrent pneumonia and bronchitis secondary to scoliosis, a complicated postoperative course must be anticipated; pulmonary studies are helpful in these patients.

A trial of halo traction may be indicated in patients with severe lung disease or cor pulmonale. This trial of traction will establish the operability of a patient's curve. Any increase in cardiac or pulmonary compromise in halo traction is a contraindication for surgery (9).

The use of preoperative casting, traction, and other modalities to make the curve more mobile (or limber) or to obtain preliminary correction has been advocated in the past. There are now few indications for these methods because they add little if any correction to the spine. With rare exception, they have limited applicability.

### SELECTION OF FUSION LEVELS

Proper selection of fusion levels is one of the most important aspects of the preoperative planning. An inadequate length of fusion will lead to progression of the curve above or below the fusion (lengthening or “adding on” to the curve). This may eventually lead to loss of spine balance. A fusion that is too long, however, unnecessarily immobilizes the spine. A careful review of curve patterns and preoperative side-bending radiographs is valuable in defining the primary and compensatory curves. In general, the primary curve should be fused and the compensatory curves should be left unfused. For idiopathic scoliosis, fusion levels should include all vertebrae that...
are measured as a part of the primary curve (9,11,16,47).

When pelvic obliquity is present in neuromuscular scoliosis, understanding the curve pattern will help avoid a common pitfall: not incorporating the sacrum into the fusion. An oblique sacrum and pelvis must be considered as part of the curvature and should be included in the instrumentation and fusion.

**Idiopathic Scoliosis**

The selection of fusion levels is controversial in combined thoracic and lumbar idiopathic scoliosis. It is generally accepted that the fusion should include all vertebrae that are a part of the measured curve. In thoracic scoliosis, Harrington (24,25) suggests fusion from one level above the curve to two levels below, as long as the inferior level falls within the “stable zone.” Moe (44,45,47) and Goldstein (20,21 and 22) stressed the importance of extending the fusion from the neutrally rotated vertebra superiorly to the neutral vertebra inferiorly. Moe advocates thoracic fusion for combined thoracic and lumbar curves when the lumbar curve is more flexible on preoperative side-bending radiographs.

In 1983, King et al. (29) reported the long-term results of the Twin Cities Scoliosis Center's management of thoracic and combined thoracic and lumbar scoliosis. A category of curve types and criteria for selection of fusion levels were established. In addition, the results of this work support the concept of selective fusion of the thoracic spine in selected cases. These authors were able to identify five different thoracic curve patterns (Table 156.4). Type I curves are managed by fusion to L-4. In curve types II through V, a selective thoracic fusion can be performed if the lowest level of the fusion is centered over the sacrum (Fig. 156.1, Fig. 156.2, Fig. 156.3, Fig. 156.4, and Fig. 156.5). The lowest level of the fusion is established by drawing a line parallel to the iliac wings. A vertical line is then drawn perpendicular to the pelvic line centered on the sacrum. (It is important that any limb-length inequality be compensated for when the radiographs are taken.) The lowest vertebra most closely bisected by this line is called the stable vertebra (Fig. 156.6). Ending the fusion at the stable vertebra gives uniformly good results.

**Figure 156.1.** Type I curve. (From King HA, Moe JH, Bradford DS, Winter RB. The Selection of Fusion Levels in Thoracic Idiopathic Scoliosis. J Bone Joint Surg Am 1983;65:1302, with permission.)

**Figure 156.2.** Type II curve. The center sacral line has been created. The stable vertebra is T-12.

**Figure 156.3.** Type III curve. (From King HA, Moe JH, Bradford DS, Winter RB. The Selection of Fusion Levels in Thoracic Idiopathic Scoliosis. J Bone Joint Surg Am 1983;65:1302, with permission.)
In most curves, this method produces a fusion area that is substantially shorter than the standard T4-L4 fusion previously recommended. King et al. \(^{(29)}\) concluded that selective thoracic fusion can give good long-term results with balanced stable spines. When the fusion falls short of the stable vertebra, the curves tend to progress, adding vertebrae to the measured curve, and occasionally an additional surgical procedure is needed to extend the fusion. Fusing beyond the stable vertebrae, especially in type II curves, tends to aggravate the lumbar curve and also removes additional valuable motion segments.

Aaro and Ohlen \(^{(1)}\) and Chochran et al. \(^{(13)}\) have clearly detailed the complications of fusion that extend into the lumbar spine. Harrington rod fusions flatten the lumbar spine, and fusions to L-4 and L-5 carry a higher incidence of back pain on long-term follow-up. In their report, 62% were fused to L-4, and 82% were fused to L-5. \(^{(1)}\) Be aware of compensatory curves and avoid extensive fusion when possible. In idiopathic scoliosis, avoid fusion to L-4. Rarely, if ever, is fusion to L-5 indicated. Fusion to the sacrum is not indicated in adolescents. However, if symptomatic spondylolisthesis is present, lumbosacral fusion might be indicated. When an asymptomatic spondylolysis or spondylolisthesis is present, fusion using the criteria just outlined can be safely performed \(^{(6)}\).

**Neuromuscular Scoliosis**

In many neuromuscular conditions (e.g., Friedreich's ataxia, Charcot-Marie-Tooth disease, and ambulators with cerebral palsy), the curve patterns are similar to idiopathic scoliosis. In those instances, fusion levels may be chosen as just described for idiopathic curves. Analysis of the lateral roentgenograms is important to avoid stopping the fusion at the apex of a kyphosis.

In the more common neuromuscular curve where pelvic obliquity is noted, the sacrum and pelvis must be considered part of the scoliosis. This situation is most frequently seen in cerebral palsy, myelomeningocele, muscular dystrophy, spinal muscle atrophy, and scoliosis secondary to spinal cord injury. If the sacrum and pelvis are not included in the instrumentation and fusion, progressive pelvic obliquity and loss of sitting balance result. If there is doubt about extending the fusion to the pelvis in a neuromuscular curve, err on the side of extending the fusion. In the nonambulator with pelvic obliquity, a short fusion invariably leads to curve progression. When the sacrum is included in the fusion, lumbar lordosis must be maintained. A flat lumbar spine leads to poor sitting balance, and to skin breakdown in patients with insensate skin.

The superior level of fusion is more controversial. In patients with idiopathic patterns, the rules are similar to idiopathic curves. In wheelchair-bound patients, the superior extension of the instrumentation and fusion should be carried high into the thoracic spine, usually to T-2 or T-3. The underlying problem is poor muscle tone or muscle imbalance. Failure to extend the fusion proximally will lead to the development of deformity above the fusion. A progressive kyphosis above a short lumbar fusion inevitably leads to loss of sitting balance and risks potential skin breakdown.

**Congenital Scoliosis**

When congenital scoliosis has progressed and surgical treatment is contemplated, carefully analyze the curves in the coronal and sagittal planes. Preoperative MRI or myelography is warranted. Use side-bending films to analyze compensatory curve flexibility. Much as in the patient with idiopathic scoliosis, the fusion must be balanced over the center of gravity, and compensatory motion must be preserved. I tend to follow guidelines similar to those given previously in the section on idiopathic scoliosis. In congenital scoliosis, curves are variable, so exact guidelines are difficult to define. Carefully analyze primary and compensatory curves and adhere to the principles of balancing the fusion mass over the center of gravity and fusing selectively, and you will generally obtain a good result. (See Chapter 158 for further details on congenital conditions of the spine.)

---

**SURGICAL TECHNIQUES**

**POSTERIOR SPINAL FUSION**
The primary goal of spinal arthrodesis is to establish an environment favorable for bone maturation and union. For the surgery, a four-poster frame (a variation of the Half-Relton frame) allows the abdomen to fall free, thereby decreasing intra-abdominal and venous pressure.

- Position the patient prone on the frame, avoiding pressure on the brachial plexus and ulnar nerves. Pad the knees and ankles. When fusion to the lumbar spine or sacrum is planned, position the patient with the hips extended to maintain normal lumbar lordosis.
- Prepare and drape the back for an extensive surgical exposure.
- Make a straight incision and infiltrate the skin with 1,000,000 epinephrine in normal saline to help control bleeding.
- Use self-retaining retractors for exposure. The pressure from the retractors also helps reduce the capillary bleeding.
- Use electrocautery to control all bleeders.
- Initiate the subperiosteal exposure of the spine with a sharp Cobb elevator.

It is absolutely mandatory that the elevators, curets, gouges, and osteotomes be sharp and well maintained. Avoid excessive force at all times around the spine! Sharp instruments make gentle surgery possible.

- Use the Cobb elevator to dissect the soft tissues from the spinous processes, lamina, and facets out to the tips of the transverse processes. Control bleeding with electrocautery and sponge packs.
- Place a metallic marker on a spinous process and obtain an intraoperative radiograph to document the position on the spine. It is amazingly easy to become confused about the proper spine level without radiographic control.
- Place Adson self-retaining retractors deep into the wound and clear the facet joints of ligaments and capsules. Sharp curets facilitate adequate clearing of the soft tissues.
- Roll and pack gauze sponges along the areas that have been exposed. Gentle pressure, along with meticulous electrocaugetion, will maintain a dry field.
- Good-quality bone and instrument work are impossible in a bloody operative field.
- Bone bleeding can also be controlled with bone wax and Gelfoam patti es soaked with topical thrombin.
- Blood loss is best reduced by meticulous operative technique and controlled hypotension by an anesthesiologist experienced in hypotensive anesthesia. (See Chapter 7 for more details.)
- When you have adequate exposure of the spine and hemostasis, obtain a bone graft from the posterior iliac crest if autologous bone is to be used for fusion.

Either use a separate incision over the iliac crest or, if the primary surgical incision is to be carried down to the lumbar spine, the same surgical incision can be used. A subperiosteal exposure of the iliac crest is preferred. (For many neuromuscular conditions and for spina bifida, I have had excellent results using cadaver bone.)

- With a Capner gouge or air-driven impact osteotome, take cortical and cancellous strips of bone from the outer table and the underlying cancellous bone. Harvest a generous amount of bone and carefully store it in saline or cover it with a blood-soaked sponge. (See Chapter 9 for bone-graft harvesting techniques.)
- Control graft-site bleeding with bone wax.
- Fuse the facet joints as a standard procedure, regardless of the instrumentation system used. The long-term success of any fusion depends on a solid arthrodesis, and it is the combination of techniques and instrumentation that will accomplish this.
- In the thoracic spine, use a Capner gouge to remove a generous portion of the inferior facets on both the concave and convex sides of the curve.
- With a curet, remove the visible cartilage. Then use the gouge to decorticate the superior portion of the junction of the transverse process and the facet. Pack a generous piece of cancellous bone into the facet with the Moe bone impactor (Fig. 156.7).

![Figure 156.7](image)

**Figure 156.7.** The techniques used for excising the thoracic joint (A) and packing with cancellous bone (B).

- In the lumbar spine, the facet joints can be excised using a straight ¼-inch Lambotte osteotome or a Lexcel rongeur. It is important to see the joint and remove the articular cartilage completely (Fig. 156.8). Then pack a piece of cancellous bone into place with the Moe impactor.

![Figure 156.8](image)

**Figure 156.8.** The technique used for excising lumbar facets and packing with cancellous bone plugs.

- After the facets have been excised and the bone grafts placed, remove the spinous processes. Complete decortication of the spine with either a sharp, curved gouge or with an air-driven impact osteotome. Use extreme caution here, because open lamina or instrument sites are present and may be entered by the gouge. Pack the bone graft obtained by decortication of the spinous processes and iliac crest along the decorticated spine.

**RESECTION OF THE RIB HUMP**

In patients with large, unsightly rib humps, rib resections can be performed through the same surgical incision.

- Develop a skin and subcutaneous flap on the affected side to the posterior axillary line.
- Subperiosteally dissect each rib and then cut it with a rib cutter medially and as far laterally as possible. Steel (88) has reported excellent cosmetic results with this technique.
- The ribs supply abundant bone graft and make a separate iliac exposure unnecessary.
- Take care to avoid entering the pleural cavity. If the pleural cavity is entered, place a chest tube and connect it to a closed water-seal suction system.
- Close the wound using a running 0 Vicryl (Ethicon) suture for the fascia.
- Prior to closure of the wound, I routinely place a suction drainage system. Place the tubing on the fascia, not next to the cancellous bone, to avoid excessive drainage of blood and to prevent clogging of the drain by the bone.
- Close the subcutaneous tissue with a 2-0 Vicryl suture and the skin with a running subcuticular 3-0 Vicryl suture. The latter makes a good cosmetic closure and avoids the cross-hatching of interrupted sutures. Relieve skin tension with adhesive skin tapes and apply a bulky pressure dressing.

**INSTRUMENTATION SYSTEM**

Recent years have brought many new spinal instrumentation systems to the forefront, and more and better systems will undoubtedly be developed. Evaluate each system on its own merits (Table 156.3). One system will probably not solve every problem, so you must be facile and knowledgeable in the use of many systems.
Table 156.5. Harrington Instrumentation System and Variations

As implant systems have come onto the market, the most successful seem to have similar characteristics. They generally have a broad range of applicability and usually combine options for the use of hooks, screws, and wires. Most combine open and closed hooks for ease of use. It is important that the implant profile is such that it is not prominent in thin patients.

Harrington Instrumentation

The Harrington instrumentation system was the gold standard in the treatment of idiopathic scoliosis for many years. New implant systems using dual rods and multiple points of fixation with hooks, wires, and screws have replaced the Harrington system. Most systems have moved away from simple distraction and have evolved into a more three-dimensional technique using translation, counter torsion, and limited distraction.

Instrumentation without Fusion

When the patient’s curve is difficult or impossible to manage with braces or orthoses, and spinal growth is desirable, instrumentation without fusion can be performed (15,35,36 and 37,40,46). The technique is useful in small children with infantile idiopathic scoliosis and in patients with selected neuromuscular conditions in whom curve control and spinal growth are necessary.

The surgical technique is similar to standard instrumentation technique, varying with the patient’s size and bone stock.

- Use standard positioning, preparation, draping, and incision as described previously, but expose the spine only at the proximal and distal hook sites. Do not expose the remainder of the spine.
- Confirm proper levels by radiography.
- I prefer to use one of the new multi-hooks and rod systems for the implant system. I originally used the Harrington system, but it allowed for simple distraction only and could not accommodate more than one hook at the top and one at the bottom of the instrumented levels. I currently prefer the ISOLA system (DePuy Acromed, Raynham, MA) because of its low profile and adaptability for difficult problems.
- Create a claw configuration at the top of the curve and use a down-going hook at the inferior end of the curve. A claw can also be created on the inferior end of the curve, if desired. This will add extra stability (Fig. 156.9, Fig. 156.10).

Figure 156.9. Create hook sites in the thoracic spine by excising a portion of the inferior facet.

Figure 156.10. A: Position of the laminar Harrington hook. B: The Cotrel-Dubousset laminar hooks are positioned with similar technique.

- It is possible to use concave and convex rods to enhance correction and control of the curve.
- Thread the rods beneath the skin and through the subcutaneous tissues in the middle of the curve, and avoid subperiosteal stripping, which risks spontaneous fusion.
- Use two rod segments connected by an axial connector (i.e., a rod sleeve into which both rods fit and are held in place with screw fixation). Axial connectors allow you to return to the site in 6–9 months and lengthen the rods without having to open the entire incision. Such lengthening can often be done as an outpatient procedure.
- It is also possible to merely leave the rods long on either end. This allows extra length for subsequent lengthenings and avoids the need of axial or side-by-side connectors.

In very young patients with very small and soft bones, expose the superior and inferior hook sites and place bone graft at these areas. This will create a localized fusion that can be used for hook placement 4–6 months later, at which time these “platforms” can be used to establish claw constructs as previously described.

Postoperative Care After subcutaneous rodding, keep the patients in a postoperative orthosis. Lengthening is generally necessary every 6–9 months and can be continued until adequate growth has been achieved. At that time, the definitive spinal fusion and instrumentation can be completed.

Luque Instrumentation

Luque has described a procedure combining segmental instrumentation and rodding but no fusion (35 and 36,37,53). Theoretically, this avoids the need for postoperative immobilization. Luque has clearly shown that subperiosteal dissection alone does not alter spinal growth. However, this is a procedure with many
complications. I prefer a modification of the Moe (15) and Marchetti (40) techniques of rodding without fusion.

The concept of segmental spine instrumentation was introduced by Eduardo Luque in 1975 (36,37). He originally developed the technique by augmenting standard Harrington rods with segmental sublaminar wires, then modified it to use dual smooth L-shaped rods with sublaminar wires and spinal fusion.

I use many of Luque’s original concepts but have adapted newer approaches combined with sublaminar wire fixation. The technique is excellent for neuromuscular scoliosis, in patients with soft bone, and in patients where fusion to the sacrum may be necessary. When fusion to the sacrum is indicated, I combine the modified Luque technique with Galveston pelvic fixation as described by Allen and Ferguson (2). I also use pedicle screw fixation in the sacrum, and I may also use pelvic screws instead of the contoured smooth rod for pelvic fixation. The addition of sacral screws has been invaluable in obtaining sacral fixation. The conventional L-shaped rod with Galveston fixation does not obtain sacral purchase. It really bypasses the sacrum, crosses the sacroiliac joint, and obtains fixation in the iliac wings. This has some obvious disadvantages; however, the fixation to the pelvis combined with screw fixation in the sacrum seems to give the best purchase and best control of the lumbosacral junction.

The Luque technique begins with the standard positioning, preparation, and surgical exposure as described earlier in this chapter.

- Excise the facets at each level and the ligamentum flavum with a Lexcel rongeur. Kerrison rongeurs can be used to complete removal of the ligamentum flavum.
- Loop a 16-gauge wire and pass it carefully under the lamina at each level to be fused. The diameter of the curve in the wire should be about the same width of the lamina, so that as the wire passes, it will smoothly pass under the lamina and then come out over the superior edge of the next lamina (Fig. 156.11, Fig. 156.12).

\[...\]

**Figure 156.11.** Luque wiring; Carefully manage sublaminar wires. A looped wire may be cut to create two wires. A: Carefully pass a looped wire beneath the lamina from inferior to superior, avoiding impingement on the spinal cord or roots. B: Centralize the wire and place a strand of wire on each side of the spinous process. C: Cut the loop of the wire and secure it around the rods on each side.

\[...\]

**Figure 156.12.** Tighten the wires. The Galveston fixation is positioned between the inner and outer tables just below the posterior superior iliac spine and above the greater sciatic notch. See text for details.

- Grasp the wire with a needle holder and pull it through. Maintain constant upward force, which keeps the wire taut against the undersurface of the lamina and avoids downward movement toward the spinal cord.
- Wire management is very important to avoid deep wire penetration into the spinal canal. I prefer the technique described by Yngve et al. (65) (Fig. 156.11).
- As the wire comes up, tighten it down over the lamina.
- After positioning the rod, cut the loop on the wire, creating two separate wires at each level (Fig. 156.11C). The wires can then be sequentially tightened, bringing the spine to the rod. This technique decreases the amount of wire handling and tends to keep the operative field easier to manage.

I have recently changed my technique for the superior portion of the rod. Luque described using wires at all levels, including the top of the rod. However, on occasion a junctional kyphosis can develop at the superior end of the fusion because of the removal of the ligamentum flavum and posterior interspinous ligaments. I now use open hooks at the top two levels to create a claw construct.

- Place a supra-laminar hook or transverse process hook from cephalad to caudad.
- Place the up-going hook at the level of the down-going hook, or at the level below (Fig. 156.13).

\[...\]

**Figure 156.13.** Create anchor sites at the superior curve and inferiorly at the stable vertebra in thoracic types II, III, IV, and V curves. See text for details. (By permission of Dr. Marc Asher.)

- Excise the inferior facet with a ¼-inch osteotome. Remove the cartilage with a sharp curet and position an open hook.
- As the rod is brought close to the spine by wire tightening, the rod will come into the open hooks and then can be secured with hook caps (Fig. 156.14, Fig. 156.15).
The choice of system is generally decided by the surgeon's own personal preference. At the inferior level of the sacrum, use sacral screw fixation in addition to the Galveston or pelvic screw fixation. The sacral screws link the ilium and the sacrum and help reduce the amount of stress on the pelvis. I have noted significantly less bone absorption around the pelvic posts with the addition of sacral screw fixation, especially in patients with neuromuscular scoliosis and soft bone.

The screws are usually situated in the sacral pedicle just below and lateral to the L5–S1 facet.

- Identify the pedicle and probe it with the gear shift probe.
- Confirm the placement with a ball-tipped pedicle probe and lateral roentgenogram.
- I generally use bicortical purchase.
- Tap for the screw, and again probe, and then position a screw of the appropriate length and diameter.
- Once the screws have been placed, attach them to the rod using slotted connectors. If the angle is difficult to accommodate with rod contouring, use a variable-angle slotted connector.

When the fusion is continued to the pelvis, I tend to favor the Galveston technique or the use of an iliac bolt, which can be attached to the rod by a slotted connector. I generally expose both iliac wings through the midline incision. Adequate exposure is necessary to visualize the greater sciatic notches bilaterally. The entry point for the L portion of the rod is usually just below the posterior superior iliac spine (PSIS).

- Make a hole in the superior border of the posterior ileum just below the PSIS with a 3/16- or ¼-inch drill, depending on the size of the rod chosen.
- Insert the rod between the tables of the ileum so that it lies 1–1.5 cm above the greater sciatic notch. The length of the rod or screw is usually 6–8 cm, depending on the size of the patient.
- Rod contour is important to correct the deformity and maintain normal sagittal balance. I generally use a malleable template to help establish the appropriate bend. The rods are then contoured using the Cotrel-Dubousset French bender and the Asher ISOLÀ bending irons.
- After appropriate bending, position the rods and sequentially tighten and secure the wires (Fig. 156.16, Fig. 156.17 and Fig. 156.18).

---

**Figure 156.14.** Place sublaminar wires at the apex to help create translation forces. See text for details. (By permission of Dr. Marc Asher.)

**Figure 156.15.** Wire tightening. (By permission of Dr. Marc Asher.) See text for details.

**Figure 156.16.** Place a convex rod to create a countertorsion force. (By permission of Dr. Marc Asher.) See text for details.

**Figure 156.17.** Complete tightening of the wires. (By permission of Dr. Marc Asher.) See text for details.
After the hardware is secured and all wires are tightened, decorticate the remaining exposed transverse processes and laminae using gouges and rongeurs. Take great care to avoid penetrating the open laminotomies.

Carefully pack autogenous iliac bone or banked bone around the decorticated spine.

Close the wound using a drain above the fascia as described previously.

Although some surgeons feel that no postoperative immobilization is necessary, Hemdon et al. reported a 10% pseudarthrosis rate when no postoperative bracing was used, and a near-zero incidence with bracing. In my experience, a custom-molded, bivalved, polypropylene brace prevents loss of correction and makes most patients more comfortable and more mobile postoperatively.

### Multi-Hooks and Rod Systems

#### Historical Background

In 1981, Yves Cotrel and Jean Dubousset of France introduced a spine implant system that combined segmental fixation with distraction compression and derotation of the spine. Their system consisted of a series of open and closed hooks and a knurled rod with a diamond-patterned surface. It allowed the two rods to be connected by cross-links, increasing the overall stability of the system. Cotrel and Dubousset stressed the importance of maintaining and creating normal sagittal contours. Their system of rotation and Luque's concept of translation were the first efforts to move away from the old concept of pure distraction and move toward an attempt to obtain three-dimensional spine correction. As the popularity of the Cotrel-Dubousset system grew, others started to develop their own implant systems. Most of the new systems have been based on the concept of flexibility in use and the ability to fix to the spine with multiple points of fixation. Most use hooks, wires, and screws, in combination, as the means of spine fixation. Virtually all of the systems, when used properly, will give good spine correction and excellent results.

The new multi-hooks and rod systems are complicated, and their application is complex. When first using these systems, obtain hands-on training with surgeons who are experienced with them.

Because these new systems use multiple hooks, screws, and wires to rigidly stabilize the cross-linked dual rods, the need for bracing is diminished, which is a huge advantage for the patient. Bracing is occasionally used for patients who have soft bone or for whom compliance is questionable. I have used bracing to control an unfused lumbar curve, surgically treating the thoracic curve and using bracing to control the unfused segment. The criteria for discontinuing the use of a brace are those used in a standard brace program.

The selection of fusion levels using the new systems has been controversial. I select fusion levels based on the criteria established by King et al. (29). Early in the Cotrel-Dubousset experience, there were numerous reports of lumbar curve decompensation after selective thoracic fusion (10,33,41). These problems had not been noted in series reporting the use of Harrington instrumentation. Cotrel and Dubousset have proposed that instrumentation levels should include all sagittally abnormal zones, create rotational neutralization, and finish in the Harrington stable zone. This frequently necessitates fusion into the upper lumbar spine. Thompson et al. (59) and Wood et al. (63,64) have reported data suggesting that overrotation of the thoracic curve locks the transitional thoracolumbar rotation segments, making it impossible for the lumbar curve to balance the thoracic spine. This situation leads to a shift of the thoracic curve to the left and frequently causes progression of the lumbar curve. Richards et al. (52) and Benson et al. (7) have shown that large curves and less flexible lumbar curves are more likely to decompensate with standard Cotrel-Dubousset techniques. Richards et al. believe that in thoracic curves greater than 60°, with a lumbar component greater than 45°, lumbar decompensation may occur with selective thoracic fusion (52). They suggested fusion of both curves when the thoracic and lumbar curves are large.

In 1949, Von Laccurm and Miller (59) advised caution when correcting the primary curve. They stated that the primary curve must not be corrected beyond the compensatory curve's ability to correct and balance the spine. It is important to realize that these words were written prior to the advent of internal fixation; with advanced corrective devices, they are more timely than ever! Massey et al. (42) have reported on their series of fusions using Cotrel-Dubousset instrumentation and fusing to levels selected according to King's criteria. They found no problems with lumbar decompensation as long as no attempt was made to overcorrect the thoracic spine. Previous implant systems have not provided the powerful corrective forces that the newer systems offer. We may have temporarily lost sight of the importance of spinal stability and balance. Our patients are not as concerned about the number of degrees of correction as they are about the appearance of a balanced stable spine. We must remember the wisdom of Von Laccurm and Miller (59).

Recent work by Asher and others has advanced our concept of scoliosis correction. Asher has done extensive three-dimensional studies to better understand and explain the findings noted in idiopathic scoliosis. In a report of his three-dimensional studies of the scoliosis deformity, Asher and Cook (6) found that in progressive curves the apex vertebrae tends to displace laterally and posteriorly, and that the spine tends to collapse toward the midcoronal plane as the curve progresses. This was consistent with Pedeniole and Vidal's (53) concept of the evolution of scoliosis in the transverse plane. Asher believes that this fits well with the engineer's concept of scoliosis as a geometrical torsion or a property of a helical line. This is in distinction to a mechanical torsion in which two objects immediately adjacent to each other are rotated on each other. It is Asher's idea that scoliosis develops as a series of imperfect torsions. He notes that the apical vertebra did not always torque posteriorly in thoracic/lumbar curves. He believes that there are many reasons for these findings, including rib cage constraints, soft tissues, and asymmetry of motion segments (3,4,5 and 6).

It is my belief that correction of scoliosis should include translation and countertorsion if we hope to correct the true complex scoliosis deformity described by Asher. I have tended to drift away from the derotation maneuver described by Cotrel and Dubousset because of the problems seen with lumbar decompensation in type II curves and the intuitive notion that the derotation movement is done in the same counterclockwise motion that scoliosis tends to develop in.

The rules of selective fusion have changed little from the days of Harrington instrumentation. I still use the concept of selective fusion in thoracic curve patterns to avoid unnecessary fusion of the lumbar spine. The fusion should end at the stable vertebra unless that vertebra is at the apex of a kyphosis. If the stable vertebra is located at the apex of those segments, variation of standard hook-and-wire patterns may be applied in compression across the kyphotic segments to correct the abnormal segment (23).

Thorough preoperative planning is essential to ensure a smooth operation (it helps avoid confusion for the surgeons and nursing staff) and a good result. One may choose to label the hook-and-wire sites on the preoperative roentgenogram, or know in advance where sites might be most appropriate. The predetermined hook sites, however, may need to be altered in response to findings during surgery.

#### Operative Technique

For the standard right thoracic curve, I use a basic hook-and-wire placement, which is useful in types II, III, IV, and V curves. The type V curve differs only in that the upper stiff thoracic curve must also be instrumented and fused to avoid an objectionable shoulder asymmetry. I generally choose the upper level of instrumentation as the upper level measured by the Cobb method, or a level that is closest to the midline (Fig. 156.6). The upper level of instrumentation is generally T-3 or T-4. I currently use the ISOLA system, which uses open and closed hooks, wire, and screw fixation.

- Prepare the upper facets on both sides of the superior vertebra by removing 4 mm of the inferior facet with a ¼-inch osteotome. Remove the cartilage with a curet.
- Position an appropriate-size hook in the up-going position (Fig. 156.9). The hook should have a nice snug fit, and the throat of the hook should allow adequate room around the facet.
- On both sides of the upper vertebra, create a "claw" by placing a closed hook on a holder, placing the foot of the hook on the superior edge of the transverse process, and allowing the hook to slide around the facet (Fig. 156.18). This should give firm fixation on the vertebra.

---

**Figure 156.18.** Application of concave distraction and convex compression complete the instrumentation sequence. See text for details. (By permission of Dr. Marc Asher.)
I generally use an intermediate up-going pedicle hook on the concave side of the curve, one or two levels below the upper end vertebra. This hook is positioned in a similar manner.

- I generally use a closed hook with an appropriate radius to just fit around the lamina (Fig. 156.10).

Some surgeons have started to use screw fixation on the inferior end vertebra for right thoracic curves. I have experience with this technique in types III and IV curves but have not used it in type II curves because the lower thoracic pedicles in adolescents tend to be quite small. The lumbar pedicles, however, can be quite large and adequate for screw placement. The advantages of screw fixation are the secure purchase and the translational control that can be achieved.

- At this point in the procedure, segmentally secure the apical three or four vertebra with sublaminar wires or cables. I use the same technique described in the Luque fixation section (Fig. 156.19).
- After the wires have been passed, excise the concave facets and graft bone.
- Fashion and contour an appropriate length of rod using French and tube benders. (A malleable template is useful to obtain rod length and contour.)
- Feed the rod up through the upper hooks and then rotate into the appropriate plane (Fig. 156.20). Then feed the rod down into the inferior hook.

The upper claw can then be secured with the compression device and the setscrews tightened (Fig. 156.21).

Sequentially tighten the wires or cables, translating the spine toward the rod (Fig. 156.22).

I generally favor wires because of their low cost and ease of use. Braided cables are an alternative.

- I generally use an intermediate up-going pedicle hook on the concave side of the curve, one or two levels below the upper end vertebra. This hook is positioned in a similar manner.
- On the convex side at the apical vertebra, create another claw to assist in the countertorsion movement with the second rod.
- Position the inferior hook on the concave side after a limited laminotomy is created. It is important that the laminotomy be large enough to position the hook, but small enough to prevent deep penetration of the hook into the spinal canal.
- I generally use a closed hook with an appropriate radius to just fit around the lamina (Fig. 156.10).

Some surgeons have started to use screw fixation on the inferior end vertebra for right thoracic curves. I have experience with this technique in types III and IV curves but have not used it in type II curves because the lower thoracic pedicles in adolescents tend to be quite small. The lumbar pedicles, however, can be quite large and adequate for screw placement. The advantages of screw fixation are the secure purchase and the translational control that can be achieved.

- At this point in the procedure, segmentally secure the apical three or four vertebra with sublaminar wires or cables. I use the same technique described in the Luque fixation section (Fig. 156.19).
- After the wires have been passed, excise the concave facets and graft bone.
- Fashion and contour an appropriate length of rod using French and tube benders. (A malleable template is useful to obtain rod length and contour.)
- Feed the rod up through the upper hooks and then rotate into the appropriate plane (Fig. 156.20). Then feed the rod down into the inferior hook.

The upper claw can then be secured with the compression device and the setscrews tightened (Fig. 156.21).

Sequentially tighten the wires or cables, translating the spine toward the rod (Fig. 156.22).

I generally favor wires because of their low cost and ease of use. Braided cables are an alternative.

- After the wires have been tightened, complete distraction and secure all setscrews.
- Position the convex rod after facets have been excised and bone grafted (Fig. 156.22).
- Pass the rod through the upper hooks, place the intermediate hooks on the rod, and bring the positioned rod down to the spine. The positioning of the rod serves as a countertorsion movement and tends to push the spine out of rotation and toward the midline (Fig. 156.23).
Place an upward-directed hook under the inferior lamina and advance the rod to engage the hook.

After the rod is positioned, apply compressive forces to complete the sequence. The sublaminar wires can be retightened; revisit and tighten all setscrews a final time.

I use cross links to create a rectangle and increase the strength of the system (Fig. 156.24).

Avoid overcorrection of the instrumented curve. The lumbar curve must be able to accommodate the corrected thoracic curve. Type II curves require particular care and caution. Overcorrection of the thoracic curve can lead to lumbar curve decompensation. I have had minimal problems with lumbar curve decompensation using the translation and countertorsion technique. It seems to cause far fewer problems than the old derotation technique that was based on the techniques of Cotrel and Dubousset. Particularly in the type II curves, we use instrumentation and fusion to treat the main thoracic curve, and then a thoracolumbosacral orthosis (TLSO) to treat the unfused lumbar curve. This has been an effective technique for young patients with a Risser sign of 0 to 2 where growth is anticipated and possible progression of the lumbar curve might be expected.

The double thoracic and lumbar type I curves can be treated with a technique different from that used for thoracic scoliosis curve types. In type I curves, fuse both thoracic and lumbar curves, choosing the upper level of fusion as for the type II to IV curve patterns. (Fig. 156.25, Fig. 156.26, Fig. 156.27, Fig. 156.28, Fig. 156.29 and Fig. 156.30 show typical cases.)
First, create bilateral claws at the upper level of the fusion, and place a claw or up-going hook at the apex of the thoracic curve. At the inferior level of the thoracic curve, place a down-going hook; it is usually preferred to use an open hook at this level. On the convex side of the lumbar curve, screw fixation is preferable to hooks, as it seems to give a better base for correction and avoids possible hardware displacement. The thoracic curve is generally managed with sublaminar wires. Place the concave thoracic and convex lumbar rod first. Before tightening the setscrew, rotate the rod counterclockwise. This rotation movement does not change the thoracic curve much, but it does effectively translate and countertorque the lumbar curve. Place the second rod and anchor it superiorly with hooks. Use an up-going hook at the thoracolumbar junction. Use sublaminar wires on the concavity of the lumbar curve, and generally use screws at the last two or three levels. Place the second rod with wires or screws in the lumbar curve. Use compression along the convexity of the thoracic curve and distraction along the concave lumbar curve. Apply transverse connectors and retighten all set-screws.

It is important to be aware of sagittal plane alignment. When fusions must be extended into the lumbar spine, maintain the normal lordosis to avoid the creation of flatback syndrome.

The postoperative program is similar to that of other techniques. Where poor bone or inadequate fixation has been encountered, a bivalved TLSO brace is used. For patients in whom firm fixation is achieved, no postoperative immobilization is required. Mobilize patients on the first or second postoperative day. Encourage them to start walking early, and let them return to school when comfortable. Generally, hold them out of sports for 6–9 months.

The ISOLA system has proven to be a very flexible system that can be applied to many spine problems. Evolution of implant systems is inevitable, and with each new change we are better able to manage more complex deformities.

POSTOPERATIVE MANAGEMENT

Postoperative management is extremely important. Careful attention to detail is as necessary for this phase as it is for the preoperative planning and the surgical procedure.

After surgery, manage patients in a conventional hospital bed (rather than turning frames or other rotating beds), as patient acceptance and nursing familiarity make this an excellent choice. Use foam pad and sheepskins to facilitate skin care. In the immediate postoperative period, log-roll the patient every 1–2 hours to prevent skin sores, improve ventilation, and reduce pulmonary complications. During the initial 48-hour postoperative period, administer intravenous fluids and limit oral intake. Avoid early oral feeding because postoperative ileus is common. An aggressive pulmonary care program with frequent coughing, deep breathing, and the use of an incentive spirometer is a standard part of the postoperative program. For patients with reduced pulmonary capacity, a respiratory therapist can be called in to use suction and a more aggressive pulmonary program.

Provide postoperative support of the spine with a plastic bivalved body jacket. It is easy to use and is equally well tolerated by patients with idiopathic scoliosis and those with a wide variety of neuromuscular conditions. If patient compliance is questionable, a more standard Risser cast can be used successfully. A cervicothoracolumbosacral orthosis (CTLSO) is helpful when instrumentation is carried into the high thoracic spine. In patients with neuromuscular curves or when instrumentation high into the thoracic spine necessitates immobilization, a sternal-occipital-mandibular immobilization (SOMI) device can be added to a bivalved jacket. Maintain postoperative immobilization for 4–6 months. The removable jackets make postoperative hygiene and skin care much easier; allow compliant patients to
and carefully review the films for lucent lines in the fusion mass. If broken hardware is noted, a pseudarthrosis is highly likely.

Obtain radiographs of the spine before the patient is discharged from the hospital. This set of films establishes the amount of correction and confirms adequate positioning of the hardware. Virtually all hardware pullout occurs in the early postoperative period. Have the patient return 3–4 weeks after discharge for posteroanterior and lateral radiographs to confirm curve stability and hardware position. Take subsequent films at 3 and 6 months. Also take oblique radiographs at the 6-month visit to check the maturity and integrity of the spinal arthrodesis. If the fusion is questionable or unclear on standard radiographs, obtain tomograms. If poor incorporation of the graft is noted, additional immobilization or augmentation of the fusion with additional bone graft may be necessary.

**PITFALLS AND COMPLICATIONS**

Unfortunately, major surgical procedures have the potential for complications. Many can be avoided by careful planning and surgical execution. Others, however, occur despite the best efforts.

**BLOOD LOSS**

The best way to avoid complications from blood transfusion is to minimize intraoperative blood loss. Proper positioning, hypotensive anesthesia, and careful surgical technique are the cornerstones of minimizing blood loss. I have used preoperative autologous blood donations for about 5 years. Preoperative donations can begin 3–4 weeks before surgery. Iron supplementation is helpful to maintain adequate red blood cell production. With a good autologous blood program, banked blood can generally be avoided. The risks of human immunodeficiency virus (HIV) transmission from bank blood are low, but they can be eliminated with an autotransfusion plan. In cases where blood loss is expected to be high (e.g., in osteotomy or reconstructive procedures), another cost-effective and safe way to reduce the need for blood transfusion is intraoperative blood salvage with a cell-saver.

If major intraoperative blood loss is encountered, immediate hematologic workup, even during the procedure, is mandatory. Transfusion of platelets and appropriate clotting factors can be lifesaving. Fortunately, in my experience, major blood loss is rare if attention to detail is observed.

**SPINAL CORD INJURY**

Spinal cord injury is one of the most feared complications in treating scoliosis. The neurologic injury may occur from direct trauma to the cord by instruments, hooks, or sublaminar wires, or by stretch of the spinal cord. Stretch of the spinal cord is presumed to cause vascular compromise that leads to neurologic loss. Certain techniques seem to carry more risks. The 1997 Morbidity and Mortality Report (available from the Scoliosis Research Society) reported an incidence of spinal cord injury during adolescent idiopathic scoliosis surgery of 0.28%. There did not seem to be a correlation based on the type of implant used. A 0.14% incidence of nerve root injury was also noted.

Excessive traction on the spinal cord can occur during correction of scoliosis. This is most frequently seen in large rigid curves but can occur with the manipulation and correction of any curve. Congenital scoliosis carries a higher risk of neurologic injury; these curves tend to be rigid and may be associated with cord tethering by bone spurs, fibrous bands, or a tight filum terminale. As discussed earlier, we recommend the use of MRI prior to the surgical treatment of congenital curves.

The advent of the wake-up test gave spine surgeons a way to assess neurologic function after instrumentation and before sending the patient to the recovery room. In this test, the patient is momentarily awakened from anesthesia and asked to move her toes. Lack of volitional movement calls for careful examination of the procedure and elimination of any potential cause of neurologic impairment. Because of the anesthetic medication, the patient usually neither recalls the wake-up test nor mentions that she felt pain during the procedure. I usually use electronic spinal cord monitoring with sensory evoked potentials (SEP) during surgery. This gives continuous readouts of cord function without wakening the patient, with the risks of extubation and the increased bleeding that occur when the blood pressure rises during wake-up. I had false-positive readings during my early experience with SEP, so the wake-up test was used to confirm that no neurologic deficits were present. With added experience and the use of multiple recording sites (epidural, scalp, and cervical), the SEP has proved to be reliable, and it is most helpful during long, involved reconstruction procedures.

Electronic monitoring necessitates careful coordination with the anesthesia staff, because many of the popular anesthetic agents interfere with accurate monitoring. If a neurologic deficit is noted during or after surgery, reduce the traction force on the spine. This usually necessitates releasing distraction and may require hardware removal. If a severe neurologic deficit is noted in the recovery room or after surgery, immediately return the patient to the operating room for wound exploration and probable hardware removal. Laminectomy is not usually indicated unless an epidural hematoma is identified or bone is encroaching on the cord. If early sublaminar wire removal is indicated, the technique should be that of cutting one end of the wire close to the lamina, grasping the other end, and pulling straight up. The work of Nicastro et al. (49) shows this to be least likely to cause the wire to push down into the spinal cord.

**WOUND INFECTION**

With careful technique and the use of intraoperative and postoperative antibiotics, postoperative wound infection should be 1% or less. If an early infection occurs, prompt wound debridement is indicated, and a successful spinal correction and fusion can be salvaged.

- Obtain blood cultures before surgery.
- Take the patient to the operating room, where, under anesthesia, the skin is prepared and draped, and the entire wound is opened. Do not disrupt the hardware and bone graft.
- Obtain cultures.
- Carefully debride the hematoma and nonviable tissue, followed by irrigation with antibiotic solution. Leave the bone graft intact.
- Generally, avoid large retention sutures.
- Close the wound in layers over suction irrigation tubes that are left in for 3–5 days.
- Administer appropriate intravenous antibiotics for 7–10 days; then, if antibiotic sensitivity allows, change to an oral agent for an additional 6 weeks.

**DURAL TEARS**

If, during the process of passing sublaminar wires or placing hardware, a dural tear is noted by the leakage of clear cerebrospinal fluid, repair it immediately. Patients fare better with early repair than with later repairs of chronic leaks. Perform a limited laminotomy, or laminectomy if necessary, to expose the dural tear. Once the extent of the tear is identified, repair by careful suturing with a fine, nontraumatic needle and 5-0 or 6-0 nylon. If large tears are noted, it may be necessary to perform a fascial graft. The lumbodorsal fascia is a good source for a patch graft. Keep patients with this complication at bed rest for several days after repair.

**FLATBACK SYNDROME**

The loss of normal lumbar lordosis is a major long-term problem (1,31,32). It creates an unsightly cosmetic deformity and leads to back pain. This flattening of the lumbar spine is associated with instrumentation of the lumbar spine and can be created by using noncontoured Harrington rods (15). The best way to prevent this iatrogenic problem is to avoid fusion of the lumbar spine when possible. As described earlier in this chapter, selective thoracic fusion is the best way to maintain lumbar motion. When fusion into the lumbar spine is necessary, position the patient on the operating table to maintain lordosis and contour the rods. When fusion to the sacrum is indicated, the Luque rods with Galveston pelvic fixation and sacral screws are the best means of creating or maintaining lumbar lordosis.

**PSEUDARTHROSIS**

Successful completion of a scoliosis procedure is based on obtaining a solid fusion. After 4–6 months, perform an evaluation for a solid arthrodesis. Take oblique views and carefully review the films for lucent lines in the fusion mass. If broken hardware is noted, a pseudarthrosis is highly likely.
When there is hardware breakage or when oblique radiographs demonstrate a pseudarthrosis, open and explore the entire wound. The pseudarthrosis may be covered by a fine layer of bone. Therefore, careful evaluation is mandatory. The pseudarthrosis is generally difficult to expose and will show motion when stressed. Freshen the bone with a gouge, and instrument the pseudarthrosis with a heavy Harrington compression system. The multi-hooks and rod system can also be used to apply compression. Apply generous quantities of local and IIac bone graft to complete the procedure. I immobilize the patient for 4–6 months in a bivalved body jacket. Lumbosacral pseudarthroses that have failed repeated attempts at repair may be best managed by an additional anterior fusion. It is mandatory that solid arthrodesis be achieved if you hope to obtain a stable balanced spine.

AUTHOR’S PERSPECTIVE

The surgical management of scoliosis requires careful preoperative evaluation and planning. Curve types and patterns must be carefully identified to select fusion levels. Spinal fusion and instrumentation techniques are demanding and should be carefully performed. The surgeon should have hands-on experience with these systems before initiating the procedure. The keys to success are attention to detail and skillful surgical execution. The new implant systems seem to offer better correction and more options in treatment, but they do not replace the need for good fusion techniques.

Myelomeningocele is a serious and complex congenital abnormality associated with a host of problems that cross several disciplines of medicine and rehabilitation. Of the problems presenting to pediatric orthopaedic surgeons, none is as daunting, complex, and fraught with pitfalls as the management of the associated spinal deformities. In addition to the kyphotic, lordotic, or scoliotic deformities typically faced by spinal-deformity surgeons, patients with myelomeningocele bring the added challenge of a generally abnormal anatomy, manifest by the absence of a significant portion of the posterior spinal elements. Additionally, these structures are frequently smaller, the bone is more osteopenic, the skin, muscle, and fascia available for coverage of hardware are frequently poor, and significant additional medical problems frequently coexist (13). A solid grounding in the treatment of idiopathic spinal deformities is therefore a prerequisite to embarking on the management of patients with myelomeningocele (6,33).

Orthopaedic care for patients with spina bifida should not exist in a vacuum. More than perhaps any other condition with which orthopaedists are concerned, myelomeningocele should be managed by a team of pediatric specialists. In addition to an orthopaedic surgeon, a pediatric neurosurgeon, a urologist, a neurologist, and a psychiatrist must be allied with a health care team consisting of occupational and physical therapy, social workers, and nutritionists. As patient demands on each of these individuals is fairly high, most major pediatric centers employ specialty clinics, where the specialists convene on individual patients, rather than each specialist seeing patients individually. Once thought to be a chronic and stable condition, myelomeningocele is now known to be a condition that changes throughout life (8). It is therefore necessary for patients to be followed well into their adult years.

While the focus of this chapter is the surgical management of spinal deformities, readers need to be ever mindful of the associated conditions and the need to manage the spine within the larger framework just discussed.

PATHOPHYSIOLOGY

The mechanism by which myelomeningocele occurs embryologically is unknown. Two major theories exist, and both have their proponents. Von Recklinghausen, who initially described the condition, felt that the abnormality was due to a failure of closure of the neural canal. The opposing theory is that a closed neural tube ruptures, exposing the neural elements (33). This theory was initially advanced by Morgagni (33). A long discussion of the points that make both theories at least histologically plausible is beyond the scope of this chapter; suffice it to say that a certain modicum of evidence exists for both viewpoints. The abnormality resulting in the formation of a myelomeningocele occurs very early in gestation—most likely at the third to fourth week after conception. In many cases, the defect is present before a woman recognizes that she is pregnant.

While there is no agreement on the embryologic process that causes the formation of a myelomeningocele, many risk factors have been identified that markedly increase the incidence of this birth defect. Use of the antiseizure medication valproic acid (Depakene) during pregnancy has been demonstrated to markedly increase the risk of myelomeningocele (9). As valproic acid can alter serum folate levels, this adds credence to the work of Yates et al. (45), who showed an association between the incidence of neural tube defects and depressed red cell folate levels. In their study, the diminished folate levels could not be entirely attributed to decreased dietary intake, suggesting that an intrinsic error of folate metabolism existed. This study was subsequently supported by Seller and Nevin (40), who noted a decreased incidence of myelomeningocele and other neural tube defects when adequate vitamin and folate supplementation began before conception. These studies led to the general dietary recommendation that all women of childbearing age consume a minimum of 1.0 μg of folic acid daily (5). Many foods are being supplemented with folic acid in direct response to this work.

The gold standard for the prenatal diagnosis of myelomeningocele remains the amniotic fluid level of alpha-fetoprotein (AFP) obtained through amniocentesis. A high concentration of AFP within the amniotic fluid, which is usually sequestered within the cerebrospinal fluid (CSF) of the fetus, is pathognomonic for an open or otherwise compromised neural canal. Most centers continue to use serum AFP levels to screen expectant mothers. While high AFP concentrations have a relatively high correlation with neural tube defects, the sensitivity and specificity of this test is only about 80% (1). Prenatal diagnosis is most useful because it is important to plan for delivery at a tertiary care facility, where neurosurgical and neurosurgical intensive care unit support is available; it is also important because it is believed that elective cesarean section may result in neural function at one or two levels higher than otherwise.

PRINCIPLES OF TREATMENT

The management of a child born with myelomeningocele begins with closure of the defect, typically by a neurosurgeon, within the first 12–24 hours of life. Without treatment, such children will typically die. Several series of untreated children reported in the 1970s demonstrated mortality rates in the range of 90% to 100% (20–23). The cause of death in untreated infants is bacterial meningoventriculitis. Those who survive meningoventriculitis have higher levels of paralysis, more profound mental retardation, and frequently uncontrolled hydrocephalus, leading to additional problems. Therapeutic nihilism was frequently practiced in the United States 40 years ago because of the difficulty in treating many of the sequelae of myelomeningocele. However, with advances in orthopaedic, neurologic, and urologic care, myelomeningocele is very treatable. It has therefore become the standard of care in the United States to perform early sac closure and ventriculoperitoneal shunting in infants with myelomeningocele (9). Many foods are being supplemented with folic acid in direct response to this work.

Positioning of the patient after sac closure is very important to protect the fragile soft tissues overlying the repair. Additionally, this period of prone recumbency is advantageous in positioning the hips to avoid subluxation or dislocation.

It is possible, though unusual, for a neurosurgeon to require the services of an orthopaedist when performing the initial shunt closure. Occasionally, the child will be born with a severe gibbous deformity that will necessitate a two- to three-level kyphectomy to facilitate closure.

PATIENT ASSESSMENT

As with the management of any spinal deformity, take a careful history and perform a thorough physical examination. Do not immediately focus on the spinal deformity. It is important relative to surgical indications, as well as other prognostic factors, to know about the general health of the child. Inquire about the patient’s mental functioning, school attendance, and level of socialization, as well as the activities of daily living that the patient is able to perform. The presence or absence of hydrocephalus or a shunt is prognostic relative to overall intellectual function (Fig. 157.1) (13). Inquire about the patient’s urologic status and bowel function. Knowledge of the status of these matters is yet another reason why a multidisciplinary clinic is so valuable. Finally, it is important to have a good understanding of parents’
perceptions and patients' needs, desires, and expectations regarding eventual ambulation and the use of ambulatory aids.

As far as the spine is concerned, determine the level of neurologic function, the perception of patients and caregivers regarding spinal curvature progression, and any symptoms or problems directly related to the curve, including pain, skin breakdown, loss of balance, difficulty with breathing, or changes in gastrointestinal (GI) or genitourinary (GU) function. It is also important to inquire about previous trials of bracing and spinal surgery.

An increasingly common finding in patients with myelomeningocele is sensitivity to latex. It is mandatory to ask a dermatologist to test patients for latex allergy in the preoperative period. Use a latex-free protocol in surgery and in the postoperative period, even with nonallergic patients. Allergic reactions to latex have become a significant health problem for patients and health care professionals over the last 5 years. It is believed that 50% of spina bifida patients in the United States have evidence of severe allergy to latex. As many as 5% to 10% of myelomeningocele patients may have a potentially life-threatening form of this allergy. The allergen causing the hypersensitivity response is a component of the latex substance itself, and therefore only strict avoidance of latex contact is effective. Immediate hypersensitivity reactions to latex have been reported through several different routes of exposure. Deaths have been reported after mucous membrane exposure and infusion through latex-containing intravenous lines. Intraoperative anaphylactic reactions have been reported simply after the opening of latex gloves in the operating suite. It is believed that patients with myelodysplasia are at increased risk for latex allergy due to the multiple contacts that they have had with the substance, although some feel that there is a yet unknown reason for their propositivity to an allergic response.

As improved non-latex-containing operative and patient care materials become available, inadvertent exposure to latex will become less and less common. The Joint Commission for the Accreditation of Hospital and Healthcare Organizations currently requires that all patients be asked specifically about a history of latex sensitivity at their initial outpatient or inpatient visit. All hospitals should have policies and procedures in place regarding bed assignment and room preparation and strict protocols for direct patient care activities in a nonlatex environment. It behooves the surgeon and operative team, however, to doubly reinforce this concept in the operating room and with the ancillary staff.

Next, perform a detailed physical examination. Examine the extremities, paying special attention to the neurologic examination. Whereas the lower extremities are typically the sites of major neurologic compromise, conditions such as hydromyelia or syringomyelia may also compromise strength and sensation in the upper extremities. Careful neurologic examination to identify the specific level of neurologic involvement is important as a predictor of both ambulatory ability and the likelihood of curve progression (Fig. 157.2). It must be kept in mind that the neurologic pattern may differ from one extremity to the other, even in rare cases nearly to the point of having one normal extremity and near-total paralysis of the other extremity, a condition known as hemimyelodysplasia.

In addition to observing the general curvature of the spine (lordosis, kyphosis, scoliosis), examine the spine to assess flexibility and balance. Additionally, assess the quality and the condition of the skin throughout the torso. This is important not only for wound coverage and closure but also for any postoperative castings or bracing that may be anticipated. While radiographic studies will convey a good deal of information regarding the underlying bony structure, careful and thorough palpation of the spine for the presence or absence of bony elements can immeasurably add to one's understanding of the deformity.

**RADIOLOGIC EVALUATION**

Plain radiographs, preferably standing or sitting in the posteroanterior (PA) and lateral projections and supine bending films, are essential for preoperative planning. Magnetic resonance imaging (MRI) of the spine, as well as spiral computed tomography (CT) with three-dimensional (3D) reconstruction, adds to one's ability to understand the nuances of the curve, note congenital elements and dysplastic features, and undertake rigorous preoperative planning. There is no aspect of spinal surgery where the adage "failure to plan is a plan for failure" better applies than in myelosurgery. Ultrasound may be useful in the very immature, minimally ossified spine and in areas where there is no bone overlying the neural elements. For the most part, myelography has been replaced by MRI.

**PRINCIPLES AND INDICATIONS FOR SURGICAL TREATMENT**

The orthopaedic management of myelomeningocele centers around three major goals: To maximize patients' abilities and maintain the stability and range of motion of the spine and extremities To provide for locomotion either by wheelchair or by ambulation with or without braces and orthotics, depending on the level of neurologic involvement To prevent deterioration of neurologic function As previously noted, myelomeningocele is a condition in which neurologic change can be expected. The observation of diminished extremity function frequently leads to the diagnosis of subtle neurologic deterioration.

The specific goal in the management of the myelomeningocele spinal deformity is to maintain or achieve a well balanced spine (Fig. 157.3). Spinal balance is important for compensated sitting, as well as standing. A well supported spine allows free use of the upper extremities, and balanced seating pressure diminishes the
In no area of orthopaedic surgery is preoperative planning more important than in the paralytic spinal deformity. Be prepared for the following:

**SURGICAL PRINCIPLES**

Arnold–Chiari malformation and any change from baseline. Be present, including syringomyelia and hydromyelia, which may need correction before a definitive spinal fusion. MRI will also demonstrate the degree of it has been said that all patients with myelomeningocele who underwent a surgical closure after birth have by definition a degree of cord tethering (9). Congenital deformities (unsegmented bars and hemivertebrae, and combinations thereof) can coexist. These will be noted at birth and tend to require surgery at an earlier age than the paralytic deformity (2). Despite the high percentage of spinal deformities, one cannot be complacent regarding the exact cause of any given curve. As in any spinal deformity, investigation is necessary to determine whether there is an underlying correctable cause for the disorder, and therefore MRI and CT are useful in evaluating the spine for hydromyelia, a tethered spinal cord, or ventricular porencephaly, which can contribute to the deformity (3).

**SURGICAL GOALS**

The goal of surgery is to provide a stable, well-balanced spine with the head centered over a nonoblique pelvis, allowing good balance and affording patients the use of both hands. Those with collapsing deformities, who must push up with their hands to support themselves or to maintain good pulmonary or GI function, are severely hindered in their ability to perform activities of daily living (27).

**SURGICAL DECISION MAKING**

As a general rule, curves that progress beyond 50° require surgery. It is assumed that most children with myelomeningocele, who will eventually require spinal surgery, will have curves greater than 50° well before skeletal maturity. Whereas it is preferable to wait until age 10–12 years for instrumented fusion, one will occasionally need to intervene at an earlier age to prevent irretrievable progression. As with surgery for other medically "delicate" patients, such as those with muscular dystrophy, optimization of general medical health at the time of surgery is important. Before surgery, any hydrocephalus should be well controlled, and shunts, if in place, should function normally. Ideally, the urinary tract should be free of any obstruction, vesicoureteral reflux managed, and the urine sterile. In many cases, of course, obtaining sterile urine is temporary at best, and in these instances, the known colonizing bacteria should be suppressed with appropriate antibiotic prophylaxis. Failure to control bacteria in the urinary tract can lead to an inordinately high infection rate (2). Finally, the condition of the skin generally and in the operative area, in particular, must be at its best. Whenever the potential for the introduction of infection into the fusion through skin contaminants is high, it is advisable to do appropriate plastic surgical reconstruction first. This will often require tissue expansion, midline scar excision, and closure. After the new area is well healed, definitive spinal surgery can then proceed with less risk of infection.

**PREOPERATIVE PLANNING AND MANAGEMENT**

**IMAGING**

The explosion in technology over the past decade has greatly enhanced the ability to image the deformed spine, immeasurably improving preoperative planning. Despite these advances, however, plain radiographs (standing or sitting PA and lateral views and supine bending films) are critical for initial planning. These images will demonstrate the existing spinal alignment, head and shoulder balance, and pelvic obliquity. Bending films assess the degree of correction that may be possible. Keep in mind that the bone in the paralytic spine is likely not to be as strong as in the idiopathic spine and may not tolerate attempts to restore true anatomic alignment.

Bene scans are generally not required, although they are useful in diagnosing a preexistent underlying osteomyelitis, which would be a short-term contraindication for instrumented fusion. Patients with chronic skin breakdown over the deformity or a history of prolonged drainage may have chronic osteomyelitis. Bone infection must be eradicated before correction of the deformity.

In the evaluation of the bony anatomy, CT is most useful when 3D reconstructions are performed. Spiral CT data can be manipulated into excellent 3D images, and this minimizes the amount of radiation to which patients are exposed. 3D reconstructions allow virtual spinal visualization and can be useful when placement angles of hooks or pedicular screws are being planned.

It has been said that all patients with myelomeningocele who underwent a surgical closure after birth have by definition a degree of cord tethering (21). In some patients, the tethering is a major factor in scoliosis progression. In addition to demonstrating significant tethering, MRI will show any other cord abnormalities that may be present, including syringomyelia and hydromyelia, which may need correction before a definitive spinal fusion. MRI will also demonstrate the degree of Arnold–Chiari malformation and any change from baseline.

**SURGICAL PRINCIPLES**

In no area of orthopaedic surgery is preoperative planning more important than in the paralytic spinal deformity. Be prepared for the following:

Patients as a rule are smaller.
The deformities are more severe and more rigid.
Bone is osteopenic.
Spinal elements in the involved area are altogether absent.
Patients' underlying medical condition is frequently more precarious than expected. Arrangements may need to be made to have special instrumentation and additional bone-grafting products available.

Most patients with spina bifida require combined anterior and posterior spinal instrumentation combined with fusion that includes the sacrum.

- Start the fusion typically two levels above the end of the curve, and extend to the sacrum or pelvis (25,34).
- The most common technical error is to perform too short a fusion that necessitates later revision for progressive imbalance.
- Wait until age 10–12 years if the curve magnitude is moderate.
- It is better to accept some permanent truncal shortening than to let a curve progress beyond 70° to 80°.
- The majority of patients with myelodysplasia have a small, underdeveloped, osteopenic pelvis. Plan to use allograft bone and other bone-graft extenders for the primary grafting material.

As these typically are lengthy procedures, controlling blood loss intraoperatively is critical (17).

- Use subcutaneous epinephrine (1:400,000–500,000) and a Bovie electrocautery, a bipolar coagulator, and in some cases an argon laser to maintain a dry operative field. Employ hypotensive anesthesia judiciously to minimize uncontrolled blood loss.
- Remember that one of the most important factors related to complications and blood loss is the prevention of hypothermia (24).

- Use blood and intravenous fluid warmers, as well as warming blankets, to maintain normothermia. Simply turning the room temperature up to 85° will not have the desired effect.
- Intraoperative salvage of blood with a cell saver is useful because the volume of blood in these patients as a result of their size is frequently not enough for salvage by conventional means. Use of state-of-the-art processing units and intraoperative plasmapheresis is an exciting new concept for intraoperative cell salvage that requires markedly less volume of salvaged cells to be useful.

A surgeon managing the spinal deformity of myelomeningocele must deal with the issue of deficient bone stock on two levels. First, is a congenital deficiency of the posterior elements that provides limited sites for traditional sublaminar wires or hooks. Secure the rods to the spine at these levels with a cable or wire encircling the pedicle through the neural foramen; otherwise do not instrument these levels. Where soft-tissue coverage is adequate, the newer, smaller pedicle screw systems appear to be an excellent means of securing these levels of the spine to the rod. Remember that the majority of pull-out strength with a pedicle screw is within the pedicle itself. The screw should be optimally sized to the pedicle and need not extend farther than 50% of the way through the vertebral body. Be fully familiar with the available instrumentation, and arrange to have a wide array of screw sizes and lengths available on the day of surgery.

The second problem with deficient bone stock is the availability of autogenous graft. Portions of both iliac crests, the ribs, and portions of the spinous processes were once the only bone available. With modern bone banking technology and the availability of graft extenders, the use of autogenous graft is now typically not advised unless absolutely necessary; commonly used products include Grafton (Grafton Corporation, Edison, NJ), a demineralized bone matrix; Coralene (Inteplor International, Irvine, CA), and Osteoperl pellets (Wright Medical Products, Arlington, TN). Additional products on the horizon will make the issue of deficient autogenous graft a moot point.

Postoperative infection is one of the most serious and devastating complications that may follow instrumented spinal fusion in this patient population. At our institution, dual-coverage antibiotics (a first-generation cephalosporin and an aminoglycoside) are typically given for 48–72 hours postoperatively.

- Prolong antibiotic coverage if drains remain in place or significant drainage persists.
- A potential for later infection is present if systemic urceus occurs or if the soft tissue overlying the instrumentation breaks down.
- Use all available means of obtaining thick, well vascularized flaps to cover the spinal instrumentation, particularly in the lumbar region, where the overlying tissue is typically the most atrophic and poorly vascularized.
- Stage procedures in instances where the scarred area has had repeated episodes of breakdown or the scar is in particular poorly repair.
- Excise nonviable scar initially, and mobilize flaps to bring new, healthy skin to the midline.
- As simple flap mobilization may not be possible, consider placing tissue-expansion bladders on either side of the midline to create new skin.
- Then resect the midline scar, bring the new expanded skin together in the midline, and allow the wound to heal for 4–6 weeks before the definitive procedure.

Much has changed in spinal instrumentation since the 1982 paper by Osebold et al. (34), for whom the best results for spinal fusion in these patients involved combined anterior and posterior instrumentation. They noted that the anterior–posterior approach gave the best degree of correction, best maintenance of correction, and best correction of pelvic obliquity. The instrumentation in this series was with Harrington rods and either the Dwyer or Zielke device anteriorly. These three systems have long since passed out of favor, but the concept of a 360° fusion still makes sense from the standpoint of maximal rigidity and stability. However, with improved posterior segmental instrumentation, a separate anterior approach is not always necessary.

Postoperative spinal deformity of myelomeningocele must deal with the issue of deficient bone stock on two levels. First, is a congenital deficiency of the posterior elements that provides limited sites for traditional sublaminar wires or hooks. Secure the rods to the spine at these levels with a cable or wire encircling the pedicle through the neural foramen; otherwise do not instrument these levels. Where soft-tissue coverage is adequate, the newer, smaller pedicle screw systems appear to be an excellent means of securing these levels of the spine to the rod. Remember that the majority of pull-out strength with a pedicle screw is within the pedicle itself. The screw should be optimally sized to the pedicle and need not extend farther than 50% of the way through the vertebral body. Be fully familiar with the available instrumentation, and arrange to have a wide array of screw sizes and lengths available on the day of surgery.

The chief problem with this technique is that the pelvis, particularly in nonambulators, tends to be osteopenic and hypoplastic. Rods can migrate within the bone and can break out through the thin cortex anteriorly or posteriorly. The other frequent problem is the difficulty in securing adequate fixation in the lower lumbar spine, where the posterior elements are absent (10). No study has yet been published in which pedicle screws were used at the lower lumbar levels along with the Galveston technique; however, one would expect that problems with iliac wing breakage would be less common.

A modification of the Luque-Galveston technique has been described by Dunn (14,19). In this technique, the rod is contoured to fit just anterior to the sacral ala or passed through a window in the superior aspect of the ala down into the sacrum itself, paralleling the sacroiliac joint rather than going into the ilium. Our experience with the latter intraosseous modification suggests that rod pull-out by fracture of the posterior sacral cortex is a major drawback.

Another technique for securing the long spinal construct to the pelvis employs an intrailiac bolt or a long pedicle screw inserted in the same manner as the end of the Luque-Galveston technique; however, one would expect that problems with iliac wing breakage would be less common.

SCOLIOSIS

Scoliosis is the most common spinal deformity in myelomeningocele, affecting 80% of patients (27,38). The risk of scoliosis is higher with progressively higher levels of neurologic involvement (10,15,17,27). As previously noted, typical management usually involves anterior and posterior fusion (32). With improved segmental fixation, a patient undergoing corrective surgery to show signs of progressive scoliosis or in whom the intradural cartilage of the acetabulum is intact (30,33) may not require additional anterior segmental fixation. However, when the anterior procedure is performed, it is done first and consists of anterior release or discectomy and fusion, anterior release with strut grafting, or, most commonly, anterior fusion and correction with CD Horizon, CD Hopf (Sofamor-Daneck, Medtronic-Sofamor-Daneck, Memphis, TN), or Keneda (Johnson & Johnson, Depuy-Acoumed, Raytham, MA) style instrumentation.

**Anterior Lumbar Fusion**

- After induction of general anesthesia, place the patient in the lateral decubitus position with the convexity of the lumbar curve placed upward. Place the apex of the curve at the break in the operating table so that the table can be gently flexed, with the head and foot portion lower than the middle. A deformable bean bag, With or without kidney rests, maintains excellent positioning of the patient. Carefully pad all bony prominences, and ensure that the Bovie pad is not over a

- Start after the thorax or two levels above the superiormost vertebrae to be instrumented. Utilizing two levels above will facilitate placing the uppermost screw in its best position, parallel to the end plates.

- If not experienced in using the Bovie cautery for all cutting beyond the dermal level, use subcutaneous epinephrine to secure hemostasis.

- A needle-tipped Bovie is particularly useful for the subcutaneous dissection.

- Start the incision proximally, approximately a hand’s-breadth from the midline over the rib in question, and extend along the rib to the costochondral junction. Then curve the incision gently distally, following the lateral edge of the rectus sheath.

- The distal extent of the incision will depend on whether the instrumentation is to be carried down to the L-3 or L-4 level. It is exceedingly difficult and perhaps
dangerous to attempt to get to the L-5 level through this approach.

- Carry the incision downward to the periosteum of the rib, and incise it longitudinally.
- Expose the rib subperiosteally without violating the chest cavity. When the rib is freed, disarticulate it from its chondral end, and with blunt finger dissection remove it entirely from its vertebral articulation.
- Place a retracted lap sponge into the proximalmost portion of the wound to maintain hemostasis.
- Incise the costal cartilage longitudinally with a knife, and find the extraperitoneal plane immediately beneath with blunt finger dissection. The key to this exposure is developing the correct retroperitoneal plane. Open the rib bed longitudinally to enter the chest, and use a self-retaining chest retractor to spread the ribs.
- Carry the incision distally under direct vision, taking care not to transect the external oblique, internal oblique, and transverse abdominal muscles other than through their tendinous condensations at the lateral aspect of the rectus sheath.
- Take down the diaphragm from the chest wall from the site of the chondral split, working posteriorly toward the diaphragmatic crus. The diaphragm may be taken off the chest wall nearly flush, as some surgeons prefer, or, more typically, with a 1–1.5 cm cuff left, which is useful for reapproximation at closure.
- Place marking sutures of alternating colors every 3–4 cm to facilitate a more anatomic closure.
- After the diaphragm has been taken down to the vertebral body or the crus and the distal extent of the abdominal portion is complete, use a self-retaining retractor system, such as a laparotomy retractor (Omnitract, Omnitract Surgical, Minneapolis, MN), to maintain broad exposure.
- Incise the pleura over the thoracic levels to be instrumented, and using a Kidner sponge, elevate the pleura generously toward the opposite side of the vertebral body and equally generously back over the heads of the ribs. Taking time at this point to mobilize the good pleura will facilitate covering the upper end of the hardware construct at the end of the procedure.
- If instrumentation is placed, then gently and carefully isolate, ligate, and tease the vertebral segmental vessels from the vertebral body with a Kidner-type sponge.
- Vessels may be ligated with suture or with vascular clips. Clips should be made of titanium, and use of an automatic clip loader will speed the process. The vessels are readily and easily exposed to the level of L-1, beyond which they are obscured by the psoas musculature.
- Be careful of the nearby genitofemoral and ilioinguinal nerves.
- Pay close attention to the tributaries of the thoracic duct, as well as the sympathetic chain. If a portion of the sympathetic chain is inadvertently cut, chylous sanguine will be evident; the two duct ends may be ligated without complication.
- After ligating the segmental arteries, remove the intervertebral discs.
- Use a long handled #15 blade to incise the annulus as near the endplate as possible.
- Resect the annulus as fully as possible, except posteriorly, where a portion is frequently left adherent to the posterior longitudinal ligament.
- The endplates are generally thick and are easily removed with a large curet within the intervertebral space. Pay particular attention not to stray through the fairly soft subchondral bone into the vertebral body itself (Fig. 157.4).

An advantage to same-day anterior–posterior surgery is that the nutritional status of any patient is usually at its best at the time of the first surgery (4, 35). It is therefore advisable, whenever possible, to do anterior and posterior surgery under the same anesthetic.

**Posterior Spinal Fusion**

Use the prone position. Depending on the patient's size, the surgeon's preference, and associated contractures and deformities, any of several positioning devices is appropriate. I believe that the four-post frame is the most useful for smaller adolescents. Once again, it is extremely important to carefully pad all bony prominences, as skin slough at the chest and anterior iliac wings is a significant potential pitfall from prolonged prone positioning.

Preoperative evaluation of the scarred, closed dural sac is mandatory. If the original scar remains in place, take meticulous care to keep the flap edges as thick as

---

**Figure 157.4.** Anterior discectomy technique. A: Intraoperative photograph demonstrates the anterior lumbar discectomies. Note the motor-potential monitoring electrodes to the left. This patient had some distal motor sparing. B: A uterine curet may be useful to remove the cartilaginous endplate. Care needs to be exercised in endplate removal, as the underlying bone is frequently very soft.

---

**Figure 157.5.** PA radiograph of the lumbar spine after Dwyer instrumentation. The lumbar component is well fused despite hardware pull-out. However, note the decancellation at the thoracolumbar junction secondary to "fusing too short."
Many myelodysplasia clinics have patients with 100° + curves that have progressed relentlessly to this point through the desire of the family to refrain from surgery or allow the contralateral portion of the spine to grow and actually provide some correction. However, in the majority of patients, epiphysiodesis serves to stop all growth, and potential for nonunion.

Many patients with scoliosis have a congenital component to their curve. Congenital curves are best addressed early and are most frequently treated by experienced orthotist make these braces.

Many myelodysplastic spine. There is much greater risk for hardware failure, and most surgeons place patients into a custom-made bivalved underarm body jacket 5–7 days after surgery. It should be worn for 9–15 months after surgery (Fig. 157.6). Approximatively 2 weeks postoperatively, the rod ends displaced dorsally through the bone. Revision surgery utilized a construct with a separate rod placed anterior to the ala and attached posteriorly with Texas Scottish Rite Hospital links (TSRH, Medtronic-Sofamor-Danek, Inc., Memphis, TN). The patient did well after the revision. (See Figure 157.11 for clinical photos.) Lateral (B) view of a patient who initially underwent pelvic fixation with insertion of rod ends into the sacral ala. Approximately 2 weeks postoperatively, the rod ends displaced dorsally through the bone. Revision surgery utilized a construct with a separate rod placed anterior to the ala and attached posteriorly with Texas Scottish Rite Hospital links (TSRH, Medtronic-Sofamor-Danek, Inc., Memphis, TN). The patient did well after the revision. (See Figure 157.11 for clinical photos.)

Pre- (A) and postoperative (B) photographs show a 12-year-old girl who underwent kyphectomy and thoracolumbar instrumented fusion. Note the improved sitting balance and the better contour for seating. (The same patient is the subject as Figure 157.7.) Additionally, there may even be cases in which the surgeon may wish to use two rods on each side connected by rod-to-rod connectors.

Figure 157.11. Pre- (A) and postoperative (B) photographs show a 12-year-old girl who underwent kyphectomy and thoracolumbar instrumented fusion. Note the improved sitting balance and the better contour for seating. (The same patient is the subject as Figure 157.7.) Additionally, there may even be cases in which the surgeon may wish to use two rods on each side connected by rod-to-rod connectors.

After completion of the instrumentation, carefully decorticate the spine before applying the bone graft. If the soft tissue has been satisfactorily removed from the bone, this may be sufficient for the myelodysplastic spine. Meticulous decortication, as done in idiopathic scoliosis, runs the risk of further weakening already weak bone, which results in lamina fracture and wire pull-through. The experienced surgeon will need to straddle this fine line between risk of hardware failure and potential for nonunion.

After positioning the patient in the prone position, make a straight midline incision as for any posterior spinal approach.

As the distal anatomy is often quite difficult, approach the abnormal anatomy from areas of normal anatomy demonstrated cephalad.

As the paraspinal musculature is stripped from the posterior elements, maintain good hemostasis and use Bovie cautery for the majority of soft-tissue cutting.

To avoid the midline scarred area, use an inverted-Y incision. With this approach, one entirely avoids the midline sac area, and the midline lumbar area is not undermined at all. This allows good exposure of the transverse processes and pedicles but avoids entering the dural sac, which increases the likelihood of wound breakdown or infection. Be prepared for a small skin slough at the junction of the Y, and be careful that the distal limbs of the Y portion are far enough apart to allow adequate collateral blood flow to this “island” flap.

When the spine has been subperiosteally exposed to the transverse processes throughout the length of the incision, facilitate further lateral exposure at the caudal end by transecting the paraspinal muscles in an L-type fashion.

Contour the appropriate-length rods to maintain the sagittal curves, especially the lumbar lordosis.

The degree of contouring toward the scoliosis will depend on the degree of correction that can be obtained once the rod is in place. Gentle pressure on the spine from two persons will allow fairly accurately prediction of what curvature correction will be possible.

Affix the upper end of the rod to the spine with a sublaminar hook or sublaminar wires or cables. Sublaminar cables have the advantage of being more flexible; however, they are clearly more expensive, and reighting a cable once crimped is generally not possible unless a second crimp device has been added first.

If one desires to maintain an all-titanium construct, however, cables may be the only option (Fig. 157.6). After completion of the instrumentation, carefully decorticate the spine before applying the bone graft. If the soft tissue has been satisfactorily removed from the bone, this may be sufficient for the myelodysplastic spine. Meticulous decortication, as done in idiopathic scoliosis, runs the risk of further weakening already weak bone, which results in lamina fracture and wire pull-through. The experienced surgeon will need to straddle this fine line between risk of hardware failure and potential for nonunion.

Many patients with scoliosis have a congenital component to their curve. Congenital curves are best addressed early and are most frequently treated by in situ fusion of the congenital curve. Resection of hemivertebrae is rarely indicated, except in the lower-lumbar regions, most typically at L-5. A hemiepiphysiodesis will occasionally allow the contralateral portion of the spine to grow and actually provide some correction. However, in the majority of patients, epiphysiodesis serves to stop all growth, and significant improvement is never realized.

Many myelodysplasia clinics have patients with 100° + curves that have progressed relentlessly to this point through the desire of the family to refrain from surgery or
by fear that early surgery will result in too much truncal shortening. Surgeons must be aggressive about treating the progressive and significant curve, even in a patient with 6–8 years of growth remaining. It is better to have a short trunk than to end up with a severe curve and loss of function. The subcutaneous “growth” rod remains an excellent short-term way of slowing some curve progression. The growth rod is similar to the concept developed for juvenile idiopathic curves, but in the rachemodysplastic spine, it frequently requires additional points of skeletal fixation. The Luque trolley, utilizing loose sublaminar wires and no bone graft, was introduced in an attempt to maintain position until formal fusion (36). The chief problem with it is the difficulty in getting the spine to truly “slide.” This may still be worth a try if it is the only alternative to fusing a spine prematurely, and has been shown of greater utility when combined with short-segment epiphysiodesis (36).

KYPHOSIS

Significant structural lumbar kyphosis occurs in approximately 15% of patients with myelomeningocele (30). Operative management of collapsing kyphosis routinely requires an anterior and posterior approach, and unlike the typical anterior procedure, these frequently require some additional posterior-element resection so that the kyphotic component can be corrected toward a more anatomic configuration.

Normal lumbar lordosis rarely develops in children with a mid- to upper-level lumbar meningocele. The absence of the posterior elements and overlying musculature, combined with tight hamstrings rocking the pelvis posteriorly, creates a hypolordotic, if not kyphotic, lumbar spine. In severe cases, the kyphosis becomes profound, and in some the lumbar spine will virtually fold over on itself, creating a near 180° gibbus deformity (Fig. 157.8). Lumbar kyphosis is more disabling than scoliosis in many respects because the forward-bent lumbar spine creates a relatively hypokyphotic thoracic spine. Such spines are not mechanically stable, and patients must prop themselves up on their hands. This creates problems with pulmonary function, as well as with GI and GU tract motility in the long-term. In addition, by constantly having to prop themselves up with their hands, patients are unable to function well in activities of daily living.

Lumbar kyphosis is often present at birth and may be significant very early on. Bracing is very difficult because of the very prominent bone underlying poor skin (5).

There are two broad categories of lumbar kyphosis. The more common type is a rigid kyphotic deformity, usually with the apex at the L1-2 level. This is associated with a rigid compensatory lower-thoracic lordosis. The other, less common, less severe kyphosis is typically less rigid and has no proximal lordosis (19). Indications for correcting lumbar kyphosis include recurrent skin ulcerations over the prominence, difficulty with wheelchair fitting, progressive pulmonary, GI, or GU problems, and difficulties with activities of daily living secondary to the forward-flexed lumbar spine creates a relatively hypokyphotic thoracic spine. Such spines are not mechanically stable, and patients must prop themselves up on their hands. This creates problems with pulmonary function, as well as with GI and GU tract motility in the long-term. In addition, by constantly having to prop themselves up with their hands, patients are unable to function well in activities of daily living. Surgical reconstruction (26,43), a major undertaking, should accomplish three goals, according to Lindseth and Slezer (22). It should (a) straighten and stabilize the spine for better sitting posture, (b) markedly diminish the prominence of the kyphos, and (c) increase the overall height of the abdominal cavity.

Sharrard (41) was the first to describe resection of vertebral bodies in the management of this condition. His 1968 study demonstrated good correction, but follow-up studies have demonstrated that simple excision of the apex leads to an unacceptable recurrence rate of the initial kyphosis (22). Lindseth and Slezer (22) showed that excision of one or two vertebral bodies proximal to the apex of the kyphosis both realigned the lumbar spine to the proximal thoracic portion and improved long-term results.

Kyphectomy is generally done at birth, in 2-5-year-olds, or most commonly in young adolescents. A one- to two-vertebral-level kyphectomy may be required at birth for the very rare situation in which skin closure is not possible. For the 2–5-year-old group, in whom the gibbus is a problem, a procedure has been described in which only one level is fused and the remainder of the lumbar and thoracic vertebral bodies continue to grow. The majority of these patients will likely require additional surgery in the long term, but the benefits tend to outweigh this minor drawback. The Luque trolley, as noted previously, has also been utilized for kyphotic deformities (36). I prefer to wait until a child is 10–12 years of age before proceeding with a multisegmented instrumentation.

Kyphectomy in a 10–12-year-old patient typically involves the same technique in which the superior portion of the apex is resected and the lumbar and thoracic segments are joined back together with an accompanying segmental instrumentation construct extending from the pelvis to the upper-lumbar spine (Fig. 157.10 and Fig. 157.11). In contrast to the approach in 2–5-year-old patients, in whom a transverse incision works very nicely, use a traditional longitudinal incision for this procedure. Start in the midline from the more normal upper-thoracic spine and extend downward to the sacrum. The dura is typically just beneath the skin, and care must be exercised as the dissection proceeds from the midline laterally to leave the dura intact and the overlying skin as thick as possible. It is very easy to violate the dural sac. Promptly close any durotomy.

Figure 157.8. A 4-year-old boy with a 180° gibbus. A: Lateral sitting view demonstrates the problems with a significant gibbus. There is limited upper-extremity mobility, as the elbows support much of his weight. B: A recumbent view demonstrates no appreciable mobility of the gibbus segment. C: Note the extensive scarring in the midline and the fragility of the skin overlying the gibbus. D: Lateral radiograph shows the hairpin bony deformity.

While dissecting laterally after exposing the posterior elements, elevate the dural sac from the spinal canal to expose the posterior aspects of the vertebral bodies. This is done after distal transection of the dura. (These patients typically have a functioning level L-1 or higher.)

Typically, when the dura is transected at the sacral level, the spinal cord itself, even in cases of significant tethering, is well proximal. Take extreme care when closing this dural transection not to ligate any element of the cord itself, as this can result in sudden increased CSF pressure that will cause profound intraoperative hypotension and possibly death. The central canal often functions as a major CSF conduit when there are poorly functioning ventricles (Fig. 157.9).

Cut the nerve roots at each level, and ligate them to prevent CSF leakage. (The roots may be ligated, as there is no CSF circulation within the nerve roots themselves.)

After these have been ligated, elevate the sac, from distal to proximal, off the posterior aspect of the vertebral bodies (Fig. 157.9D).

Avoid significant blood loss by taking care to stop the bleeding from the numerous venous sinuses lying within the canal. Bovie electrocautery is useful for extraocular bleeding, and bone wax packed into the interstices is useful for bone bleeding.

After the sac has been mobilized anteriorly and the stump is closed without evidence of leakage, turn your attention to the kyphotic segment. With the nerve roots transected, the dura is sutured distally to allow the dural sac to fall back into its original position, and close the wound in routine fashion. Some authors advise against using a suction drain because it may increase the potential for CSF leak in their view.

Note that before you allow the dural sac to lay back down over the lumbar spine, several intravertebral discs will be exposed. This exposes an excellent opportunity to perform a posterior lumbar interbody fusion (PLIF) and obliterate a second stage of fusion to be performed later from the front. Obviously, in certain situations, a formal anterior fusion may be needed, but with several levels of PLIF in a patient who is unlikely to crankshaft, a second-stage anterior procedure is not always necessary.

Begin mobilizing patients by 1 week after surgery after fabrication of a custom bivalved underarm body jacket, which is worn for 12–18 months after surgery.

POSTOPERATIVE CARE AND REHABILITATION

Scoliosis correction and kyphectomy are extensive operations in children with multiple medical problems. Blood loss can be high, anesthesia times are long, and a postoperative pediatic intensive care unit is therefore mandatory. Many patients will remain intubated for 24 hours, and some will require short-term ventilatory support. Aggressive blood replacement therapy is indicated, and good urinary output must be maintained. As these patients are at higher risk for postoperative infection, maintain a longer period of prophylactic antibiotic therapy (often 5–7 days after surgery), and at the very least prescribe one dose beyond the point when all drains and central lines are removed. Use an aminoglycoside together with a cephalosporin to adequately cover the gram-negative organisms associated with chronic GU tract colonization and infection.

Other authors have advocated the use of total parenteral nutrition for patients undergoing staged procedures whose nutritional status is poor. This is certainly an option if the anterior–posterior fusion cannot be accomplished under one anesthetic. While monitoring of somatosensory-evoked potentials is typically not used intraoperatively, postoperative clinical neurologic monitoring is extremely important, especially in patients who have a history of hydrocephalus and a working shunt.

After patients have been medically stabilized, it is imperative to mobilize them as quickly as possible. However, do not place a patient in a sitting or standing position until the custom orthosis is available. A good relationship with the orthotist will facilitate obtaining a brace with 24° to 48° postoperatively. Early mobilization helps prevent muscle atrophy and acute postoperative osteopenia. There is typically no reason or indication for prolonged bed rest after surgery.

Physical skills, which these patients have slowly gained, are rapidly lost after surgery, and physical therapy is exceedingly important to regaining their preoperative level of function. Whereas the surgery should improve sitting and standing balance, there is definitely a risk for marginal ambulators to become wheelchair-bound, particularly after fusion to the pelvis. This functional loss frequently occurs in patients with myelomeningocele in the early teenage years, but this possibility or eventually occurring should be discussed and well understood by patients and families before the surgical procedure. As socialization of these patients is of high importance as well, they should be allowed to return to their school setting as soon as they are ready—usually at about 4 weeks after surgery.

PITFALLS AND COMPLICATIONS

The surgical management of spinal deformity in myelodysplasia is difficult because of the severity of the deformity, the abnormal anatomy, and the multiple medical problems with which patients present. The first caveat therefore regarding this sort of spine surgery is that it is not for the casual spinal surgeon. Even in the best of hands, the postoperative complication rate is high. Without an experienced surgical team and an experienced surgeon in charge, the results can be disastrous.

Whereas any spinal deformity in any patient should be approached on an individual case-by-case basis, patients with myelomeningocele, perhaps even more so, cannot be treated in assembly-line or cookbook fashion. While the newer instrumentation may make it somewhat less necessary to combine anterior with posterior fusion, one must be careful not to neglect to perform both when both are necessary. It can be difficult to achieve a good, solid fusion if the posterior elements do not lend themselves to good bone-rod fixation or the exposed areas are too sparse to achieve a good fusion mass.

As these procedures are not cookbook in their design, the surgeon must be willing and able to compromise, devise, create, and improvise intraoperatively. Routine surgery always needs a flexible plan. Surgery of this nature requires not only plans A and B but plans C, D, and E, as well.

One of the most common technical errors is to attempt to preserve distal-lumbar motion segments and to "fuse too short" (6). Whereas maintaining lumbar motion is desirable in virtually any other spinal surgery, it is a significant mistake to leave the L5-S1 junction mobile in the paralytic spine. Not only will this area degenerate and...
cause pain over time in some patients, but it will almost certainly be unstable and can result in a junctional kyphosis or hyperlordosis in the paralytic spine. Similarly, stopping the fusion too short proximally can allow the upper portion of the thoracic spine to develop forward kyphosis, which will cause postural difficulties.

Never perform a unilateral fusion. The amount of bone stock present is rarely sufficient to provide significant stability by fusion of only one side of the spine.

Infection, the second most common postoperative complication, rears its ugly head in up to 25% of cases (34). As previously noted, prophylaxis with two antibiotics is considered the standard of care. It is very difficult to achieve true urine sterility in most patients, but if the organisms can be suppressed to the colonization level, postoperative sepsis secondary to GU contamination is less likely. Infection secondary to hematoma and dead-space and wound breakdown secondary to poor skin is best addressed preoperatively, as previously noted. The two best options for preventing deep infection because of skin problems include using an inverted Y incision or doing a two-stage tissue expansion, as previously outlined.

Pseudarthrosis has been a common problem in the past. With the availability of bone graft and bone-graft extenders, the pseudarthrosis rate should decline in future studies. However, it is important to realize that bone must fuse to bone and therefore meticulous preparation of the bone graft bed is a requirement.

Instrumentation failure is also a common problem both intraoperatively and in the early postoperative period. Its cause is rarely metal breakage, but rather rod, hook, or wire pull-out from osteopenic bone. Addressing calcium balance and osteopenia preoperatively can be of use. One must be careful about being overly aggressive in tightening wires and distracting hooks. Despite adequate segmental fixation, the postoperative brace is still key in the postoperative management. Late instrumentation failure (wire or rod breakage) must be considered a pseudarthrosis until proven otherwise. Again, meticulous attention to bone grafting technique will minimize the pseudarthrosis rate.

Sometimes, even when the most extreme care has been exercised in providing postoperative hardware coverage, a sore will form over a prominent portion of the hardware. Once this covering is violated to the point where the metal is observable from the outside, securing a sterile environment is virtually impossible until all metal has been removed. If the wound becomes colonized and infected, significant long-term complications can ensue, resulting in difficult-to-treat chronic deep infections. If spinal osteomyelitis occurs, I have used debridement, long-term parenteral antibiotics, free-flap coverage to provide improved blood supply, and even hyperbaric oxygen to manage this most difficult problem.

The development of the spine may be upset by abnormalities of connective tissue, muscle balance, or ossification. Although a congenital syndrome is by definition present at birth, an associated spinal deformity in most cases is not. It may develop with growth as a result of bone dysplasia, a connective tissue disorder, or miscellaneous chromosomal abnormalities. The orthopaedic surgeon must understand the natural history of these growth disturbances to determine when, as well as how, to intervene. Three factors should always be kept in mind when evaluating the patient with a congenital syndrome: (a) coexisting medical problems, (b) characteristics of bone shape and quality, and (c) the effect of the syndrome on the neural elements.

CERVICAL SPINE ABNORMALITIES

The cervical spine in many congenital syndromes is vulnerable to deformity, stenosis, and, most important, instability. The surgical team must rule out or characterize the potentially unstable cervical spine before general anesthesia is administered or any skeletal surgery is performed. Plain film radiography with or without flexion–extension may be helpful. Table 158.1 lists characteristic cervical spine problems in most common congenital syndromes.

Table 158.1. Characteristic Cervical Spine Problems in Common Congenital Syndromes

ODONTOID HYPOPLASIA/ATLANTOAXIAL INSTABILITY

The term hypoplastic odontoid generally refers to an odontoid process that does not extend to the midpoint of the ring of the atlas. It may be seen in numerous conditions, the most common are skeletal dysplasia and Down syndrome (21,31-35). Odontoid hypoplasia may also be an idiopathic occurrence. In extreme cases, the dens may be essentially absent (aplasia). The majority of these cases of odontoid hypoplasia are the result of skeletal dysplasias. Another condition that exhibits similar clinical symptoms is transverse ligament insufficiency, which may be caused by ligamentous laxity or damage to the ligament. Finally, a number of patients have an os odontoideum, a chronic condition in which the odontoid is present only as a small ossicle, not united to the body of the axis. Although os odontoideum was long presumed to be a congenital lesion, more recent evidence suggests that most cases may be the result of unrecognized fracture of the odontoid.

Patients with any of these four problems share a variety of symptoms: (a) They may show signs and symptoms of neck instability, manifested by the muscles’ response to guard it: neck pain and spasm, torticollis, or headache. These symptoms appear most often after activity or a fall. (b) Neurologic symptoms involving the long spinal tracts may be present, such as developmental delay, hyporeflexia or hyperreflexia, and weakness. (c) Finally, cerebrovascular symptoms may prevail, from ischemia to stroke involving the posterior circulation. Plain radiographs are helpful in establishing the diagnosis, and computed tomography (CT) can usually demonstrate the pathology clearly, if needed.

Plain films that include lateral views in flexion and extension will help to quantify the instability. The normal space available for the cord at this level should be at least 13 mm, and the translation of the ring of the atlas should be less than 5 mm. Magnetic resonance imaging (MRI) may be helpful to demonstrate cord impingement, but this can often be deduced from plain films and clinical exam alone.

If radiography reveals signs of instability beyond a critical limit (more than 5–8 mm of translation on flexion/extension films), stenosis, or neurologic signs, surgical fusion of C-1 to C-2 is indicated (24). Reduction to a neutral position is the goal; if this cannot be accomplished, decompression may also be required.

CERVICAL STENOSIS

When cervical stenosis is seen in children, the diagnosis is usually achondroplasia, Klippel-Feil syndrome (36), or idiopathic congenital cervical stenosis. Signs and symptoms include those of acute compression (numbness and tingling in the extremities, acute weakness) or chronic myelopathy with developmental delay, spasticity, weakness, and muscle atrophy. In the teenage athlete with idiopathic cervical stenosis, transient quadriparesis is a common presenting phenomenon, with forced hyperextension in the presence of a narrowed spinal canal (41). Fortunately, this symptom tends to resolve rapidly if there is no vertebral subluxation or dislocation. In the child with achondroplasia, the greatest degree of stenosis occurs at the foramen magnum, causing failure to meet developmental milestones and a tendency to develop sleep apnea. Clinically significant stenosis of the remainder of the cervical spine in the person with achondroplasia generally develops only in adulthood, if at
Certain other skeletal dysplasias (such as spondyloepiphyseal dysplasia and mucopolysaccharidosis) may produce localized stenosis of the ring of the axis as well as atlantoaxial instability; these can cause additive damage to the cord. On lateral radiographs, cervical stenosis should be suspected if the distance from the posterior laminar line to the posterior vertebral body line is less than 80% of the width of the vertebral bodies (Pavlov’s ratio). Also, the distance from the posterior laminar line to the line of the facets is diminished (Fig. 158.1). Patients with Klippel-Feil syndrome, this finding may be missed because attention is drawn to the vertebral fusions. The stenosis is made more problematic if there are large blocks of fusion with just a few motion segments.

Figure 158.1. Torticollis in a young child, in this case due to three consecutive hemivertebrae in the upper cervical spine. In infants, computed tomograms provide superior visualization compared with plain films, because of the baby’s large head, difficulty positioning, and the complexity of the case. Treatment was by realignment with distraction of the concave side and derotation in a halo-vest, followed by fusion.

Patients with known cervical stenosis should be counseled to avoid contact sports, especially those that produce forcible flexion or extension of the cervical spine, such as wrestling and playing lineman in American football. Surgical decompression of the lower cervical spine is generally best avoided, as it could produce a region of decreased stability adjacent to further stenosis. Localized decompression and fusion may be carried out if indicated. Patients with congenital stenosis of the upper cervical spine may require decompression. If this is so, fusion should be considered if there is associated instability or if the decompression involves more than two segments, in order to prevent development of localized kyphosis.

CERVICAL SPINA BIFIDA

Occult defects in the cervical spine occur primarily in two congenital syndromes: Larsen syndrome and diastrophic dysplasia. Larsen syndrome is characterized by multiple joint dislocations, foot deformities, and an accessory calcaneal apophysis. In one series, more than half the patients had cervical spine biffida and resultant kyphosis. In diastrophic dysplasia, diastrophic patients are often born with significantly short stature, rigid clubfeet, joint contractures, and a closed cervical spine biffida, although the incidence of kyphosis is not as high.

The presence of spina bifida in the cervical region indicates a deficiency of posterior ligamentous support (interspinous ligament, ligamentum flavum) as well as of posterior muscle control. This may be a reason for the development of kyphosis. In addition, the vertebral bodies in the region are hypoplastic and may be rounded or wedge shaped. The kyphosis may progress as the child becomes upright. Initially, the physical features of kyphosis are not externally evident, except for a slight loss of the normal cervical lordosis. There are no external clues to the presence of bifid cervical laminae. Therefore, a high index of suspicion must be maintained for these conditions.

Patients may exhibit myelopathy, which may be difficult to detect in children with severe skeletal deformities. Signs such as muscle weakness, failure to achieve normal milestones, and hyperreflexia or clonus may be seen. Endotracheal intubation for other surgical procedures in the presence of this kyphosis may worsen the neurologic condition if not done by knowledgeable persons. In some patients with diastrophic dysplasia, a mild cervical kyphosis may improve spontaneously with time. Observation may be indicated if there are no established signs of neurologic compromise. Bracing, however, does not seem to be feasible or warranted. In Larsen syndrome, progression is more likely.

Posterior Fusion

The optimal treatment is an early posterior fusion, which may function as a tether and allow spontaneous correction of the deformity.

- Perform fusion early in the patient with Larsen syndrome, before the kyphosis exceeds 50° and becomes rigid. Consider fusion in patients with diastrophic dysplasia who do not improve over the first several years of life, or whose deformity or neurologic condition worsens.
- Perform posterior fusion over the levels involved in the kyphosis, using autogenous bone graft from the iliac crest or the tibial metaphysis.
- Use a halo-vest or halo-cast to control the head and prevent the kyphosis from worsening during incorporation of the fusion. For mild deformities, a Minerva-type cast or orthosis is also an option. Order them in advance of the procedure.
- Take care in exposing the spine, because of the open laminae.
- Dissect the muscles off only the extent of the spine intended for fusion, since extension of the fusion to exposed levels is a risk. Confirm levels radiographically.
- Deoricate the spine gently and perform a bone graft.

Instrumentation of the spine is not possible for patients of a very young age. Some degree of correction in the halo-vest may be possible by a combination of three maneuvers: (a) positioning the head in slight extension and posterior translation, (b) securing the shoulder straps of the vest so that they are snug (but not too tight), to maintain the length of the cervical spine rather than allowing it to settle, and (c) placing a padded sling behind the apex of the kyphosis, which is attached to the bars of the halo-vest, to prevent the kyphosis from settling posteriorly. When this is done, the tension of the strap must be checked periodically to be certain that there is not too much pressure on the skin.

If the deformity is severe or there is significant neurologic compromise, an anterior decompression and strut graft may be needed in addition to the posterior fusion. The spine should be immobilized for a minimum of 3 months, and continuity of the fusion mass should be demonstrated radiographically at the end of this period to prevent loss of position due to a pseudarthrosis.

Congenital fusion of the cervical spine, or Klippel-Feil syndrome, may occur with congenital upper or lower thoracic or lumbar fusion, or it may be present as an isolated finding. It has been classified into three types: Type I involves fusion of cervical and upper thoracic vertebrae, type II involves isolated fusions of the cervical spine, and type III refers to cervical fusions associated with lower thoracic or upper lumbar fusion. Surgery is almost never required for the cervical anomaly itself.

The main significance of the diagnosis is to encourage a search for other anomalies both within and outside the spine, such as Sprengel deformity, hearing impairment, spina biffida, and associated scoliosis. Scoliosis is most common in types I and III. Progressive congenital cervical scoliosis is rare and usually involves the cervicothoracic junction. Monitor young children with this finding closely, since the shoulder tilt it produces may be highly deformable. Perform surgery if progression of more than 10° is seen. A posterior fusion in situ is the gold standard for this region.

Scoliosis of the upper cervical spine is quite rare and usually presents as torticollis, which must be differentiated from muscular torticollis, Grisel syndrome, ocular disturbance, and abnormalities of the brainstem and cord. Other causes of fusion in a young child include juvenile rheumatoid arthritis, as well as residual or infection in the region. The upper cervical spine may be very hard to image in children under age 5; it is frequently necessary to obtain a multiplanar CT or an MRI under sedation.

If a vertebral anomaly is seen that is deforming, surgery may be indicated. HINTS AND TRICKS

HINTS AND TRICKS
**OPERATIVE TECHNIQUES**

Because in many congenital syndromes, age and bone quality affect halo application and upper cervical fusion, these techniques deserve special consideration (19).

**Halo Application**

Check the halo size and shape in advance, and modify it if there is plagiocephaly or cranial disproportion (14). Also, if there is risk of positional neurologic damage in children too young to cooperate with examination, evoked potentials are useful.

- General anesthesia is preferred for halo application, although local anesthesia and sedation are possible.
- Because of the danger of hyperflexion caused in part by children's relatively large head size, elevate the torso or have an assistant hold the head off the end of the table.
- Do not place pins in the thin temporal regions (13).
- In children under 2 years of age, Mubarak et al. (23) recommend placement of six to ten pins at low torque (finger tightness through 2 inch-pounds) in the four traditional regions (Figs. 158.2, 158.3). Kopits and Steingass (25) found four pins to be sufficient in most cases, and loads up to 5 inch-pounds to be safe in older children. My experience confirms these findings. At our institution, we use 4 inch-pounds of torque for children up to age 4 years, 6 inch-pounds for those aged 5 to 10, and 8 inch-pounds for those over 10.

**Posterior Cervical Fusion**

Many congenital disorders require fusion of the upper cervical spine for deformity or instability. Techniques of fusion are well described elsewhere (in Chapter 139, Chapter 150, and Chapter 154). Two special aspects require further comment. First, anomalies of the posterior arches are common in several syndromes. Second, in very young children, the posterior elements and occipital cortex may not allow construction of a rigid construct, because the bone may be resorbed in cases of stenosis. Study good plain radiographs and, in most cases, CT scans in the areas of planned fusion to rule out spina bifida or anomalies of the arches. If anomalies are present, start dissection from a "normal" area, where depth can safely be established, and proceed up and down over the facets in the deficient areas.

**Posterior Occipitocervical Fusion**

**Koop Technique** Koop et al. demonstrated a union rate of greater than 90% for upper cervical fusion in children with halo immobilization, even when grafts are not wired in place (23). This finding is relevant for infants or certain patients with skeletal dysplasia who do not have adequate bone size or quality for wire fixation.

- Apply the halo as described previously for young children.
- Turn the patient prone and affix the halo to a halo-holder. Use spinal cord monitoring during turning and throughout the entire procedure.
- Check a lateral radiograph to confirm proper alignment of the neck.
- Gently expose the spine, taking care to remain medial to the vertebral arteries at C1–C2.
- Avoid unnecessary exposure of caudal levels, which often leads to unwanted extension of the fusion distally. If a distal level is exposed unintentionally, covering it with bone wax may prevent it from incorporating into the fusion mass.
- After exposure and wide decortication, place autologous bone in the desired areas (Fig. 158.3).

**Dormans and Drummond Technique** An alternative technique has been described by Dormans and Drummond for children whose bone is adequate to permit wire fixation (11). Use of autogenous bicortical iliac crest in combination with occipitocervical wires forms a construct that is stable in flexion and extension.

- Perform the halo placement, with positioning and exposure as previously described.
- Fashion a trough in the outer table of the base of the occiput below the inion, at a level so that a graft can be inserted on top of the laminae (Fig. 158.4).
CONGENITAL STENOSIS

Congenital stenosis of the thoracic and lumbar spine is seen mainly in achondroplasia; to a lesser degree, it is seen in other skeletal dysplasias such as hypochondroplasia, diastrophic dysplasia, and spondyloepiphyseal dysplasia. Patients with isolated congenital spinal malformations such as scoliosis and kyphosis also commonly have associated narrowing of the spinal canal in the region. Take this narrowing into account when planning deformity correction and instrumentation.

A rare syndrome of focal, severe congenital stenosis, termed segmental spinal dysgenesis, has been described (13). It is usually present at the thoracolumbar junction and may be associated with segmental instability, scoliosis, or kyphosis. In patients with complete neurologic deficit, return has not been seen after decompression and stabilization, but these are indicated in those with preservation of at least some distal neurologic function who have progression or instability.

In addition, there are some young patients without any congenital malformation, who exhibit spinal stenosis that has been made symptomatic by disc protrusion or mild degenerative change. Symptoms include pain and tingling or numbness in the lower extremities more than pain in the back. Standing or walking worsens these symptoms, and rest usually relieves them. Plain films suggest stenosis by virtue of the narrow distance between the posterior laminar line and the posterior vertebral line, but they are less accurate in identification of stenosis in the thoracic and lumbar spine than they are in the cervical spine. MRI more clearly delineates the degree of stenosis, but they are less accurate in identification of stenosis in the thoracic and lumbar spine than they are in the cervical spine. MRI more clearly delineates the degree of stenosis.

THORACOLUMBAR ABNORMALITIES

CONGENITAL STENOSIS

Congenital stenosis of the thoracic and lumbar spine is seen mainly in achondroplasia; to a lesser degree, it is seen in other skeletal dysplasias such as hypochondroplasia, diastrophic dysplasia, and spondyloepiphyseal dysplasia. Patients with isolated congenital spinal malformations such as scoliosis and kyphosis also commonly have associated narrowing of the spinal canal in the region. Take this narrowing into account when planning deformity correction and instrumentation.

A rare syndrome of focal, severe congenital stenosis, termed segmental spinal dysgenesis, has been described (13). It is usually present at the thoracolumbar junction and may be associated with segmental instability, scoliosis, or kyphosis. In patients with complete neurologic deficit, return has not been seen after decompression and stabilization, but these are indicated in those with preservation of at least some distal neurologic function who have progression or instability.

In addition, there are some young patients without any congenital malformation, who exhibit spinal stenosis that has been made symptomatic by disc protrusion or mild degenerative change. Symptoms include pain and tingling or numbness in the lower extremities more than pain in the back. Standing or walking worsens these symptoms, and rest usually relieves them. Plain films suggest stenosis by virtue of the narrow distance between the posterior laminar line and the posterior vertebral line, but they are less accurate in identification of stenosis in the thoracic and lumbar spine than they are in the cervical spine. MRI more clearly delineates the degree of stenosis.
of neurologic compression.

Conservative treatment such as activity modification or a flexion back brace may alleviate symptoms. Hip flexion contractures may need to be addressed, as they increase the obligatory lumbar lordosis. Decompressive laminectomy may be necessary if these measures fail; careful examination and judgment are necessary to determine the extent of unroofing required. Techniques of decompression may involve traditional laminectomy, laminoplasty (enlarging the canal by hing open the lamina), or fenestration (removal of the stenotic inferior portion of each involved lamina and the medial facets). Further details are discussed in the later section on achondroplasia.

CONGENITAL AND ACQUIRED KYPHOSIS

Congenital kyphosis is less common but has potentially more serious neurologic consequences than congenital scoliosis. The basic types include failure of vertebral formation (type I) and failure of segmentation (type II) (see Chapter 161). If progression is seen, treatment is required. Bracing has no value in halting the increase of the curve.

Surgery is indicated at an early age if any progression at all is discovered. It should take the form of an in situ posterior fusion of the level above and the one below the abnormal vertebra in a type I kyphosis, unless it exceeds about 55°. If it exceeds this value, the fusion mass will be under tension and will not effectively halt growth; an anterior ephysesoideosis may be needed as well. A type II kyphosis may be fused posteriorly between the two involved vertebrae, to match the anterior bar; this may be extended one level above and one below in young children if it is desired to achieve some correction with cast and growth.

Postoperative cast immobilization for 3 months is the rule; follow-up should be performed to rule out pseudoarthrosis and progression. Undertake osteotomy or vertebrectomy in treatment of congenital kyphosis only if the deformity is severe and is causing neurologic compromise or an unacceptable appearance.

Acquired kyphosis in children is seen most often after laminectomy, especially of the cervicothoracic or thoracolumbar junctions. In congenital syndromes, this situation may occur after decompression of spinal stenosis (in achondroplasia) or of intradural tumors (in neurofibromatosis) (17,19). More detail is given later in the sections on these conditions. It is important to realize that the risk of this phenomenon is greater in children than it is in adults. When there is preexisting kyphosis or vertebral wedging, it becomes even more likely.

Prevention of kyphosis is much easier than later treatment of an established deformity, if it can be anticipated. Limited posterior fusion in situ over the region of the junction is usually effective. Another alternative is laminoplasty, which allows many of the interlaminar ligaments to remain intact and may prevent kyphosis from developing.

CONGENITAL SCOLIOSIS

Congenital scoliosis may be an isolated finding, or it may be associated with various syndromes. The most common association is with the VATER syndrome (vertebral anomaly, anal atresia, tracheoesophageal fistula, renal and radial abnormalities). Some physicians include a C for cardiac abnormalities. The vertebral anomalies are the most common component of the VATER syndrome, so orthopaedic surgeons will see most of these children. Other syndromes that include congenital vertebral anomalies are Goldenhar (oculoauriculovertebral) syndrome, myelomeningocele, Klippel-Feil syndrome, and Jarcho-Levin syndrome (spondylothoracic dysplasia).

Although there may be a dimple, a vascular marking, or a patch of hair over the spine in the occasional case of congenital scoliosis, often patients have no external physical findings except for the deformity, which may be mild in early childhood. Early diagnosis usually comes about because of an incidental event such as a radiograph for trauma or a chest film. Vertebral anomalies are frequently seen on ultrasound of fetuses, and concerned parents as well as sonographers often consult the orthopaedist for a diagnosis. Isolated hemivertebrae without neural tube defects or other sonographic anomalies typically have a good outcome. The presence of other abnormalities reduces the rate of survival.

Radiographic findings in congenital scoliosis usually include hemivertebra, wedged vertebra, or fusion of vertebrae (bar). Many times there are elements of both in a given curve. The best opportunity to understand the underlying growth abnormality is to study the films of the patient at the youngest possible age; they will show the asymmetries of ossification and allow diagnosis of hemivertebra and fusion.

If a hemivertebra does not have a growth plate on both surfaces, or if it is “carved into” the adjacent vertebra (incarcerated), it is less likely to produce an increasing curve. Upon diagnosis of congenital scoliosis, do a thorough exam, searching for limb atrophy or other deformities. Chest auscultation should be done, but cardiac imaging is not routinely indicated. However, the genitourinary tract should be visualized at least once by ultrasound or intravenous pyelogram. Some experts recommend a routine MRI on all children with this diagnosis, since at least 25% will show some abnormality such as a Chiari malformation, syrinx, or tether. This is not a well-accepted recommendation, however, as the indications for treating these conditions in the asymptomatic stage are highly debatable. Most surgeons instead prefer to order an MRI only when corrective surgery is planned, or if unexplained progression occurs.

Treatment of congenital scoliosis is largely surgical. There is no documented efficacy of brace treatment. Some curves such as those with a segmented hemivertebra and a contralateral bar have a virtual certainty of progression and should be fused when first seen. All others should be followed during growth with serial radiographs, always comparing them to the first film, rather than to the last prior film.

If progression of more than 5° to 10° is seen, I recommend surgery. There are several surgical options, whose indications depend on the characteristics of the curve, the acceptability of the current deformity, and the likelihood of future increase in the curve. Options include the following:

- Posterior fusion in situ
- Anterior and posterior fusion
- Hemiepiphyseal fusion
- Hemivertebrectomy
- Spinal osteotomy for correction

Operative Techniques

Posterior Fusion in Situ Posterior fusion in situ is the most widely accepted procedure. It is indicated for progressive curves if the deformity is acceptable and the likelihood of anterior crankshaft progression is not high.

- Take care in exposing the spine, since midline laminar defects are sometimes seen in congenital curves.
- Fuse all vertebrae within the curve.
- Some correction may be obtained through bracing if there is flexibility in the curve.
- Postoperatively, immobilize the patient in a cast or brace for 3 to 4 months, when consolidation of the fusion should be demonstrated.

Anterior and Posterior Fusion If you suspect that significant growth potential also exists anteriorly that could cause a deformity due to the crankshaft phenomenon, perform anterior and posterior fusion.

- Perform the anterior procedure in the traditional open fashion, through a thorascopic approach, or by a transpedicular or costotransversectomy approach. See Chapter 155.
- Consider a hemiepiphyseodesis, as a variation on this theme, for young patients’ curves with some growth potential on the concave side.
- Fuse the curve anteriorly and posteriorly only on the convexity, to allow for some corrective growth on the concavity. Measurable correction is seen only in children under age 6 at surgery, and the amount of correction rarely exceeds 10° to 20°.
- Posterior fusion is now accepted as a safe alternative for curve correction in experienced hands (6) (see the Surgical Techniques section later). It is mostly, although not solely, applicable to anomalies at or below the thoracolumbar junction. Use this technique for curves too large to be fused in situ.
- Both anterior and posterior procedures may be performed in the same operative session.
- Spinal osteotomy may be needed to correct large, stiff curves composed of multiple bars, or ones that have been fused previously. It carries an element of risk and should be performed by experienced surgeons and only for curves that are significantly disabling.
- In all cases where corrective surgery is planned for congenital deformities, a preoperative MRI of the spinal canal is indicated.

MANAGEMENT OF SPECIFIC SYNDROMES
Down syndrome (trisomy or translocation involving chromosome 21) is commonly associated with cervical abnormalities. Anterior subluxation of C-1 on C-2 of more than 5 mm in flexion is seen in 15% to 20% of patients. Over 4 mm posterior translation of the occiput on C-1 is seen in 60% (28,31). Also seen is increased frequency of os odontoideum, occipital terminale, and spina bifida of any upper cervical vertebra (31). Management of the instability is controversial.

Screen all Down syndrome children, and restrict from high-risk sports those with more than 5 mm C1–C2 subluxation. Perform fusion for those with more than 1 cm subluxation, neurologic deficit, or persistent neck pain. In cases to be fused, it may be necessary to extend the fusion to the occiput (42) if there is significant posterior atlanto-occipital translation in extension. Increasing quadripareisia during surgery has been reported in cases of preoperative myelopathy or longstanding displacement. It appears that in such cases there may be chronic degeneration within the cord, rendering it extremely susceptible to insult. In addition, the space available for passing wires is decreased. Reduction, if necessary, should be achieved before surgery with evoked potential monitoring or preoperative awake traction. If significant reduction cannot be achieved but the patient’s neurologic condition is acceptable, only a fusion without wires is recommended. Use a CT scan to rule out spina bifida.

SKELETAL DYSPLASIAS

Cervical spine abnormalities are common in many skeletal dysplasias. Odontoid hypoplasia and ligamentous laxity are common in spondyloepiphyseal dysplasia (congenita more than tarda), Morquio syndrome, Kniest syndrome, and metatrophic dysplasia (2,38). It may also be seen in the occasional patient with pseudoachondroplasia. Symptomatic instability frequently results. In addition, cervical stenosis may be seen with metatrophic dysplasia, Maroteaux-Lamy syndrome, or achondroplasia. Obtain neutral, flexion, and extension cervical spine films in all patients with these conditions. Diagnosis of cervical myelopathy is difficult in infants and may be aided by checking motor milestones, and spinal cord monitoring, flexion-extension MRI, and sleep studies. Metatrophic patients may also have painful torticollis due to rotatory C1–C2 instability (Fig. 158.6).

Figure 158.6. A: A 15-month-old child with metatrophic dysplasia and painful torticollis. The head is kept in marked hyperextension. B: Lateral roentgenogram shows some anterior C-1 displacement with rotation and stenosis. C: CT-myelogram confirms rotational malalignment and stenosis. D: Posterior C-1–C2 decompression and occiput to C-3 fusion done by the method of Koop. Wires seen are through facets (Southwick type). Tibial graft is used. Unfortunately, the patient died 3 months postoperatively due to the restrictive lung disease associated with metatrophic dysplasia.

In contrast to the upper cervical abnormalities seen in other dysplasias, diastrophic dysplasia frequently causes mild cervical kyphosis and spina bifida (19). Surprisingly, many of these kyphoses, especially those that are less than 80°, resolve over time with or without bracing. Quadriplegia has been reported with some larger kyphoses, however, so surgical treatment is indicated for those with progression or neurologic deficit.

If the curve is flexible, correction may be accomplished by postural reduction and posterior fusion. Place the patient in a halo body jacket, and gradually extend the head over several days with serial neurologic examinations. A posterior slings may be added at the apex of the curve. If satisfactory improvement is obtained, identify bifid areas on CT and perform a posterior fusion with a tibial cortical graft. If the kyphosis is rigid, anterior release and strut graft fusion, followed by posterior fusion, are indicated. Apply the halo before the fusion, to protect the strut graft in young patients. The anterior bar of the frame should be removable on the side of the anterior approach.

Larsen syndrome of multiple joint dislocations with flattened facies is occasionally associated with cervical spondyloysis and kyphosis, causing neurologic deficit (22). Screening of the cervical spine is recommended for all patients with this diagnosis. Treatment follows the guidelines given for diastrophic dwarfism. Note, however, that spontaneous resolution has not been documented in this condition, and the posterior arches may also be deficient.

Achondroplasia

In achondroplasia, panspinal developmental stenosis, sagittal deformity, and arthrosis combine to produce compressive neurologic lesions in 30% to 80% of patients. Infantile kyphosis at the thoracolumbar junction, resulting from muscular hypotonia, ligamentous laxity, and a relatively large head, resolves in 75% to 85% of cases but persists or progresses in the remainder, leading to wedging of thoracolumbar vertebrae (19,26,37,49). Wedging may be focal, involving a single vertebra, or gradual, involving multiple levels. Some geneticists feel that it is important to prevent children with achondroplasia from sitting unsupported, and to use hard-backed sitting devices (30). I feel that it is impossible to prevent a child from sitting who is developmentally ready, and that the only effective support is a thoracolumbosacral orthosis. Therefore, it seems prudent to brace all achondroplastic children with significant kyphosis after 2 to 3 years of age.

Correction of kyphosis should be undertaken in the following situations:

- For any curve more than 50° to 60° with focal wedging, in patients over age 5 to 6 years
- In any patient undergoing laminectomy with a curve over 30° in the thoracolumbar region or 50° in the thoracic region
- For any curve that progresses on its own (37)

Fusion should always be both anterior and posterior because of deformity and small posterior elements, especially after laminectomy. If the kyphosis is sharp and angular, and if neurologic deficit is present, perform a corpectomy with strut graft fusion. Follow with posterior fusion. Both procedures can be done on 1 day if the patient is young, or 1–2 weeks apart in older patients or those requiring extensive laminectomy. Correction of deformity may be either by cast or instrumentation. There is a 25% or greater chance of somatosensory evoked potential or clinical neurologic deterioration when instrumentation is used, although recovery is common (37). This effect is probably caused by instrumentation impinging on a narrowed canal, downward pressure on apical laminae, or stretch of nerve roots in lordotic segments. This risk can be minimized by using cast correction only, with 4–6 months of recumbency. If instrumentation is used, it should include only pedicle screws in the lower thoracic or lumbar region (Fig. 158.7). Stabilization and fusion, rather than significant correction, should be the goals. It is best not to fuse below L-4 in most cases, because mobility is always a problem in patients with achondroplasia. Laminectomies should be done in marginally stenotic levels. Spinal stenosis in achondroplasia is caused by deficient endochondral growth in the neurocentral synchondroses, with decreased sagittal and coronal canal dimensions, increasing in severity caudally. Foramen magnum and cervical stenosis may occur in addition to the more common thoracolumbar stenosis.

Figure 158.7. A: A 6-month-old girl with achondroplasia, never braced. B: The same patient at age 12 with severe 90° wedging of L-2 with early weakness. C: One
Degenerative changes or disc bulge may make the narrowing symptomatic. True disc herniations are a distinct minority, however. Symptoms in older teenagers or adults include leg pain while standing or walking, decreased endurance, numbness, and urgency or incontinence. On examination, an upper or lower motor neuron picture may be seen, depending on the level of compression. Evaluation should include CT-myelography, cisternogram, and postvoid residual. MRI is less helpful because it does not show the bony compressive structures as well. If stenosis symptoms or any neurologic deficit is present, decompressive laminectomy should be done, after ruling out disc herniation (43). Laminectomy should include all involved levels, most commonly T8–S1. The most frequently reported surgical error is insufficient length of laminectomy. Because of the limited canal space, dural tear or cord contusion during decompression is not infrequent.

**Diatrophic Dysplasia**

In diastrophic dysplasia, scoliosis or kyphosis is extremely common (4,5,19), having been seen in over 70% of patients in the largest reported series. Only 30% of the curves, however, were over 30°. Two curve types are seen: benign and idiopathic-like, and severe, rigid types with kyphosis. The latter are considered by Tolo to be the result of wedged or unsegmented vertebrae like those seen in congenital scoliosis (39). These curves are apparent before age 4, often in infancy.

Try bracing early, for all curves. It is sometimes successful for the gradual idiopathic-like curves. If the curve progresses past 45° despite bracing, consider instrumentation without fusion in young children if there is not too much kyphosis. Tolo and Kopits (39) state that significant growth ceases at age 9–10 in these patients, so fusion at this age, if it is necessary, would have little effect on height. At any point where the curve progresses significantly despite subcutaneous instrumentation, perform fusion, for little of what is lost in progression can be regained.

To arrest progression effectively, add anterior release and fusion if the kyphosis or scoliosis is large or if there is much growth remaining before skeletal maturity. Although the canal is relatively stenotic in the lower lumbar region, hook placement can be done safely (38). The incidence of postoperative neurologic deficit in hook placement was more than 50% in one series (6). The deficit seems to be due to zealous attempts to correct these rigid curves, rather than to the instrumentation itself.

**Pseudoachondroplasia**

Pseudoachondroplasia is occasionally associated with thoracolumbar kyphosis and hip flexion contractures. Treat the kyphosis by anterior and posterior fusion if severe. Neurologic injury from surgery is less common than in achondroplasia because the canal is larger. Sublaminar instrumentation may be used. If excessive lumbar lordosis is present and flexible, correction of any hip flexion contracture by femoral extension osteotomies should be the first step.

**Metatrophic Dysplasia**

Metatrophic dysplasia is usually associated with curves that appear early and are difficult to control. The most common pattern is a double major scoliotic curve with a severe junctional kyphosis, which may equal or exceed the scoliosis in magnitude. The curves are rigid, and bracing is poorly tolerated. The kyphosis and poor bone quality contraindicate subcutaneous instrumentation. Definitive spine fusion is frequently necessary at an early age. Restrictive lung disease is common because of short ribs. Consult a pulmonary specialist if you are contemplating anterior fusion or to determine if even posterior fusion will be tolerated. Fusion with cast correction is the most common method used.

**Kniest Syndrome**

Kniest syndrome and its resultant scoliosis are similar to metatrophic dysplasia but less severe. Rib length is normal, and restrictive lung disease is not as frequent as in metatrophic dysplasia (2).

**Mucopolysaccharidoses**

The mucopolysaccharidoses, kyphosis with or without scoliosis is common in Hunter syndrome. It most often has an apex at the thoracolumbar junction, where wedging of vertebrae and translation may occur. Bracing is warranted, but its efficacy remains unproven. The limited life expectancy of these patients historically has made fusion untenable. With the increasing success of bone marrow transplantation, patients who are longer-term survivors may require treatment by a limited posterior fusion over the kyphotic segment if it is progressive.

**Spondyloepiphyseal Dysplasia**

Spondyloepiphyseal dysplasia is manifested in the spine by marked platyspondyly and, frequently, thoracic kyphosis and scoliosis (2). Bracing is advised for scoliosis less than 45° or for any increased increase in growing children. In some cases, the kyphosis has been permanently improved by bracing. Scoliosis should be fused if the curve is over 45°. Pseudarthrosis is common after posterior fusion of either kyphosis or scoliosis, resulting in significant loss of correction. Therefore, patients with severe curves may need an anterior as well as a posterior fusion if the curve is rigid, if the patient is adult, or if he has had prior laminectomy.

**OSTEOGENESIS IMPERFECTA**

Spine deformity in osteogenesis imperfecta correlates with bone involvement (3,16,47) (see Chapter 180). Although many classification systems have been proposed, the radiographic system of Hanscom has been best correlated with spinal involvement (16). Type A patients, those with only bowing of the long bones, have the best bone quality and generally maintain some correction if scoliosis surgery and instrumentation are required. Type B patients, who also have biconcave vertebrae, and type C, who have a trefoil pelvis, have a greater tendency to kyphosis. Type D patients are more severely involved, having also cystic changes in the metaphyses. With these latter three types, less correction is obtainable, and there is more postoperative loss. Type E patients, with absent long-bone cortices, should not be subjected to instrumentation at all.

Brace treatment has little if any role in osteogenesis imperfecta curves except for postoperative protection because of the potential for rib deformity. Posterior fusion should be done for curves of more than 45° in type A, or 35° to 40° in types B through E. Even at a young age, delaying fusion to preserve trunk height should not be a consideration, because the trunk is so short in nonscoliotic adults of these types, let alone those with curves.

In some cases of severe deformity with poor bone stock, carefully applied halo–gravity traction after anterior release may be used to decrease the amount of force that must be applied through the rods. All patients should be evaluated preoperatively for basilar invagination and for pulmonary compromise. Segmental fixation using hooks at as many levels as possible, augmented when necessary by doubled Luque wires, is the preferred technique. The following points should be noted:

- Hooks placed on fragile laminae may be supplemented with methylmethacrylate.
- Pack the methylmethacrylate after the hook is inserted; it should extend to the lamina above and below.
- Preserve the spinous processes at these levels.
- Supplement the fusion with banked bone.
- Bone from other spinous processes is also helpful; these may be relatively large in osteogenesis imperfecta.
- Blood loss is usually greater than in other conditions.
- Use postoperative recumbency and orthoses as the quality of fixation dictates.

**ARTHROGYROPSIS MULTIPLE CONGENITA**

Scoliosis is present in up to one third of patients with the diagnosis of arthrogryposis multiplex congenita. Usually the curve is a long, uncompensated, “paralytic” type. Increased lumbar lordosis may occur, especially with hip flexion contractures. In a sizable minority, congenital anomalies may occur; take care to distinguish these patients from those with multiple pterygium syndrome.

Congenital curves should be treated according to the usual rules. Noncongenital curves can be braced if less than 50°, but fusion should be performed for larger curves. The spine, like the joints, is stiff, and correction is not often great unless the spine is mobilized extensively anteriorly and posteriorly. Bone is osteoporotic and hypervascular. Low lumbar curves with pelvic obliquity should have fixation extended to the pelvis. Where excessive lumbar lordosis is the main problem, patients...
respond poorly to posterior distraction, and anterior column shortening by multiple partial vertebrectomies is most successful.

**NEUROFIBROMATOSIS**

Neurofibromatosis is estimated to make up 1% to 2% of a scoliosis clinic population, so its signs should be looked for on all initial examinations (9,44). The diagnosis can be made with the presence of two or more of the criteria from the 1987 Consensus Development Conference of the National Institutes of Health (Table 158.2). In a patient with neurofibromatosis, it is important to make the distinction between dystrophic and nondystrophic curves (44). Nondystrophic curves can be treated with brace or surgery according to guidelines for idiopathic scoliosis. They are in the minority, however, making up 25% to 35% of most series.

Treatment of neurologic deficit depends on its cause. If it is due to intracanal tumor or rib penetration, decompress it posteriorly and do subsequent fusion according to previous guidelines. If it is due to kyphosis, correct it anteriorly and posteriorly with decompression if focal.

In summary, spinal curvature in neurofibromatosis patients ranks as a major threat to patient welfare. Take all possible care in preoperative planning, surgery, and postoperative follow-up.

**MARFAN SYNDROME**

Improved cardiovascular management has greatly increased the life expectancy of patients with Marfan syndrome to nearly that of the general population, thereby increasing the importance of appropriate treatment of spinal disorders. Scoliosis of greater than 10° is present in approximately half of these patients. Less than 10%, however, will require a brace or surgery (33). There is no typical curve: In Marfan syndrome, the patient may have any of the curve types seen in idiopathic scoliosis. Sagittal plane deformities are equally common and vary from hyperkyphosis to hypokyphosis. There is a fairly common finding of thoracolumbar kyphosis. Use bracing for the same standard indications as in idiopathic scoliosis, although the success rate is lower, there are cases where the brace has been associated with curve stabilization.

Severe infantile or early juvenile curves are in some cases treated with subcutaneous distraction instrumentation if they are greater than 50° (34). This technique is contraindicated, however, in cases where significant kyphosis exists. The rod should be contoured to match the patient's sagittal profile—that is, not too straight. Dorsal displacement of hooks is a frequent cause of failure of this technique, and it is due in part to inadequate contouring. Postoperative bracing is mandatory. Despite all of these precautions, the rate of hook cutout or continued progression is significant. If cutout occurs, undertake posterior fusion with or without anterior fusion, depending on curve size and the patient's overall condition.

Curve patterns in adolescents and adults are similar to idiopathic patterns (33). One difference is the tendency to develop moderate thoracolumbar kyphosis and the marked rotational listhesis that sometimes occurs in lumbar curves. Evidence suggests an increased risk of pseudarthrosis in patients with Marfan syndrome, especially in regions of kyphosis at the thoracolumbar junction (7). Anterior release and fusion should be added in such cases (Fig. 158.8) or when curves are large and rigid. Spondylolisthesis of severe degree occurs in approximately 2% of Marfan patients. Check for it on lateral radiographs.

![Figure 158.8](image)

Progressive kyphoscoliosis in Marfan syndrome. A,B: Posteroanterior and lateral films at age 25, with 53° thoracolumbar scoliosis and 22° kyphosis. C,D: Repeat films 6 years later (after two pregnancies) show increase of scoliosis to 64° and, especially, of kyphosis to 64°. E,F: One year after anterior release and fusion and posterior fusion with Cotrel-Dubousset instrumentation. Note that standard rods were not long enough in this patient; longer rods may be specially ordered.

Other features of Marfan syndrome that should be kept in mind include the following: (a) The rate of dural ectasia is high (63%) in the lower lumbar or sacral canal (32) (Fig. 158.9). The dural ectasia is probably another manifestation of the effect of gravity on abnormal connective tissues. The enlarged sac has thin dural walls and may...
HEMIVERTEBRA EXCISION

**SURGICAL TECHNIQUES**

Some authors advocate subcutaneous instrumentation for young patients with considerable growth remaining. I try to avoid subcutaneous instrumentation in almost all cases, because the gains over time are minimal and not worth the time and morbidity.

Hemiepiphyseodesis for Congenital Deformity Due to Hemivertebrae

Hemiepiphyseodesis (Winter technique) is intended not only to prevent progression of a congenital curve but also to allow some correction of the curve with growth (45). It is indicated for patients under about age 6 years who have some growth potential on the concavity of the curve. The advantage of the procedure is that it does

not destabilize the spine and does not require internal fixation, even though it is a corrective procedure. The disadvantage is that it does not work for very large curves

is not recommended for curves over 70°. There should be no significant kyphosis or lordosis in the area to be fused. Although the anterior portion of the procedure

may be performed endoscopically, the patient must be a satisfactory candidate for a thoracotomy. Take bending films to assess the flexibility of the spine

prooperatively. If some correction of the curve is possible, accomplish it in the cast after surgery.

- Place the patient in the lateral position so that both anterior and posterior exposures may be performed without repositioning (Fig. 158.10).
- In the open technique, expose the spine anteriorly through the rib that is one level above the most cranial to be fused.
- Confine dissection primarily to the convexity of the curve, and confirm the levels either by the characteristic shapes of the vertebrae, or by an intraoperative

radiograph with markers both anteriorly and posteriorly over the levels to be fused.
- Remove the lateral one third to one half of the disc along with the corresponding portion of the endplates of the vertebral.
- Obtain bone graft from the morcelized rib or from another source and pack into the disc spaces to promote fusion (Fig. 158.10C).
- Make a trough across consecutive vertebrae to allow a bone graft (such as rib) to be placed longitudinally, bridging them.
- Perform posterior exposure at the same time, to be sure that the levels fused in the front and in the back correspond exactly (Fig. 158.10D).
- Expose only the convexity of the posterior curve.
- Avoid elevating the muscles from the concavity of the curve, to prevent fusion from occurring on this side as well.
- Verify which levels are the end vertebrae to be fused by palpating the vertebrae from the front and the back simultaneously.
- If in doubt, pass small Kirschner wires from front to back at the tip of a transverse process to help confirm levels.
- Excise the convex facets and decorticate the spine.
- If additional correction is desired, a level above and below the curve itself may be partially fused as well, to allow further correction with growth.
- Postoperatively, place the patient in a cast to correct as much of the flexible portion of the deformity as possible. Apply the cast either in the operating room, or a few days after surgery, if there is significant edema or need to have access to the patient. The patient wears the cast, or a cast followed by a brace, for at least 6 months postoperatively. In the series of 13 patients reported by Winter et al. (45), prevention of curve progression was achieved in all but one, and in five of these, curve correction occurred with growth. The mean correction for these five patients was 10° (Fig. 158.11).

**Figure 158.11.** Result of convex hemiepiphyseodesis at 6-year follow-up. A: Curve measures 27° at age 4, due to unincarcerated hemivertebra with a bar just

distal to it on the opposite side. The hemiepiphyseodesis extended two levels above and one level below the hemivertebra. B: At age 10½, the curve has

corrected itself to 10°.

HEMIVERTEBRA EXCISION

- In the open technique, expose the spine anteriorly through the rib that is one level above the most cranial to be fused.
- Confine dissection primarily to the convexity of the curve, and confirm the levels either by the characteristic shapes of the vertebrae, or by an intraoperative

radiograph with markers both anteriorly and posteriorly over the levels to be fused.
- Remove the lateral one third to one half of the disc along with the corresponding portion of the endplates of the vertebrae.
- Obtain bone graft from the morcelized rib or from another source and pack into the disc spaces to promote fusion (Fig. 158.10C).
- Make a trough across consecutive vertebrae to allow a bone graft (such as rib) to be placed longitudinally, bridging them.
- Perform posterior exposure at the same time, to be sure that the levels fused in the front and in the back correspond exactly (Fig. 158.10D).
- Expose only the convexity of the posterior curve.
- Avoid elevating the muscles from the concavity of the curve, to prevent fusion from occurring on this side as well.
- Verify which levels are the end vertebrae to be fused by palpating the vertebrae from the front and the back simultaneously.
- If in doubt, pass small Kirschner wires from front to back at the tip of a transverse process to help confirm levels.
- Excise the convex facets and decorticate the spine.
- If additional correction is desired, a level above and below the curve itself may be partially fused as well, to allow further correction with growth.
- Postoperatively, place the patient in a cast to correct as much of the flexible portion of the deformity as possible. Apply the cast either in the operating room, or a few days after surgery, if there is significant edema or need to have access to the patient. The patient wears the cast, or a cast followed by a brace, for at least 6 months postoperatively. In the series of 13 patients reported by Winter et al. (45), prevention of curve progression was achieved in all but one, and in five of these, curve correction occurred with growth. The mean correction for these five patients was 10° (Fig. 158.11).
Excision is indicated for rigid decompensation of the spine due to a hemivertebra. It entails somewhat more risk than a hemiepiphyseodesis because the spinal canal is entered both anteriorly and posteriorly, and the spine is partially destabilized to achieve the correction. A significant degree of correction is possible, however, and the risks are generally acceptable with current techniques in experienced hands (8).

Preoperative assessment may include bending films to determine whether the desired degree of correction can be obtained without vertebral resection. In addition, MRI should be performed in all patients preoperatively because there is an increased frequency of abnormalities within the spinal canal (Chiari malformation, syrinx, diastematomyelia, and fibrous tether), which may predispose the patient to neurologic complications. Hemivertebra excision in the thoracic spine generally entails more neurologic risk as well as less correction, but it is not contraindicated.

Usually, both the anterior and the posterior portions of the procedure are performed in the same surgical session, if possible. Use sensory and motor spinal cord monitoring.

- Place the patient in the straight lateral position (Fig. 158.12).

Figure 158.12. Hemivertebra excision. A: Remove discs and endplates above and below the hemivertebra. B: Curet and remove the hemivertebra. C: Resect the corresponding posterior elements. D: Complete the correction with posterior compression rod or wire fixation.

- Make a transpleural, transdiaphragmatic, or retroperitoneal anterior approach as dictated by the level of the curve.
- Identification may be possible by local landmarks as well as by the shape of the vertebrae, but it should be confirmed by a radiograph if there is any question.
- If segmental arteries are to be ligated in the thoracic spine of a patient with congenital anomalies, some surgeons recommend placing a "bulldog" vascular clamp on the vessels to occlude flow for 10 minutes, using spinal cord monitoring to be sure that the intended vessels do not provide critical perfusion to the cord (1).

- Resect the discs above and below the vertebrae first, followed by the body.
- Leave the posterior portion of the vertebra and the medial cortex of the pedicle intact until last, as their resection may cause epidural bleeding.
- Place bone graft into the defect, but not so much as to limit the correction.
- Resect the posterior elements over the corresponding level.

In young patients whose correction is maintained without excessive difficulty, a pantaloon cast may be all that is necessary for correction. However, if the patient's size and bone density are adequate, use internal fixation, which may include a wire for a simple resection, or more rigid and complex fixation. It is the surgeon's judgment whether to perform these procedures in the same position, or whether to turn the patient prone for the posterior fixation. It depends on the complexity of the fixation intended.

The entire extent of the curve should generally be fused. Bone from the resected vertebra and rib usually provides adequate graft. The need for a postoperative brace depends on the security of fixation and the presence of other, noncongenital curves in the spine (Fig. 158.12, Fig. 158.13). In the largest recently reported series (21), the mean final correction was 35%, and there were 16% neurologic complications, but only 3% were permanent.

Figure 158.13. Patient with congenital scoliosis due to thoracic hemivertebra, treated with anterior and posterior convex hemiepiphyseodesis. A: At age 4, immediately before surgery, the curve had progressed to 27°. B: At 6 years postoperatively, the curve has improved to 10°.

THORACOLUMBAR LAMINOPLASTY VERSUS LAMINECTOMY

Spinal decompression in young people is most commonly indicated for tumor or for stenosis, as in achondroplasia. In both cases, the presence of mild preexisting kyphosis when there is remaining growth increases the risk of progression postoperatively. This is greatest at the cervicothoracic and thoracolumbar junctions. Progressive kyphosis may be prevented by performing a fusion at the time of decompression, or in some cases by performing a laminoplasty.

To accomplish a safe and effective decompression in achondroplasia, Uematsu et al. recommend a technique that involves minimal use of instruments in the canal (Fig. 158.14) (43). Spinal motor and sensory monitoring is helpful.

Figure 158.14. A 5-year-old girl with congenital scoliosis due to hemivertebra at <2. She has the VATER association. Her curve has progressed to 45°. Treatment by hemivertebra excision was selected because the hemivertebra is easily accessible and the patient is significantly off-balance. A: Preoperatively, the hemivertebra may be easily seen. B: Two years after excision and fusion, the patient is in much better balance.
- Position the patient prone, taking care to reverse as much of the increased lumbar lordosis as possible.
- Make bilateral laminar grooves just medial to the facets, using a high-speed burr.
- Carry these down to the deep cortex, and gently lift off the laminae.
- Preserve the facets if possible.
- Perform the amount of length and width of decompression necessary.
- A small (#10) rubber catheter should be able to pass centrally into the opening in the canal when the decompression is adequate.
- Suture paraspinous muscles over the defect.

If there is kyphosis more than 30° over the area to be decompressed, posterior (with possible anterior) fusion should be done as described previously. Even if no significant kyphosis is present preoperatively, it should be watched for postoperatively and fused if it develops. If laminoplasty is to be performed, the laminae with interspinous ligaments are elevated in one continuous strip, and reattached at the end with sutures into the adjacent facets, using bony "shims" if needed to elevate the laminae.

Chapter References

Adult scoliosis is usually the product of an unarrested adolescent idiopathic curve. It may also develop secondary to progressive degenerative collapse or neuromuscular disease. It may, rarely, be attributable to a progressive idiopathic curve arising after skeletal maturity, in which the curves tend to be more rigid than those seen in adolescence.

Scoliosis in adults brings with it a host of associated problems (pain, neurologic signs and symptoms, progression of deformity, and cosmetic concerns). Postsurgical complications are more common, more severe, and less well tolerated than in younger patients. Even though advances in diagnostic modalities and surgical technique provide for more effective treatment options than in the past, the treatment of adult scoliosis remains one of the most complex and challenging disorders confronting the spinal surgeon.

NATURAL HISTORY

Adolescent idiopathic scoliosis was once believed not to progress past skeletal maturity. It is now well documented that large curves continue to progress into adulthood. Curves less than 30° at the end of growth rarely progress and do not need close observation, but as Weinstein and Ponseti have shown, curves measuring greater than 50° at skeletal maturity are at significant risk for progression (28). Thoracic curves are even more likely to progress than lumbar curves.

Scoliosis arising from degenerative disc disease with asymmetric disc space collapse is distinct from adolescent and adult idiopathic scoliosis. The degenerative scoliosis is commonly a lumbar curve of moderate severity characterized by less rotation at the apex and more lateral l isthesis between adjacent segments. Degenerative scoliosis is discussed more fully in Chapter 160.

CLINICAL PRESENTATION

Pain is the most common complaint among adults with scoliosis. The pain tends to be mechanical in nature, worse in the morning and late evening, exacerbated by strenuous activity and certain bending or twisting activities, and characterized by limited sitting tolerance. Pain along the convexity of the curve can also be due to muscle fatigue or scapulothoracic incongruity. With advancing age and curve severity, the pain tends to concentrate in the concavity of the curve. Focal back pain across the concavity may be due to disc degeneration, facet arthrosis, junctional disc degeneration, or segmental instability (30).

Patients with scoliosis experience the same progression of disc degeneration as seen in normal spines, but eccentric loads may accelerate the degenerative process. Distortion of the outer annulus or posterior longitudinal ligament could generate back pain localized to the site of highest compressive load. The degenerating disc may release pain mediators that sensitize local receptors or the nerve root itself. The asymmetrically loaded facet joints could also be the source of pain in some patients.

Facet arthrosis or subluxation in both the concavity and convexity of the curve can stimulate capsular receptors capable of generating pain. Painful degeneration of the junctional disc may occur at the end of a rigid structural segment, within a flexible compensatory curve, or between opposing curves. In these areas, exaggerated bending forces tend to break down normal restraints and produce instability that may eventually result in coronal or sagittal displacements, abnormal motion, or axial and radicular pain. Radicular pain usually occurs on the concavity of lumbar or thoracolumbar curves, where nerve root compression in the lateral recess or foramens is caused by facet arthrosis and hypertrophy, disc herniation, or a combination of the two (Fig. 159.1). Radicular symptoms may also occur on the convexity when traction and kinking of the nerve root occur as it passes around the pedicle and out of the foramens.

Figure 159.1. A 55-year-old woman with a large lumbar curve that was not progressing. She developed radicular pain in her lower left extremity that markedly limited her walking and standing tolerance. Back pain had not changed for years. Myelogram (A) and postmyelographic (B) CT scan demonstrated nonfilling of left L-5 nerve root and displacement of left S-1 nerve root secondary to facet hypertrophy and subarticular and foraminal stenosis. Limited decompression consisting of left hemilaminotomy, partial medial facetectomy, and internal foraminotomy provided relief of lower extremity radicular pain. The curve has not progressed in over 1 year since surgery.

Curve progression is another common presenting complaint. Patients may complain of a loss of height, an increase in rib prominence, or changes in shoulder or waistline symmetry. In general, scoliosis in the adult progresses slowly. In the range of 1° per year (28). More rapid changes in posture may signal a more complex underlying disorder (i.e., metabolic bone disease, associated neurologic disorders, unrecognized congenital abnormalities) or may simply mean that the patient is losing the ability to compensate for the longstanding deformity.
When compared with progressive adolescent curves, the progressive adult scoliotic spine acts more like a leaning tower of Pisa, in that the rigid spine cannot compensate for curve progression to maintain sagittal or coronal balance. Since the primary curve (thoracic, thoracolumbar, or lumbar) becomes rigid early in the curve's development, it can no longer compensate in the sagittal or coronal plane as the compensatory curve progresses and eventually becomes structural. Frequently, the patient notices progression of coronal and sagittal imbalance as he or she falls farther and farther to one side (Fig. 159.2).

**INDICATIONS FOR SURGERY**

The major indications for surgery in adults with scoliosis are the following:

- Pain, focal or radicular
- Documented curve progression
- Curve greater than 60°
- Severe cosmetic deformity
- Flatback syndrome, sagittal or coronal imbalance
- Vertebral translation or instability due to severe lumbar curve

Once curve progression has been documented, nonsurgical modalities are ineffective in stopping it and surgical treatment should be considered. Because of the high likelihood of progression, patients with thoracic curves measuring 60° or more should generally consider surgical treatment. Patients with lumbar curves of less magnitude may sometimes require surgery because of pain and progression (4).

If pain alone is the indication for surgery, the patient must decide if the symptoms are severe and limiting enough to justify the risks of major surgery. The physician must be certain that the pain is related to a structural spinal problem, since idiopathic back pain is just as common in people with scoliosis as in the general population. Discography may be helpful in determining whether symptoms of low back pain are related to disc degeneration or functional problems. The radiographic appearance of the discogram is not important, but the reproduction of the patient's pain pattern during injection is diagnostic (13,26).

**PREOPERATIVE PLANNING AND PREPARATION**

Before embarking on surgical treatment, clearly define the goals of surgery and the treatment expectations to the patient. The treatment recommendations must be tailored to the patient's specific complaints. In most cases, they represent a combination of pain, neurologic symptoms, curve progression, and cosmesis. When pain is the major complaint, the *pain generator* must be identified and treatment targeted accordingly. The contribution of sagittal and coronal imbalance to pain must be evaluated and treatment planned to include the appropriate realignment procedure. If neurologic symptoms are the major concern, the source of root or cord compression must be identified and treated.

Neurologic symptoms may be addressed through direct posterior decompression or may be alleviated by indirect decompression through curve realignment. When curve progression is the most significant concern, its rate and extent must be documented to provide the correct treatment recommendation—fusion in situ or curve correction. If cosmesis is the primary indication for surgery, then the curve flexibility must be evaluated and the most appropriate realignment technique utilized. Thoracoplasty may be needed to correct the rib hump in patients with adult scoliosis.

During preoperative planning, mark radiographs to indicate the location of implants and the application of corrective forces to be used (Fig. 159.3). Side-bending radiographs are crucial to the decision process. Measure bending films to determine the best passive correction obtainable for each curve. Most adult curves can be adequately treated with posterior techniques alone, but larger, more rigid curves are better treated with a combined approach of anterior release and interbody grafting followed by posterior instrumentation and grafting. Anterior release and interbody fusion should be considered when...
The thoracic and thoracolumbar curves do not correct to an angle of less than 50° on lateral-bending radiographs; The primary curve cannot be corrected on lateral-bending radiographs to match the corrected compensatory curve (to achieve two balanced curves) (5).

The patient has a higher than usual risk of pseudarthrosis (neurofibromatosis).

L-4 does not reach neutral on maximal side-bending radiographs and the surgeon wants to avoid fusion to L-5 or the sacrum;

Fusion to the sacrum is necessary.

An L-5–S-1 interbody fusion minimizes the risk of pseudarthrosis in a posterior lumbosacral fusion. In painful curves, discography can ensure that the fusion is not terminated at the level of a symptomatic degenerative disc. If radicular symptoms are prominent, magnetic resonance imaging (MRI) is indicated.

When possible, plan to do anterior and posterior fusions as a single surgical procedure. Preoperative autologous blood donation is routine unless contraindicated. Perform pulmonary function tests, measure nutritional parameters, and do a full medical workup before undertaking a combined procedure. Although a single-stage operation is physically taxing, complications for it are significantly less than for two-stage procedures (15,20). If blood loss during the anterior approach is excessive or the patient is hemodynamically unstable, the posterior procedure may be postponed for 5–7 days. In the interim, maximize pulmonary function, prevent or treat urinary tract or wound infections, and maintain sound nutritional status.

If a severe rigid curve is encountered and maximal correction is the goal, consider a staged procedure incorporating 2 to 3 weeks of halo–femoral traction between the anterior and posterior surgeries. Most adults can tolerate this regimen physically and psychologically. Pin site and skin care must be meticulous. We recommend prophylaxis against deep-vein thrombosis. Initiate physical therapy to encourage deep breathing and extremity range-of-motion exercises. During traction, tilt the head of the bed up 15° to 20°. Attach the halo ring to the bed frame and apply 10–20 pounds of weight to each of the femoral traction pins. The patients may be out of traction for bathing and may be up with a walking or wheelchair traction frame as tolerated.

**PRINCIPLES OF SEGMENTAL INSTRUMENTATION**

Segmental fixation is the preferred method of internal fixation in adult scoliosis. Greater curve correction and better sagittal plane balance are possible with segmental instrumentation than with traditional Harrington instrumentation. Modern segmental instrumentation systems are based on a longitudinal member to which a variety of hooks, screws, sublaminar wires, or connectors can be attached. Stronger spinal fixation is afforded by multiple fixation points along the rod and by using strategic combinations of screws, sublaminar wires, and hooks to gain firm purchase on the pedicles, laminae, and transverse processes.

Place additional fixation whenever possible to increase implant stability, as adults fuse more slowly than adolescents, and they have stiffer curves and often poorer bone stock. The rate of pseudarthrosis and rod failure with segmental instrumentation is lower than with Harrington instrumentation (19,22,23). In addition, the prolonged postoperative immobilization necessary after Harrington instrumentation is often unnecessary after segmental instrumentation.

The use of pedicle screws in the treatment of scoliosis is controversial and does carry a theoretically greater risk of screw misplacement because of the bony deformity. Pedicle screws do provide superior fixation in adult patients, however, and their use can enhance correction by harnessing the “force nucleus” (junction of pedicle lamina and transverse process), as described by Steffee et al. (23) and others (27). Pedicle screws also allow for parallel, purely axial corrective forces between adjacent segments.

Hooks, by contrast, may produce focal kyphosis or lordosis when distraction or compression forces are applied. Specifically, pure distraction in the lumbar spine can produce a painful flatback syndrome unless multiple hooks are used and rods are carefully contoured to maintain lordosis. Sublaminar wires are most valuable in lateral translation of the spine during correction. They cannot control rotation or axial collapse and as such work best in a combined construct with hooks or screws.

Traditional teaching has been that the fusion should end at the stable vertebra, which is the vertebra intersected by the central sacral line (12) (see chapter 156). With segmental instrumentation, the lower end of the fusion should be the vertebra that becomes level on maximal side-bend radiographs. Patients with a rigid lumbosacral curve who have significant residual tilt of L-4 on bending films, and those with low back pain due to disc degeneration at L-4–L-5 or L-5–S-1, require fusion to the sacrum. Avoid fusion down to L-5 alone, as the incidence of subsequent low back pain is high (6).

Segmental instrumentation systems improve correction of spinal deformity by addressing all three planes of deformity (7):

- Coronal plane deformities can be corrected by longitudinal compression and distraction forces.
- Sagittal plane contours can be restored by properly contouring the rods and avoiding strong distraction forces in the lower lumbar segment.
- Finally, there is limited potential to improve rotational deformity through proper contouring of the rods.

By correcting rotational deformity, the cosmetic results of surgery can be improved, especially with regard to the thoracic rib hump. The cosmetic correction possible in the adult is usually less than what can be achieved in the adolescent, but it can be maximized by a circumferential release of the spine including concave and convex facetectomies. Severe rib-cage deformities may be improved through thoracoplasty, but not without some additional pain and potential morbidity.

Long scoliosis fusions ending at the sacrum have a high rate of pseudarthrosis and fixation failure. For neuromuscular scoliosis, the modified Galveston technique of Allen and Ferguson achieves firm pelvic fixation and a high fusion rate (5). For ambulatory patients, instrumenting across the intact sacroiliac joints is not recommended and sacral fixation is needed. Single-level hook or screw purchase into the sacrum is often inadequate when an extended construct acts as a long lever arm above the sacrum. The two options that can be considered are (a) additional pedicle screws into S-2 and (b) an intrasacral rod technique. Any long construct terminating at the sacrum should be augmented with an L-5–S-1 interbody fusion using either an anterior or a posterolateral technique.

Anterior segmental instrumentation can correct and stabilize a curve until fusion is achieved. The Zielke instrumentation is the prototype, but many useful systems are now available. Double-rod anterior systems have recently been described (11) and appear promising. Anterior instrumentation can be more advantageous than posterior and may even preclude a posterior procedure.

By virtue of their anatomic location, anterior instrumentation systems are better suited to correct deformity in the coronal, sagittal, and axial planes (8,10,14), but they have their limitations. If screws are not properly aligned, anterior instrumentation may produce kyphosis in the thoracolumbar and lumbar spine. Also, instrumentation extending to the low lumbar spine may impinge on the vascular structures.

Placement of the screws must be meticulous to avoid penetration of the spinal canal. Protect the spinal canal by identifying landmarks and bluntly dissecting around the opposite side of the vertebral body. Place a finger at the junction of the transverse process, pedicle, and vertebral body to act as an aiming guide.

With the first-generation anterior implant systems, screw and rod breakage were common. With more modern, robust instrumentation, breakage is far less common, but screw pullout at the proximal or distal end of the construct remains a problem. To prevent this problem, use a pullout-resistant nut on the opposite side of the vertebral body (16), or extend the instrumentation to other levels to distribute the load.

---

Figure 159.3. Radiograph marked before surgery to indicate types and sites of hook placement in a 24-year-old woman with double major thoracic and lumbar curves.
POSTERIOR PROCEDURES

- Position the patient on an appropriate spinal frame, ensuring that the abdomen hangs freely and that compression of the inferior vena cava is minimized. If pedicle screws will be needed, use a radiolucent table or frame; otherwise, use either a Wilson frame or longitudinal bolsters. Take care during positioning to make sure that the face is well padded and that there is no pressure on the eyes. Drape the back to provide access to the entire spine and to the iliac crest for graft harvest.
- Center a longitudinal midline incision over the apical vertebra. After stripping the paraspinal musculature, expose the spine subperiosteally to the tips of the transverse processes.
- Identify levels radiographically by placing a towel clip through the transverse process of the selected vertebra.
- After exposing the lamina at the levels to be fused, identify hook and screw sites and prepare them for implant placement. The technique of hook insertion is identical to that performed in adolescent patients (Fig. 159.4).

**Figure 159.4.** A: Insertion of the pedicle hook. B: Construction of the upper claw. Two forms of transverse-pedicular claws can be used to secure the upper end of the construct. A single-level claw using a transverse process hook and standard pedicle hook is the most common combination. C: For longer constructs, a two-level claw may be easier to apply. Use standard closed lumbar lamina and pedicle hooks. Either of these constructs can be substituted for the other when a transverse process is fractured during instrumentation.

- After excising the inferior facet with a narrow osteotome, remove the articular surface of the underlying superior facet with a straight curet. Locate the pedicle, which lies at the level of the transverse processes, with the pedicle finder. With the finder well seated on the pedicle, the vertebral body can be moved side to side with the finder. If the two do not move as a unit, the purchase is inadequate.
- Then insert the pedicle hook, taking care not to split the lamina during placement.
- Place additional hooks, if desired, to increase the overall strength of the construct and to distribute forces over a greater number of vertebrae (Fig. 159.5). Extra hooks may be especially helpful in patients with osteoporotic bone (Fig. 159.6).

**Figure 159.5.** Postoperative radiograph of patient in Figure 159.3, treated with Cotrel-Dubousset segmental instrumentation. This triple-rod technique distributes corrective forces over many spinal segments using multiple fixation hooks. Combined with anterior thoracic and lumbar releases, this approach provided 45% correction of the thoracic curve (101° to 95°) and 55% correction of the lumbar curve (108° to 48°).

- Although rotational correction is possible in reasonably flexible curves, derotation may not be possible or safe in very stiff curves. Overzealous attempts to derotate or translate vertebral elements may result in fractures of the laminae or pedicles, and possible penetration of implants into the spinal canal (Fig. 159.7).
- For stiffer curves, gain correction by segmental distraction, along with appropriate sagittal contouring to maintain or correct kyphotic or lordotic segments. Large, rigid thoracic curves may be partially corrected with a short apical rod placed in the concavity, before completing the construct with a long distraction rod. The long rod can then be coupled to the short apical distraction rod, and, after distraction, both can be coupled to the convex rod (Fig. 159.7).
Always crosslink rod constructs to increase the torsional stiffness of the construct (2).

Before completing the instrumentation, excise all facet joints and thoroughly decorticate the exposed spine. Although segmental instrumentation offers rigid fixation, strict adherence to these principles is crucial to obtain a consistent fusion in adult patients. During decortication, preserve the integrity of the laminae and transverse processes on which hooks are to be placed.

We advocate the use of autogenous iliac bone graft, particularly if wide laminectomy has been performed in the lumbar spine, in cases of pseudarthrosis, or with fusion to the sacrum.

Radicular pain resulting from foraminal or lateral recess stenosis often resolves with curve correction and stabilization. Medial facetectomies and foraminotomies, however, may be carried out if there is documented foraminal or lateral recess stenosis consistent with the lower extremity symptoms. If the curve is stable, and not progressive, root compression may be treated with decompression alone. Partial medial facetectomies and foraminotomies may be carried out through a limited laminotomy, taking care to preserve the pars interarticularis and dorsal facet joints.

Achieve posterior releases by performing an osteotomy at each of the rigid periapical segments. Beginning in the midline, open the ligamentum flavum, and then use Kerrison rongeers to excise the ligamentum flavum. In longstanding deformities, the ligamentum flavum may be ossified and will need to be taken down with a burr and Kerrison rongeers. Proceeding laterally on both sides, excise the facets and enter the neural foramen. These osteotomies will significantly increase the mobility of the curve.

ANTERIOR PROCEDURES

Treat rigid, high-degree curves by anterior release and interbody grafting before proceeding with posterior instrumentation, correction, and grafting. Carry out the traditional anterior release as described in Chapter 155, with two particular precautions: First, because vascular supply to the cord is less robust in adults, and particularly tenuous in kyphotic segments, exercise caution when approaching those segments anteriorly. It may be wise to preserve segmental vessels in these regions, or at least to temporarily occlude large segmentals with a vascular clamp and observe for changes in the somatosensory evoked potentials. Second, very rigid curves may require an extensive release, including excision of the posterior longitudinal ligament, before correction can be obtained. In order to shorten the vertebral column (to restore thoracic kyphosis and avoid stretching the neural elements) during correction, partial vertebrectomy may be necessary at apical levels.

Anterior instrumentation may improve curve correction and may allow the surgeon to spare lower lumbar segments in some patients with thoracolumbar and lumbar curves. Place vertebral body screws as far posteriorly as possible on the convex side of the spine, traversing each body in an anterolateral direction, slightly away from the canal. In a badly rotated specimen, this orientation can be difficult to obtain. By placing the end-vertebral screws slightly more anterior to the periapical screws, instrumentation and correction will naturally tend to rotate the lumbar curve and restore lumbar lordosis.

Because the vertebral cortex in the midbody is thin, create the starting hole with a hand-held awl. Bicortical purchase is desirable, particularly at end vertebrae. If posterior pedicle screw instrumentation is planned, place the anterior vertebral body screws below the midpoint of the vertebral body.

With the advent of endoscopic techniques, thoracotomy and thoracolumbotomy may be avoided and the anterior release and interbody grafting performed in a minimally invasive fashion. Using endoscopy, the anterior and posterior procedures may even be performed simultaneously with the patient in the prone position (17).

POSTOPERATIVE MANAGEMENT

Try to get patients out of bed to a chair the day after surgery, and walking within 3–5 days. If bone quality is good and implant purchase is thought to be secure, no brace is needed. If there is any concern about the security of internal fixation, use a thoracolumbasacral orthosis (TLSO) for 4 to 6 months. Bracing is also commonly used in patients fused to L-3 or L-4, as there is greater stress on the lower lumbar implants. Bracing to neutralize lower lumbar or lumbosacral curves should include a thigh cuff with a drop-lock hinge.

Patients are allowed to sleep and shower without the brace. Walking is recommended from the outset. A walking program, progressing to 1 mile daily, provides regular exercise during fusion consolidation.

PITFALLS AND COMPLICATIONS

Potential complications in the surgical treatment of adult scoliosis are the following:

- Blood-loss-induced anemia
- Pulmonary compromise
- Pseudarthrosis
- Failure of instrumentation
- Flatback syndrome
- Neurologic compromise
- Continued pain
- Infection

PSEUDARTHROSIS AND FAILURE OF INSTRUMENTATION

The complication rate in adults is significantly higher than in adolescents undergoing surgery for scoliosis (21). The most common complication, pseudarthrosis, occurs in 9% to 27% of patients (18,22,24,25). Hook dislodgment and rod fractures have been common, but primarily with Harrington instrumentation.

Although long-term complication rates of segmental instrumentation are not yet known, these will probably be lower than with older systems due to the more rigid fixation, lack of displacement and cutting-out of lumbar hooks have been reported with Cotrel-Dubousset and instrumentation (2). "Claw" hook configurations on a single lamina may predispose to lamina fracture, and an inferior claw spanning two laminae is recommended to help prevent pullout. The use of pedicle screws in lower lumbar vertebrae may improve purchase in osteoporotic patients and those with stiff lumbar curves. The surgeon may use multiple pedicle screws or a pedicle–laminar claw for maximum fixation (Fig. 159.8).
off-axis, rotated position. For severe curves, the thoracic and lumbar sagittal curves may reflect the existing scoliotic curves, and rod placement may be easier if the rods are placed in an off-axis, rotated position.

AUTHORS’ PREFERRED TECHNIQUE

There is no routine approach to adult patients with scoliosis; each curve has its own “personality,” and each patient presents with his own confounding variables. The presenting complaint, level of deformity, and rigidity of the curves dictate the specifics, but a general approach can be proposed.

FLATBACK SYNDROME

Lumbar flatback syndrome is a known complication of distraction instrumentation, but it has been less troublesome since the introduction of segmental systems. This disabling condition causes back pain, forward tilt of the trunk, and severe sagittal imbalance. It can be avoided in segmental fixation systems by carefully contouring the rods to the normal lumbar lordosis and avoiding excessive distraction in the lumbar spine. Preventing this complication is critical, as surgical correction of the established condition is fraught with complications and often gives a poor result.

PERSISTENT PAIN

Few patients become completely pain free after spinal fusion, but, if a discreet pain generator has been identified, improvement can generally be expected. Even though the curve has been stabilized, patients may continue to experience back pain.

NEUROLOGIC-compromise

Intraoperative complications, such as excessive blood loss and neurologic injury, are more common in adults than in adolescents. Neurologic complications with Harrington instrumentation have been uncommon; the risk of spinal cord injury is primarily related to overdistraction of a rigid curve. The same risks are present during distraction using segmental instrumentation and may be magnified by the increased mechanical advantage provided by segmental systems. Attempts to derotate a rigid curve in an osteoporotic spine may cause a concave pedicle hook to fracture the pedicle and penetrate the spinal canal. Gurr and McAfee reported such a case, which resulted in a Brown-Séquard syndrome. Rigid curves, especially in the presence of osteoporosis, should be treated with distraction and compression, avoiding derotation or strong translation forces. Remember that the primary goal of surgery in the adult with scoliosis is to stabilize the curve and halt progression; correction is a secondary objective.

Spinal cord monitoring should be used in all cases, as this allows recognition of subtle neurologic changes, permitting the surgeon to take prompt action to reverse them.

AUTHORS’ PREFERRED TECHNIQUE

There is no routine approach to adult patients with scoliosis; each curve has its own “personality,” and each patient presents with his own confounding variables. The presenting complaint, level of deformity, and rigidity of the curves dictate the specifics, but a general approach can be proposed.

Figure 159.9. A 46-year-old woman with severe, progressive thoracolumbar scoliosis. A: Preoperative PA radiograph demonstrates high-degree thoracic and lumbar curves. Bending films revealed little correction of either curve. Occiput was 4.0 cm left of the central sacral line. B: After anterior lumbar release and instrumentation, the lumbar curve was improved but the thoracic curve was no better and out of balance. C: Thoracic release and posterior instrumentation were performed 7 days later, under one anesthetic. Lateral view shows pedicle screws properly placed in the lumbar pedicles, passing above the vertebral body screws that were placed low in each vertebral body. Thoracolumbar kyphosis has been improved to mild lordosis. Custom-designed pullout nuts improve pullout strength of the vertebral body screws. D: Anterior thoracic release, combined with posterior segmental instrumentation, provided 50% correction of the thoracic curve. The combined approach to the lumbar curve provided correction of almost 60%.

- Release any curve that cannot be reduced to less than 50° on bending films anteriorly prior to posterior instrumentation.
- If both thoracic and lumbar curves must be addressed, carry out the lumbar retroperitoneal approach at the initial operation. Perform an anterior release, interbody fusion, and anterior instrumentation.
- Give the patient 5–7 days to recover before performing the definitive second procedure.

At the second operation, carry out an anterior thoracic release and full-length posterior instrumentation as staged or simultaneous procedures.

- In the staged procedure, place the patient in a lateral decubitus position with the curve convexity up. Through the anterior approach, release as many levels as can be reached, removing as much of the concave soft tissues as is necessary to allow motion when pressure is applied to the vertebral body.
- Once the convex release is completed, lightly pack the morcelized rib into the intervertebral spaces, close the wound, and turn the patient prone on the spinal frame.
- Perform posterior instrumentation, incorporating all of the thoracic and lumbar curves.
- Place multiple hooks to correct both coronal and sagittal alignment. Place pedicle screws distally to obtain the most stable foundation for the rest of the construct.
- Contour the rods to impart more normal thoracic kyphosis and lumbar lordosis, and then lock them into the lumbar screws distally.
- Sequentially reduce the rods into remaining hooks, taking time to allow viscoelastic forces to dissipate.

For severe curves, the thoracic and lumbar sagittal curves may reflect the existing scoliotic curves, and rod placement may be easier if the rods are placed in an off-axis, rotated position.
After loosely affixing the hooks and screws to the rod, apply C-rings to prevent hooks from displacing. Slowly rotate the rods back into normal orientation, placing the kyphotic and lordotic curves back in the sagittal plane. This "derotation" maneuver simply uses rod contours to apply translational forces to correct the coronal deformity. There is no actual derotation of the vertebrae.

In the simultaneous approach, place the patient prone, and prep anteriorly to the midaxillary line on the side of the concavity. A thoracoscopic approach can then be used to release multiple disc spaces through a few periscapular portals. Carry out the posterior instrumentation without changing the patient's position.

**AUTHORS' PERSPECTIVE**

Adult idiopathic scoliosis is a complex disorder requiring thorough patient evaluation and careful preoperative planning. An accurate assessment of spinal pain and curve progression, and knowledge of the natural history of scoliosis are essential components in formulating an appropriate treatment plan. With more advanced surgical techniques, patients once thought to be untreatable may now be effectively managed. Although surgery is a major undertaking, with a significant complication rate, the results of surgical treatment of adult scoliosis can be extremely gratifying.

Degenerative scoliosis is a curvature that develops in the adult secondary to degenerative disc disease. It may be difficult in many cases to determine whether scoliosis is arising de novo or if patients had mild to moderate degrees of scoliosis that became symptomatic or progressed late in adulthood. The treatment of degenerative scoliosis follows many of the same principles as the treatment of adult idiopathic scoliosis, however, so the distinction in many cases may be moot. This chapter discusses the factors that should be considered in treating patients with this condition.

**CLINICAL PRESENTATION**

**NATURAL HISTORY**

Mild to moderate degrees of degenerative scoliosis may not progress, and they may not be symptomatic. With more advanced disease, axial pain and neurogenic claudication are typical symptoms. As with any degenerative spine disease, facet hypertrophy, diffuse disc bulges, disc degeneration, and narrowing and redundant ligamentum flavum can result in spinal stenosis and produce symptoms of neurogenic claudication and radiculopathy (25). The degree of compression can be aggravated in the presence of lateral listhesis or spondylolisthesis, on traction on the nerve roots. Lateral listhesis, where slippage of one vertebra upon another occurs in the coronal plane, appears to correlate with a greater risk of curve progression (25,27). Significant lateral listhesis, particularly when it occurs at multiple adjacent levels, can result in significant truncal imbalance with resultant pain and fatigue. In many patients, these symptoms can be managed conservatively with anti-inflammatory drugs, physical therapy, and epidural steroids. With progression of the patient’s curvature, however, failure to respond to conservative measures or significant compromise of the patient’s quality of life may call for consideration of surgical intervention.

Curve progression is variable, but among those who progress, it has been reported to average 3° a year (25). Risk factors for curve progression include curve magnitude greater than 30°, osteoporosis, and lateral listhesis or rotatory spondylolisthesis (6,14). Prior decompressive surgery, such as a laminectomy, can increase curve progression as well, sometimes secondary to development of a post-surgical fracture of the pars interarticularis and spondylolisthesis. Rapid progression of scoliosis in a patient with a prior laminectomy is highly suspect for a pars fracture, which should be sought in the workup of such a patient.

**COMPONENTS OF DEFORMITY**

Asymmetric disc space collapse can result in spinal deformity, as can rotatory spondylolisthesis or lateral listhesis. Compression fractures with a lateral wedge component may aggravate or cause development of scoliosis. These patients may have a relative loss of lumbar lordosis as well. Patients with lateral listhesis appear to be at greater risk for curve progression (25,27), and, in addition, they are subject to traction on their nerve roots at the involved levels. Asymmetric wear on the facet joints may contribute to facet arthropathy, leading to central or foraminal stenosis. Although almost all patients present with pain secondary to nerve root compression, others present with weakness. Pain and weakness may be particularly intractable from severe disc space collapse, with or without listhesis, and decreasing space between the adjacent pedicles results in foraminal stenosis. Patients with stenosis secondary to degenerative scoliosis suffer a similar pathophysiology as a cause of their neurogenic claudication—namely, a vascular insufficiency to the neural elements secondary to the stenosis, which is generally worsened by lumbar extension.

Clearly, vascular claudication and neurogenic claudication occur in similar patient populations, and it is important to distinguish the true cause of the patient's leg pain. A careful history, palpation of distal pulses, examination of feet and skin, and, if indicated, referral to a vascular specialist may be needed. In general, neurogenic claudication is improved by forward flexion of the spine, including sitting, and it may be worse going downhill because hyperextension is necessary (see Chapter 147). However, at least some patients with stenosis secondary to degenerative scoliosis have reported that their extremity symptoms are not reliably relieved by forward flexion (11).

**CONSERVATIVE MANAGEMENT**

Patients with degenerative scoliosis can be managed according to the conditions that cause the most symptoms. For example, the patient with more back pain secondary to the degenerative disease can be managed successfully using nonsteroidal anti-inflammatory drugs, rest, physical therapy, cardiovascular conditioning, and, occasionally, bracing. Patients with neurogenic claudication may respond to any of these measures but may receive relief from epidural cortisone injections. Bracing can be used on occasion for the patient with mild degenerative scoliosis with back pain only. Rigid bracing has not been shown to prevent progression in adults with scoliosis. However, bracing may be a reasonable alternative for a patient who has a degenerative scoliosis with mild to moderate progression, but who is medically unable to tolerate a major reconstructive procedure.

Bracing may need to include a rigid molded thoracolumbar orthosis for more severe scoliosis or kyphosis, or it may simply be a lightweight, corset-type brace for milder curves. However, since symptom improvement is the primary goal, rather than curve control, results with a specific patient will be the final determining factor.

**INDICATIONS FOR SURGERY**

As for adult idiopathic scoliosis, pain, curve, and neurologic deterioration are the main indications for surgical intervention. In general, bracing in adults is discouraged because it does not halt progression and may result in patient dependence on the brace and associated trunk deconditioning. However, in certain cases, such as an elderly patient who is too ill to tolerate a major surgical procedure, or a patient whose severely osteoporotic bone is too weak to support instrumentation, bracing may slow progression or attenuate the pain symptoms.

Determining whether a patient's back pain can be improved by stabilization and fusion of her degenerative scoliosis can be difficult. Once surgery has been deemed likely to help such a patient, however, choice of the fusion levels requires consideration of curve pattern, sagittal and coronal balance, pain locale, levels needing decompression, and the presence of degenerated or listhetic levels, as well as patient expectations and activity levels. Facet blocks, discography, and nerve root blocks may be helpful in determining symptomatic levels, although their predictive value for fusion surgery has not been proven. Grubb et al. (12) used provocative discography to help determine fusion levels in adult scoliosis patients (degenerative and idiopathic) and felt that this aided them in their surgical planning. However, in
their study, all positive discograms were at morphologically abnormal levels, and it is not clear whether they might have included such levels based on radiographic or magnetic resonance imaging (MRI)—determined degenerative levels. Fortunately, fusion for back pain secondary to scoliosis appears more predictable than fusion for back pain secondary to degenerative disc disease without deformity. We do not routinely perform discography in these patients, because it has not proven of benefit in predicting the outcome of fusion surgery.

Patients with degenerative scoliosis and neurogenic claudication should have their stenosis decompressed concurrently with stabilization of the curvature. In most patients, an MRI will give adequate information for localization of stenotic levels; in some patients, however, the lateral deformity or rotatory component precludes clear delineation of the anatomy. In these cases, computed tomography (CT) or myelography is indicated for preoperative planning.

Surgical Techniques

Decompression

For patients with limited regions of spinal stenosis, neurogenic claudication, and only mild degrees of scoliosis, it may be reasonable to approach the decompression as an anterior-only or posterior-only procedure. However, aggressive decompression can result in curve progression; this isolated procedure should be reserved for milder cases in which limited decompression can be expected to help the patient. Be sure the patient understands the possibility of curve progression and recurrence of symptoms.

Fusion in Situ

For patients with limited disease, a posterior fusion alone may be sufficient. The majority of patients with degenerative scoliosis will require instrumentation and grafting to achieve fusion over multiple segments that require stabilization. Because of the increased pseudarthrosis rate with multiple-level fusions, it is rare to have a patient who can be managed without instrumentation. However, certain older patients, particularly the medically fragile, may better tolerate laminectomy and limited uninstrumented fusion (i.e., at the level where there is a degenerative spondylolisthesis). In some patients, moderate to severe osteoporosis may preclude fixation, but, as with laminectomy alone, there is a risk of curve progression and recurrence of symptoms. Therefore, this approach is limited to patients who clearly understand the limitations of what surgery can accomplish and are willing to risk recurrent symptoms. In general, we have not found age or osteopenia to be a contraindication for fusion with instrumentation.

Selection of fusion levels should take into account several factors. The levels that should be fused should include at least the entirety of the symptomatic curve, but often additional levels must be included to address symptomatic degenerative levels and permit maintenance or restoration of coronal and sagittal balance. Generally, preoperative bending films can help predict the amount of correction that can be obtained after exposure, facetectomy, and application of appropriate corrective forces. The end vertebra, particularly distally, should be a vertebra that is level on side bending. Sagittal balance is exceedingly important to consider, particularly because many of these patients have osteoporosis. Most degenerative curves are kyphotic; if the kyphosis is not flexible, a combined anterior–posterior approach may be important to achieve correction and success. It is also important not to end the fusion at the end vertebra of the kyphotic segment. Many of these patients have lumbar or thoracolumbar curvatures, and including only the major curve often can result in ending the fusion at the mid or lower thoracic spine—in the middle of the kyphosis. Such patients are at considerable risk for development of progressive junctional kyphosis, and in general it is best to include the minor compensatory thoracic curve and end the fusion at the end vertebra of the kyphosis (usually T-4 or T-5).

Only in patients with acceptable bone quality and a nonkyphotic thoracolumbar junction can the fusion safely stop at the thoracolumbar junction. Choosing the distal end vertebra can be difficult in the patient with degenerative scoliosis and low back pain. Deciding whether L-4–L-5 and/or L-5–S-1 is symptomatic is crucial because long fusions to the sacrum generally necessitate combined anterior and posterior surgery and have a higher rate of complications. Not including a symptomatic level will result in limited pain relief, however, and thus it will decrease the success of the surgery. In addition, fusions ending at L-4 or L-5 are at risk for development of symptomatic degeneration below the fusion. This development 5–10 years after the surgery may be acceptable for the older patient, but its occurrence 2 years or so after the surgery is not. Therefore, consider whether a more distal fusion is indicated. Involvement of the lumbosacral region is very common in degenerative scoliosis, and the majority of these patients require combined anterior and posterior spinal fusion to the sacrum.

Considerations for Instrumentation

Segmental instrumentation in the form of variable hook-and rod systems are preferred for instrumentation of degenerative scoliosis. These systems allow much better correction of coronal and particularly sagittal plane deformity. However, such surgery is technically demanding, and the surgeon must have a clear understanding of the corrective forces that should be applied and how they affect the patient’s curvature, coronal balance, sagittal balance, and should obliquity. The following considerations are important:

- Avoid distraction in the lumbar spine to avoid flattening it. Apply compression across the curve convexity first in the lumbar spine.
- It is rare to be able to perform rod rotation in the patient who has degenerative scoliosis.
- If the patient has significant osteoporosis, and multiple-level laminectomy is not required for coexisting spinal stenosis (see below), consider using sublaminar wires supplemented by hooks and/or pedicle screws at strategic levels (generally the end vertebrae of each curve and sometimes the apical vertebra as well). Such wires are quite easy to attach to rods, and, for an osteoporotic patient whose trabecular bone has numerous vascular channels, their use can potentially decrease operative time and therefore decrease blood loss.
- Do not affix rods to end vertebrae with sublaminar wires, because wires do not provide axial control of the spine and can allow axial collapse and subsequent junctional kyphosis. Use pedicular fixation or hook combinations at the ends of constructs to decrease the likelihood of this problem.
- To maintain sagittal balance, we prefer to obtain intraoperative long radiographs of the entire spine after the correction has been partially or completely performed. Adjustments in the corrective forces can be made at this time if desired.
- Although in situ bending to fine-tune the coronal balance can be performed in some adult scoliosis patients, most patients with degenerative scoliosis have osteoporotic bone, and in situ bending can result in loss of fixation.

Decompression and Fusion

Many patients with degenerative scoliosis also have spinal stenosis as part of their degenerative process. As part of preoperative planning, evaluate with an MRI or CT/myelogram any patient with degenerative scoliosis who notes leg pain or buttock pain. As previously noted, the MRI is adequate for many patients; with greater degrees of curvature, however, CT/myelography provides better sensory detail and permits better understanding of the anatomy in the presence of the curvature. It is important to identify symptomatic levels of stenosis so that decompression can be performed at the time of posterior fusion. In most cases, this can be determined anatomically according to dermatal levels and nerve root distributions; however, occasionally, selective nerve root injections may be needed to determine which levels with mild to moderate degrees of stenosis are the symptomatic ones. Once laminectomy has been performed for decompression, pedicle screw instrumentation may be needed to attain fixation. Generally, fusion rates are improved with instrumentation, particularly in patients with conditions such as degenerative scoliosis (13). As with deformity surgery in general, try to visualize the medial wall of the pedicle before screw placement, to correctly account for spinal rotation. This is a simple matter after laminotomy or laminectomy has already been performed. Frazier et al. (8) reported on patients who underwent decompression for spinal stenosis, including 19 who had at least 15° of scoliosis preoperatively. The majority of their patients with scoliosis did not have fusion performed at the time of decompression. They found that a greater degree of preoperative scoliosis was associated with less improvement in back pain. We have not found curve severity to correlate with outcomes of reconstructive surgery in these patients. We do take a more aggressive approach, however, preferring to fuse patients with scoliosis who are undergoing a laminectomy even if the underlying medical condition permits only limited fusion. Selection of fusion levels and instrumentation guidelines are otherwise as noted in the prior section.

Combined Anterior–Posterior Techniques

If they are fairly healthy, the majority of patients with degenerative scoliosis will require anterior and posterior procedures to achieve fusion, as well as coronal and sagittal balance. There are several indications for combined techniques in this complex patient population.

- Inflexible sagittal-plane imbalance is one of the most common indications for combined surgery. Relative lumbar kyphosis must be corrected to achieve sagittal plane balance. The use of structural allografts facilitates the restoration of lumbar lordosis. We favor femoral allografts, packed with autogenous cancellous graft; Harms-type mesh cages with autograft may also be used. Consideration of the scoliotic deformity is necessary; otherwise, mere placement of the structural grafts on the side of the approach—usually the curve convexity—will limit correction of the scoliosis.
- Degenerative curves of significant magnitude, especially with limited flexibility, may also require combined surgery. Coronal imbalance may also indicate the need
for combined surgery.

- Patients who require a long fusion to the sacrum should also have a combined procedure because posterior fusion alone in this setting has a high incidence of failure (4,12). Most of these patients have significant degeneration across the lumbosacral junction, and many also have thoracolumbar kyphosis (which is a contraindication for ending the fusion at the thoracicolumbar junction), so combined surgery is frequently indicated.

- In patients who have had failed posterior instrumented fusions, consider combined surgery. We and others (1,10,23) have found iliac fixation in the form of Galveston rods or iliac screws to be useful for achieving distal fixation (Fig. 160.1). For patients with reasonable bone quality, anterior structural allograft at the lumbosacral junction coupled with sacral screws alone that penetrate the anterior cortex may be adequate. Others (2,7,16,17) have used iliosacral screws or intrasacral screws (Jackson technique) for distal fixation.

As with posterior instrumented fusions, segmental fixation is preferred for combined surgery in this patient population. Sublaminar wires may be used as a component of the fixation, but use fixed components (hooks in a claw construct in the mid and upper thoracic spine, pedicle screws at the thoracolumbar junction) at the proximal end of the construct to decrease the risk of junctional kyphosis.

When the patient can tolerate it, perform both procedures under a single anesthetic to lower overall incidence of complications, nutritional depletion, and blood loss (5,21,24). Older patients, particularly those with coexisting medical conditions or significant osteoporosis, may be less able to tolerate the lengthy anesthetic, however. Older patients with significantly osteoporotic bone may experience increased blood loss, which can lead to development of a coagulopathy during a prolonged procedure. If the combined procedures in these older patients cannot be completed in 8–10 hours, then stage the procedure. The scheduled delay between stages may be 3–7 days, depending on coexisting medical conditions, the age of the patient, and scheduling issues. The occurrence of complications, however, may further delay the second-stage procedure.

Staged spinal surgery can result in nutritional depletion, which may lead to an increased incidence of infection, pneumonia, and urinary tract infection (5,21,24). We have shown that, particularly in the older patient population, use of total parenteral nutrition may decrease the rate of nutritional depletion, which may in turn decrease the risk of complications (15).

Grubb et al. (12) have found an average of 70% reduction of pain in patients fused for painful degenerative scoliosis, which is somewhat less than that seen for patients fused for painful adult idiopathic scoliosis (80% pain relief).

ANTERIOR FUSION WITH FEMORAL RINGS

- Perform a standard thoracoabdominal or retroperitoneal approach on the convexity of the curve to be addressed. Be sure to prep down to the pubic symphysis if L5–S1 is to be fused, as is the case in most of these patients.
- Identify segmental vessels and ligate or clip. Sweep the psoas muscle posteriorly, using bipolar cautery to control bleeding. Use blunt but careful dissection to sweep the great vessels forward. The common iliac will need to be mobilized if L4–L5 or L5–S1 is to be exposed. This generally requires ligating the recurrent lumbar vein.
- Incise the disc space with a #11 blade. Use a rongeur to remove loose disc material, and a rongeur or osteotome to remove the osteophyte so that the endplate can be visualized. Peel the disc from the endplate using a Cobb elevator—exercise care in patients with osteoporosis.
- Remove additional disc material with a curved or straight curette, supplementing with a rongeur. A Blunt spreader may be used with care to keep the disc space from collapsing in the convexity. The release must extend across to the contralateral annulus. If there is significant kyphosis, divide the anterior longitudinal ligament.
- The most important levels generally are in the fractional curve and also are most important for maintaining lordosis. Therefore, placement of the structural allograft should not block correction. If disc spaces in the convexity are to be placed, take care to place them as far toward the concavity as possible; do not place so large a graft that correction is blocked. For disc spaces that are not to receive structural allograft, pack morcelized cancellous bone lightly within, preferably autograft, although allograft can be used.
- Measure the height of the disc space to be filled with allograft. We use femoral shaft pieces cut at the time of surgery to fit the evacuated disc space. (Other surgeons prefer mesh cages.) The graft should be snug but not overly tight; that is, the release should open the disc space, not the graft itself. After confirming the size, fill the marrow cavity of the femoral allograft with rib graft or local bone graft, or morcelized cancellous allograft, and impact gently into place. Forcing an overly large graft or inadequate release will result in graft breakage (with high risk for pseudarthrosis) or endplate fracture (with increased risk for subsidence).
- Use interference screws to prevent allograft migration. Place a 6.5 mm cancellous screw with a plastic washer lateral to the graft, into the vertebral body.
- Alternatively, a long enough screw can be placed lateral to the adjacent graft, skewering the graft below, to prevent migration of two allografts. It may be necessary to burr a small impression into the lateral aspect of the adjacent allograft to allow the washer to seat snugly. Although theoretically possible, we have not generally found that these screws impair our ability to place pedicle screws during the posterior instrumentation. Since instituting the use of these interference screws, we have not needed to replace anterior structural allograft.

PITFALLS AND COMPLICATIONS

Technically, surgery in this patient population can be very challenging for the following reasons:

- Osteoporotic bone is nearly always present and its vascular channels can contribute to greater bleeding rates than seen in the patient with normal bone.
- Many of these patients may have chronic hypertension, coronary artery disease, or other vascular conditions that contraindicate or limit the use of controlled hypotension to decrease surgical blood loss.
- One must select fusion levels carefully. Ending the fusion at a kyphotic level can lead to junctional kyphosis. Although sublaminar wires may be preferred in many patients because their use spreads corrective forces over many levels, they should not be used at the end vertebra because they do not control the spine in the axial plane; they may also result in junctional kyphosis. Use hooks or screws at the ends of the construct.
- Overcorrection of the curve may lead to truncal imbalance, which, if significant, may require revision surgery.
- Patients who undergo fusion surgery are at risk for developing degeneration above or below the fusion. Consider including severely degenerated adjacent levels to avoid rapid development of this problem. Extending the fusion should be balanced by the consideration of how much surgery should be done on the older, less healthy patient.
- Although osteoporotic patients have not been shown to have a higher rate of pseudarthrosis, poorer fixation due to poor bone quality, combined with autogenous bone graft from a site with more fat infiltration and fewer osteoprogenitor cells, is of concern.

The risk of complications among older patients undergoing spiral surgery is about 60% (6,12,18,19,22). Although the rate is not significantly greater with increasing age (60–70 years, 70–85 years), there is no doubt that older patients are less able to tolerate complications and recover quickly from them. Keep this in mind when...
planning the surgery. We have shown that older patients may be more at risk for development of complications such as pneumonia and urinary tract infections, particularly if they are undergoing staged surgery. Consider nutritional supplementation to decrease their risk of nutritional depletion (15). Thromboembolic disease leading to pulmonary embolism occurs more commonly in older patients, particularly after combined anterior and posterior surgery (3). Our current practice is to use elastic stockings and sequential compression boots for prophylaxis of deep venous thrombosis. We remain vigilant in patients who have combined surgery, but we do not routinely anticoagulate these patients.

Although the mortality rate is not known, and most published studies in this patient population include small numbers of patients, we estimate it to be 1% to 5%. Discuss fully the numerous potential risks of spinal surgery with the patient, as well as her family, if desired, when she is offered any spinal surgery.

**MINIMALLY INVASIVE TECHNIQUES**

Recent advances in minimally invasive surgery have suggested that endoscopic surgery, both thoracoscopic and lumbar endoscopy, may result in lower morbidity and decreased length of hospital stay (20,26). Unfortunately, such techniques are difficult to learn and have not yet been proven to demonstrate comparable fusion rates to that achieved in open procedures. In general, for degenerative scoliosis, the indicated anterior procedure is in the lumbar or lumbosacral spine. Currently, most of the lumbar endoscopic techniques have concentrated on screw-in–type cages, which are not well suited for degenerative scoliosis because of the presence of multiplanar deformity.

**AUTHORS’ PERSPECTIVES**

Reconstructive surgery in the patient with degenerative scoliosis is complex and requires a thorough understanding of a multitude of factors, including pain sources, coronal and sagittal balance, fusion techniques, indications for decompression, indications for combined anterior and posterior surgery, and instrumentation choices, as well as the potential for complications. With appropriate patient selection, however, and realistic expectations of surgery on the part of both the patient and the surgeon, the majority of patients will have a satisfactory outcome.

PRINCIPLES OF TREATMENT

Kyphosis is a posteriorly directed convex curvature of the spine in the sagittal plane. In the thoracic spine, the normal kyphosis ranges from 20° to 40° as measured from the superior endplate of the second thoracic vertebra to the inferior endplate of the twelfth thoracic vertebra. In the adult cervical and lumbar spine, both of which are normally lordotic, any posteriorly directed curvature of 5° or greater is considered abnormal kyphosis.

A distinction should also be made between a short-radius and a long-radius kyphotic deformity. A short-radius curve is one that is more angular over a few vertebral

Figure 161.1. This 1-year-old child has a short-radius sagittal kyphosis secondary to radiation and laminectomy for neuroblastoma.

Figure 161.2. A: A 9-year-old child has a paralytic right thoracolumbar scoliosis of 125°. B: In addition to the paralytic scoliosis, a rotational thoracolumbar kyphosis of 107° is present. C: The rotational kyphosis corrects to 36° on supine hyperextension (a flexible kyphosis).

A distinction should also be made between sagittal kyphosis and rotational kyphosis. In sagittal kyphosis, the vertebral bodies remain in the sagittal plane and the spine angulates in that plane (Fig. 161.1). In rotational kyphosis, however, the vertebral bodies are rotated out of the sagittal plane, as is commonly seen in paralytic curvatures and kyphosis secondary to neurofibromatosis (Fig. 161.2). In either situation, once the anterior vertebral column is no longer in the sagittal plane, there is reduced resistance to kyphotic bending moments and thus an increased propensity for a kyphosis to progress. Most kyphotic deformities seem to fall within the sagittal kyphosis category.
segments, and a long-radius kyphosis is a smooth curve of less acute angulation over many vertebral segments (Fig. 161.1, Fig. 161.3).

Figure 161.3. At age 17 years, this patient developed a long-radius thoracolumbar kyphosis of 70° as a result of radiation. This kyphosis corrects to 45° on a supine hyperextension lateral radiograph.

All kyphotic spinal deformities have variable degrees of rigidity and flexibility. Frequently there is an element of apical rigidity with variable degrees of flexibility at the ends of the curvature. The goal in correcting the kyphosis is to mobilize the rigid apex or to correct the flexible ends of the curve to bring the apex closer to the center of gravity, thereby placing the bone graft in the area of fusion under maximum compression (Fig. 161.4).

Figure 161.4. A: Diagram of kyphosis. B: The apex has been corrected somewhat and the flexible ends of the kyphosis are corrected so that the anterior strut graft is now in line with the body weight (BW).

The degree of flexibility can be determined before surgery by a supine hyperextension lateral radiograph of the spine taken with a bolster placed under the apex of the kyphosis (Fig. 161.3) in short-radius kyphosis, and by a lateral radiograph of the spine with the patient in traction in long-radius paralytic curves.

Although traction as a means of correction has been gradually replaced by more aggressive anterior and posterior fusion and segmental instrumentation, in some situations traction can be helpful. Three traction techniques can be beneficial in the treatment of kyphosis: halo-wheelchair traction, halo-femoral traction, and halo-hyperextension traction. Halo-wheelchair traction provides longitudinal traction against gravity and allows the patient mobility. Halo-femoral traction provides stronger, steady axial forces if continuous traction is essential.

A word of caution, however, is necessary about the use of heavy axial traction. If there is apical rigidity of the curve as determined by hyperextension lateral radiographs, paraplegia can be a complication because of the spinal cord's stretching over the rigid acute kyphotic apex. Mobilizing the apex of a kyphotic deformity is essential before heavy traction is used. In large kyphotic deformities with a long radius (such as Scheuermann’s kyphosis) respond more effectively to three-point bending. In comparison, large kyphotic deformities with a short radius (such as spondylolisthesis), a combination of axial traction and three-point bending is needed (Fig. 161.5) (13).

Figure 161.5. Halo-femoral longitudinal and pelvic hyperextension traction for lumbosacral kyphosis from spondylolisthesis.

Many disorders manifest kyphotic spine deformities that may need treatment. Any kyphosis that is increasing in magnitude may need surgical stabilization. It is helpful to classify the disorders by the degree of rigidity and flexibility as well as the magnitude of curve radius (Table 161.1).

Table 161.1. Classification of Kyphoses
INDICATIONS FOR SURGERY

Indications for surgical treatment of kyphosis depend on the diagnosis, the etiology of the kyphosis, the curve progression, the location of the kyphosis, and the age of the patient. In general, the kyphotic spine deformity that is increasing in magnitude in an adult needs surgical stabilization. In the child, however, a brace may be helpful, depending on the age of the child, the etiology of the kyphosis, and the magnitude of the curve.

CONGENITAL TYPE I KYPHOSIS

The congenital type I kyphotic spinal deformity, in which there is incomplete vertebral formation, is usually diagnosed in childhood and has an average progression of 5° yearly (25,27,29). It usually involves only two to three vertebrae, and surgical stabilization is usually recommended when progression has been documented. There is a high incidence of spinal cord compression with large degrees of kyphosis, and early stabilization in a young child when the curve is small is ideal. An in situ posterior fusion before the age of 3 years will prevent late deformity. In situ posterior fusion must include the normal vertebrae above and below the congenital kyphosis. The posterior fusion will tether the posterior growth of these normal vertebrae so that their anterior growth will correct the deformity (these normal vertebrae will become trapezoidal in shape with growth) (Fig. 161.6).

Augment the posterior fusion at 6 months to achieve a thick posterior mass, thick enough to withstand the anterior growth forces. When an angulation of 50° or more is present, an anterior fusion is also needed. If the spinal cord is compressed anteriorly, perform an anterior decompression concomitantly with the anterior strut graft fusion. In the adult, I recommend a second-stage posterior fusion with instrumentation after the anterior correction. Osteotomies for deformity correction are not commonly used as in type II congenital kyphosis.

CONGENITAL TYPE II KYPHOSIS

In the congenital type II kyphotic disorder, in which failure of segmentation of the spine occurs anteriorly, progression of the kyphosis usually averages 5° yearly (15). The segmentation failure can involve only two vertebrae but also may involve many contiguous vertebrae. For young patients, I recommend an in situ posterior fusion to include one normal vertebral segment at each end of the curve. In the young child, an augmentation posterior spinal fusion may be necessary 6 months later to generate a thick fusion (Fig. 161.6). In the adolescent patient with an unacceptable kyphosis greater than 50°, a staged correction is indicated, with anterior osteotomy and anterior fusion using an intervertebral cage structural graft, followed by posterior fusion and instrumentation (15,26,27,29). Spinal cord compression is usually not seen in type II congenital kyphosis.

POSTTRAUMATIC KYPHOSIS

Acute kyphosis associated with spinal instability due to fracture or dislocation usually requires reduction of the kyphosis, with spinal fusion (14,19). When the kyphosis occurs late and is increasing in magnitude, surgical stabilization and fusion are indicated. Particularly if the kyphosis spans multiple vertebral segments, a two-stage anterior and posterior fusion and stabilization are frequently necessary. In late posttraumatic kyphosis, the use of intervertebral structural cages with anterior fusion maintains lumbar lordosis below the fracture more effectively than an interbody fusion alone.

SPONDYLOLISTHESIS GRADES IV AND V

Anatomically, the grade IV and V spondylolistheses are usually lumbosacral kyphotic deformities and require reduction, stabilization, and fusion (4).

POSTLAMINECTOMY KYPHOSIS

Any progressive postlaminecctomy kyphotic deformity (usually in a child) requires stabilization and fusion (11). Posterior segmental instrumentation and fusion will be necessary along with anterior fusion. Frequently, strut graft stabilization will be needed in larger kyphotic deformities. The entire kyphotic deformity must be instrumented and fused (11).

SCHUEERMANN'S KYPHOSIS

Scheuermann's kyphosis is seen in older adolescents and adults (19). In older adolescents with little vertebral growth remaining, a kyphosis of 70° or more usually requires surgical correction and fusion, especially if associated with back pain. In the adult, back pain associated with thoracic kyphosis greater than 75° to 80° is an indication for surgical treatment. If the kyphosis is located in the thoracolumbar spine, surgical treatment is indicated when the curve magnitude is much less than 70° because of the acute lumbar hyperlordosis below the kyphosis and associated problems with low back pain in an adult. A staged anterior interbody fusion followed by a posterior fusion with segmental instrumentation will effectively correct and stabilize this kyphosis; intervertebral cages could be used to maintain correction of the kyphosis and maintain lumbar lordosis (Fig. 161.7).

Figure 161.6. A: This 1½-year-old girl has type II congenital kyphosis at T-12–L-1 of 55°. B: At age 10, after in situ posterior fusion that included the normal vertebra above and below the congenital kyphosis. The kyphosis has corrected to 8°.

Figure 161.7. A: An 18-year-old man with 101° thoracic kyphosis from Scheuermann's disease. B: Four years after staged anterior interbody fusion and posterior fusion and segmental instrumentation. The kyphosis is corrected to 38°.
POSTRADIATION KYPHOSIS

Surgery in children is indicated when postradiation kyphosis (12) is documented to be progressive despite adequate orthotic treatment. It is also indicated when the kyphosis is too large for orthotic control, or the deformity is cosmetically unacceptable. These curves are usually rigid and the potential for correction is limited.

PARALYTIC KYPHOSIS

Paralytic kyphoses are usually collapsing deformities that are seen in children (14,16). Surgical treatment of the kyphosis is usually planned when the child has a skeletal age of 10–12 years, when most of the axial skeletal growth has occurred. Until that age, orthotic treatment is recommended.

NEUROFIBROMATOSIS

Kyphosis in neurofibromatosis does not respond to orthotic treatment, and surgery is indicated when the kyphosis is 50° or more in a child or is documented to be increasing in magnitude (1,28). Anterior and posterior arthrodesis and instrumentation are usually necessary. Complications are common.

DIASTROPHIC DWARFSM

Progressive cervical kyphosis in diastrophic dwarfism should be stabilized early to prevent neurologic complications (8). Thoracic and thoracolumbar kyphoses usually appear in the juvenile years, is associated with scoliosis, and should receive early orthotic treatment. If progression occurs despite orthotic treatment, surgical treatment of the kyphosis is indicated.

ACHONDROPLASIA

Kyphosis usually occurs in the thoracolumbar spine and may occur at an early age, but most kyphoses resolve. When apical vertebral hypoplasia is present (achondroplasia) (25), progression may occur and orthotic treatment is recommended. Surgical treatment of the kyphosis is indicated if progression occurs despite orthotic treatment or if anterior spinal cord compression occurs.

ADULT IDIOPATHIC KYPHOSCOLIOSIS

Rotational kyphosis in the adult is usually treated surgically when the kyphoscoliosis is progressing and if the scoliosis is greater than 60° to 70° (19). Frequently, the lumbar curve in kyphoscoliosis has rotational vertebral subluxation and is relatively kyphotic. Adult scoliosis frequently requires anterior and posterior arthrodesis and instrumentation. Structural intervertebral cage grafts anteriorly are useful in creating and maintaining lumbar lordosis.

FLATBACK SYNDROME

Flatback syndrome results from the loss of lumbar lordosis and normal sacral slope. For patients with flatback syndrome to stand, their trunks must remain bent forward. To maintain this position, they are required to flex their knees, and they complain of pain and fatigue (6,8,10). This syndrome is frequently seen after posterior distraction instrumentation in the lumbar spine, especially if the instrumentation approaches L-5 or the sacrum without supplemental anterior support (Fig. 161.8).

In young children with osteopenic bone, posterior compression instrumentation cannot maintain correct sagittal alignment. In this situation, intervertebral structural cage arthrodesis may be helpful to correct and maintain lumbar lordosis, in conjunction with posterior segmental instrumentation and arthrodesis. A flatback from a previous fusion needs posterior osteotomies along with anterior and posterior stabilization and arthrodesis.

RHEUMATOID SPONDYLITIS

Progressive kyphosis in rheumatoid spondylitis (Marie-Strümpel Kyphosis) is common and requires surgical treatment to maintain an upright head position. Usually, anterior and posterior osteotomies with segmental instrumentation are necessary. Single-level or multiple-level osteotomies may be utilized (5,7,9,21,22,24) (see Chapter 153, Chapter 154).

PREOPERATIVE PLANNING

In preoperative planning, distinguish between a short-radius and a long-radius kyphosis, and determine whether the curve is flexible or rigid. In short-radius curves, obtain a hyperextension cross-table lateral radiograph with a bolster under the apex of the kyphosis. Two interpretations should be made: the correctability of the apex of the kyphosis and the correctability of the ends of the kyphosis (Fig. 161.4) (13).

In Figure 161.4, the correction occurs in the more flexible ends of the kyphotic curve. When the ends of the kyphosis are flexible, a long-radius, unstable kyphosis can be converted to a short-radius stable curve. In this situation, use an anterior strut and interbody fusion as a first stage to stabilize the apical rigid component. Follow with a posterior approach to correct the flexible ends of the kyphosis, usually with segmental instrumentation. The goal at completion is to have the body weight in line with the apical strut graft, a curve configuration that is biomechanically stable (Fig. 161.4) (13).

In long-radius curves, a cross-table lateral radiograph, with the patient in longitudinal traction, is more helpful, particularly in paralytic curves. In general, rigid kyphotic deformities require strut grafting and interbody fusion of the rigid apical component in addition to posterior fusion and stabilization. Some mobilization of the rigid apex can be accomplished with disc excision and osteotomy, placing a strong strut graft in the corrected position.

Traction

Preoperative traction in rigid kyphotic curves (e.g., congenital kyphosis) is generally contraindicated because of the risk of precipitating anterior spinal cord compression. Preoperative traction for relatively inflexible long-radius curves is usually not beneficial, but it can be beneficial after an anterior disc excision, interbody fusion, and anterior release. In this situation, halo-hyperextension traction for 2 weeks between an anterior spinal release and fusion and a second-stage posterior fusion and instrumentation can be useful.

In neurofibromatosis with kyphoscoliosis and early spinal cord compression, careful and judicious halo-femoral traction may provide enough correction to improve
neurologic function before surgical stabilization. Preoperative traction is useful in this situation, because the apex of the kyphosis is frequently rotated and inherently more flexible. A preoperative myelogram and computed tomography (CT) scan are recommended in neurofibromatosis because of the high incidence of dural ectasia and intradural and extradural tumors.

In cervical kyphosis resulting from diastrophic dwarfism and in thoracolumbar kyphosis in achondroplasia, obtain a CT scan to verify the spinal-canal size and bony architecture before surgery. Preoperative somatosensory, evoked potentials are useful for baseline measurements in preparation for intraoperative spinal cord monitoring.

In preoperative planning, determine the levels of posterior instrumentation. To be mechanically sound, the posterior instrumented end vertebrae should be close to the weight-bearing line. Include the entire length of the kyphotic curve in the fusion and instrumentation.

**SURGICAL TECHNIQUES**

The anterior surgical techniques used in the surgical treatment of kyphosis are as follows:

- Strut graft (fibula or rib)
- Inlay rib graft
- Interbody fusion
- Vascularized rib or fibular graft
- Anterior vertebral osteotomy
- Interbody screw and rod instrumentation for rotational kyphosis
- Intervertebral structural cages

The posterior techniques for the surgical treatment of kyphosis are the following:

- Posterior spinal fusion with Moe facet fusion
- Posterior segmental instrumentation
- Posterior vertebral osteotomy
- Eggshell technique

**ANTERIOR STRUT GRAFT**

In all nonrotational kyphosis surgery, a subperiosteal exposure of the spine is recommended for maximal bone exposure for arthrodesis.

- Note the end vertebrae of the kyphosis and perform complete discectomies at each disc space between the end vertebrae. Incise the annulus fibrosus with a knife and excise the annulus with a narrow Luxsell rongeur.
- Incise the periphery of the cartilaginous endplate down to bone with a knife and peel it off the bony vertebral endplate with a narrow Cobb elevator.
- Remove the endplates with rongeurs, and remove the remaining disc with straight and angled curets.
- Pack the disc space with thrombin-soaked Gelfoam.

Once all disc spaces are cleaned back to the posterior annulus, curet the endplates and interior of the bodies of the end vertebrae to create a seating hole for the strut.

- Correct the kyphosis by pushing on the apex of the curve and measure the length of strut required in the corrected position.
- Cut the graft (rib or fibula) longer than measured and round the ends with bone cutters.
- Insert one end of the strut in the end vertebra. Cut a trough in the lateral aspect in the other end vertebra. Correct the kyphosis by pushing on its apex, and impact the strut through the side trough and into the undercut end vertebra. The intervening vertebra may have to be fashioned to allow the strut graft to fit.

*Figure 161.9. Intraoperative picture of an anterior strut graft.*

- Pack the intervertebral disc spaces solidly with morselized rib graft.
- If the kyphosis is larger and angular, several parallel struts may have to be used. Use Pinto distractors to correct the kyphosis while the struts are inserted. These distractors are nonimplantable and come in three sizes. Each distractor is a turnbuckle with pronged feet at each end that anchor in the vertebral bodies. When maximum correction of the apical kyphosis is achieved, insert the struts and remove the Pinto distractors.

*Figure 161.10. A: Pinto distractors (nonimplantable). B: Acute angular kyphosis with two Pinto distractors holding the deformity in a corrected position. C: The Pinto distractors are removed and the three strut grafts are anchored in the vertebrae.*

- In large kyphotic deformities it is important to fill the dead space between the vertebral bodies and the strut graft with bone graft.
**Figure 161.11.** Radiograph shows an anterior fibular graft with bone graft positioned back to the vertebral bodies.

In rotational kyphosis, an additional and very useful strut graft technique, originally pioneered by P. Stagnara, consists of creating an osteoperiosteal flap from the vertebral bodies that are in the kyphotic area (23).

- Use a wide osteotome to reflect the anterior portion of the vertebrae for the length of the kyphotic curve. This technique creates a good vascular bed.
- Countersink the fibular or rib strut graft, with the bony flap adjacent to the graft, usually on the concavity of the scoliotic curve.
- Pack the intervertebral disc spaces with bone graft (Fig. 161.12).

**Figure 161.12.** A: A Lambotte osteotome is used to create a vertebral flap. B: The vertebral flap is mobilized. C: The fibular strut graft is placed with the intervertebral disc spaces filled with bone graft. Bone graft is then placed from the flap to the vertebral bodies.

**INTERBODY ARTHRODESIS**

Perform an intervertebral disc excision as previously described. Break the bony endplates with an angled Lambotte osteotome or curet, and pack the entire disc space with rib graft (see Chapter 146, Chapter 155).

**INLAY GRAFT**

The inlay graft technique is useful when the kyphosis is not acutely angulated.

- Clean all the intervening disc spaces and prepare each end vertebra of the curve as described in the strut graft technique.
- Cut a trough in the interposed vertebral bodies with large Luxsell and Adson rongeurs and curved curets. The trough should be deep enough to bury the rib or fibular graft.
- The trough may also be filled with morcelized bone graft if anterior flexibility is needed during the posterior instrumentation.
- Correct the kyphosis by pushing on the apex of the curve, countersink the premeasured graft in the trough, and lock it in the end vertebrae.

**VASCULARIZED RIB GRAFT**

A vascularized rib graft has a distinct advantage in circumstances when early stabilization, earlier arthodesis, and shorter immobilization are needed.

- When the thoracotomy is performed, make the entrance to the chest cavity through the intercostal muscle of the rib that articulates with the superior end vertebra of the kyphosis.
- Determine the length of the vascular pedicle needed. Measure the length of the strut graft that is needed on the anterior portion of the rib and cut it free with a rib cutter, leaving all soft tissue attached.
- Sharply dissect the neurovascular pedicle back to the rib base to allow mobilization of the strut. Expose each end of the strut subperiosteally for approximately 2 cm and impact and countersink these graft ends in the prepared end vertebra of the kyphosis, being careful not to kink the vascular pedicle (Fig. 161.13) (3).

**Figure 161.13.** A: A 72-year-old man with vertebral osteomyelitis T-6–T-7. B: The vascularized rib graft with the neurovascular pedicle is at the left. C: This postoperative radiograph shows the anchored vascularized rib graft. Note the supplemental inlay and interbody grafts in the area of the osteomyelitis.

**ANTERIOR VERTEBRAL OSTEOTOMY**

After performing a subperiosteal exposure of the vertebra in a type II congenital kyphosis, the remnant of the posterior disc can be visualized. If the disc remnant cannot be visualized, perform the osteotomy at the level of the vertebral foramina to allow sagittal correction after the osteotomy.

- Perform multiple vertebral osteotomies at the levels of the posterior disc remnants or foramina using gouges, osteotomes, and curets. A power burr can be helpful for a portion of the osteotomy.
- Clean the disc spaces of all soft tissue back to the posterior annulus using curets and rongeurs.
- Use angled curets to complete the osteotomy on the opposite side, back to the posterior annulus.
- Check mobility of each intervertebral space with a Blount spreader, and pack each space with rib graft cut into small pieces (Fig. 161.14) (19).

**Figure 161.14.** A: Type II congenital kyphosis. Note the posterior disc remnants in the area of the anterior bar. B: After osteotomy is completed with angled
Use intervertebral structural cages to correct sagittal alignment and prevent vertebral collapse at the site of the osteotomies. The longer kyphotic curves will also need strut graft support.

**ANTEROIOR INSTRUMENTATION TO_correct ROTATIONAL KYPHOSIS**

- Expose the anterior spine extraperiosteally on the convex side.
- Using rongeurs and curets, clean the disc space of its annulus fibrosus and nucleus pulposus, along with the cartilage endplates at each vertebral level to be instrumented (the same technique as an interbody fusion).
- Measure the vertebral body size with a caliper to determine the appropriate length of screw to be used.
- Prepare a hole with a trocar in each vertebral body to be instrumented at the midlateral aspect of the rotated vertebra.
- Insert a vertebral screw and washer, aiming each screw toward the opposite pedicle or anterior to the pedicle.
- Take great care to identify the anterior longitudinal ligament at each level so that the degree of vertebral rotation is appreciated before the screw is inserted.
- Prepare the disc spaces for grafting by breaking the bony endplates with an osteotome and curets to ensure good cancellous bony exposure.
- Distract the disc spaces with a Blount spreader, and hold them open with whole-rib grafts.
- After assembling the rod-and-screw construct, correct the sagittal deformity.
- With the Zielke system, attach the derotation bar and derotate the spine as the nuts are sequentially tightened. As the spine is derotated, the scoliosis and rotational kyphosis are corrected.
- With segmental rod-and-screw systems, sequentially distract the intervertebral segments as the rod is introduced into one screw at a time.

The whole-rib intervertebral grafts prevent intervertebral collapse and the development of sagittal kyphosis after derotation has occurred. A supplementary posterior fusion and segmental instrumentation is usually done as a second-stage procedure (Fig. 161.15).

**INTERVERTEBRAL CAGES AND FEMORAL ALLOGRAFT DOWELS OR RINGS**

The use of metallic intervertebral cages and femoral allograft dowels or rings as structural grafts has been useful in correcting and maintaining correction of kyphosis. They unload the posterior segmental instrumentation by participating in load sharing. This combination creates a more rigid construct for arthrodesis. They are especially useful in maintaining lumbar lordosis.

- Expose the spine extraperiosteally and create a flap of the annulus. Tag the flap with suture, then clean the disc spaces of all soft tissue as previously described.
- The most useful cages are those that allow abundant bony ingrowth through a mesh design and add sufficient structural support. The allografts are hollow in the center for autografts, for early bony ingrowth.
- Insert a wedge into the disc space and impact it. Measure the height of the disc space and select the size of the cage. Fill the cage or allograft with bone graft and insert and impact it into place.
- Remove the wedge and insert the second cage or allograft.
- Decorotate the remaining vertebral endplates and fill the remaining space with autogenous graft (20).
- Reapproximate the annular flap and suture the margins together to act as a barrier for the bone graft.

Two small cages side by side or one large cage may be used, depending on the circumstances; usually a single allograft is sufficient. Follow the anterior procedure by a posterior arthrodesis and segmental instrumentation (Fig. 161.16).

**SEGMENTAL SPINAL INSTRUMENTATION**

The posterior surgical techniques used in correcting kyphosis are (a) segmental spinal instrumentation and Moe facet fusion and posterior arthrodesis, (b) posterior spinal osteotomy, and (c) the eggshell procedure.

Multiple segmental spinal instrumentation systems are now available, and most are strong enough to be acceptable. Which system to use is based on the experience of the surgeon. It is important to note, however, that some systems have a lower design profile than others. It is important to minimize the prominence of the instrumentation beneath the skin (see Chapter 156).

**POSTERIOR SPINAL OSTEOTOMY**
In previously fused patients, especially those with flatback syndrome, posterior osteotomies will be necessary for correction. When the spine is also fused anteriorly, combined anterior and posterior osteotomies will be necessary. The osteotomy site is selected by locating the vertebral foramina across which the osteotomy will be performed. The cranial-caudal width of the osteotomy is determined by the degree of closure that is necessary. Multiple osteotomies will spread the degree of correction across multiple levels and reduce the risk of neurologic compromise as compared with a single-level osteotomy. Single-level osteotomies can be useful, however, in ankylosing spondylitis and in patients with paralysis.

- Perform the osteotomy with osteotomes, gouges, curets, and Kerrison rongeurs (see Chapter 163). Remove the bone in sizeable pieces and save them for later use as an autograft.
- A power burr can be used, although bone that can be used as an autograft is often lost. By attaching a Luken's trap to the suction system, much of the fine bone removed by the burr can be recaptured.
- Carry the osteotomy down to the inner cortical table, which is then ostetomized with Kerrison rongeurs.
- It is important to adequately decompress the spinal canal and undercut the osteotomy at the edges of the canal to prevent nerve root entrapment or central canal stenosis upon closure of the osteotomy (10, 17).
- Provide adequate fixation to maintain correction and prevent displacement of the osteotomy.

In patients who have not had a previous fusion, the osteotomy should include removal of lamina, spinous processes, facets, and bilateral pars interarticularis. The amount of bone removal is determined by the degree of correction that is desired and that is judged to be safe (7, 16, 17, 21, 22, 24).

**EGGSHELL PROCEDURE**

The eggshell procedure (9) is an operative technique that allows the spine surgeon to operate on the anterior thoracic or lumbar vertebral column through a posterior approach. It is most useful caudal to T-6 because of the more rigid conduit to the anterior spine (transpedicular vertebrectomy) (18). This approach can be used for a vertebral biopsy or decompression of a vertebral body abscess, but most eggshell procedures are done for chronic or acute deformity. In deformity surgery, the eggshell procedure is performed in addition to other procedures done for correction, arthrodesis, and stabilization.

- Position the patient prone on a spinal frame.
- Prepare the spine for segmental posterior instrumentation by inserting all hooks and screws in preparation for stabilization at the time of deformity correction.
- Locate the pedicle by plain radiographs or image intensification. The location of the pedicle is identified by the bifurcation of a line transecting the transverse process and a line along the lateral margin of the pars interarticularis (Fig. 161.17).
- Enter the pedicle with either a power burr or osteotomes and curets. Introduce a small curet into the pedicle and into the vertebral body.
- Enlarge the pedicle hole by progressively increasing the size of the curets.
- Leave the posterior elements intact and do not disturb the medial wall of the pedicles at this time. An extension moment promotes kyphosis correction and posterior bone removal may not be necessary.
- Use a sweeping motion to remove progressively more of the cancellous bone of the vertebral body.
- The surgeon can operate at an angle of approximately 45° from lateral to medial and decancellate an area directly anterior to the spinal canal.
- Perform the same procedure through the opposite pedicle (Fig. 161.18) and continue until the desired amount of material (e.g., bone, tumor) is removed.
- To remove additional bone from just anterior to the spinal canal, remove the lateral wall of the pedicle to allow a more oblique angle for the curet to approach this area. Once this is accomplished, an eggshell is created (Fig. 161.18).
- If correction of localized kyphosis is planned, fracture the lateral wall of the pedicles and extend the fracture into the shell of the vertebral body. An extension moment applied to the spine may assist in this technique. If additional correction is necessary, perform a sequential posterior decompression by removing the spinous process, lamina, pars interarticularis, and pedicles (Posterior Subtraction Osteotomy) (Fig. 161.19).
- In the thoracic spine, it is often necessary to remove the proximal ribs and rib heads for adequate correction and closure of the osteotomy.
- Pack morcelized bone graft anteriorly before closing the osteotomy for anterior arthrodesis.
- Complete this wedge osteotomy and use segmental posterior instrumentation to correct the kyphosis and stabilize the spine. When the posterior elements are removed, a slow correction of the deformity is recommended to be sure that there is no encroachment of bone on the spinal canal or malalignment of the vertebra causing dural compression. Be careful of nerve root impingement.
- The inferior and superior laminae need to be undercut to avoid impingement on the dura during closure of the osteotomy.
- The axis of the closure of the osteotomy is anterior to the spinal canal, thus shortening the neural tube.
- Stable posterior fixation is required to maintain osteotomy stability, kyphotic correction, and arthrodesis (Fig. 161.20).
POSTOPERATIVE CARE AND REHABILITATION

Between the stages of operative correction, maintain patients on egg-crate or air mattresses, and log-roll them frequently to prevent decubiti and atelectasis. Prescribe daily bedside physical therapy for muscle strengthening, and joint range-of-motion exercises. Remove any chest tube and posterior drains on the second postoperative day or when the drainage is minimal.

At 5–7 days after the last staged procedure, place the patient in a bivalved polypropylene body jacket. If the patient is a teenager or young adult with good fixation and good-quality bone, bracing may not be needed. If there is any question about the stability of the instrumentation, bone weakness, or situations in which instrumentation cannot be used in the cervicothoracic spine (e.g., achondroplasia, diastrophic dwarfism), use a halo brace. In cervical kyphosis, apply a halo brace intraoperatively. Then allow patients to ambulate in the brace.

In patients with shorter kyphotic curves, do the anterior and posterior procedures at the same surgical setting to minimize anesthesia and recovery times. Sometimes a staged procedure may be indicated in patients who have had previously failed attempts at correction with resultant pseudarthroses and progressive curves, depending on the individual circumstances.

PITFALLS AND COMPLICATIONS

Many potential pitfalls are recognized:

- Failing to fuse the entire kyphotic curve (fusion too short) may allow progression of the kyphosis. This is especially true in children due to the adding-on phenomenon, in which vertebrae cranially and caudally tilt into the curve and are added to the curve.
- Placing the strut graft too far anteriorly with no bony contact with the apex of the kyphosis will lead to graft fracture.
- Placing the anterior strut graft too far posterior to the weight-bearing axis may lead to failure and progressive deformity.
- Failure to supplement an anterior procedure with a posterior fusion and instrumentation may lead to inadequate correction or late failure.
- Inadequately countersinking the strut graft may result in graft dislodgement after surgery.
- Failure to make osteotomies wide enough and the vertebral canal edges round enough may lead to nerve root entrapment at osteotomy closure.
- Dural, spinal cord, and nerve root injuries from too aggressive disc removal can occur.
- Inadequate disc removal will lead to failed fusion or to late progression of the deformity.
- Focusing on spinal instrumentation and inattention to fusion technique may lead to pseudoarthrosis and failure.
- Inadequate placement of posterior instrumentation may result in incomplete correction or an unbalanced torso, and failure to maintain lumbar lordosis below the kyphosis will lead to unbalanced sagittal alignment.
- Too-vigorous correction of the kyphotic deformity with posterior instrumentation in osteopenic bone can lead to bony failure, with loss of fixation and correction.
- Too-vigorous derotation with the Zielke instrumentation can cause spinal root injuries.
- With any anterior instrumentation, take care to prevent flatback syndrome.
- When there is severe vertebral rotation, anterior screw placement is critical so that spinal canal penetration does not occur.
- Finally, a well-applied brace is extremely important in some patients and should not be delegated to the inexperienced surgeon, or a less-than-ideal result may occur in an otherwise masterfully performed surgical procedure.

CHAPTER REFERENCES

SPONDYLOLISTHESIS

John D. Miles and Robert W. Gaines, Jr.

The concepts of spondylolysis, spondylolisthesis, and spondyloptosis have caused considerable confusion for students of orthopaedics. This chapter conveys the essentials of what is understood about these lesions to provide a foundation for rational treatment.

Spondylolisthesis is derived from the Greek spondylos (vertebra) and olisthanein (to slip or fall). This most commonly describes the forward slippage of a cephalad vertebra on a caudal vertebra (Fig. 162.1A). The term spondylolysis is also derived from the Greek word lysis (loosening). Spondylolysis is now specifically used to describe a bony defect in the pars interarticularis, the portion of the neural arch just caudal to the confluence of the pedicle and the superior articular process and at the most cephalad part of the lamina and inferior articular process (Fig. 162.1B). Spondylolisthesis can be present with or without spondylolysis (Fig. 162.1C).

Spondyloptosis has similar origins, with the same root appended to the Greek word ptosis (falling). In modern usage, this refers to the most severe form of spondylolisthesis, when the body of L-5 has slipped into the pelvis and is positioned directly anterior to the sacrum (Fig. 162.1D).

Figure 162.1: A: Spondylolysis. B: Spondylolysis with listhesis. C: Spondylolisthesis and elongation of the pars interarticularis (without lysis). D: Severe spondylolisthesis (dashed line indicates top of sacrum).

PATHOPHYSIOLOGY

Two processes—dysplastic and traumatic—can give rise to spondylolisthesis. These can occur simultaneously, but generally one predominates.

The first, so-called dysplastic pathway is initiated by a congenital defect in the bony hook or its catch. The hook is composed of the pedicle, pars interarticularis, and inferior articular process of the cephalad vertebra, and the catch is the superior articular process of the caudal level. Dysplasia of any of these structures sets the stage for olisthesis when the weight of the trunk is transferred through the area at the initiation of upright stance and ambulation. The olisthesis is only potential at birth. Subluxation occurs when the soft-tissue restraints (intervertebral disc, anterior and posterior longitudinal ligaments, ligamentum flavum, and posterior ligamentous complex) undergo plastic deformation due to repetitive loading unopposed by bony constraints. If pronounced subluxation occurs while significant growth still remains, the slippage will be accompanied by abnormal growth in the involved vertebral bodies or sacrum. These dysplastic changes form the basis for various classification schemes. Such changes include a trapezoidal shape of L-5, rounding of the superoanterior aspect of the sacrum, vertical orientation of the sacrum, junctional kyphosis at the involved segments, and a compensatory hyperlordosis at adjacent levels. There is evidence to support a genetic predisposition to this process, although no pattern of inheritance has been identified.

The second, so-called traumatic pathway is initiated by repetitive cyclic loading that ultimately results in a stress fracture. Impingement between the inferior articular process of the cephalad vertebra and the superarticular process of the caudal vertebra creates a bending moment that must be resisted by the pars (Fig. 162.2). Repetitive impingement causing loads in excess of the fatigue limit results in a fatigue (stress) fracture of an otherwise normal pars interarticularis. This repetitive loading is the same process that causes stress fractures in other anatomic locations, such as the femoral neck or the fifth metatarsal. The hard cortical bone of the pars predisposes it to fatigue fracture, as well as nonunion, decreasing the likelihood of spontaneous healing. If healing occurs, the pars often heals in an elongated position. Either outcome (nonunion or healing with elongation) permits vertebral subluxation. This fundamental change in bony anatomy exposes the disc to increased shear load, even though the axial load remains unchanged. The increased shear load on the disc causes premature disc degeneration. Activities involving repetitive maximal flexion and extension (e.g., interior line play in football, pole vaulting, or gymnastics) are notoriously associated with fatigue fractures of the pars.
Spondylolisthesis may also be caused by other processes, although these are sufficiently different as to be considered distinct entities. They are included here for completeness.

Degenerative spondylolisthesis represents segmental instability and subluxation caused solely by degenerative change in the intervertebral disc and facet joints. The degree of subluxation is necessarily mild because the intact neural arch provides a bony limit to forward translation. Relatively more sagittal orientation of the facet joints is associated with degenerative spondylolisthesis (22).

A local or systemic pathologic process may cause a defect in the neural arch that can then permit subluxation. This is a pathologic fracture with resultant translational deformity.

High-energy trauma can cause translocation deformity. In this setting, the spine will have sustained multiple bony and soft-tissue injuries, which may include a fracture in the pars. Other skeletal and visceral injuries will typically be present. This traumatic type of spondylolisthesis is a fracture–dislocation from high-energy trauma, not from repeated low-energy injuries.

Finally, a laminectomy that removes an entire articular process or more than half of each articular process can functionally destabilize the spine and permit translational deformity. This is iatrogenic postsurgical instability. Segments adjacent to previously fused segments are also at risk for development of degenerative spondylolisthesis (45). This subluxation is likely due to resection of the capsular, interspinous, or supraspinous ligaments at the adjacent level, but the loss of motion of the fused segment may contribute by increasing the motion demands at the next open level.

**CLASSIFICATIONS**

The classification scheme of Wiltse et al. (58) has gained wide acceptance (Table 162.1). It combines both anatomic and etiologic elements; however, this combination is one criticism of this system.

Table 162.1. Wiltse–Newman–Mcnab Classification of Spondylolisthesis

Marchetti and Bartolozzi (34) proposed a classification scheme based on etiologic criteria that has also gained wide acceptance (Table 162.2). The principal distinction in their system is between developmental and acquired forms, which correspond respectively to the dysplastic and traumatic pathways discussed previously.

Table 162.2. Marchetti and Bartolozzi Classification of Spondylolisthesis

**CLINICAL ASSESSMENT**

The symptoms associated with spondylolisthesis are caused by chronic muscle contraction (spasm) as the body attempts to limit motion around a painful pseudarthrosis of the pars interarticularis, by tears in the annulus fibrosus of the degenerating discs, or by compression of nerve roots. Pain may also derive directly from impingement at the fibrous pars nonunion, as nerve endings have been identified there (47). Children and younger adults who have symptomatic high-grade spondylolisthesis commonly complain of back fatigue and back pain on movement, particularly with hyperextension, as well as hamstring fatigue and pain. On examination, the paraspinal muscles are in chronic reactive contraction (spasm) to splint the painful underlying motion segment, and the hamstring muscles are in reactive contraction to stabilize the pelvis under the painful spinal motion segments. After months of continuous contraction in a growing child, fixed contractures of the hamstrings and paraspinal muscles may occur, limiting forward bending and hip flexion. These may be evident on clinical examination (Fig. 162.3A). Palpation elicits tenderness over the pars defect when the patient is lying prone with the spinal muscles relaxed, similar to the tenderness that exists over any other skeletal nonunion.
Figure 162.3. Physical findings in spondylolisthesis. A: Severely limited forward bending in a patient with moderate slippage and paravertebral muscle and hamstring spasm. B: Sciatic scoliosis in a patient with a disc rupture at the level above a pars defect. This patient’s chief complaint was sciatica with mild back pain. C: Accentuated lordosis in a patient with mild slippage and a low slippage angle. D: Severe posterior tilting of the pelvis and secondary thoracolumbar lordosis are evident in this patient with a high-grade spondylolisthesis and high slippage angle. E: Heart-shaped buttocks and trunk foreshortening are visible in this patient with a high-grade slip. F: The same patient demonstrates an abdominal crease. G: Standing posture of a patient during olisthetic crisis with severe deformity, canal occlusion, and multiple root compression.

As aging proceeds and disc degeneration occurs (either at the level of the slippage or at the level above it), episodes of the back “giving out” may occur. These episodes may or may not involve sciatica and vary in severity. As disc degeneration or subluxation increases, both the spinal canal and the lateral root foramina narrow, often causing symptoms related to nerve root compression (Fig. 162.3B). Such compression is manifested by sciatic pain radiating from the buttock into the posterior thigh and into the calf and foot. It is associated with numbness in a similar dermatomal distribution and with positive nerve stretch signs, such as straight-leg raising. Symptoms of spinal claudication indicate high-level stenosis. Compression of the central canal is confirmed by one or more of the following:

- Bowel or bladder symptoms or dysfunction
- Bilateral leg symptoms
- Positive straight-leg-raising test bilaterally
- Positive crossed straight-leg-raising test

Patients with spondylolysis or minor slips have no spinal deformity. As the amount of subluxation increases, spinal deformity becomes increasingly visible on inspection of the patient’s torso. As the spine slides forward, the pelvis rotates posteriorly so that the top of S-1 becomes progressively more horizontal. This produces lumbosacral kyphosis and a relative posterior prominence of the posterior parts of the iliac crests (Fig. 162.3C, Fig. 162.3D). The gluteal muscles become less prominent. Patients with high-grade spondylolisthesis are often described as having heart-shaped buttocks (Fig. 162.3E). As the amount of telescoping approaches total dislocation (spondyloptosis), foreshortening of the lumbar spine becomes obvious on inspection of the patient’s torso, and a crease appears across the abdomen (Fig. 162.3F). Patients in olisthetic crisis with total canal occlusion (the most severe type of spinal stenosis) relieve disc pressure and reduce nerve root tension by supporting trunk weight with hands on knees (Fig. 162.3G).

RADIOGRAPHIC ASSESSMENT

Plain anteroposterior and lateral radiographs document the amount of vertebral subluxation; often, they also reveal a pars interarticularis defect if one is present (Fig. 162.4). Oblique views have also been used to highlight the Scotty-dog sign (Fig. 162.5). In young patients, flexion–extension views can be used to show excessive movement across the site of pseudarthrosis in the pars interarticularis and subluxation of the vertebral body as the patient moves from extension into flexion. This motion may be more evident if the films are taken with the patient lying in the lateral decubitus position rather than standing (60). Plain standing radiographs are also quite useful for documenting progression of deformity (Fig. 162.6).

Figure 162.4. Spondylolisthesis in five patients with varied combinations of slippage, slippage angle, sacral inclination, sacral rounding, and disc degeneration. A: Moderate dysplastic spondylolisthesis. No pars defect is seen, and the slippage angle is low. B: Moderate isthmic spondylolisthesis. A pars defect is seen, and the slippage angle is higher than in the previous image. C: Moderate isthmic spondylolisthesis with moderate disc degeneration. The slippage angle is low, but striking retrolisthesis is present at the level above (L-4-5). D: Moderate isthmic slippage with severe disc degeneration and a vacuum disc. E: High-grade slip with a higher slippage angle, vertical sacrum, high lumbar index, and severe disc degeneration. F: Low-grade slip with low slippage angle and minimal disc degeneration. A pars defect is present.

Figure 162.5. Varied radiographic appearance of spondylolysis without olisthesis. A: Oblique radiograph shows lysis at L-3. Note the collar on Scotty dog. B: Oblique radiograph reveals atrophic nonunion at an L-5 pars defect. Oblique (Scotty dog) radiographs reveal a pars defect (C) and an elongated healed pars (D) in the same patient with a low-grade slip. (Courtesy of Harry Griffiths, MD, University of Missouri Health Sciences Center, Columbia, MO.)
Older references grade the degree of vertebral subluxation by the Meyerding classification, which is based only on the amount of anterior (forward) subluxation of the cephalad vertebra in reference to the caudal vertebra (Fig. 162.7A). Slippage is graded as a percentage relative to the sagittal diameter of the inferior body:

<table>
<thead>
<tr>
<th>Grade</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>I</td>
<td>0% to 25%</td>
</tr>
<tr>
<td>II</td>
<td>25% to 50%</td>
</tr>
<tr>
<td>III</td>
<td>50% to 75%</td>
</tr>
<tr>
<td>IV</td>
<td>75% to 100%</td>
</tr>
<tr>
<td>V</td>
<td>Greater than 100%</td>
</tr>
</tbody>
</table>

This classification is particularly useful for low-grade (grade I or II) slips.

Boxall et al. (5) described the many adaptive changes in vertebral and disc anatomy that occur in response to chronic vertebral subluxation (Fig. 162.7B, Fig. 162.7C and Fig. 162.7D). In particular, they emphasized the importance of the kyphotic component of the deformity in producing canal narrowing and sagittal-plane malalignment. Correction of kyphosis is very important in treating the condition, especially with regard to achieving a solid fusion (13). The radiographic measurement techniques described by Boxall et al. (5) emphasize the importance of the slippage angle as the best way to quantify the degree of kyphosis in a patient with spondylolisthesis.

Bone scintigraphy or single-photon emission computed tomography may occasionally be useful in symptomatic patients without radiographic evidence of spondylolisthesis (Fig. 162.8) (33). These studies document increased bone metabolic activity in an acutely injured pars interarticularis; however, they may revert to normal in a chronic unhealed defect or after a stress fracture heals (33).

Plain radiographs are sufficient for evaluating patients with solely mechanical complaints. If root symptoms, bowel or bladder complaints, or physical evidence of cord or root compression are present, then evaluate the soft tissues of the back with magnetic resonance imaging (MRI) (Fig. 162.9), myelography (Fig. 162.10), computed tomography, or a combination of these studies. MRI findings have been well correlated with clinical evidence of radiculopathy (29). Cystometric studies are helpful in patients with bladder dysfunction, although they are often confirmatory rather than diagnostic. Somatosensory-evoked cortical or spinal potentials may be of diagnostic value but are usually only confirmatory.
NATURAL HISTORY AND RISK FACTORS FOR PROGRESSION

Dysplastic spondylolisthesis most commonly occurs at the lumbosacral junction, with decreasing frequency at more cephalad levels in the lumbar spine. It is seldom seen in the cervical spine and rarely in the thoracic spine. Pars defects (spondylolysis) have not been reported at birth. However, the prevalence by early childhood is between 4% and 5% (17). By adulthood, the prevalence has increased to 6% or 7% (57,31). The great majority of patients with spondylolysis (radiographic evidence of a pars defect) are asymptomatic, and substantial slippage (spondylolisthesis) never develops (11,19,49). In a long-term study of adolescents with isthmic spondylolisthesis, 80% of slips occurred at the time of the initial presentation, and the only factor predictive of progression was the magnitude of the initial slippage (50). Pronounced vertebral subluxation (>75%), if it occurs, generally arises during late childhood, at the time of the adolescent growth spurt, or during pregnancy (1,44). In patients who manifest a major deformity during adulthood, it is generally thought that the deformity developed before 20 years of age. The prevalence of spondylolisthesis is no higher in groups with chronic debilitating low back pain than in the general population (59). The association between low-back pain and spondylolisthesis is weak but is significant in women (56). The degree of dysplasia, including spina bifida occulta and small transverse processes, has been associated with progression but has not proven to be predictive. Rounding of the sacral promontory, trapezoidal wedging of L-5, vertical position of the sacrum, and segmental kyphosis all contribute to the mechanics of progression but are believed to be secondary changes. Similar to Harrington’s stable zone in scoliosis, there may be a point of no return, beyond which progression is a certainty; however, documentation of this has not yet occurred.

Conversely, slippages that develop after 20 years of age (acquired) tend to be more stable, less symptomatic, and less likely to progress (38). Spondylolisthesis due to a fatigue fracture of the pars interarticularis will frequently occur in a high-level athlete. However, participation in athletics has little effect on progression of symptoms (35).

Degenerative spondylolisthesis usually occurs after 60 years of age, and progression is limited by the intact neural arch. Symptoms are generally due to stenosis, and progression to surgery is variable. A more sagittal orientation of the facet joints at L4-5 is strongly associated with the development of degenerative and postlaminectomy spondylolisthesis (22,43). Oophorectomy has also been identified as a risk factor for degenerative spondylolisthesis (58).

Both postsurgical and pathologic spondylolisthesis are relatively uncommon. Each patient must be evaluated and treated individually. Nerve root decompression and instrumented spinal fusion are the fundamentals of treatment.

Traumatic spondylolisthesis is a fracture–dislocation, and hence it is extremely unstable (24). Surgical stabilization is usually required.

NONOPERATIVE MANAGEMENT

Most patients who have a greater proportion of back pain than leg pain can be managed nonsurgically. In the pediatric population, symptoms may be controlled by a period of bed rest, bracing, or cessation of aggravating activities. For adults with any type of spondylolisthesis, initial nonoperative treatment is the rule.

- A corset and activity modifications are usually beneficial.
- For exacerbations, prescribe periods of bed rest.
- Palliate symptoms with hot or cold therapy, and use massage to treat the muscle fatigue or spasm resulting from disproportionate effort to limit movement across a painful motion segment.
- Initiate a program of aerobic conditioning; specific back exercises have variable effectiveness.
- Obese patients should lose weight to return to their healthy physiologic range.
- Nonsteroidal antiinflammatory medications and epidural steroid injections may be of some value.

These conservative measures are usually effective because fewer than 10% of symptomatic patients eventually require operative treatment. Surgery should be contemplated only after a trial of nonoperative care. In adult patients with predominantly sciatic complaints, nonoperative treatment may be less effective.

INDICATIONS AND SURGICAL TECHNIQUES

The surgical indications are different for children and adolescents than for adults. For children and adolescents, the indications for surgery are as follows:

- Documented progression of a slip beyond 25%
- Presentation with a high-grade slip (>50%)
- Intractable pain or neurologic symptoms
- Progressive postural deformity or gait abnormality

For adults, the usual surgical indication is persistent back pain and neurologic or radicular symptoms unresponsive to nonoperative management. As with other spine surgery, sciatica is more responsive than back pain to surgery (9). Patients with more severe symptoms will generally experience greater benefit from surgery than those with milder symptoms. Poor outcomes following surgery have been strongly associated with active workers’ compensation claims and smoking (48-55).

TREATMENT OF SPONDYLOLYSIS AND LOW-GRADE (<50%) Spondylolisthesis

PRIMARY REPAIR OF PARS DEFECT

In 1970, Buck (7) described a technique for direct repair of a pars defect with a screw placed through the lamina across the defect. There have since been other direct-repair techniques involving wires, hooks, and pedicle screws (50). The appropriate patient has spondylolysis but no olisthesis and a normal disc. Good results have been reported with these techniques, but because of the simplicity and predictability of fusion in situ, repair is not performed as often as fusion (3).

INSTRUMENTED POSTEROLATERAL FUSION IN SITU

The majority of symptomatic patients with mild to moderate (<50%) slips can be successfully treated with posterolateral fusion in situ (typically from L-5 to S-1) (6,19-27). Even patients with radicular symptoms may get good relief with fusion in situ (12). Wiltse et al. (58) advocated a muscle-splitting approach with two
paramedian incisions; we favor a midline approach.

Internal fixation is rarely needed for children, although it is commonly used for adolescents and adults. The most popular systems today use pedicle screws. The biomechanical superiority of these systems for stabilizing spondylolisthesis has been demonstrated. Their effect on fusion rates and clinical outcomes is less clear, although generally beneficial (16–42, 53, 54, 61).

- Position the patient prone on a Jackson table or blanket rolls without changing the patient’s kyphosis or lordosis.
- Make a midline incision of sufficient length, and expose the posterior elements laterally to the tips of the transverse processes and sacral ala and thoroughly decorticate.
- For most adult-sized patients, we then place pedicle screws across the defect.
- We now routinely perform a laminectomy of the loose arch to provide local graft, instead of iliac crest, to reduce postoperative morbidity.
- Place morcellized autologous bone graft from the laminectomy in the prepared gutter under the plates (between the screws).
- Place rods or plates.
- Perform routine closure over a suction drain and epidural catheter.

Postoperatively, allow patients to be ambulatory, as tolerated, in a corset. Prohibit driving and sitting, except on a raised toilet seat, for 2 months.

The healing rate for a one-level fusion is approximately 95%. Most children have good or excellent results, with eventual return to full activity. As in other spine surgery, children do better than adults. The most common long-term problem is degenerative change at the level above the fusion (59).

DECOMPRESSION

Neural decompression is seldom required for children unless there is a cauda equina syndrome. Although foraminal stenosis with associated root pain is common in adults with isthmic spondylolisthesis, the indications for decompression are unclear because the addition of decompression may increase the rate of postoperative pseudarthrosis (16). Some authors have reported excellent fusion rates and relief of sciatica with fusion in situ (59), whereas others advocate formal decompression (6).

Adults with degenerative spondylolisthesis and secondary stenosis commonly present with claudication. Pedicle-to-pedicle posterior decompression is generally accepted, although the addition of intertransverse fusion has been shown to produce significantly better results than decompression alone for the treatment of degenerative spondylolisthesis (23).

The Gill procedure (excision of the loose laminar arch), long considered adequate decompression, actually fails to decompress the root in the neural foramen. A thorough decompression must include a foraminotomy, especially in the patient with radicular complaints. The best use of the loose laminar arch is as bone graft. We routinely perform Gill's procedure to obtain bone graft, not for the purpose of neural decompression.

ANTERIOR INTERBODY FUSION

Anterior interbody fusion is rarely indicated as a primary treatment for low-grade spondylolisthesis. It can be useful for failed posterior spinal fusion, however. Complications are potentially severe and include injury of the great vessels, sexual dysfunction, and retrograde ejaculation (see Chapter 146).

TREATMENT OF HIGH-GRADE SPONDYLOLITHESIS (>50%)

High-grade spondylolisthesis is rare but is a clinical challenge. Opinions vary widely as to optimal management.

ARTHRODESIS

Essentially, all authors would incorporate a bilateral posterolateral fusion in the treatment plan, but the agreement would stop there. Some authors have reported good results with isolated posterior fusion in situ (14, 27, 29). However, the pseudarthrosis rates are high, and progression is common, even with a radiographically solid fusion. In addition, fusion in situ fails to correct the clinical deformity and sagittal imbalance that generally accompany these severe deformities (51).

INSTRUMENTATION AND REDUCTION

The indications for instrumentation and reduction remain controversial (4, 13). The relative indications for instrumented reduction include oblastic crisis, cauda equina syndrome, a slip greater than 50% with a slippage angle greater than 30°, and major clinical deformity with global sagittal imbalance. Most intraoperative reduction techniques involve insertion of pedicle screws into L-4, L-5, and the sacrum. Often, a second point of pelvic fixation is added (iliac screws, intrasacral rods, or S-2 screws) to gain mechanical advantage. The forces applied are distraction, posterior translation of L-5, and sacral flexion. The terminal portion of the reduction maneuver has been shown to produce a disproportionate amount of nerve root tension, suggesting that posterior sagittal decompression is a reasonable intermediate alternative (40). Many authors stress the importance of sacral flexion for restoring sagittal-plane balance (45). All series of instrumented reductions have reported nerve root injury, typically L-5, which manifests as foot drop. For the majority of affected patients, there is complete or partial recovery. These procedures are technically demanding and should be attempted only by experienced surgeons for patients who understand the potential risks. At long-term follow-up, most series have reported durable correction and clinical improvement with acceptable complication rates (15, 25, 37).

ANTERIOR INTERBODY FUSION

The addition of anterior interbody fusion is controversial (36). Some series report good results with isolated posterior spinal fusion, whereas others report higher fusion rates, less progression, and fewer implant failures with circumferential fusion (4, 6). The relative indications are incomplete reduction, residual kyphotic slippage angle, and revision for previous pseudarthrosis. We favor the addition of anterior interbody fusion because of the relative difficulty of obtaining arthrodesis on the tension side of the lumbosacral kyphosis. The anterior interbody fusion generally heals readily on the compression side, but the lower pseudarthrosis rate must be weighed against the increased morbidity.

DECOMPRESSION

The need for decompression is also controversial. Decompression is commonly used in conjunction with fusion for patients with radicular or neurologic symptoms (53). However, relief of radicular symptoms has been reported with isolated posterior fusion (39). We use the presence of a positive seated straight-leg-raising test as an indication for nerve root exploration.

TREATMENT OF SPONDYLOPTOSIS

A patient with spondylolisthesis presents a difficult, and fortunately rare, clinical challenge. In spondylolisthesis, the entire body of L-5 is caudal to the sacrum. Although the slippage angle varies widely, the inferior endplate of L-4 is always closer than the inferior endplate of L-5 to the S-1 endplate. This observation provides the anatomic rationale for our technique, which is the resection of L-5 and reduction of L-4 onto the sacrum. The relative paucity of cases and the variable clinical presentation have led to a plethora of suggested techniques (4, 13, 27, 36, 37, 41, 48, 52). Treatment options include observation, reduction and casting, fusion in situ, reduction of L-5 onto the sacrum, and resection of L-5 with reduction of L-4 onto the sacrum. All options, including nonoperative management, have been associated with similar complications, including motor and sensory deficits or a cauda equina syndrome (49). The two-stage technique described in the following section is designed to eliminate lumbosacral kyphosis, restore sagittal-plane balance, and realign the spinal and nerve root canals while avoiding distraction and potentially devastating iatrogenic cauda equina injury.

AUTHORS’ PREFERRED TECHNIQUE FOR SPONDYLOPTOSIS

Our preferred technique for spondylolisthesis involves resection, instrumentation, and reduction of L-4 onto S-1. As in other forms of spondylolisthesis, the severity of clinical symptoms in patients with spondylolisthesis does not necessarily correlate with the degree of subluxation. Thus, L-5 vertebrectomy and reduction are advised only for severely disabled patients (Fig. 162, 11).
The procedure consists of two parts performed 1 week apart (21).

- Perform the first part through an anterior retroperitoneal approach (see Chapter 146).
- Resect the L-4–5 disc, the body of L-5, and the L-5–S1 disc.
- Take the resection back to the base of each pedicle, and take care to avoid injury to the L-5 root.
- Remove the inferior cartilage endplate of L-4. Retain the bony endplate.

Postoperatively, place the patient in an intensive care unit for 1 week to await the second stage. Nursing care includes use of a rotokinetic bed.

- Perform the second stage through a midline posterior approach.
- Place Harrington outriggers from L-2 onto the sacral ala to provide very gentle (1–2 cm) distraction. (This step may be omitted after the surgeon gains more experience.)
- Remove the loose posterior elements, transverse processes, and pedicles of L-5. Take special care to avoid injury to the L-5 root.
- Remove the cartilage endplate of S-1 before reduction. Preserve the bony endplate.
- Place pedicle screws into L-4 and S-1, Cortical purchase is essential.
- Accomplish reduction of L-4 onto the sacrum by removing the outriggers or by gentle distraction and translation applied to the screws in L-4. Constantly assess the L-4 and L-5 nerve roots during reduction both visually and with a nerve hook.
- Decoricate the transverse processes of L-4 and the sacral ala.
- Place autograft retained from the vertebrectomy and from the posterior elements of L-5 in the lateral gutter.
- Apply rods or plates to the screws. Two nerve roots (L-4 and L-5) will pass through the reconstructed neural foramen at L4–S1. Check to ensure that there is no impingement on the nerve roots before and after application of the rods or plates.

Postoperatively, keep patients at bed rest in a thoracolumbar spinal orthosis for 6 weeks, at which time begin mobilizing patients.

With this technique, 18 of 27 patients have experienced weakness in dorsiflexion postoperatively. This has been transient for all but two. All patients with preoperative cauda equina syndrome recovered postoperatively; no patient has had iatrogenic cauda equina injury (because the spine is not lengthened). When reviewed by an independent observer, patients reported very high satisfaction, with significant improvements in pain, function, and appearance (22).

**PITFALLS AND COMPLICATIONS**

The resection described is one of the most difficult operations in spinal reconstruction. It should be only performed by surgical teams that are accustomed by experience to performing spinal osteotomies on a routine basis and are very experienced in handling the dural tube and nerve roots.

The anterior exposure requires extensive mobilization of the aorta, vena cava, and both internal and external iliac arteries and veins. Two to four assistants are regularly required to retract major vessels, roots, or vertebral during various portions of the procedure.

Incomplete removal of the L-4-5 or L-5-S discs or the L-5 vertebra creates the potential for iatrogenic single- or multiple-root injury or incomplete reduction. Slow rehabilitation of patients is essential. One month of bed rest is routine before ambulation in a brace. No work or physical rehabilitation is started until convincing evidence of union is obvious.

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *, classic article; #, review article; &, basic research article; and +, clinical results/outcome study.

Surgical therapy for scoliosis has evolved considerably over the years, from in situ fusions and fusion with casting, to fusion using Harrington and Luque instrumentation, to the current generation of segmental systems that attempt to correct spinal deformity in three planes. Regardless of the treatment method, there have always been some patients who lose correction—either because of a pseudarthrosis or by progression of the curve—or who have poor results because of pain. Although acute failures can be treated by immediately reinstrumenting and augmenting the fusion, patients who have lost correction over time typically require a more aggressive approach to reconstruction. To successfully manage these patients, the surgeon must understand why the loss of correction occurred, develop a sound preoperative plan, and choose a surgical approach designed to provide a painless arthrodasis, good correction of deformity, and a well-balanced trunk.

CAUSES OF FAILURE

The therapeutic failures of the past have led to changes in the way fusions are performed, the way fusion levels are selected, and the types of instrumentation used to stabilize the spine (2,7,8,21). Despite technical advances, the following remain the most common causes of failure:

- Pseudarthrosis
- Fixation failure
- Inadequate fusion length
- Progression of deformity due to the "crankshaft" phenomenon
- Addition of new segments to the old curve
- Progression of an untreated, secondary curve

PSEUDARTHROSIS

In 1964, Moe and Gustilo (2) reported the results of 196 patients treated by cast correction and posterior fusion. They noted that 46 patients (23%) required reoperation for pseudarthrosis repair or a combination of pseudarthrosis repair and osteotomy. McMaster and James (20) reviewed the experience of a number of authors and concluded that pseudarthrosis rates ranged from 3.3% to 68.3% (average, 22.5%) in patients treated without internal fixation. When internal fixation was used, this rate was significantly lower (2% to 17%, average, 6.4%). With current instrumentation techniques, a pseudarthrosis rate of between 2% and 5% is typical in adolescent idiopathic scoliosis (1,5,7,10). However, other deformity groups remain at much greater risk. Adults treated for idiopathic and paralytic scoliosis have a 10% to 15% incidence of pseudarthrosis (12,23,25,26,28). Patients with myelodysplasia and paralytic scoliosis have a 20% to 45% incidence of pseudarthrosis (18,22).

Three factors have contributed to improved fusion rates. First, the fusion technique itself has improved over the years. Decortication of transverse processes, removal of facet joints, and meticulous exposure of the lumbar transverse processes have all resulted in improvements in fusion rates. Second, the use of autograft bone to augment the fusion mass has greatly improved success rates. Finally, the use of spinal instrumentation and the subsequent improvement in instrumentation constructs have further reduced pseudarthrosis rates. Still, some failures are inevitable. The surgeon has no control over the patient's age at the time of surgery, the nature of the deformity (paralytic, congenital, or those associated with neurofibromatosis or Marfan's syndrome), or the location and severity of the curve at presentation. All of these factors have an impact on fusion rates. Regardless of technique or instrumentation, pseudarthroses will continue to occur in patients with severe and recalcitrant curves.

FIXATION FAILURE

Despite a variety of hook types, construct patterns, and the addition of pedicle screws, instrumentation failures are inevitable. Excessive distraction and rotational forces applied to large, rigid curves can result in hardware displacement if the hook fractures through the lamina. Poor purchase of the hook over a deformed or rotated lamina may result in hook displacement at either end of the curve. Transverse process fractures may compromise the transversospinocaudal claw even in a well-designed scoliosis construct. Patients with poor bone quality or osteomalacia are also at increased risk for hardware displacement. Rod breakage, seen in 7% to 10% of Harrington constructs, is less common with current segmental systems but can still occur as either an acute or a late complication (7). Whether fixation is lost because of failure through the bone or failure of the hardware itself, the patient is exposed to a great risk of pseudarthrosis, pain, and loss of any correction gained at the initial surgery.

INADEQUATE FUSION LENGTH

In 1973, Kostuik et al. (12) reported that, among adult patients requiring revision surgery, the initial spinal fusion had been too short in a significant number. Cummine et al. (4) found that 40 of 59 patients requiring reconstruction for failed scoliosis fusion had curve progression due to incorrect selection of fusion levels at the initial operation. Inadequate fusion length may result in the following situations:

- The initial surgery stopped short of the appropriate end vertebra, leaving part of the primary curve unfused.
- The surgeon inadvertently selected a fusion level that did not address all the involved segments, particularly when there were a number of parallel end-vertebrae in the primary curve.
- Sagittal malalignment was not corrected, leaving an unfused kyphosis that tended to increase over time (17).
- In children fused at a young age, progression can be seen even when the initial fusion correctly addressed the entire primary curve. Over time, additional vertebrae not part of the original scoliotic curve may become involved.

CRANKSHAFT PHENOMENON
Bending of the fusion mass may occur in children fused at an early age. These patients, through growth and remodeling, experience an increase in curve magnitude without an increase in curve length. One of the earliest descriptions of what is now considered the “crankshaft” phenomenon was provided in Ponseti and Friedman's 1950 paper on progressive deformity after fusion (24). Leits and Bobechko (16) reviewed the outcome of children undergoing spine fusion before the age of 8 years and found that 29% had age the curve progressed despite successful arthrodesis. They found that progression was an even bigger problem in children fused at less than 4 years of age. Curve progression was greatest during the rapid growth phase, and the patients who had the greatest problem with this type of curve progression were those with a congenital scoliosis requiring fusion at a very early age. The progressive bending of an apparently solid fusion mass has been explained as the continued growth of the anterior vertebral elements within a spinal segment that has been fused ( tethered) posteriorly (2, 13). As the anterior elements elongate, the vertebral bodies are forced farther out from the midline, increasing both the sagittal and scoliotic deformities. Anterior fusion at the time of the initial posterior surgery prevents this phenomenon.

PROGRESSION OF THE SECONDARY CURVE

A small number of patients present with progressive imbalance and deformity despite appropriate initial treatment and a successful primary fusion. In these patients, the progression occurs in the secondary curve either above or below the primary curve, resulting in significant trunk imbalance and an increase in apparent deformity. Whether this happens because of relentless progression of the secondary curve or the patient's progressive inability to compensate for the fused primary curve, the problem generally begins with a mild to moderate compensatory curve that, with age, becomes more severe and structural.

Progressive lumbar curves are a particular problem in the adult population. Curve progression in the lumbar segments results in low back pain, degenerative disc disease, translational deformities, and, in some cases, nerve root compression in the concavity of the curve. Once these curves become structural, correction may not be possible without simultaneously addressing the previously fused primary curve.

INDICATIONS FOR SURGERY

PAIN

Pain is the most common symptom in patients requiring reconstructive surgery of the spine (2, 17). Generalized pain may involve either the convexity or the concavity of the curve. In the thoracic region, pain over the convexity of the curve usually involves paraspinal muscles overlying the ribs and bony prominence. Patients may also complain of subcapsular or intercapsular pain in the region of the ribmold and levator muscle attachments. Pain on the concavity may be localized to the paraspinal muscles or may be radicular in nature. Thoracolumbar and lumbar curves, pain in the concavity is frequently associated with degenerative disease and facet arthrosis. Translational shifts, commonly seen in degenerative curves of the lumbar spine, may cause severe and debilitating pain related to both segmental instability and muscle spasm, as well as nerve root impingement and stenosis.

Conservative therapy is as appropriate for these patients as for any patient with chronic low back pain. Patients complaining primarily of pain without evidence of curve progression warrant a full course of nonoperative treatment, including physical therapy, anti-inflammatory medications, pain behavior modification, and a trial of bracing, before entertaining surgical options. All reasonable conservative measures should be explored prior to scheduling surgery.

When pain is severe and well localized to a region of previous fusion, suspect a pseudarthrosis. Pain from pseudarthrosis usually increases with activity and improves with rest. The area may be tender; however, if spinal instrumentation is in place, palpation may not produce symptoms. The patient may complain of a popping or grating sensation with movement, fatigue at the end of the day, or a sense that the deformity is progressing. Fixation failure, broken hardware, and progressive deformity strongly suggest the presence of a pseudarthrosis. Standard tomography is the most reliable method of demonstrating the defect.

Patients with pain at the end of a spinal fusion usually suffer at the levels immediately caudal to the fusion mass. This may be related either to discongenic pain or to facet arthrosis. Cochran et al. (3) demonstrated a proportionately greater incidence of degenerative disc disease as fusions are carried more distally. Their study showed that patients with fusions to L-2 had a 20% incidence of symptomatic disc degeneration; those with fusions to L-3, a 40% incidence; those with fusions to L-4, a 60% incidence; and those with fusions to L-5, an 80% incidence. Changes in spinal mechanics result in degeneration of the intervertebral disc and facet joints at the junction of the fused and mobile segments. Disc prolapse, facet hypertrophy, and translational deformities may produce spinal or foraminal stenosis. Patients with these disorders typically have radicular symptoms as well as back pain. Discography, done correctly, is frequently helpful in confirming the diagnosis of a painful disc below a previous fusion (2, 11).

DEFORMITY

A perception of increased deformity is the second most common symptom among patients presenting for revision surgery. Patients frequently sense that the curve has changed in magnitude or contour, and they complain of changes in shoulder alignment, height, or comfort when sitting or standing. They may also complain of alteration in waistline contour or discomfort in the flank caused by impingement of their ribs on the iliac crest. Patients may develop progressive deformity in either the sagittal or coronal plane, or both.

IMBALANCE

Although progressive trunk imbalance is related directly to progression of the deformity, it is a more particular concern in patients with a previous fusion; increasing curvature below a solid fusion, which allows no compensation, can generate a disproportionate imbalance relative to the change in curvature. With age, a previously compensatory curve may become structural, compromising the patient's ability to compensate for the original, static curve. As trunk imbalance increases, the patient's function is progressively impaired, and the pain may increase dramatically.

DYSNEA

While only 15% of patients with idiopathic curves complain of dyspnea, pulmonary dysfunction is much more common in neuromuscular and postpoliomyelitic patients (4, 17). Winter et al. (31) and Weinstein et al. (29) noted that patients with idiopathic scoliosis develop pulmonary insufficiency only when their curves become severe. However, advanced age may significantly aggravate this problem in patients undergoing revision surgery. Scoliosis surgery is more often done to prevent pulmonary complications in high-risk patients than to treat existing or progressive dysfunction.

PREOPERATIVE PLANNING

Obtain upright anteroposterior (AP) and lateral scoliosis radiographs to carefully document the magnitude of deformity and establish the correct end-vertebrae. The lateral view is particularly important because sagittal imbalance is common and debilitating in these patients. Loss of normal lordosis, or marked lateral deviation of the transversospinal axis, characterizes patients who are forced to stand with one or both knees flexed; it is important that upright radiographs be taken with the knees extended to adequately represent the deformity. Other studies include supine, oblique radiographs to evaluate the fusion mass, and tomograms to confirm the presence of pseudarthrosis. Assess spinal rigidity through side-bending views in scoliotic patients, and use hyperextension views, supine over a bolster, for kyphotic deformities. Side-bending films should visualize the full extent of both upper and lower curves, assessing the cervicothoracic junction in thoracic curves and the lumbarcurvular junction in thoracolumbar or lumbar curves. Use magnetic resonance imaging (MRI) or myelography to evaluate any neurologic abnormality in a patient with progressive scoliosis. Diametamytelica, tethered cord, syringa, and cord or root compression may be ruled out by using these studies.

Careful evaluation of pulmonary reserve is always important in adults, where pulmonary complications are common and potentially life-threatening. Pulmonary function testing is indicated in any patient complaining of dyspnea and in all those with neuromuscular or chronic pulmonary disease. Patients with a severe thoracic lordosis, with a reduced AP chest diameter, may also need pulmonary function testing even if asymptomatic. A medicine consultation is often appropriate for middle-aged patients preparing to undergo a major spine reconstruction, and it is particularly important in those with underlying cardiovascular, pulmonary, or renal disease.

Autologous blood donation is beneficial and should be initiated 3–4 weeks prior to the operation. Prescribe supplemental iron for any patient donating her own blood.

TREATMENT

The key to treating most failures of scoliosis fusion is early identification of the problem. If a pseudarthrosis or failure of fixation is identified in the early postoperative phase, reintubation can be carried out easily without osteotomies or major reconstruction. Likewise, if progression of an adjacent compensatory curve is identified early, it may be corrected by simply extending the fusion while the curve is still supple. If these problems are neglected for long, however, compensatory curves may become structural and pseudarthroses may lead to progressive deformity and decapsulation. In these patients, reconstruction and hardware revision can be
PSEUDARTHROSIS

Pseudarthrosis may be present with or without progressive deformity. In cases with no loss of correction, the surgeon may address the pseudarthrosis directly, retaining or replacing hardware as necessary.

- After exposing the fusion mass over its full length, strip the thickened periosteum laterally with Cobb elevators. Carefully expose the cortical bone of the fusion mass and its length and from transverse process to transverse process.
- At the pseudarthrosis, the periosteum will be bound down to the fibrous tissue insinuated into the bony defect. At this point, it becomes difficult to strip the periosteum away, and the persistent fibrous tissue left behind reveals the defect.
- The fusion defect is usually located at the level of unfused facets. Using curets and rongeurs, remove this fibrous tissue completely from the pseudarthrosis.
- Expose the facet joints, remove any residual fibrous tissue or articular cartilage, and pack the joints with cancellous autograft bone. If the transverse processes were not previously exposed, strip away the soft tissue and decorticate the bone prior to applying the bone graft.

If pseudarthrosis is associated with progressive deformity, correct the deformity at the time of the pseudarthrosis repair. Better curve correction at the time of revision surgery correlates with a significantly better fusion rate (15). Increased age, lower lumbar pseudarthrosis, and nonsegmental instrumentation are associated with a significantly higher rate of salvage failure.

- If segmental instrumentation is in place and in good alignment, do not remove it to treat the pseudarthrosis. Revise hardware that has failed or is loose, however.
- Remove and replace nonsegmental instrumentation with segmental fixation: Pseudarthrosis repair using Harrington rods is successful in fewer than 60% of patients, while repair using segmental instrumentation has provided 100% success in some series (15,36).
- Substitute a shorter construct at the site of the pseudarthrosis, if possible, to avoid reinstrumenting the entire spine.
- In a mature fusion, insert compression hooks through the dorsal cortex of the fusion mass without entering the neural canal.
- Place pedicle screws in the thoracolumbar region to restore fixation where hooks have failed. Position pedicle screws under fluoroscopic or stereotactic control.
- Once the pseudarthrosis has been debrided of all soft tissue, decorticate the facets and pack the defect with cancellous bone. Then reapply the instrumentation, decorticate the fusion mass extensively with a gouge, and reapply local and autograft bone to obtain fusion.

In patients with failed pseudarthrosis repairs, and in adult patients with risk factors for delayed healing or recurrent pseudarthrosis, perform anterior interbody fusion in conjunction with the posterior repair. Particularly in pseudarthroses of the lower lumbar spine or where fusion crosses the lumbosacral junction, anterior interbody fusion increases the chances of a successful arthrodesis. Likewise, in patients with pseudarthrosis and progressive deformity, anterior release and fusion may be necessary to obtain sagittal correction and maximize the chance of a solid fusion. The debilitating sagittal imbalance associated with the lumbar flatback syndrome is most successfully corrected through a combined approach, coupling anterior osteotomy and interbody fusion with posterior osteotomy or pseudarthrosis repair and instrumentation (13).

FIXATION FAILURE

Failure of fixation in the early postoperative period is usually heralded by the sudden onset of severe pain. Pain is usually well localized to the region of failure, and the displaced hook or rod is sometimes palpable through the skin. There is sometimes an associated episode of trauma, and symptoms may begin several days before the instrumentation actually displaces. If the patient's curve was particularly rigid, or if poor bone quality or severe rotation made fixation particularly difficult, have a higher index of suspicion for hardware displacement.

There are three options for treatment:

1. First, if correction has not been lost and the patient's pain is tolerable, postpone surgical revision and treat the patient in a rigid orthosis until fusion occurs. Solid fusion of the operated segments will eliminate the problem of the displaced hardware, and any prominent hardware can be removed at a later date if necessary.
2. A second option is to reoperate, and either reinset the dislodged hook or remove it, shortening the construct. This may reduce the patient's pain and eliminate the prominent hardware, but it could lead to a loss of correction.
   - If the dislodged hook is surgically replaced, take care to see that other fixation hooks are not displaced during the revision.
   - Carefully inspect the lamina under which the hook was seated to ensure that it is not fractured and that the bone is sound enough to allow rigid fixation; reinstrumenting a damaged or disrupted lamina is unwise.
   - If you choose to remove the dislodged hook and shorten the instrumentation construct, you may significantly compromise construct stiffness. Only when fusion is established and curve progression is unlikely does removal of an end-hook make good sense.
3. The third option is to revise the hardware with a modified construct. This is most often necessary in patients with end-hook displacement, particularly those with rigid curves. In these cases, revising the terminal segment fixation may salvage the overall construct.
   - Where a single hook has pulled out or dislodged, a claw configuration may provide rigid fixation and salvage the construct.
   - Salve a transverse process fracture by applying a sublaminar hook in place of the transverse process hook.
   - Use one or two pedicle screws on the convex side to salvage hook failure in lower lumbar curves (Fig. 163.1).

Figure 163.1. Pedicle screws can be used to salvage sites where hooks have loosened or pulled through the lamina. Orientation of the pedicles is determined on preoperative computed tomography. Pedicle screw fixation allows the surgeon to reinstrument the spine without extending the fusion to adjacent segments.

When the vertebral lamina has been so disrupted by hook pullout that it is unsalvageable, you must make a critical judgment. If shortening the construct to the next intact lamina will compromise fixation of the appropriate segments of the curve, then the instrumentation must be extended over a longer segment. This may necessitate removal of the previous instrumentation.

- In some cases it may be possible to salvage and lengthen an instrumentation construct by using “domino” rod connectors, extending the construct to the next stable level. This provides a bulky construct, however, which is more acceptable in the lumbar region than in the upper thoracic segments. This technique is particularly useful if fusion must be extended to the sacrum. Short segmental rods may be fixed to the sacrum either directly, using pedicle screws, or using a Galveston technique to instrument the iliac wings. These rods are then joined to the original construct using the “domino” connectors.

If the fixation rod has broken, then the whole construct must be replaced. All hook and screw attachments should be checked in the process. Reactive bone often reinforces the hook or screw insertion site, and these implants may be left in place. If the hook or screw site has been eroded by excessive motion or has fractured, a new fixation point must be chosen, or a different implant used—exchanging a pedicle screw for a hook, for example.

PROGRESSIVE DEFORMITY

In patients who have progressive deformity because of multiple pseudarthroses, adding unfused segments or bending the fusion mass may require multiple osteotomies, reinstrumentation, and extensive fusion before the spine is adequately corrected, stable, and balanced over the sacrum.
When a progressive curve develops below a previous thoracic fusion, correct the upper curve when you correct the lumbar curve to avoid causing significant coronal imbalance (Fig. 163.2).

**OPERATIVE TECHNIQUE**

In cases where the deformity is severe and rigid, it is necessary to perform anterior release and interbody fusion prior to posterior reconstruction. Both procedures may be performed under one anesthetic, but the two procedures in combination are time-consuming and demanding on both surgeon and patient. If excessive blood loss occurs or the patient experiences problems, perform a two-staged procedure.

- **For the anterior procedure**, place the patient in a lateral decubitus position. Establish appropriate monitoring lines prior to positioning the patient: Arterial and central venous lines are usually indicated, and some patients may require Swan-Ganz catheterization to more carefully monitor pulmonary pressures and cardiac output.
- Position the patient with the convexity of the most rigid and severe curve upward.
- Use a transthoracic or thoracolumbar surgical approach, taking one rib, or in some cases two, to expose the anterior spinal column.
- Expose as many interspaces as can be reached and excise the discs.
- Isolate and ligate segmental vessels on one side only, and spare particularly prominent vessels.
- If the patient has a severe kyphosis, peripheral vascular disease, or any other risk factor for cord ischemia, place a “bull-dog” vascular clip across the segmental vessels to temporarily occlude segmental flow. Spinal cord monitoring may then determine whether the vessel is crucial to cord perfusion.
- Once the interspaces are exposed, remove the discs with a scalpel and rongeurs, and remove the endplates with a sharp osteotome directed away from the spinal canal. In very rigid deformities, it may be necessary to release the entire posterior longitudinal ligament and lateral annulus before correction can be obtained. This is not necessary in more supple curves.
- When the endplates have been removed, morcelize iliac crest or rib graft and gently pack it into the interspace. Do not entirely fill the interspace with bone, as this may interfere with correction during the posterior procedure.
- Correct kyphotic segments by distracting the disc space anteriorly with a large vertebral body spreader and inserting a tricortical graft or titanium cage to restore spinal canal. In very rigid deformities, it may be necessary to release the entire posterior longitudinal ligament and lateral annulus before correction can be obtained.
- At the end of the anterior procedure, pull the pleura, or the paraspinal muscles in the thoracolumbar region, gently over the spinal column to prevent graft extrusion.
- Place a chest tube and close the wound.
- **For the posterior part of the procedure**, turn the patient or dress the wound and return the patient to the intensive care unit in anticipation of a staged posterior fusion.
- Perform the posterior reconstruction through the old surgical wound. Expose the old fusion mass and the spinous processes and lamina of the secondary curve.
- Obtain a radiograph after the rigid and compensatory curves are fully exposed, to verify levels.
- Perform thoracic osteotomies at levels previously chosen in the preoperative plan (Fig. 163.3). Center the initial osteotomy over the apex of the curve, and subsequent osteotomies at every second level above and below the apex for the length of the previous fusion (Fig. 163.3).
- Take care to complete the osteotomy across the full width of the fusion, and to take a wide enough wedge to allow correction of the scoliosis.
- Remove the outer cortex with either a burr or rongeurs, creating a defect that spans the fusion mass just below the transverse processes (Fig. 163.4).
- Remove the cancellous bone down to the anterior, or volar, cortex of the fusion mass. To avoid plunging through the inner cortex, direct the forces away from the midline and in an axial direction (Fig. 163.4).

---

*Figure 163.2.* AP (A) and lateral (B) views of a 36-year-old woman with Marfan syndrome who presented 20 years after an in situ thoracic fusion for scoliosis (T-6 to T-12). She had low-back pain, progressive shoulder asymmetry, and progressive thoracic and lumbar deformities. The lateral view shows a significant thoracolumbar kyphosis, centered at T-9, which resulted in sagittal imbalance. The thoracic fusion was substantial and solid. (From McLain RF. Revision and Salvage in Deformity Surgery. Semin Spine Surg 1993;5:214, with permission.)

*Figure 163.3.* The preoperative plan for the patient in Figure 163.2. To correct the progressive lumbar curvature without precipitating a marked thoracic imbalance, multiple osteotomies were planned as indicated. The initial osteotomy was centered over the curve apex; subsequent ones were located at every second level above and below the apex. (From McLain RF. Revision and Salvage in Deformity Surgery. Semin Spine Surg 1993;5:214, with permission.)

*Figure 163.4.* Osteotomy technique. See text for details. (From McLain RF. Revision and Salvage in Deformity Surgery. Semin Spine Surg 1993;5:214, with permission.)
A key to a good surgical result is careful preoperative planning. In those patients who do develop rigid curvatures with marked loss of correction, early recognition of curve progression or pseudarthrosis remains the most reliable way to limit the complications associated with reconstructive surgery of the scoliotic spine. Improvements in preoperative planning, patient management, surgical technique, and instrumentation technology will not eliminate the common complications in revision scoliosis surgery. The overall complication rate for primary surgery ranges from 53% to 62%, with a mortality rate of roughly 1.5%. Thromboembolic disease and pulmonary embolism are likely to remain high, particularly in older patients and those with multiple medical comorbidities. Currently, protocols for deep venous thrombosis prophylaxis and the routine use of prophylactic antibiotics have significantly reduced the incidence of pulmonary embolism and deep wound infections over those seen in previous studies. Likewise, the use of autograft bone and improved techniques in instrumentation and surgical fusion should reduce pseudarthrosis rates. Nonetheless, complications in revision scoliosis surgery are likely to remain high, particularly in older patients and those with neurovascular or paralytic disorders.

Postoperative care begins with the immediate recognition and management of complications. The overall incidence of pseudarthrosis in this group was 23%, as opposed to a 6.5% incidence in adults undergoing primary fusion. He noted a 10% incidence of pulmonary complications, including nine pneumothoraces. The overall incidence of pseudarthrosis in this group was 23%, as opposed to a 6.5% incidence in adults undergoing primary fusion. He noted a 10% incidence of pulmonary complications, including nine pneumothoraces.

Immediate complications are common in adults undergoing scoliosis surgery, and even more frequent when it is revision surgery. Complications in revision scoliosis surgery include the following:

- Pneumothorax, pneumonia, and/or respiratory insufficiency
- Infection
- Persistent or adjacent-level pseudarthrosis
- Instrumentation failure
- Neurologic injury
- Sagittal or coronal imbalance
- Thromboembolic disease and pulmonary embolism
- Death (1% to 2% mortality rate)

Swank et al. (26) demonstrated that the risks associated with scoliosis surgery appear to go up with each decade of life. The overall complication rate for primary surgery ranges from 53% to 62%, with a mortality rate of roughly 1.5%. Floman et al. (27) reviewed 59 patients undergoing reconstructive surgery for failed scoliosis fusion. The overall complication rate was 71%, with two postoperative deaths (3.4%) in the group. They noted a 17% incidence of pseudarthrosis, a 5% incidence of pulmonary complications, and an 8% incidence of deep wound infections. There was one fatal and one nonfatal pulmonary embolism in this study group.

Semin Spine Surg

HINTS AND TRICKS

- Monitor patients postoperatively to maintain an adequate blood pressure. Postoperative hypotension can lead to cord ischemia, particularly after extensive anterior dissection or multiple procedures that may have compromised collateral blood flow. Case reports have documented transient and permanent neurologic injuries associated with episodes of postoperative hypotension (27,29).

Current protocols for deep venous thrombosis prophylaxis and the routine use of prophylactic antibiotics have significantly reduced the incidence of pulmonary embolism and deep wound infections over those seen in previous studies. Likewise, the use of autograft bone and improved techniques in instrumentation and surgical fusion should reduce pseudarthrosis rates. Nonetheless, complications in revision scoliosis surgery are likely to remain high, particularly in older patients and those with neurovascular or paralytic disorders.

Improvements in preoperative planning, patient management, surgical technique, and instrumentation technology will not eliminate the common complications associated with reconstructive surgery of the scoliotic spine. Early recognition of curve progression or pseudarthrosis remains the most reliable way to limit the complexity of these challenging reconstructions. In those patients who do develop rigid curvatures with marked loss of correction, careful preoperative planning is the key to a good surgical result.

CHAPTER 164

OPERATIVE TREATMENT OF CHILDREN’S FRACTURES AND INJURIES OF THE PHYSES

George T. Rab and Brian E. Grottkau

General Approach to Surgery

Fracture treatment in children is often simpler than in adults because of the rapid healing and remodeling of bone that occurs in children. A perceptive surgeon realizes that children differ a great deal from adults and care of their fractures can be affected by a child's preinjury status, the specific fracture mechanics of childhood injuries, the response to injury, and the unique treatment problems and complications that occur in the pediatric age group.

Although fracture management in children is usually nonoperative, there are certain instances when surgical management is required, desirable, or optional. Open surgical treatment is indicated in certain physeal fractures where there is joint incongruence and closed reduction has not led to satisfactory position, and where exact reduction improves the chances of normal physeal growth. Open reduction should be performed when anatomic reduction is required for normal function, as in a displaced, both-bone forearm fracture in an older adolescent. Surgical treatment should be considered in children with multiple trauma if stabilization of major long-bone fractures will enhance nursing care and pulmonary management. It should also be considered in children with major long-bone fractures (especially femoral shaft) in the presence of a severe head injury.

An additional relative indication for open reduction and internal fixation is to alleviate the psychological stress of either children or parents associated with prolonged hospitalization. An example is a 13-year-old boy with a closed midshaft femoral fracture that would eventually heal with skeletal traction and spica-cast treatment—a treatment that might take 8 weeks or more. A closed intramedullary nail would allow rapid mobilization, discharge from the hospital in a few days, and return to home and school within 1 week.

PHYSEAL INJURIES

The Salter–Harris classification of injuries to the growing physis is widely accepted in North America (Fig. 164.1):

- **Type I**: Separation of the epiphysis
- **Type II**: Separation of the epiphysis with fracture through the metaphysis
- **Type III**: Intra-articular fracture of part of the epiphysis that extends through the physis, causing it to separate from the metaphysis
- **Type IV**: Intra-articular fracture of part of the epiphysis that extends through the physis and the metaphysis (malreduction of the physis results in bony union across the growth plate at the fracture site).
- **Type V**: Crush injury to the physis resulting in premature closure of the growth plate
- **Type VI**: Avulsion or crushing of the peripheral physis

Specific injuries are covered elsewhere in this chapter, but some general principles will be reviewed here. Nondisplaced fractures through the growth plate tend to be stable and require immobilization without internal fixation. Minimally displaced growth-plate injuries do not require reduction, and the chance of growth arrest is not increased by leaving them displaced. Displaced fractures requiring reduction should be treated early (within 48 hours) because growth arrest is common after attempts at late reduction. Atraumatic fracture reduction and suitable fixation (casting or surgical) are mandatory.

The younger the patient, the more remodeling potential exists and greater degrees of displacement are acceptable. However, younger patients in whom physeal arrest develops have a greater potential for deformity. Likewise, a growth plate that requires higher energy to cause failure because of its geometry tends to have a higher rate of problems with growth arrest. For instance, the distal femoral and proximal tibial growth plates are only rarely injured but are responsible for the majority of longitudinal and angular growth abnormalities following growth-plate fracture. Salter–Harris types III and IV fractures require anatomic reduction of both the growth...
plate and the articular surface; thus they frequently require open reduction with internal fixation.

An extensive discussion of operative fracture management of children's fractures is beyond the scope of this chapter. Following are descriptions of techniques that we have found useful for the surgical treatment of common pediatric injuries, as well as uncommon injuries requiring surgery. This chapter includes some generalizations and personal preferences in both indications and treatment options; readers should consult fracture textbooks and the scientific literature for more extensive descriptions.

UPPER EXTREMITY

PROXIMAL HUMERAL EPIPHYSEAL FRACTURES

Fractures of the proximal humerus (6,16,40,49) are most frequently seen in neonates and adolescents. Neonatal fractures are typically Salter–Harris type I injuries caused by an abduction–external rotation force imparted during the process of delivery. Orthopaedic consultation is obtained in these cases because a neonate will not actively move the involved extremity. Fracture of the clavicle, Erb's palsy, and infection are the main differential diagnoses. Radiographs may not be helpful, although ultrasonography yields a clear representation of this cartilaginous injury. Simple immobilization of the arm to the trunk with a loose elastic bandage for 1–2 weeks allows complete healing.

Adolescents are more prone to Salter–Harris type II and metaphyseal fractures of the humerus. Most of these can be managed by splinting because remodeling is rapid in this region and anatomic reduction is not required for excellent function. Fortunately, physiologic growth arrest is rare and neurovascular injury uncommon. Closed reduction is generally necessary only in patients near skeletal maturity whose fracture has greater than 50° to 70° of angulation in either the sagittal or the coronal plane. After initial muscle spasm abate after treatment in a sling for 5–7 days, however, fracture alignment frequently improves enough to eliminate the need for closed reduction. If closed reduction does not yield an acceptable position, reduction under anesthesia with shoulder spica-cast immobilization usually suffices. On occasions when a spica cast may not be appropriate (e.g., when there is a chest injury), surgical fixation may be accomplished by introducing a large, smooth Steinmann pin into the reduced humeral head through a 1 cm incision over the deltoid tubercle. Bend the pin end to decrease the chance of proximal migration, and immobilize the arm with a sling and swath. Image intensification is necessary, and it is surprisingly difficult to place the pin in the head with enough purchase to fix the fracture. Remove the pin at 3–4 weeks.

SUPRACONDYLAR FRACTURES OF THE HUMERUS

Supracondylar humeral fractures (2,24,41,54,64,68,73) have the highest rates of complications of any pediatric fracture. Volkman's ischemic contracture due to compartment syndrome, neurologic or vascular compromise, and cubitus varus have historically complicated the treatment of these fractures. Supracondylar fracture of the humerus is a surgical emergency, and prompt reduction and stabilization will reduce the incidence of complications. Although closed methods of immobilization may be used, percutaneous pin fixation has emerged in the last decade as the preferred method for unstable, displaced fractures. Pin fixation, properly done, is a low-risk procedure that provides excellent control of fracture fragments, nearly eliminating the risk of cubitus varus that accompanies cast immobilization. In addition, percutaneous pinning allows partial extension of the elbow without loss of reduction, which is much safer when there is swelling and vascular compromise.

Before attempting reduction, carefully evaluate the extremity for neurovascular compromise or compartment syndrome (usually in the flexor compartment of the forearm). After the fracture has been noted, the findings in the child can be placed in one of two categories. In the first, the pulse may not be palpable at this time. In the second, the pulse may be palpable. If palpable, it through the opposite cortex of the proximal fragment. Place a second pin in a similar manner. Withdraw the needles, bend the pins outside the skin to avoid migration, and apply pin caps (Figs. 164.3).

Posteromedial displacement is more common than posterolateral displacement. Regardless of the direction of displacement of the distal fragment in an extension-type supracondylar fracture, the posterior periosteum is generally intact and may be used to assist reduction. Most supracondylar fractures occur with the forearm in pronation; therefore, the distal fragment is internally rotated relative to the proximal fragment. Thus, most are more unstable after reduction with the arm internally rotated, a fact that has implications when radiographs are obtained (see later discussion).

Approximately 2% of supracondylar fractures are anteriorly displaced as a result of a flexion force applied to the elbow. The remaining supracondylar fractures are caused by hyperextension injuries of the elbow. They have been classified by Wilkins (23) as follows:

- **Type I**: Nondisplaced
- **Type II**: Displaced with an intact posterior cortex
- **Type III**: Completely displaced

Posteromedial displacement is more common than posterolateral displacement. Regardless of the direction of displacement of the distal fragment in an extension-type supracondylar fracture, the posterior periosteum is generally intact and may be used to assist reduction. Most supracondylar fractures occur with the forearm in pronation; therefore, the distal fragment is internally rotated relative to the proximal fragment. Thus, most are more unstable after reduction with the arm internally rotated, a fact that has implications when radiographs are obtained (see later discussion).

Closed Reduction and Percutaneous Pinning

1. Place the patient in the supine position, and administer a general anesthetic. Use an image intensifier in a vertical position next to the table. The receiver can be used as a minitable to set the arm on.

2. Perform closed reduction by manually distracting the fracture with the elbow slightly hyperextended and the forearm in supination. Correct the medial or lateral displacement, and then align the varus–valgus position of the arm to match the opposite normal elbow. While still distracting, flex the supinated arm while pushing posteriorly on the distal portion of the humeral shaft (proximal fragment). Flex the elbow acutely, and temporarily hold it flexed by wrapping a gauze or tape between the wrist and shoulder (Fig. 164.24); pronation of the forearm to "lock" the fracture is unnecessary if percutaneous fixation is to be used. The pulse may not be palpable at this time.

- **Figure 164.2.** Surgical technique for percutaneous pinning of supracondylar fracture of the humerus. A: The hand and wrist are secured to the upper arm. B: AP and lateral image intensifier views are obtained by rotating the arm. C: A 14-ga needle is useful as a pin guide. See text for explanation.

3. Check an anteroposterior (AP) image, using the image intensifier. Obtain a lateral view by externally rotating the flexed arm on the image intensifier (Fig. 164.2B); internal rotation can destabilize the fracture at this point and cause loss of reduction. Exact anatomic reduction is unnecessary, but the carrying angle should be restored. Some translation or angulation on the lateral x-ray film is acceptable because it should correct with remodeling.

4. Percutaneous pinning requires two pins, usually 0.045 Kirschner wires (K-wires), both of which may be inserted from lateral and parallel or from medial, lateral, and crossed. If crossed, they should not cross at the fracture site. Although crossed pins have been shown to be biomechanically advantageous, two parallel lateral pins are safer. An ulnar nerve palsy may result from injury to the nerve at the time of insertion of a medial pin or from chronic contact with the pin throughout the course of treatment. These neurotmeses usually resolve in 3–4 months. When a medial pin is used, massage the medial epicondyle for a few minutes to "milk out" edema to be sure that the ulnar nerve is avoided, or insert the pin through a 1 cm incision under direct visualization. If the medial epicondyle cannot be palpated, two lateral pins must be used. In either event, the pins must pass through the distal fragment and engage the opposite cortex of the proximal (shaft) fragment by passing just through the entire cortex. We always use two lateral pins, if possible.

5. To make pinning easier, insert a 14-gauge needle into the periosteum of the distal fragment laterally at the desired angle of the pin (Fig. 164.2C). Obtain AP and lateral views (by external rotation), using the image intensifier. After adjustment of the direction of the needle, insert an 0.045 K-wire through the needle, and drill it through the same periosteal cortex of the proximal fragment. Place a second pin in a similar manner. Withdraw the needles, bend the pins outside the skin to avoid migration, and apply pin caps (Fig. 164.3).

6. Check an anteroposterior (AP) image, using the image intensifier. Obtain a lateral view by externally rotating the flexed arm on the image intensifier (Fig. 164.2B); internal rotation can destabilize the fracture at this point and cause loss of reduction. Exact anatomic reduction is unnecessary, but the carrying angle should be restored. Some translation or angulation on the lateral x-ray film is acceptable because it should correct with remodeling.

7. Percutaneous pinning requires two pins, usually 0.045 Kirschner wires (K-wires), both of which may be inserted from lateral and parallel or from medial, lateral, and crossed. If crossed, they should not cross at the fracture site. Although crossed pins have been shown to be biomechanically advantageous, two parallel lateral pins are safer. An ulnar nerve palsy may result from injury to the nerve at the time of insertion of a medial pin or from chronic contact with the pin throughout the course of treatment. These neurotmeses usually resolve in 3–4 months. When a medial pin is used, massage the medial epicondyle for a few minutes to "milk out" edema to be sure that the ulnar nerve is avoided, or insert the pin through a 1 cm incision under direct visualization. If the medial epicondyle cannot be palpated, two lateral pins must be used. In either event, the pins must pass through the distal fragment and engage the opposite cortex of the proximal (shaft) fragment by passing just through the entire cortex. We always use two lateral pins, if possible.
Open Reduction

perform open reduction because the joint surface is often remarkably displaced.

have advocated closed reduction and pinning for selected minimally displaced lateral condylar injuries (G.

The indication for surgical management of lateral condylar fractures is displacement, either acute or progressive, of the visible fragments by more than 2 mm. Some have advocated closed reduction and pinning for selected minimally displaced lateral condylar injuries (447) as determined by intraoperative arthrography. We generally perform open reduction because the joint surface is often remarkably displaced.

Supracondylar Fractures with Vascular Injury

Displaced (Salter–Harris type III) supracondylar humeral fractures may be associated with injury to the brachial artery. The brachial artery and the median nerve are juxtaposed to the fracture site and thus are subject to direct and stretch injury at the time of fracture and reduction. A well-documented neurovascular examination before closed reduction is mandatory to avoid unnecessary exploration afterward. Brachial artery compromise may be due to acute thrombi, intimal tears, laceration, transection, or entrapment within the fracture site. Absence of a radial pulse or the presence of a mottled arm and hand is an indication to proceed urgently to surgery for closed reduction. Do not delay treatment because circulation returns with fracture reduction. Because the site of vascular compromise is known, angiography is usually not necessary.

If an absent pulse does not return after reduction and extension, make a decision based on clinical examination of the hand. If the fingers are pink and well perfused, it is safe to observe, even if pulses are present. If the fingers are dusky, exploration of the artery is indicated.

If the pulse was present before reduction but absent afterward, obtain a vascular surgery consultation. The vascular surgeon may choose to obtain an angiogram with the image intensifier on the operating-room table or proceed directly to exploration. If revascularization is needed, closely monitor the patient for compartment syndrome, and give serious consideration to performing prophylactic forearm compartment releases.

Open Reduction

If an adequate closed reduction cannot be attained, consider an open reduction. Remember that anterior-to-posterior translation and angulation are generally acceptable, and even the AP radiograph does not need to be anatomic as long as the carrying angle is satisfactory with the elbow extended. Open reduction usually proves to be more difficult than anticipated. Use a surgical approach on the side of the largest fracture gap. Periosteum and the brachial muscle, nerve, and artery can all block reduction and should be looked for and extricated. Open reduction has not been associated with increased stiffness in children with this complication.

LATERAL CONDYLAR FRACTURES OF THE HUMERUS

Lateral condylar fractures (4,22,23,30,37,47,65,74) usually occur as the result of a fall on an outstretched hand and consequently are Salter–Harris type IV intra-articular fractures, with the initial failure beginning at the capitellar or trochlear surface. Errors in interpretation of the radiograph can lead to a missed diagnosis. Such fractures may be mistaken for type II fractures because of their metaphyseal component (Fig. 164.4A), but they are usually highly unstable injuries that require surgical treatment. Lateral condylar fractures that are truly nondisplaced may be treated nonoperatively, but they must be radiographed weekly because they have a propensity to displace late.

True type II fractures (transcondylar fractures) may be seen in children approximately 2 years of age. They are usually hyperextension injuries and are analogous to supracondylar fractures. They can be distinguished from lateral condylar fractures by their longer, more posterior metaphyseal fragment. Closed reduction (occasionally together with percutaneous pinning) is appropriate for these injuries.

The indication for surgical management of lateral condylar fractures is displacement, either acute or progressive, of the visible fragments by more than 2 mm. Some have advocated closed reduction and pinning for selected minimally displaced lateral condylar injuries (447) as determined by intraoperative arthrography. We generally perform open reduction because the joint surface is often remarkably displaced.

Open Reduction
Under tourniquet control, make a curved longitudinal incision over the lateral humeral condyle. There is usually a longitudinal rent in the brachioradialis muscle; develop this interval and carefully expose the lateral margin of the condyle. Take great care at this point to keep all subsequent dissection anterior to the condyle because the blood supply of the capitellum lies posteriorly and a major complication of this procedure is osteonecrosis of this fragment.

- Open the elbow joint, and retract the synovium anteriorly, using the long end of an army–navy retractor. The distal fragment is frequently rotated up to 90° and may be much larger than expected, including a sizable portion of the cartilaginous trochlea.
- Gently clean the fracture ends of hematoma and fibrous tissue, and reduce the fracture. Reduction may be unstable. Sometimes, stability is facilitated by inserting a K-wire in the fragment and using it as a “joystick” to control the fragment; however, be careful to plan its insertion point so that it may be used later to fix the fracture.
- Fix the fracture with two K-wires (Fig. 164.4B). If the metaphyseal fracture is large, they may pass through it, but often they must begin in the distal cartilaginous portion of the condylar fragment. Leave a space of at least 3 mm between the wires, and pass them just through the medial cortex of the proximal shaft to ensure stability. Bring the wires out through small stab wounds in the skin in the appropriate site. Bend the ends to prevent migration and place pin caps.
- Close the wound with fine, absorbable suture. Apply a splint at 90° of elbow flexion.

Remove the pins and splint at 4 weeks postoperatively, and begin motion as tolerated. Immobilization beyond 4 weeks is unnecessary.

The most common complications of lateral condylar fractures in children are missed diagnosis, nonunion, malunion, lateral growth arrest, and cubitus valgus. Tardy ulnar nerve palsy is possible late but fortunately is rare. Fractures treated by cast immobilization only that do not heal by 8 weeks after the injury should be treated with pin fixation and in situ bone grafting of the metaphyseal portion. If an arthrogram shows contrast agent between the capitellum and the trochlea, then do an open reduction with pin fixation. This can be done as late as 8 weeks after the injury. If contrast does not penetrate the fracture, then we pin the fracture percutaneously to add stability and facilitate healing. Leave wires in for 6 weeks, and then remove them.

Nonunions that are older than 12 weeks are difficult to treat. If the fracture is pain-free and there is no joint instability, treatment is not required. This avoids the possibility of stiffness secondary to bone grafting.

**RADIAL NECK FRACTURES**

Radial neck fractures (27,38,50,57,67,72) generally occur as a consequence of a fall on an outstretched hand that causes buckling and impaction of the radial neck. They are uncommon injuries. Their treatment is highly controversial because they often have good potential for remodeling and the results of open reduction are often poor. Despite the relatively minor appearance of some of these fractures, they are significant injuries, and compartment syndrome may occur.

Unless there are other considerations, we do not reduce fractures with angulations of 45° or less, particularly in children younger than 10 years. With greater angulation, closed manipulative reduction or percutaneous reduction techniques are indicated (Fig. 164.5). Remember that open reduction can be complicated by elbow stiffness, heterotopic ossification, growth arrest, and synostosis. A percutaneous technique described by Metaizeau uses a curved K-wire inserted retrograde into the canal from the distal radius (27). We have no experience with this technique, but it has been reported to be simple and effective.

**Closed or Percutaneous Reduction**

- Under general anesthesia, attempt a closed reduction first; an assistant is helpful. Supinate the forearm, apply traction and varus stress to the elbow, and place the thumb over the radial head. By pronation and supination of the forearm, the deformity may be palpable. When the radial head feels most prominent, reduce the fracture by forceful pressure with the thumb (Fig. 164.5A). An image intensifier may be helpful for localizing the deformity. If reduction to 45° or less is obtained, accept the reduction, and immobilize the elbow in a splint for 3 weeks.
- If reduction fails, rotate the forearm so that the tilt of the radial head is maximal, and pass a Steinmann pin percutaneously just below (distal to) the physis of the radial head, using the image intensifier. Use the Steinmann pin to push the head fragment back to an acceptable position (Fig. 164.5B). If this succeeds, immobilize the elbow for 3 weeks.
- If this fails in an older child with an ossified radial head, a third option is to carefully pass an 0.035 K-wire transversely into the ossified radial head (be sure not to damage the physis). Use this wire to manipulate the head fragment into an improved position (Fig. 164.5C).
- If both of these percutaneous techniques, if the fracture is unstable, it may be held for 2–3 weeks with a small K-wire inserted percutaneously obliquely, usually from proximal to distal, from the radial head to the shaft fragment. Be careful when using pins for manipulation or fixation near the radial head not to pass through the radius into the ulna, even one pass may cause synostosis.

**MEDIAL EPICONDYLAR FRACTURES OF THE HUMERUS**

There has been much debate in the literature regarding the proper treatment of medial condylar fractures of the humerus (24,79), with particular concern about how much displacement of the fragment is acceptable. The true significance of this fracture, however, is that avulsion of the epicondyke is due to a subluxation or dislocation of the elbow joint. Consequently, the fracture should be thought of as similar to a medial collateral ligament injury, and the proper treatment is dictated by the instability of the elbow and not by some arbitrary degree of fracture displacement seen on radiographs.

The prognosis after medial condylar fractures is guarded. Periarticular injury may accompany an elbow dislocation, whether recognized or not, and can lead to permanent loss of elbow motion of a magnitude unexpected in a child. Warn parents about this early in the course of treatment. The medial epicondyle has a tendency to enlarge because of hyperemia after surgery; thus, the cosmetic result may be compromised after treatment.

Indications for operative reduction and fixation of medial condylar fractures include the following:

- Incarceration of the medial condylar fragment in a dislocated, unreducible elbow
- Gross valgus instability of the elbow
- Displacement of 1.5–2 cm if accompanied by rotation of the fragment and marked weakness of the forearm flexors
- Displacement of 1–2 cm in the dominant elbow of a child heavily involved in throwing sports

However, these indications, which we use, are arbitrary, and each child must be individually evaluated. The surgical technique is straightforward, but take care to avoid injury to the ulnar nerve during the dissection. Fixation may involve either K-wires or small-fragment screws because the amount of growth remaining in the usual patient is so small that cubitus varus will not develop.
FOREARM FRACTURES

In children younger than 10–12 years, closed management of forearm fractures (3,17,51,56,62,77) is usually successful. Growing children exhibit excellent remodeling potential, and angular and rotational deformities up to 15° are well tolerated. In older children, treatment can be closed, as long as reduction achieves satisfactory alignment, because union is rapid and stiffness unlikely. Adolescents with both-bone forearm fractures, however, represent a transitional situation between that of young children (who tolerate imperfect reduction) and that of adults (who generally require open reduction). We treat both-bone forearm fractures in older adolescents with open distal radial or ulnar physes, regardless of age, by performing closed reduction first; if the reduction is anatomic or nearly so, we accept it and follow the child with weekly radiographs until union occurs. If the reduction is not acceptable, we proceed with open reduction, using either one-third tubular plates or 3.5 mm compression plates and the same technique employed in adults (see Chapter 16). In most cases, it is wise to use the larger, 3.5 mm plate because nonunion is not unusual in this age group. After open reduction, immobilize the forearm in a long-arm cast until union occurs.

Occasionally, in younger children, diaphyseal both-bone forearm fractures either cannot be reduced by closed means or, once reduced, are too unstable to maintain the reduction in a cast (usually when the fractures are at the same level in the bone). Unreducible fractures may require a small incision to remove soft tissues blocking the reduction. An intramedullary K-wire or flexible nail can then be introduced either proximally through the olecranon in the ulna or distally in the radial metaphysis. Flynn (22) showed that intramedullary fixation of a single bone in both-bone forearm fractures in conjunction with long-arm casting results in excellent fracture fixation. The pins are left outside the skin and the ends bent over. They can be removed in the office 4–6 weeks after insertion.

Noonan and Price (61) outlined the acceptable limits of reduction for pediatric forearm fractures. In children younger than 9 years, 15° of angulation, 45° of malrotation, and complete displacement can be accepted. In children age 9 years or older, bayonet apposition, 30° of angulation, and 10° of malrotation are acceptable. The closer the fracture is to the growth plate and the younger the child, the greater the remodeling potential in all planes, except for rotational malalignment.

A special situation requiring open reduction arises in younger children (approximately 10 years) with distal both-bone fractures in which the ulnar fracture is a greenstick fracture and the radial fracture is displaced and translated dorsally with shortening of approximately 1 cm. The radial fragment is often buttonholed through a rent in the periosteum and cannot be reduced back to length. In such cases, make a small dorsal incision, and pray the fragment back with an elevator. Usually, no internal fixation is required after reduction is achieved.

LOWER EXTREMITY

PELVIS

Relevant literature on pediatric pelvic fractures spans four decades (9,26,28,33,46,55,59). Unlike adults, most children with massive pelvis injuries do not exhibit gross instability of the fragments. Pubic symphysis widening is well tolerated and tends to decrease after the child begins to walk. Proximal displacement of the iliac bone is rare, but patients with fracture patterns susceptible to displacement must be followed with serial radiographs. In rare instances, they require external or internal fixation, as in adults. For most children, bed rest followed by mobilization to a chair and progression to weight bearing as tolerated, along with pain control, is all that is required.

Acetabular fractures in children are likewise rare and can usually be treated nonoperatively. When fragment displacement is wide, assessment with computed tomography (CT) or, especially, magnetic resonance imaging (MRI) will determine whether there is involvement of the triradiate cartilage. The surgical principles for the management of acetabular fractures in adults are outlined in Chapter 18. They must be applied sparingly in children because triradiate cartilage closure can be a serious complication in younger children, and nonoperative treatment may be safer. Sometimes, cartilage joint surfaces may remain intact, even though the underlying bone is displaced, and these fractures need not be surgically treated (Fig. 164.6).

![Figure 164.6](image1.png)

Figure 164.6. An 11-year-old boy with a fracture of the pubic ramus apparently involving the acetabulum. In reality, the triradiate cartilage and acetabular articular cartilage were intact, and the acetabulum was normal 1 year later without reduction.

Avulsion fractures of an iliac or ischial apophysis, seen in adolescent athletes, are known as transitional fractures because they occur when the muscle forces approximate those in adults but the bone is still immature. Surgical reattachment of the avulsed fragment usually results in redispacement; therefore, symptomatic treatment is best for these injuries.

PROXIMAL FEMORAL FRACTURES

Femoral neck and intertrochanteric fractures in children (12,18,33,35,42,48,58) are dangerous injuries and do not behave similarly to their adult counterparts. Because they are so rare, few orthopaedic surgeons have extensive experience with them, and there is a natural tendency to treat them as one would in adults, which can lead to significant complications. Most proximal femoral fractures in children require operative management (Fig. 164.7). General principles and guidelines for surgical management include the following:

- Do not cross the proximal femoral physis with internal fixation devices. The exception to this occurs in older children with a very proximal femoral neck fracture (e.g., Salter–Harris type I fracture of the hip) in whom fixation into the head is necessary and leg-length discrepancy may be addressed later. Depending on the patient’s age and the fracture configuration, devices may include pins, cancellous screws, cannulated screws, or specialized pediatric blade-plate or screw-plate devices.
- Use a spica cast as supplemental fixation for all proximal femoral fractures, whether or not they are surgically stabilized. For most children, we prefer a full double-spica cast because it provides more effective mobilization.

![Figure 164.7](image2.png)

Figure 164.7. Operative fixation used for pediatric femoral neck fracture. The patient was immobilized in a spica cast.
Flexible Intramedullary Nail Fixation of Femoral-shaft Fractures

- Treat most nondisplaced fractures of the femoral neck in a spica cast. Internal fixation with a Steinmann pin or cancellous bone screw, combined with a cast, is used by some surgeons for additional protection against displacement.
- Gently reduce and internally fix displaced fractures of the femoral neck, and supplement this with a spica cast until union.
- Interfragmentary fractures of the femur in children have a tendency to drift late into varus. If they are nondisplaced, treat in a double-spica cast. Follow with serial radiographs, and continue cast immobilization for 8–10 weeks. If they are displaced, treat with closed reduction and fixation, using a pediatric hip screw-plate device supplemented by spica-cast immobilization.
- Most subtrochanteric fractures of the femur are treated in 90°/90° traction with the use of a distal femoral traction pin. A below-knee cast with a suspension loop to support the leg makes this form of traction easy to adjust and comfortable for children. Once callus is present, bring the leg into extension, and apply a spica cast. An alternative to traction is operative reduction and fixation with a screw and plate device, but this must be supplemented with a spica cast during healing.

Avascular necrosis may follow hip fracture in children. The involvement may be epiphyseal (partial or complete), physeal (limiting growth potential or causing angulation of the femoral neck with growth), or metaphyseal. Long-term follow-up of pediatric hip fractures is therefore essential to allow prompt detection of complications and timely intervention if required.

**FEMORAL-SHAFT FRACTURES**

Treatment of fractures of the femoral shaft (1, 5, 13, 32, 33, 34, 36, 44, 45, 46, 69, 71, 78, 79) differs for young children and older children. Simple skin traction and early spica-cast application generally work well for younger children with fractures of the femoral shaft. Although such treatment leads to shortening, the predictable overgrowth of 1–2 cm that occurs in children 2–10 years of age allows excellent functional results. Angulation of up to 15° in the frontal plane and up to 30° in the sagittal plane will quickly remodel.

However, in children age 10 years or older, traction treatment is more difficult. Because overgrowth does not occur, prolonged traction (up to 4 weeks) may be required to ensure maintenance of length before cast application. The callus that forms in such patients may be flexible, and early anunion is common after casting; often, the angulated femur then heals rapidly with resulting malunion. The expense (both emotional and financial) of prolonged traction may be considerable, and school education can be severely disrupted. For these reasons, we often favor operative treatment of femoral-shaft fractures in children older than 10 years.

Surgical fixation may involve plate and screws (generally with a cast for additional protection) or external fixation; however, we usually favor intramedullary fixation. There are two general approaches to intramedullary fixation in children.

In highly unstable fractures, especially in older adolescents, standard intramedullary fixation with interlocking may be used. Use nails as small as 9 mm in diameter, and bend great care to avoid penetrating the distal femoral physeal with either the guidewire or the nail. Keep the proximal entry site as lateral as possible; using an entry guide pin is safer than using an awl to avoid inadvertently slipping posteriorly. Standard interlocking techniques, when required, can be safely applied to children (Fig. 164.8). It is wise to leave the proximal rod a little “proud” to facilitate later removal. Heterotopic bone often forms at the insertion site and may be symptomatic, but the pain resolves when the rod and heterotopic bone are removed 1 year postinjury. There have been reports of avascular necrosis of the proximal femoral epiphysis with intramedullary nailing, especially with larger nails or posterior and medial insertion sites. For this reason, we prefer flexible nails, such as the Ender nail (See Chapter 19 and Chapter 20). In stable fractures, flexible intramedullary nails can be inserted antegrade or retrograde without risk to the blood supply to the femoral head.

The second option is external fixation of closed pediatric femoral fractures. Use a stable unilateral fixator along the lateral aspect. Once callus appears, apply compression across the fracture because early callus is soft and flexible and reducing distraction may help the callus mature. Do not remove the fixator too early, as malunion will occur. A main disadvantage of external fixation is the high rate of refracture; it is difficult to tell when the fracture is healed enough to discontinue the fixator. Dynalyze the fixator, if possible, to minimize the risk.

Indications for operative treatment of pediatric femoral fractures include open femoral fractures and fractures in patients with multiple injuries or a serious head injury. Grade I open femoral fractures can be treated as outlined above after thorough irrigation and debridement. Fractures with more extensive wounds may require external fixation, although skeletal traction is often a viable option. If a head injury is likely to lead to spasticity and posturing, fixation of femoral fractures by one of the methods outlined previously is helpful. Even in younger head-injured children, intramedullary nailing with antegrade Ender nails, Rush rods inserted antegrade distal to the greater trochanter, flexible Nancy nails, or external fixation is usually necessary. It has been our experience that children with head injuries recover neurologic function more completely than adults; therefore, pay great care to avoid penetrating the distal femoral physis with either the guidewire or the nail. Keep the proximal entry site as lateral as possible; using an entry guide pin is safer than using an awl to avoid inadvertently slipping posteriorly. Standard interlocking techniques, when required, can be safely applied to children (Fig. 164.8). It is wise to leave the proximal rod a little “proud” to facilitate later removal. Heterotopic bone often forms at the insertion site and may be symptomatic, but the pain resolves when the rod and heterotopic bone are removed 1 year postinjury. There have been reports of avascular necrosis of the proximal femoral epiphysis with intramedullary nailing, especially with larger nails or posterior and medial insertion sites. For this reason, we prefer flexible nails, such as the Ender nail (See Chapter 19 and Chapter 20). In stable fractures, flexible intramedullary nails can be inserted antegrade or retrograde without risk to the blood supply to the femoral head.

**Flexible Intramedullary Nail Fixation of Femoral-shaft Fractures**

- Place the child supine on a fracture table. Skin or foot traction usually suffices for children younger than 11–12 years with recent fractures, but the fracture should be reducible under fluoroscopy before the skin incision is made. If necessary, use skeletal traction while avoiding injury to the physis (see Chapter 20).
- For antegrade nailing, size the Ender nail by holding it over the leg, with the eye at the greater trochanter. The nail should end short of the distal femoral physeal. Make a longitudinal incision from the lateral prominence of the trochanter proximally for about 5–7 cm. Incise the fascia lata to expose the trochanter. The entry point is the flat lateral surface of the trochanter (Fig. 164.9A). Make an entry hole with a 6.5 mm drill, and introduce a curved Ender nail. Keep it aligned with the longitudinal axis of the femur. Gently tap it down the shaft, allowing the oblique blunt end to “bounce” off the medial cortex and pass down the canal. Verify its position on the image intensifier in two planes. At the fracture site, use the curve of the nail to hook the distal fragment, or make a small incision to openly reduce the fracture so that the nail can be passed. Once it is past the fracture, trap the nail distally so that it ends up in the lateral condyle, short of the physis. Leave the eye of the nail outside the cortex proximally for later removal.
- If the canal is large enough, insert a second nail. Many surgeons bend the nail into an S shape so that it will anchor in the medial condyle distally. Place the S point is the flat lateral surface of the trochanter (Fig. 164.9A). Make an entry hole with a 6.5 mm drill, and introduce a curved Ender nail. Keep it aligned with the longitudinal axis of the femur. Gently tap it down the shaft, allowing the oblique blunt end to “bounce” off the medial cortex and pass down the canal. Verify its position on the image intensifier in two planes. At the fracture site, use the curve of the nail to hook the distal fragment, or make a small incision to openly reduce the fracture so that the nail can be passed. Once it is past the fracture, trap the nail distally so that it ends up in the lateral condyle, short of the physis. Leave the eye of the nail outside the cortex proximally for later removal.

**Figure 164.8.** Interlocked intramedullary nail used to fix femoral-shaft fractures in children with open physes.

**Figure 164.9.** Approach for flexible (Ender) nailing of the femur. A: The entry point is generally at the lateral trochanter (for antegrade nail) or medial distal metaphysis (for retrograde nail). B: If an S-shaped nail is needed, perform the bending at the eyelet end of the nail to maintain proper entry shape. C: Multiple pins are used to fill the canal; a transverse, minimally comminuted fracture pattern is best for flexible-nail techniques.
deformity may be a complication of treatment. Metaphyseal fragment is usually detectable (type IV). Plan surgical fixation to avoid the physis, if at all possible, because growth remains in the distal tibia and a varus reduction is not anatomic. It has been our experience that Salter–Harris type III fractures are quite rare; if radiographs are taken in various degrees of rotation, a type III or IV injuries can be seen, and joint incongruence and physeal alignment may necessitate open reduction if closed operative management is required.

Before physeal closure (age 11 years and younger), Salter–Harris type II fractures are common and can usually be managed by nonoperative means. When inversion is included in the mechanism, Salter–Harris type III or IV injuries can be seen, and joint incongruence and physeal alignment may necessitate open reduction if closed reduction is not anatomic. It has been our experience that Salter–Harris type III fractures are quite rare; if radiographs are taken in various degrees of rotation, a metaphyseal fragment is usually detectable (type IV). Plan surgical fixation to avoid the physis, if at all possible, because growth remains in the distal tibia and a varus deformity may be a complication of treatment.

**PHYSICAL INJURIES OF THE DISTAL FEMUR**

Most physial injuries of the distal femur are Salter–Harris type I or II fractures. Unlike similar fractures in other anatomic locations, these have a likelihood of growth arrest as high as a 50%. This is both because high energy is required to fracture the distal femur and because the physial mamilary processes are frequently sheared off during injury. Leq-length inequality can ensue from altered growth of this rapidly growing physial.

Distal femoral physial fractures are occasionally accompanied by neurovascular injuries but not as frequently as are knee dislocations in adults. They are often unstable and may require internal fixation.

**Closed Reduction and Fixation of Distal Femoral Physeal Fractures**

- Use general anesthesia and muscle relaxation for the reduction. Closed reduction may require surprising force. Occasionally, the bone end will buttress through the periosteum, making closed reduction impossible and necessitating open reduction. Once the fracture is reduced, test the stability of the reduction, as internal fixation is usually required. If there is a large metaphyseal component, it may be possible to stabilize the fracture by inserting a screw percutaneously across the metaphyseal fracture parallel to the physis. Otherwise, stabilize the fracture with two medium-sized, smooth Steinmann pins inserted from the medial and lateral femoral condyles at a 45° angle. Be sure that the pins pass into and just through the cortex of the proximal fragment; otherwise, the fracture may remain unstable. Drive the pins slowly so as not to cause thermal damage.
- Bury the pin ends because they are intra-articular and the risk of infection is great if they are left protruding. After fixation, check the stability of the fixation. If it is stable, apply an above-knee cast; if there is any question, use a one-half hip spica cast with the knee in extension.
- Postoperatively, remove the pins under general anesthesia after 3–4 weeks. Immobilization for 4–6 weeks is sufficient for healing. Obtain follow-up radiographs every 3 months to look for evidence of growth arrest; if it occurs, it can be managed by methods outlined in Chapter 170 on leq-length discrepancy. In older children, however, an early epiphysiodesis of the contralateral distal femur may be a simple solution.

**TIBIAL TUBERCLE AVULSION**

Avulsion of the tibial tubercle (15,29,33) is characterized as a jumper's injury and occurs most commonly in boys 14 years of age. It usually happens when the patient lands, and the quadriceps muscles contract to support the falling weight. The avulsion may involve only the tubercle or may extend through the condyles and the tibial articular surface of the knee. Use CT to delineate the exact fracture pattern.

Anatomically reduce and rigidly fix displaced fractures of the tibial tubercle. Because the fracture usually occurs in a physial, it is unnecessary to avoid crossing the growth plate because growth arrest that can cause hyperextension will not be significant. For this reason, use fixation that provides the optimal strength and stability.

**OPEN FRACTURES OF THE TIBIAL SHAFT**

Treatment of open fractures of the tibial shaft is easier in children than in adults because children possess excellent healing potential (10,33,61,63,70). Initially, administer antibiotics, and irrigate and debride all open tibial-shaft fractures under a general anesthetic as described in Chapter 12. In younger children with Gustilo type I injuries and little periosteal injury, it is usually possible to treat the fracture with a long-leg cast. Some children may exhibit overgrowth, but this is unpredictable.

In older children or children with severe soft-tissue wounds, external fixation is usually required to manage the soft-tissue injury.

Although plate fixation is possible, we prefer external fixation for the vast majority of open tibial-shaft fractures with a Gustilo type II or III wound. This allows excellent fracture control for repeated wound debridements as required. Usually, a single unilateral half-pin anterior frame is sufficient if supplemented by a posterior splint or cast. In most cases, we have achieved excellent immobilization and pain control, using a supplementary below-knee cast. This can be placed directly over the fixator if fluff gauze is packed in the recesses of the device, and the whole construct is then covered with cast padding. It can be removed and replaced by splitting the cast and opening it like a clamshell. Leave the fixator in place until callus is present, which usually requires 8 weeks or more, or until pin loosening occurs. Remove the fixator under a general anesthetic, and apply a long-leg cast with the knee straight until the fracture has united.

**DISTAL TIBIAL EPIPHYSEAL FRACTURES**

The anatomy of physial closure as maturity approaches and the susceptibility of the distal tibia physis to fracture produce a group of fractures that may require operative management (20,21,39,45,66). The physis begins to close centrally, and then over 18 months to 2 years closure progresses medially, posteriorly, and laterally, sweeping like the hand of a clock. The last portion of the physis to close is the anterolateral corner (Fig. 164.10).

Depending on the portions of physes that are closed, stresses may be directed to open physial regions, leading to a specific group of fracture patterns (Fig. 164.11). Before physeal closure (age 11 years and younger), Salter–Harris type II fractures are common and can usually be managed by nonoperative means. When inversion is included in the mechanism, Salter–Harris type III or IV injuries can be seen, and joint incongruence and physial alignment may necessitate open reduction if closed reduction is not anatomic. It has been our experience that Salter–Harris type III fractures are quite rare; if radiographs are taken in various degrees of rotation, a metaphyseal fragment is usually detectable (type IV). Plan surgical fixation to avoid the physis, if at all possible, because growth remains in the distal tibia and a varus deformity may be a complication of treatment.

![Figure 164.10](image_url). The sweep of closure of the distal tibia physis is a process that takes 18 months to 2 years to complete. Fracture patterns often parallel this pattern.
When the central or centromedial physeal closes (age 12–14 years), a triplane fracture, originally described by Marmor (45), becomes common. This complex fracture may consist of two, three, or occasionally more parts, and the fibula may be fractured (Fig. 164.11). Open reduction may be required for joint incongruence. Interpret standard radiographs cautiously because the fragments can be spread posteriorly while reduced anteriorly, giving a false sense of security on the AP view, or there may be out-of-plane fractures. A transverse plane CT cut is often most helpful for exact delineation of the fracture pattern and displacement. We generally recommend open reduction if displacement after closed reduction is greater than 2 mm or if there is an articular surface step-off visible on the AP view, which is rare. Because the physis is in the process of closing, angular deformity does not occur if fixation devices cross it; fixation may therefore be planned for maximum fixation effectiveness.

When the medial and posterior portions of the physis close, which occurs age 15 years or older, the remaining anterolateral component may be avulsed by the ligaments of the anterior syndesmosis during forced external rotation. This is known as a juvenile Tillaux fracture, and surgical treatment is indicated if closed reduction does not close the gap to 2–3 mm or less. Like the triplane fracture, this fracture does not lead to late angular deformity because the physeal is nearly closed.

**Open Reduction of Salter–Harris Type III or IV Fractures of the Distal Tibial Physeal**

- Make a medial or anteromedial incision over the malleolus. Take care not to strip more periosteum than is required, and do not further injure the physis. Carefully reduce the fracture; a fluoroscopic image intensifier may be helpful. If a Salter–Harris type IV fracture has a small metaphyseal component, carefully remove it with a rongeur to allow better visualization and alignment of the physeal plate (Fig. 164.12).

- Fix the fracture with a transverse screw directed entirely within the epiphysis (a small cannulated screw works well if available). Try not to cross the physis, even with a smooth K-wire, because of the risk of physeal closure.

Postoperatively, immobilize the limb in a below-knee cast for 6 weeks. Weight bearing may then be increased as tolerated.

**Open Reduction of Triplane Fractures**

- Two incisions may be required. Reduce the medial epiphyseal fragment first through a medial or anteromedial incision, and fix it by stabilizing the posterior metaphyseal fragment with small-fragment screws or K-wires. Reduce the lateral (Salter–Harris type III) component through a lateral incision, and fix it with a cancellous small-fragment screw. It is unnecessary to avoid the physis because so little growth remains in the distal tibia.

- A Tillaux fracture is treated surgically in the same fashion as the Salter–Harris type III component of a triplane fracture.

Postoperatively, immobilize the limb in a below-knee cast for 6 weeks. Weight bearing may then be increased as tolerated.

**MANAGEMENT OF GROWTH-PLATE INJURIES AND PHYSEAL BARS**

The majority of growth-plate injuries heal uneventfully and proceed with no alteration in growth of the extremity. Occasionally, complete growth arrest will result in limb-length inequality, or partial growth arrest through formation of a bony bar will result in longitudinal and angular bone deformity. These complications are less significant the closer a patient is to skeletal maturity. In the lower extremity, if the limb-length difference is projected to be greater than 2–3 cm at skeletal maturity, consider treatment.

Base the treatment of significant posttraumatic growth arrest on a patient’s (and parent’s) height, projected degree of longitudinal or angular deformity, extent of physeal injury (size of the bony bar), and the patient’s tolerance for the proposed treatment. Partial arrests of more than 30% to 50% of the cross-sectional area of the growth plate are not amenable to treatment designed to restore growth; they can be treated by early contralateral epiphysiodesis (see Chapter 170) or bone lengthening (Chapter 171). Children who are projected to be tall may be more easily treated by epiphysiodesis of the noninjured side than very short children. Partial arrest of less than 30% of the area of the growth plate in a patient with at least 2 years of growth remaining may be considered for excision of the bony bar if it is surgically accessible. The most common sites requiring surgery are the distal femur, proximal tibia, or distal radius, where significant loss of length will have functional consequences.

When there is angular deformity, it is preferable in some instances to treat by acute opening-wedge osteotomy. This gains length and avoids complex, prolonged treatment. Such osteotomies, utilizing a tricortical wedge of iliac bone and appropriate internal fixation, heal rapidly in adolescents. If osteotomy is carried out before skeletal maturity, remember to complete the growth arrest by total epiphysiodesis to avoid recurrent deformity, with epiphysiodesis of the opposite extremity if indicated.

The feasibility of bar excision depends on its size and location within the physis. Plain x-ray films, scanogram, and bone-age determinations are important initially in determining which patients should be considered for bar excision. Standard tomography, triplanar tomography, CT, and MRI have each been advocated for physeal mapping. Plain tomography has long been utilized for characterizing physeal bars, but resolution is frequently inadequate. Images must be taken in two projections, and radiation exposure is quite high. Spiral and hypocycloidal tomography improve the resolution, but radiation exposure and scanning time remain high.

Axial CT of physeal bars requires precise placement of the extremity within the scanner and multiple thin cuts. The transverse section of these studies is inadequate, so sagittal and coronal reconstructions must be used and detail is poor. Direct and specific communication with the radiologist is frequently required to obtain clinically useful images. Helical CT has been reported to offer many advantages over other methods of growth-plate mapping. These include excellent bony detail, diminished radiation exposure, ability to manipulate the images into multiple perspectives, and significantly decreased scanning times that obviate sedation or anesthesia (Fig. 164.13). Advocates of MRI mapping cite the lack of ionizing-radiation exposure and excellent detail afforded. Scanning times are prolonged, and children frequently require sedation or general anesthesia. MRI data can be processed by either three-dimensional (3D) rendering or 3D projection to provide excellent detail to assist...
preoperative planning.

**Figure 164.13.** Reconstruction of the position of a physeal bar by AP and lateral tomograms. Scaled graph paper is used to plot the presence of physeal bar on all radiographs in two planes; the resulting graph gives a good indication of the extent and location of the area of growth arrest.

When significant angular deformity accompanies partial physeal arrest, the surgeon must decide whether to correct the angulation and complete the epiphysiodesis, correct the angulation and resect the physeal bar, or resect the physeal bar alone and allow remodeling with growth. Even though there are no simple answers to this dilemma, the basic guidelines used for management of postfracture angular deformities may be applied. For example, a 25° flexion deformity of the distal femur in an 8-year-old child might be expected to remodel after resection of a peripheral posterior bar, but a similar degree of varus deformity with a medial bar would not remodel, necessitating concurrent osteotomy. Central bars that are readily approached from a metaphyseal osteotomy site may lead to a decision to perform full early correction of an angular deformity. In the upper extremity, completion of epiphysiodesis and closure of the physis of the other forearm bone (usually the ulna) may be technically easier and appropriate, given the functional unimportance of equal upper-limb length.

**Excision of a Physeal Bar**

Assess the extent of the bar and its anatomic location with tomography or CT or MRI reconstructions. If a bar is 30% or less of the total physeal area, resection has a fairly high likelihood of success; with bars greater than 50% of the physeal area, failure is almost certain.

Plan the best approach to the bar (Fig. 164.14). If the bar is peripheral, it can be directly approached from the surface. Approach central bars through a large metaphyseal window proximal to the physis. If osteotomy is required, it is usually easiest to perform a transverse osteotomy and position the limb to avoid neurovascular damage; the bar is then approached from above through the distal face of the osteotomy.

**Excision of a Physeal Bar**

Assess the extent of the bar and its anatomic location with tomography or CT or MRI reconstructions. If a bar is 30% or less of the total physeal area, resection has a fairly high likelihood of success; with bars greater than 50% of the physeal area, failure is almost certain.

Plan the best approach to the bar (Fig. 164.14). If the bar is peripheral, it can be directly approached from the surface. Approach central bars through a large metaphyseal window proximal to the physis. If osteotomy is required, it is usually easiest to perform a transverse osteotomy and position the limb to avoid neurovascular damage; the bar is then approached from above through the distal face of the osteotomy.

**Figure 164.14.** Approach to a physeal bar depends on its location. **A:** Peripheral bars are approached directly. **B:** Central bars may be approached through a metaphyseal window or osteotomy. Use a burr for this procedure.

- Complete exsanguination and tourniquet control are essential for a dry field.
- When resecting a peripheral bar, directly expose the region of the bar, using an image intensifier as necessary to confirm the location. With a #15 blade, sharply incise the perichondrial ring and a small cuff of proximal periosteum at the resection site, and completely remove both structures to a point where the edge of the resection contains the visualized physis; this helps prevent peripheral recurrence.
- Use a small, high-speed burr to carefully remove the bar in layers; it will have a dense, slightly yellow appearance that will change into the normal cancellous-bone appearance as the edge of the bar is reached. Use irrigation to avoid overheating. Do not stray too far distally; if deeper visualization is required, burr more proximally. Eventually, the blue-gray cartilage of the physis will be visible, and with patience the physeal line will be exposed completely around the cavity of the resected bar (Fig. 164.15). Carefully sweep the burr up and down to smooth the edge of the physis and the contiguous bone.

**Figure 164.15.** A burr is used to remove the dense, yellowish bar material until the physis is visualized throughout the cavity.

- When resecting a central bar, remove a large cortical window in the metaphysis through a periosteal window, taking care not to damage the actual physis or perichondrial ring. Alternatively, perform a transverse osteotomy with a saw, and displace it by bending to allow visualization from above.
- Using the burr and generous irrigation, slowly advance until the dense, yellow bony bridge is identified, and carefully burr in layers to follow the yellowish structure down through the physeal plane. An image intensifier will help avoid burring too far. Use a dental mirror to view difficult corners, and enlarge the cortical window proximally as necessary for exposure. Eventually, identify the length of the blue-gray cartilage physis completely as it surrounds the cavity, and smooth it and the attached bone with an up-and-down motion of the burr. At this point, place radiographic markers such as vascular clips or small K-wire fragments in the epiphyseal and metaphyseal portions of the bone to allow later measurement of longitudinal growth (Fig. 164.16).
Before deflating the tourniquet, fill the cavity to prevent blood and eventual fibrous tissue from filling the space. We prefer Cranioplast, a slow-polymerizing polymethyl methacrylate (PMMA) that gives off very little heat as it cures. This material, familiar to orthopaedic surgeons, fully fills the cavity and leaves very little space for accumulation of organizing fibrous tissue. Alternatively, autogenous fat may be used, harvested locally or from the buttock. Fat tends to float out of the wound, and provides no structural compressive strength, so we no longer recommend it. Medical-grade Silastic has also been used; however, it is not available to surgeons for this use and offers no distinct advantages. The object of the filling is to completely obliterate the cavity without interlocking with cancellous bone above and below the physis.

Allow the PMMA to become doughy before inserting it, and gently push (do not “pressurize”) it while it cures, irrigating with cool saline to minimize thermal damage. Once the PMMA is cured, replace the cortical window or fix the osteotomy if one has been made (see discussion above). Use iliac bone graft as needed for stability in opening-wedge osteotomies.

Close the wound, and immobilize the limb, even if internal fixation has been used for an osteotomy.

Postoperatively, protect the patient until the bone is well healed, usually 6 weeks, and gradually begin increasing protected weight bearing. PMMA is load-sharing and allows safe weight bearing once muscle strength has recovered.

Physes that have been injured and partially closed will often exhibit premature closure after several years of normal growth after successful bar resection. Patients must be carefully monitored with periodic clinical, radiographic, and limb-length examinations until skeletal maturity. Be prepared to reassess late physeal closure and to carry out prompt treatment by epiphysiodasis, osteotomy, or other indicated procedure.

Chapter References

Congenital malformations of the shoulder and elbow are frequently accompanied by hand malformations or absence; in these cases, treatment of the shoulder and elbow must be integrated with treatment of the hand. Surgical reconstruction of the shoulder or elbow, or both, is not indicated if the hand is absent or nonfunctional, unless the goal of surgery is to reduce pain. See Chapter 69, Congenital Hand Malformations, for a discussion of pathophysiology and principles of treatment of congenital malformations of the upper extremity.

ARTHROGRYPOSIS
PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT

Arthrogryposis multiplex congenita (sometimes termed amyoplasia) is characterized by multiple, symmetric, nonprogressive, congenital joint contractures (45) (Fig. 165.1A). Many etiologic factors have been associated with arthrogryposis (including fetal exposure to mutagens, toxins, hyperthermia, neuromuscular blocking agents, and mechanical immobilization) (156). The final common pathway for these etiologies is probably lack of fetal movement. Because fetal movement is necessary for joint development, immobile joints fail to develop normally and become contracted (43,108,182).
Although myopathic arthrogryposis has been reported, most cases studied show evidence of a neuropathic condition, possibly a disorder of the anterior horn cells, which partially paralyzes the fetus. Even though many different fetal exposures to drugs, chemicals, and mutagens have been associated with arthrogryposis in humans, in most cases, the cause remains unknown (50, 72). Arthrogryposis is not an inherited condition (121), but many other syndromes that feature multiple joint contractures are inherited (72), and most children with this condition should be seen by a geneticist. The incidence of arthrogryposis is unknown, although congenital joint contractures are seen in about 1 in 3,000 live births (72).

Treatment of arthrogryposis focuses on enhancing the child’s ability to perform activities of daily living, especially eating, toileting, and dressing (50).

ASSOCIATION, INDICATIONS, AND RELATIVE RESULTS

Arthrogryposis is a clinical diagnosis, usually made at birth. Mothers of children with this condition frequently report that fetal movement was diminished compared with their other pregnancies. Oligohydramnios is a frequent finding.

Joint contractures associated with arthrogryposis are usually more severe distally than proximally, and most patients have upper extremity involvement (65). The shoulder lacks abduction and external rotation (178), and the elbow (one of the most frequently involved joints) (108) may lack flexion or extension (161, 167). The wrist is usually flexed and deviated ulnarward (176), the fingers flexed, and the thumb flexed in the palm (164) (see The Fingers: Camptodactyly and The Thumb: Clasped Thumb in Chapter 69, Congenital Hand Malformations). Severe clubfoot, knee flexion contracture, dislocated hip, and scoliosis are frequently associated with arthrogryposis (45, 161). Joint contractures similar to those seen in arthrogryposis are associated with syndromes such as cranio-carpo-tarsal dysplasia (Freeman–Sheldon syndrome) (Figs. 165.18, 165.19).

Shoulder contractures do not usually limit performance of activities of daily living (20) and are not usually amenable to range-of-motion exercises, splinting, or surgery. The most limiting deficit, lack of active elbow flexion, prevents the child from reaching the mouth and head, especially when accompanied by an elbow extension contracture. Children with only passive elbow flexion frequently discover “tricks” to help get their hand to their face, such as leaning the forearm on the edge of a table or on their leg. Serial casting, splinting, and range-of-motion exercises may improve elbow range of motion. If less than 90° of passive elbow flexion is gained after 6 months of supervised elbow stretching, posterior capsulotomy with triceps lengthening is indicated (167). In one study of this operation, postoperative improvement in passive elbow flexion was maintained for at least 2 years, although range of motion was occasionally limited by intra-articular incongruity (167).

Many different tendon transfers have been used to provide active elbow flexion, including pectoralis major, latissimus dorsi, triceps-to-biceps transfers, or proximal realignment of the wrist and finger flexor muscles (Steindler flexorplasty) (124, 167, 178). Tendon transfer is indicated in children older than 4 years of age who lack active elbow flexion and have at least 90° of passive elbow motion, reasonable ipsilateral hand function, absent contralateral active elbow flexion, and an available donor muscle. Bilateral tendon transfer is not usually indicated; asymmetric function is usually desirable, especially when the triceps is the best donor available, and elbow extension is sacrificed for elbow flexion. Potential donor muscles must be carefully assessed preoperatively because they may be weak and therefore unsuitable for transfer. Triceps-to-biceps transfer gives the most reliable results (167), although this operation creates an elbow flexion contracture (161) and is contraindicated in children who need active elbow extension to ambulate or transfer because of lower extremity contractures. The pectoralis major is the best donor when the triceps is unavailable, but the scar left by this operation is large (extending from sternum to antecubital fossa) and crosses the breast, and transfer of the pectoralis may cause breast asymmetry. Latissimus dorsi and finger and wrist flexors are frequently weak in arthrogryposis, so latissimus dorsi-to-biceps transfer and Steindler flexorplasty are rarely indicated.

CLASSIFICATIONS

Many different terms have been used to describe arthrogryposis, including arthrogryposis multiplex congenita, multiple congenital articular rigidities, amyoplasia congenita, myodystrophia foetalis deformans, and congenital arthromyoaplasia (162). No classification scheme useful to orthopaedists has been described for this disorder.

PREOPERATIVE MANAGEMENT

Stretching, splinting, and serial casting of contracted elbows and wrists may increase passive range of motion, particularly for infants younger than 1 year of age. A creative occupational therapist may help the child improve function with the use of mechanical aids.

OPERATIVE TECHNIQUES

Posterior Elbow Capsulotomy with Triceps Lengthening

- Use loupe magnification (for the ulnar nerve dissection) and perform the operation under general anesthesia and a tourniquet. A sterile tourniquet may be necessary.
- Through a longitudinal incision on the posterior elbow, find the ulnar nerve. Open the cubital tunnel and retract the nerve with a Penrose drain, taking care not to damage branches to the flexor carpi ulnaris.
- Perform a V-Y lengthening of the triceps tendon. First, make a V incision through the tendon, with the point of the V proximal. Expose the humeroulnar joint, leaving the triangular tail of tendon attached to the olecranon.
- Using scissors, transect the posterior elbow joint capsule. If necessary to obtain flexion, transect the lateral and medial capsule, including collateral ligaments.
- Repair the triceps tendon with nonabsorbable suture while holding the elbow in maximum flexion.
- The ulnar nerve does not usually require transposition.
- Close the skin with an absorbable, running subcuticular suture. Apply a long-arm cast with the elbow in maximum flexion.

Remove the cast after 2 weeks and begin a program of frequent gentle passive elbow flexion exercises, supervised by an occupational therapist. Supplement with night splinting in maximum flexion, to be continued indefinitely.

Triceps-to-Biceps Transfer

- Open the cubital tunnel, retract the nerve with a Penrose drain, and transect the posterior elbow joint capsule.
- Repair the triceps tendon with nonabsorbable suture while holding the elbow in maximum flexion. The ulnar nerve does not usually require transposition.
- Close the skin with an absorbable, running subcuticular suture. Apply a long-arm cast with the elbow in maximum flexion.

Figure 165.2 shows a typical triceps-to-biceps transfer (31).
Perform the operation under general anesthesia and a tourniquet. A sterile tourniquet may be required.

Through a posterolateral longitudinal elbow incision, expose the triceps tendon and divide it at its insertion. Dissect it from the posterior aspect of the distal fourth of the humerus, and transfer it around the lateral aspect, superficial to the radial nerve.

Through a separate anterior zigzag elbow incision, expose the biceps tendon.

Pass the triceps tendon through a longitudinal slit in the biceps tendon, and suture it under tension with the elbow in flexion.

Close the skin with an absorbable, running subcuticular suture. Apply a long-arm cast with the elbow in maximum flexion and neutral rotation.

Im mobilize the elbow for 6 weeks, then begin a program of active elbow flexion exercises. Supplement with night splinting until active flexion strength is at least antigravity.

**Pectoralis Major-to-Biceps Transfer**

For the surgical technique for a pectoralis major-to-biceps transfer, see the article by Schottstaedt et al. (147).

**COMPLICATIONS**

Inadequate lengthening of the triceps tendon will restrict elbow flexion following posterior elbow capsulotomy. The outcome of elbow flexion tendon transfer is frequently unsatisfactory, even when the donor muscle is normal; in arthrogryposis, donor muscles are likely to be weak and have poor excursion.

**CONCLUSIONS**

Children with arthrogryposis frequently function much better than their strength and range-of-motion measurements would predict. Surgery should be directed at functional goals shared by the surgeon, child, and family.

Although triceps-to-biceps transfer provides the best elbow flexion, patients may not like the mandatory elbow flexion contracture that accompanies this operation.

**BRACHIAL PLEXUS BIRTH PALSY**

**PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT**

Brachial plexus birth palsy (BPBP), also known as obstetric palsy, occurs when the brachial plexus is injured by traction during birth. The mechanism of injury is forceful separation of the head from the shoulder by lateral flexion of the cervical spine and depression of the shoulder (Fig. 165.3). This most commonly occurs during a cephalic vaginal birth, owing to shoulder dystocia. The primary cause of shoulder dystocia is fetal macrosomia, which may be associated with maternal diabetes or a multiparous mother. The brachial plexus may also be injured during a breech delivery; injury during caesarian section is very rare (7, 65). Obstetrics literature indicates that injury may occur prenatally (56, 130, 133), although this finding is controversial (38, 60).

**BPBP occurs in 0.5 to 2.6 per 1,000 live births, with the incidence unchanged or possibly increasing in the past 30 years, in spite of an increasing rate of caesarian sections (64, 75, 76, 88, 103, 117, 118, 134, 170). Although BPBP may often be attributable to poor prenatal care or obstetrician error, some cases cannot be reliably predicted or prevented. Macrosomia (fetal weight greater than 4,500 g) is difficult or impossible to detect with current prenatal diagnostic techniques (63), and shoulder dystocia, which occurs in up to 2% of deliveries, may be difficult to recognize and treat (63, 74, 85, 118). In addition, shoulder dystocia and BPBP frequently occur in normal birth-weight fetuses (64, 128). Other variables, including prolonged gestation, prolonged labor, use of oxytocin, use of forceps or vacuum suction, and previous maternal obstetric history of macrosomia are all associated with birth injuries, but even when combined, these problems fail to predict most birth injuries (134). BPBP in an older sibling is the only factor that may reliably predict BPBP (4) (Fig. 165.4).**

**Figure 165.2. Triceps-to-biceps transfer (Reprinted from ref. 44, with permission).**

**Figure 165.3. Breech (A) and Vertex births (B), showing wide separation of the head from the downside shoulder.**

**Figure 165.4. A to C: Three siblings with brachial plexus birth palsy. Both boys (A, B) have Horner's syndrome.**
The disability caused by BPBP varies from mild, partial, and transient upper extremity weakness [approximately 80% of newborns have full or near-full recovery of function (66,76,88,122)] to complete permanent upper extremity paralysis. Most of the improvement gained from nerve recovery is seen in the first 12 months of life, and the remainder by 2 years of age (5); recovery of sensation is more complete than recovery of motor function. Residual disability depends on the severity and location of the plexus injury (78) (Fig. 165.5). Injury to the upper trunk, where the C5 and C6 nerve roots join and the suprascapular nerve leaves the plexus, is called Erb's palsy (49). This the most common type of plexus injury; the child with this type of BPBP has weakness or paralysis of shoulder external rotation and possibly abduction. The next most common type is global plexus palsy. Isolated injury to the lower trunk (C-8 and T-1 nerve roots), called Klumpke’s palsy, is the least common type (6,68) and may actually represent partial recovery from global plexus palsy rather than injury to the lower trunk alone (172) (Fig. 165.6).

![Figure 165.5. Different types of brachial plexus injury (78).](image1)

The muscle imbalance resulting from BPBP may cause multiple deformities at the shoulder, including internal rotation contracture and posterior subluxation or dislocation, as well as at the elbow, including flexion, supination, or pronation contracture, radial head dislocation, or complete elbow dislocation (3,13,41,83,104,110,174). The affected arm is smaller than the opposite side, in proportion to the severity of the BPBP (Fig. 165.7).

![Figure 165.6. The brachial plexus (172).](image2)

![Figure 165.7. Severe brachial plexus birth palsy in a teenager.](image3)

The goals of treatment are to prevent the formation of contractures while recovery is occurring, to restore neurologic function, to augment weak muscles, and to improve the appearance of deformities that occur as a result of muscle imbalance. Treatment depends on age and extent of weakness, and may include passive range-of-motion exercises (PROM), goal-directed occupational therapy, brachial plexus exploration and grafting, tendon transfers, osteotomies, and arthrodeses. Because of the complexity of their care, children with BPBP benefit from a multidisciplinary team approach (36). The BPBP team may include an orthopaedic surgeon, a surgeon with microneurosurgery expertise, a physiatrist, a pediatric neurologist, occupational and physical therapists, a social worker, and a therapeutic recreation specialist. Parents and older children appreciate team-sponsored activities, such as play groups and peer contacts (Fig. 165.8).

![Figure 165.8. Two children who met through a peer contact program, wearing shoulder abduction splints following shoulder external rotation tendon transfers.](image4)

**ASSESSMENT, INDICATIONS, AND RELATIVE RESULTS**

The infant with BPBP presents with asymmetric upper extremity motion. The affected side is typically held in internal rotation at the shoulder, with the elbow extended and the wrist flexed (Fig. 165.9). The differential diagnosis includes hemiparesis, a septic glenohumeral joint, and congenital elevation of the scapula (Sprengel’s deformity). Clavicle fracture and proximal humeral epiphysial separation may be either differential diagnoses or associated lesions (5,59,103). Although most infants with BPBP recover useful function, those with an ipsilateral Horner's syndrome (due to injury to the sympathetic ganglia, associated with avulsion of the C-8 and T-1
nerv roots off the spinal cord) or hemidiaphragm paralysis (injury to the phrenic nerve) have a poor prognosis for recovery (122).

Figure 165.9. Infant with left brachial plexus birth palsy.

Teach parents to begin PROM exercises of the shoulder when the infant is 3 to 4 weeks of age. Examine the infant every 1 to 2 months for signs of recovery. The Infant Active Movement Scale (38) (Table 165.1) helps the examiner measure muscle recovery more accurately than do scales devised for adults because it does not require cooperation for testing muscles against resistance. Brachial plexus exploration with nerve grafting and transfer may be indicated if the infant does not recover elbow flexion strength.

Table 165.1. Infant Active Movement Scale

Recovery of active elbow flexion is closely monitored for three reasons: It is easy to observe; the timing of natural recovery of elbow flexion may be a prognostic sign for plexus recovery; and early nerve grafting to the lateral cord of the plexus (Fig. 165.9) may be the best way to restore elbow flexion, which is difficult to replace with tendon transfers (112). In one often-quoted but unpublished study, children with full recovery from BPBP at 5 years of age showed antigravity elbow flexion and shoulder abduction by age 3 months (59,160). Later recovery of elbow flexion (between 3 and 6 months of age) has been associated with residual shoulder weakness (160,171). In contrast, however, other investigators have reported that most children with biceps recovery after 3 months of age are likely to have a good ultimate outcome, but lack of sensation and wrist extension at 3 months are poor prognostic signs (21).

Electromyography (EMG), nerve conduction studies (NCS), contrast computerized tomography (CT) myelography, magnetic resonance imaging (MRI), and intraoperative somatosensory-evoked potentials have all been used to measure and provide images of damage to the neonatal brachial plexus, with the goal of differentiating nonrepairable preganglionic rupture from postganglionic injury, which may be repairable or may recover without surgical treatment (52,77,123,153). EMG and NCS may help differentiate neuropriaxia from axonal degeneration. CT myelography and MRI can identify preganglionic nerve root injuries (avulsions) if they are associated with traumatic pseudomeningoceles, as they are in many avulsions; however, root avulsions may occur without creating a pseudomeningocele, and pseudomeningoceles may be visualized at the level of a root that has not been avulsed. All tests require sedation, and CT myelography is invasive. Testing should be reserved for infants who are candidates for nerve surgery, to help the surgeon plan the operation.

Thus, the indications for brachial plexus exploration with nerve grafting and transfer are unclear. Some surgeons recommend this procedure for all children without full recovery of active elbow flexion and shoulder abduction by 3 months of age (69); others prefer to allow more time for recovery (35,73,102,137). Most surgeons agree that complete avulsion of the plexus is rare, so at least one root has a repairable injury in most cases, and the results are poor for surgical plexus reconstruction for BPBP performed after 12 months of age. Most surgeons resect the scarred plexus and graft nonavulsed roots to the lateral cord, suprascapular nerve, and posterior cord (79) (see Chapter 60). Nerve transfer (neurotization) of the accessory nerve may be helpful (35). To diminish unopposed internal rotation, Sever (150) recommended releasing the pectoral major and subscapularis. In 1934, L’Episcopo (19) described the results of combining Sever’s anterior release with transferring the teres major to the proximal humerus in order to provide active shoulder external rotation. This operation was later modified by Hoffer and colleagues (19,84,136), who described latissimus dorsi and teres major transfer to the supraspinatus, with release of the pectoralis major only (because release of the subscapularis can cause glenohumeral instability), and Covey et al. (39), who described latissimus dorsi and teres major rerouting around the proximal humerus.

Children with upper-trunk BPBP frequently have residual weakness of shoulder external rotation and abduction (Fig. 165.10). Such a child may have difficulty positioning his or her hand in space, particularly to reach the head and face, or to throw, climb, turn a jump rope, or play a musical instrument. Eventually, the child may develop a shoulder internal rotation contracture, with glenohumeral joint changes and eventual posterior dislocation of the humeral head (70,81,174). Shoulder function may be classified using Mallet’s scale (108,172) (Fig. 165.11). To diminish unopposed internal rotation, Sever (150), in 1925, recommended releasing the pectoralis major and subscapularis.

Figure 165.10. Decreased shoulder abduction and external rotation due to right brachial plexus birth palsy.
Shoulder external rotation tendon transfer and rerouting both reliably increase abduction, as well as external rotation in abduction by an average of 20° to 40° each. Abduction is increased because the transfer helps stabilize the glenohumeral joint, allowing the deltoid to function more efficiently. The rerouting procedure is more technically demanding and requires more excursion of the teres and latissimus muscles but may provide more external rotation than the transfer procedure (62). Other patient requirements for these operations include sufficient maturity to work with a therapist postoperatively to strengthen the transfer (4 years of age or older), minimal changes in the glenohumeral joint from unopposed internal rotation (usually 12 years of age or younger), and enough deltoid strength to abduct to at least 60° against gravity. However, Hoff and Phipps (63) have reported that when posterior shoulder dislocation occurs early (before 4 years of age) latissimus and teres transfer and pectoralis release can be combined with closed shoulder reduction with good results and maintenance of reduction (63).

Tendon transfers do not reliably restore elbow flexion (112,127) but they may restore wrist extension, finger extension and flexion, and thumb opposition if adequate donors are available (26). For forearm supination deformity, biceps rerouting and forearm osteotomy improve forearm position (23,106,110,185). Elbow flexion contractures can be treated with serial elbow drop-out casts (long-arm casts applied in maximum elbow extension, with the posterior above-elbow aspect cut out so that the elbow can extend farther but cannot flex). Surgical release of elbow flexion contractures is not usually indicated.

For the untreated older child or teenager, glenohumeral deformity and contracture may make shoulder tendon transfers less effective. External rotation osteotomy of the humerus improves the appearance and function of a limb with a shoulder internal rotation contracture in the older child (61,74).

If the deltoid is completely paralyzed, shoulder arthrodesis may improve function by conferring stability (139) (see Chapter 101). Wrist arthrodesis can improve hand position when wrist motors are paralyzed and no muscles are available for transfer (see Chapter 72). Arm-lengthening procedures are not indicated for treating the global extremity hypoplasia associated with severe BPBP.

Throughout childhood, the child with BPBP may benefit from goal-directed occupational and physical therapy.

CLASSIFICATIONS

There is no standard classification system for BPBP, aside from classification by level of plexus involvement, as described previously. Shoulder limitation has been classified by Mallet (80,109,172) (Fig. 165.11).

PREOPERATIVE MANAGEMENT

PROM exercises help prevent or diminish contractures due to BPBP. PROM is especially important in the infant, because the shoulder can become fixed in internal rotation and subluxate or dislocate before the child is old enough to undergo shoulder external rotation tendon transfer or rerouting (63,164). Weekly manipulation by a therapist is not adequate; the child’s shoulder should undergo PROM several times each day, so the child’s caregivers must be trained to do shoulder PROM exercises.

PREOPERATIVE PLANNING

CT myelography or MRI may be helpful for planning brachial plexus exploration and nerve grafting, although the decision to proceed with this operation is based on lack of clinical recovery, and the most helpful planning information is gained from somatosensory-evoked potentials performed intraoperatively.

Before shoulder external rotation tendon transfer or rerouting, the waist portion of the shoulder spica cast can be applied with the child standing, to improve fit, then removed and reapplied at the end of the operation. Postoperative therapy is especially important following these procedures, so arrangements for this should be made prior to surgery.

OPERATIVE TECHNIQUES

Brachial Plexus Exploration and Nerve Grafting

See Chapter 60 and Figure 165.12 for details on surgical techniques for brachial plexus exploration. Repair of BPBP differs slightly from repair of traumatic brachial plexus palsy in adults. The differences stem from the following aspects of BPBP:

- Nerve transfer (neurotization) is not usually necessary; at least one root is usually available as a proximal source of intact neurons.
- The entire plexus is often shifted distally, so landmarks such as the clavicle crossing the plexus at the level of the divisions are not reliable.
- Clavicular osteotomy is not usually necessary.

If sural nerve grafts are obtained and the child is ambulatory, apply short-leg walking casts. Apply a custom-fabricated chest and neck splint at the end of the operation (Fig. 165.13). The ipsilateral arm can be placed in a sling or attached to the chest splint with a Velpeau wrap. Remove the chest and neck splint, sling, and short-leg walking casts and resume shoulder PROM exercises 3 weeks after surgery. Return of function may take 6 months to 2 years.

Figure 165.11. Modified Mallet’s classification (172). Grade I has no function.

Figure 165.12. A: Marks indicate planned incision for brachial plexus exploration (child is supine, with head to the left). B: Intraoperative view of scarred plexus (same child as in A). The head is to the left, vessel loops surround the roots; the central horizontal structure is the plexus. C: Intraoperative view of clavicle and sural nerve cable grafts (same child as A and B; head is to the left, central vertical structure is clavicle).
Figure 165.13. Infants in custom-fabricated neck brace following brachial plexus exploration and grafting.

Shoulder External Rotation Tendon Transfer

Tendon transfers (84,136) (Fig. 165.14 and Fig. 165.15) are methods used to improve shoulder motion in children with BPBP. The surgical technique is as follows:

Figure 165.14. Tendon transfer procedure (84). A: Pectoralis major release. B: Teres major and latissimus dorsi, before attachment from humerus. C: Teres major and latissimus dorsi, after detachment from humerus. D: Teres major and latissimus dorsi transferred to rotator cuff.

Figure 165.15. Shoulder external rotation tendon transfer. A: Transverse axillary incision. The patient is in right lateral decubitus position, with left arm abducted to 90°. B: Latissimus dorsi and teres major tendons after detachment from humerus. C: Latissimus dorsi and teres major tendons have been sutured to supraspinatus tendon (at tip of Army-Navy retractor).

Perform the operation under general anesthesia. Place the patient in a lateral decubitus position and hold with a beanbag. Isolate the affected axilla and arm with a U drape. Range the shoulder under anesthesia; if there is less than 80° passive external rotation when the arm is abducted to 90°, perform the pectoralis major lengthening as described later. If there is more than 80° rotation, pectoralis lengthening is not necessary.

Make a transverse axillary incision after infiltrating the area with bupivacaine with epinephrine. Extend the incision posteriorly to the deltoid-triceps interval. In the anterior end of the incision, locate the pectoralis major muscle. The tendon is short and most prominent on the deep side of the muscle. Using Bovie cautery, transect the tendinous and fascial portions of the muscle near its insertion on the humerus. Do not transect the entire muscle. Subscapularis lengthening is rarely necessary and may destabilize the shoulder.

In the posterior part of the incision, locate the teres major and latissimus dorsi muscles. Trace them to their humeral insertions, using blunt dissection; these tendons are frequently conjoined (19). The axillary nerve and posterior humeral circumflex artery cross from anterior to posterior deep to the latissimus and teres major tendons, just proximal to their insertions. They are easier to visualize after detaching the tendons.

Detach the teres major and latissimus tendons from their humeral insertions. Bluntly free the muscle bellies from surrounding attachments, avoiding the circumflex scapular and thoracodorsal vessels. Tag the tendons with 0 nonabsorbable suture. Through the deltoid-triceps interval, locate the rotator cuff tendon. Stay proximal to avoid the axillary nerve.

Position the arm in 90° of abduction and 60° to 80° of external rotation, bringing the latissimus and teres major tendons posterior to the triceps muscle, and suture them into the rotator cuff tendon as high as possible.

Close the skin incision in two layers. Apply the prefabricated waist portion of the spica cast, and attach a long-arm cast to the waist portion (Fig. 165.16).

Figure 165.16. Shoulder spica cast used after shoulder external rotation tendon transfer or rerouting. (Drawing by Anthony Marotta, with permission).

Remove the shoulder spica cast 6 weeks after surgery. Apply an adjustable removable shoulder abduction splint (Fig. 165.8). Prescribe twice-daily occupational therapy (OT) for 2 weeks. The OT program is designed to strengthen the tendon transfer. Have the child wear the splint for the first week whenever he or she is not in therapy; in the second week, the splint can be discontinued during the day. The child should continue to wear the splint at night for 6 months. Continue OT at less frequent intervals for 6 to 12 months.
Shoulder External Rotation Tendon Rerouting

The surgical technique for tendon rerouting (39) (Fig. 165.17 and Fig. 165.18) follows the same first five steps as those used for tendon transfer (preceding technique). If the teres major and latissimus tendons are conjoined, this operation cannot be performed; the tendons must be transferred instead of rerouted. The surgical technique continues as follows:

Figure 165.17. Tendon rerouting procedure. A: Latissimus dorsi tendon and teres major tendon pulled through a split in the deltoid. B: Latissimus dorsi tendon and teres major tendon after anastomosis. Reprinted from ref. 39, with permission.

Figure 165.18. Tendon rerouting procedure. A: Left axilla, upper sutures are in the latissimus dorsi tendon, lower sutures are in the teres major tendon. B: Left shoulder, head is to the right. Latissimus dorsi and teres major tendons pulled through a split in the deltoid muscle.

- Transect the latissimus at the muscle–tendon junction. Attach the latissimus muscle belly side to side to the teres major muscle belly; avoid excess tension, or mobilization of the teres will be difficult. Tag the latissimus tendon, which is still attached to the humerus at its insertion, with 0 nonabsorbable suture.
- Detach the teres major from its humeral insertion. Tag it with 0 nonabsorbable suture.
- Make a 3 cm incision starting at the acromion, at the posterior one third or anterior two thirds junction of the deltoid, after infiltrating with bupivacaine and epinephrine. Split the deltoid fibers bluntly down to the humerus. Stay proximal to the axillary nerve insertion.
- Bluntly make tunnels around the proximal humerus, starting at the humeral insertion site of the teres major. Each tunnel should reach the deltoid incision superiorly. The posterior tunnel must be large enough to accommodate the teres major muscle; the latissimus tendon will pass through the anterior tunnel.
- Pass the latissimus tendon anteriorly, and the teres major muscle posteriorly. Both should be visible through the deltoid incision.
- Attach the latissimus tendon to the teres major muscle by tying their tag sutures together through the deltoid incision, with the shoulder in 90° of abduction and 45° to 90° of external rotation.
- Close the skin incision in two layers. Apply the prefabricated waist portion of the spica cast, and attach a long-arm cast to the waist portion (Fig. 165.16).

External Rotation Osteotomy of Humerus

Goddard and Fixsen (61) address the rotational osteotomy of the humerus for birth injuries of the brachial plexus. The surgical technique for osteotomy is as follows:

- Perform the operation under general anesthesia.
- Place the patient in supine position with a small beanbag under the scapula. Examine the arm carefully, estimating the amount of external rotation necessary for the patient to reach the face and head. Prepare and drape the affected arm using a U drape.
- Make a longitudinal anterolateral shoulder incision after infiltrating with bupivacaine and epinephrine. Approach the humerus through the deltopectoral and anterior deltoid–biceps intervals (between the radial and musculocutaneous nerves, neither of which are usually visualized). The radial nerve will be more anterior than usual because of the internal rotation contracture.
- Select the osteotomy site at the deltoid insertion, with enough exposure proximally and distally to apply a small six-hole AO plate. Predrill, measure, and tap two holes proximal to the osteotomy site before making the osteotomy.
- Make the osteotomy after making a longitudinal mark across the osteotomy site.
- Rotate the distal fragment the amount previously estimated to allow the patient to reach the face and head. Insert two screws proximally and one distal to the osteotomy, and carefully range the shoulder to make sure the new position is optimal. Remove the distal screw and adjust the rotation if necessary. Insert the remaining screws, check the position of the fixation on a radiograph, if necessary, and close the wound in layers.
- Apply a shoulder immobilizer with an abduction pillow.

Remove the shoulder immobilizer 6 weeks after surgery and check radiographs for bridging callus. If callus is present, discontinue immobilization. Postoperative rehabilitation is not usually necessary.

Biceps Rerouting and Forearm Osteoclasis for Supination Deformity

Manske and McCarroll (110) discuss biceps rerouting (Fig. 165.19) and osteoclasis (Fig. 165.20) in treating supination deformity in obstetric palsy. The general surgical technique is as follows:

Figure 165.19. Rerouting of the biceps tendon. See text for description of the surgical technique. Reprinted with permission from Manske PR, McCarroll HR Jr. Biceps

Figure 165.20. Osteoclasis of the forearm. See text for a description of technique (110).

- Perform the operation under general anesthesia, and use a tourniquet. A sterile tourniquet may be necessary.
- Approach the biceps tendon through an anterior zigzag incision, placing the transverse limb of the zigzag along the elbow flexion crease (Fig. 165.19A).
- Incise the lacertus fibrosis, and retract the median nerve and brachial artery ulnarward (Fig. 165.19B).
- Expose the biceps tendon to its insertion on the bicipital tuberosity of the radius. Divide the biceps tendon by a Z lengthening (the Z should be as long as possible). Protect the radial artery, which crosses the palmar surface of the tendon near its insertion.
- Pass a folded wire suture or a curved suture carrier around the neck of the radius. Reroute the distal tendon segment so that it has a pronating torque by attaching it to the suture carrier (Fig. 165.19C).
- Reattach the distal tendon to the proximal tendon in a side-to-side fashion using nonabsorbable suture. The biceps tendon usually requires 1.5 cm of lengthening to be repaired after rerouting (110). Close the wound in layers and apply a long-arm cast in neutral forearm rotation, with the elbow flexed 90° (Fig. 165.19D, Fig. 165.19E).
- If biceps rerouting does not achieve adequate correction of the supination deformity, perform two-stage forearm osteoclasis any time after the rerouting has healed (Fig. 165.20).
- Perform the operation under general anesthesia, and use a tourniquet.
- Through small incisions, use a one-eighth-inch drill to make three bicortical drill holes in the middle third of the radius and ulna (Fig. 165.20A). Fracture the bones by manipulating the forearm (Fig. 165.20B). Do not rotate the distal fragment at this time, or the fragments will displace. Close the wounds.
- Place the arm in a long-arm cast, with the elbow at 90°.

After 10 to 14 days, under sedation or general anesthesia, remove the cast and manipulate the distal forearm to the desired position (0° to 40° of pronation) (Fig. 165.20C). Enough callus will have formed by this time that the fragments will not displace. Reapply the long-arm cast, with the elbow at 90° and the forearm in the desired position of rotation. Immobilize for 6 weeks after biceps rerouting. Focus the postoperative rehabilitation on active elbow flexion and extension, and forearm rotation. Then immobilize for 3 to 4 weeks after the second stage of forearm osteoclasis. Postoperative rehabilitation is not usually necessary.

Other Surgical Techniques

See Chapter 55 for the surgical technique for the wrist extension transfer, Chapter 56 for the opponensplasty, Chapter 101 for shoulder arthrodesis, and Chapter 72 for wrist arthrodesis.

COMPLICATIONS

Most pitfalls related to brachial plexus exploration and nerve grafting occur in patient selection. If the surgeon underestimates the infant's potential for recovery, resection and grafting of the plexus may do more harm than good. If the surgeon waits too long to operate (after 1 year of age), the limited improvement achieved before surgery will be lost and may not be recovered.

Just as in nerve exploration and grafting, most pitfalls related to shoulder external rotation tendon transfer and rerouting occur in patient selection. If the deltoid is too weak, the tendon transfer will not improve range of motion. If the patient is unable to cooperate with postoperative therapy, the tendon transfer will probably not function as well. If the shoulder contracture is due to extensive glenohumeral changes, or if long-standing posterior shoulder dislocation is present, the tendon transfer will not improve range of motion. The transverse axillary scar in this procedure is nearly invisible.

In an external rotation osteotomy of the humerus, if the elbow flexion contracture is severe (more than 45°), the patient will probably be unhappy with the position of the forearm after the humerus is rotated externally. With the shoulder internally rotated, the forearm can lie across the front of the body, but after an external rotation osteotomy, the forearm and hand will “stick out.” Also, the anterolateral arm scar widens and is quite noticeable.

Likewise, the anterior elbow scar from biceps rerouting and forearm osteoclasis often widens and is quite noticeable.

CONCLUSIONS

BPBP is very distressing to parents, perhaps because of the etiology, that is, because it is an injury rather than a congenital malformation. BPBP is a common cause of malpractice claims against obstetricians. The well-documented increased risk of recurrent BPBP with subsequent pregnancies has not been featured in the obstetrics literature; we advise parents of this risk so they can pass this information along to their obstetrician.

Although most series show high rates of full recovery, these data are based on relatively short follow-up. We frequently see 3- to 4-year-old children with functional limitations from BPBP who were declared fully recovered at 3 to 6 months of age, before they could cooperate with a thorough active motion and strength examination. However, many children with slightly limited shoulder range of motion and strength can function almost normally, and even when function is limited, older children and parents may be bothered more by the decreased size of the extremity and length discrepancy than the decreased function.

CONGENITAL TRANSVERSE FAILURE OF FORMATION OF THE UPPER EXTREMITY

PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT

Transverse failure of formation, often inaccurately termed “congenital amputation,” occurs when the upper limb fails to form below a certain level. Finger nubbins usually form at the distal end of the limb, regardless of level (Fig. 165.21); their presence helps differentiate this condition from congenital constriction ring syndrome, in which nubbins do not form (see Chapter 69).
Transverse failure of formation is not inherited. The leading hypothesis for the etiology of transverse failure of formation is the subclavian artery supply disruption sequence theory: disruption of the embryonic subclavian blood supply causes transverse failure of formation, Poland anomaly, symbrachydactyly, Mobius syndrome, or other conditions, depending on the location of the blockage and the timing and duration of disruption (16,154,175). One study (86) showed evidence of fetal vascular occlusive disease in the placentas of infants with transverse failure of formation, and hypothesized that embolization from placental vascular thrombi caused this condition. Others (85,115) have found an increased incidence of transverse failure of formation and other limb defects in infants whose mothers underwent chorionic villus sampling before 10 weeks’ gestation.

The most common level of transverse failure of formation is proximal forearm (below elbow), followed by transcarpal, distal forearm, and through humerus (above elbow) (181). This condition is almost always unilateral (146), and the left side is more commonly affected (91). Children with this condition have remarkably few functional deficits, and surgery has not been proven to improve their abilities (18). A prosthesis enhances prehension and possibly appearance but blocks sensory feedback. When indicated, goal-directed occupational therapy may help the school-aged child learn to perform activities of daily living with and without a prosthesis.

Assessment, Indications, and Relative Results

Transverse failure of formation is usually an isolated anomaly, but children with amelia (failure of formation at the shoulder level) have a high incidence of scoliosis (138) (Fig. 165.23). Cognition and developmental milestones are usually normal, except that the child with a very short arm may not crawl.

The child with above-elbow or below-elbow failure of formation should be assessed by a prosthetic team (which includes a physician, a prosthetist, and an occupational therapist, and may include a recreation therapist and social worker) at around 6 months of age, and fitted with a prosthesis with a passive hand or mitt when able to sit independently (91) (Fig. 165.24). Parents are encouraged to gradually increase wearing time until the child tolerates the prosthesis for the majority of the waking hours. Children with more proximal or distal failure of formation are not usually fitted with a prosthesis in infancy. If the deficiency is at shoulder level, the prosthesis is too heavy for comfortable wear; if the deficiency is at the distal forearm or through the carpus, the child functions better without a prosthesis (149).
Follow the child's condition closely (three to four times each year) to check prosthesis fit and reinforce the importance of regular wear. Children who are fitted with a prosthesis before 2 years of age are more likely to continue to use the prosthesis throughout childhood. At 2 to 3 years of age, evaluate the child for readiness for an active terminal device (TD). If the child readily bears weight on the passive prosthesis when crawling and uses it for pulling up, balance, and two-handed activities, such as throwing and catching, he or she is probably ready to learn to use an active TD.

**Figure 165.25.** Doll with prosthesis.

At this point, the physician and parents choose between a body-powered (cable-operated) prosthesis, which works best with a hook or similar type TD, and a prosthesis powered by electrical signals from proximal forearm muscle contractions (myoelectric prosthesis), which usually has a TD that looks like a hand and uses a chuck pinch (Fig. 165.26 and Table 165.2). Each of these prostheses has advantages and disadvantages; fortunately, because the growing child needs a new prosthesis every 1 to 2 years, no choice is permanent. The body-powered hook prosthesis is more difficult to learn to use, but children who learn to use this type of prosthesis first can usually learn to use a myoelectric prosthesis easily. Children who learn to use a myoelectric prosthesis first have more difficulty learning to use a body-powered hook prosthesis. Most studies comparing performance of body-powered and myoelectric prostheses use a hand TD on both prostheses. The cosmetic glove used with this TD increases resistance to opening, which is easily overcome by the myoelectric motor but makes the body-powered prosthesis very difficult to use. In spite of this handicap, however, these studies show that children perform most tasks faster with the body-powered prosthesis and consistent users of a body-powered prosthesis are more likely to be pleased with prosthetic function. However, parents and older children are often influenced by the "high-tech" image of the myoelectric prosthesis and the fact that the TD most commonly used with this prosthesis looks like a hand.

**Figure 165.26. A and B:** Body-powered hook prosthesis. **C and D:** Myoelectric hand prosthesis.

Forearm lengthening has been described for the very short below-elbow stump to improve prosthetic fitting; this is very rarely indicated. The Krukenberg procedure, in which the radius and ulna are separated and muscles reattached so that the radius pinches against the ulna, is most useful for blind bilateral distal forearm amputees, because it provides unilateral prehension with sensory feedback. This operation may occasionally be indicated for a sighted child with above-wrist failure of formation who does not have access to prosthetic facilities. However, because children with unilateral above-wrist failure of formation have very few functional deficits and the appearance of the Krukenberg forearm is strikingly abnormal, this operation is rarely indicated for the child with unilateral deficiency.

**CLASSIFICATIONS**

There is no classification system for transverse failure of formation other than level, which has been previously described.

**CONCLUSIONS**

The biggest challenge in the treatment of children with transverse failure of formation is helping parents adjust their often unrealistically high expectations of prosthetic technology. The importance of good communication with the child and family cannot be overstressed. We focus on:

- The remarkable abilities of the child with or without the prosthesis (most children with below-elbow failure of formation tell us that the only activity they cannot perform is traveling hand over hand on the monkey bars).
- The opportunity to try a different type of prosthesis when the child outgrows the current one.
- The need for improved prosthetic technology [well documented in a recent nationwide survey of upper-extremity prosthesis users].
- The importance of maintaining the prosthesis so that the child can use it, and the responsibilities of the child, family, prosthetist, and physician in accomplishing this task.

We prefer to prescribe a body-powered hook TD prosthesis, but will prescribe a myoelectric prosthesis if the family strongly prefers it and has demonstrated that they can keep their clinic appointments and return promptly if the prosthesis breaks or if the child outgrows it. Older children who use a body-powered prosthesis may appreciate interchangeable TDs: a hook for function and a prosthetic hand when appearance is more important than function.
CONGENITAL DISLOCATION OF THE RADIAL HEAD

PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT

Congenital dislocation of the radial head (CDRH) is the most common congenital anomaly of the elbow (1,9,125). Although the etiology of CDRH is unknown, it is known to be associated with dysplasia of the capitellum and proximal radius, as well as shortening of the ulna (65,125). In CDRH, the radial head may be dislocated in an anterior, posterior, or lateral direction; in one series, 47% were anterior, 43% posterior, and 10% lateral (9).

CDRH is usually bilateral (1,9,111,125). It may be isolated and either sporadic or familial, or it may be associated with congenital radioulnar synostosis (124), or with a syndrome, such as Klinefelter's, Cornelia de Lange, Ehlers–Danlos, and nail-patella syndrome (1,9,46,71,97,111,128,140,156). Not all cases are congenital; progressive subluxation of the radial head progressing to dislocation has also been reported (97).

ASSESSMENT, INDICATIONS, AND RELATIVE RESULTS

CDRH may be noted in infancy but often escapes detection until the child is of school age (97). The presenting complaint is usually posterolateral elbow prominence, restricted elbow extension and forearm rotation, elbow “popping,” or pain with activity (1,95), although pain is uncommon before adolescence. Often, the limitations due to CDRH are first perceived after an unrelated elbow injury and may be erroneously attributed to that injury. When the condition is unilateral, CDRH may be difficult to distinguish from chronic traumatic dislocation (29) (Table 165.3).

Table 165.3. Congenital vs Traumatic Radial Head Dislocation

The dislocated radial head is palpable just distal to the cubital fossa in anterior CDRH, and palpable and visible laterally in posterior CDRH (see Fig. 165.27 and Fig. 165.28). Elbow motion deficits are often minimal, usually nonprogressive, and worse in anterior than posterior CDRH. Loss of supination is the most prominent limitation in both anterior and posterior CDRH. Anterior CDRH blocks full flexion, and posterior CDRH blocks full extension, causing a flexion contracture (usually 30° or less). Wrist range of motion may also be limited (1,9,111,125). In the infant, the unossified dislocated radial head may be visualized with diagnostic ultrasound (14), but the diagnosis is most commonly made by plain radiography (Fig. 165.27 and Fig. 165.28).

Figure 165.27. Anterior congenital dislocation of the radial head.

Figure 165.28. AP and lateral views of a posterior dislocation of the radial head.

Surgical intervention is seldom necessary in childhood because most children are asymptomatic and have minimal functional limitations (46,125). Radial head resection before skeletal maturity has been associated with several different complications (see Complications, later). Surgical reduction of the radial head and reconstruction of the annular ligament or rotational radial and ulnar osteotomies have not been consistently successful (9,124,125). In adolescence or adulthood, the laterally or posteriorly dislocated radial head may become painful owing to degenerative changes at the contact point between the radial head and the distal humerus; radial head excision relieves pain, improves appearance, and may improve range of motion (29,97).

CLASSIFICATIONS

CDRH is classified by the direction of the dislocation, as previously described.

PREOPERATIVE PLANNING

Examine the wrist for distal radioulnar joint (DRUJ) instability, and obtain bilateral wrist radiographs before radial head resection. If the DRUJ is unstable and the symptomatic side is ulna positive, resection of the radial head may cause wrist pain.
OPERATIVE TECHNIQUE

Resection of the Radial Head (Posterior or Lateral Dislocation)

- Perform the operation under general anesthesia, and use a tourniquet.
- Make a longitudinal incision using a Kocher approach over the dislocated radial head. Develop the interval between the extensor carpi ulnaris and anconeus muscles.
- Incise the capsule with the forearm in maximal pronation, and do not extend the capsular incision distal to the radial neck, to avoid injuring the posterior interosseous nerve. Preserve the annular ligament to enhance proximal radius stability and protect the posterior interosseous nerve. Avoid violating the periosteum of the proximal ulna to prevent radioulnar synostosis.
- Excise the radial head with an oscillating saw, osteotome, or rongeur perpendicular to the radial neck. Check elbow flexion and extension and forearm pronation and supination to make sure that the proximal radius does not contact the distal humerus; if it does, resect more until it moves freely. Remove any loose intra-articular osteochondral fragments.
- Close the capsule with nonabsorbable suture. Close the subcutaneous tissue with interrupted absorbable suture, and close the skin with running subcuticular suture.
- Immobilize the elbow at 90° of flexion in a long-arm splint.

Remove the splint after 7 to 10 days, and begin early range-of-motion exercises.

COMPLICATIONS

If radial head resection is performed before skeletal maturity, several complications can occur, including regrowth of the proximal radius, postoperative radioulnar synostosis (29), and cubitus valgus deformity. However, radial head resection for a variety of indications, including CDRH, did not cause cubitus valgus in 27 elbows of 25 children with an average age of 14 years (range 5 to 18 years) (87). Other potential complications include injury to the posterior interosseous nerve, radioulnar synostosis, proximal migration of the radius, valgus elbow instability, cubitus valgus, and wrist pain (9,29,97,111).

CONCLUSIONS

If the dislocated radial head rubs against the distal humerus, painful degenerative changes can occur. Radial head resection reliably relieves pain and is sometimes necessary, even when the DRUJ is unstable. When wrist pain occurs following radial head resection for CDRH, it is usually mild and activity related.

CONGENITAL ELEVATION OF THE SCAPULA (SPRENGEL’S DEFORMITY)

PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT

Congenital elevation of the scapula results from a failure of the normal caudal migration of the scapula during the fetal period of development (32,48). The scapula with this malformation is usually hypoplastic with decreased vertical length and increased horizontal width-to-height ratio (27), which is 2 to 10 cm more cephalad than normal (Fig. 165.29). The inferior pole is rotated medially with the glenoid displaced inferiorly. The periscapular muscles may be hypoplastic or absent, causing scapular winging (32,33). In 20% to 30% of cases, the superomedial scapula is connected to the spinous processes, laminae, or transverse processes by a fibrous tissue, cartilage, or bone called the omovertebral connection; this connection is diagnostic of congenital elevation of the scapula (27,32,33). Right and left sides are affected with equal frequency, and bilateral involvement occurs in 10% to 30% of the cases (168).

Figure 165.29. Congenital elevation of the scapula.

The majority of patients with congenital elevation of the scapula have associated anomalies, most commonly congenital scoliosis, Klippel-Feil syndrome, fused or absent ribs, spina bifida, and VATER association (17,27,32,33).

This condition is usually treated nonoperatively, except for resection of the omovertebral connection. Surgical mobilization and caudal repositioning of the scapula have been recommended, but most children with congenital elevation of the scapula do not need surgical treatment (168).

ASSESSMENT, INDICATIONS, AND RELATIVE RESULTS

Children usually present with evaluation of scapular asymmetry, diminished shoulder motion, and fullness at the base of the neck. The affected scapula appears to be elevated and hypoplastic. Shoulder abduction is significantly limited in 40% of patients, and elevation is often limited (33,73). Basilar neck fullness is due to the prominence of the superomedial angle of the scapula (27). Congenital elevation of the scapula is usually not painful.

Differential diagnosis includes brachial plexus birth palsy and isolated scoliosis or Klippel-Feil syndrome (33). An anteroposterior (AP) radiograph of the shoulder demonstrates scapular elevation, especially when compared with the contralateral normal side. A bony omovertebral connection may be seen on the AP view (Fig. 165.30) or on lateral oblique views and CT scan. Examine the child for scoliosis and other associated anomalies.

Figure 165.30. Bony omovertebral connection.
Function may be limited by decreased shoulder abduction, but many children with this condition have excellent shoulder function. Passive stretching and abduction early in infancy may improve shoulder range of motion, and removal of an omovertebral connection may also improve range of motion.

The cosmetic deformity and degree of disability are proportional to the severity of deformity; children with mild grade 1 to grade 2 elevation (see next section, on classifications and terminology) have little functional impairment.

For more severe malformations with functional impairment, surgical repositioning of the scapula may be indicated in addition to resection of the omovertebral connection, with the goal of improving appearance and range of motion. Various methods of scapular mobilization have been described. Woodward (180) recommended moving the trapezius and rhomboid muscle origins to a more caudal position along the spine. Borges et al. (27) modified Woodward’s procedure to include excision of the superomedial scapular prominence, to improve appearance. Clavicular osteotomy is recommended to allow further scapular descent and prevent damage to the brachial plexus (27,33,67).

One long-term study (67) of 23 patients who underwent four different operations for congenital elevation of the scapula found that the average reduction of elevation was 2.7 cm, and average improvement in abduction was 19 degrees for repositioning procedures, with the best results in patients who underwent Woodward’s procedure. Optimal age for surgery is probably between 3 and 8 years of age (32,68). Good results of scapular mobilization have been reported in older patients, but with less functional improvement (27). Normal appearance and function should not be expected at any age (33).

CLASSIFICATIONS AND TERMINOLOGY

Although congenital elevation of the scapula is commonly called Sprengel’s deformity, it is actually a malformation instead of a deformity (see Chapter 69). The condition has been classified by severity (Table 165.4). This classification helps the surgeon determine treatment and prognosis and evaluate the postoperative result (33).

Table 165.4. Classification of Congenital Elevation of the Scapula

OPERATIVE TECHNIQUES

Resection of Omovertebral Connection

Figure 165-31 is an intraoperative photo of a resection of an omovertebral connection for the same patient whose radiograph is shown in Figure 165-30. The surgical procedure is as follows:

- Place the patient in the prone or lateral decubitus position with the affected side up.
- Place the incision directly over the omovertebral connection, in a transverse direction, if possible. Inject skin and subcutaneous tissue with bupivacaine and epinephrine; this provides pre-emptive analgesia and improves hemostasis.
- Expose and transect the connection at its scapular and spinous connections, and remove it.
- Close the incision in layers, and immobilize the arm in a sling or shoulder immobilizer.

Allow normal use of the shoulder as soon as postoperative pain has diminished.

Surgical Repositioning of the Scapula

This operation is rarely indicated, and its description is beyond the scope if this text. For details, please see Woodward (180), Wilkinson and Campbell (177), Klisic et al. (99), and Borges et al. (27).

COMPLICATIONS

Complications of omovertebral resection are uncommon. Complications of surgical repositioning of the scapula include scar widening and residual scapular elevation (27,33,177,180). Brachial plexus and vascular injury can occur (27); clavicular osteotomy (or morcellation) may prevent neurovascular injury with scapular repositioning (142). In addition, the suprascapular nerve may be injured with resection of the superior scapula.

CONCLUSIONS

Resection of the omovertebral connection is simple and usually improves appearance and range of motion. Scapular repositioning, a major operation with considerable risk of neurovascular injury and a good possibility of inadequate correction, is rarely indicated.

CONGENITAL PSEUDARTHROSIS OF THE CLAVICLE
PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT

Congenital pseudarthrosis of the clavicle is a rare anomaly that results from failure of normal clavicular ossification. The etiology is unknown; one hypothesis suggests that the subclavian artery may compress the developing right clavicle, which might explain the predominance of right-sided lesions and the occurrence of left-sided lesions in association with dextrocardia. Bilateral involvement is rare. Another hypothesis is that the pseudarthrosis is caused by the failure of two ossification centers to fuse, but the normal clavicle in the developing embryo has only one ossification center. Unlike congenital pseudarthrosis of the tibia and ulna, this condition is not associated with neurofibromatosis, although it may be inherited in an autosomal recessive fashion.

This condition does not usually require surgical treatment, and historically surgery for clavicular pseudarthrosis has had a high rate of serious complications. Surgical resection of the pseudarthrosis and internal fixation may be indicated if the pseudarthrosis is very prominent or painful.

ASSESSMENT, INDICATIONS, AND RELATIVE RESULTS

Children with this rare condition are often noted to have a prominent middle third of the right clavicle at birth or soon thereafter; the prominence may increase with age. The pseudarthrosis is usually not painful, and shoulder range of motion is normal. Radiographs of the pseudarthrosis reveal an osseous separation with enlarged, rounded bone ends, and a distinctive absence of fracture callus (Fig. 165.32). Although case reports indicate that the natural history of pseudarthrosis of the clavicle is benign, no large series of cases has been reported.

Differential diagnosis includes traumatic clavicle fracture (a common birth injury, which is accompanied by pseudoparalysis of the involved limb, painful range of motion, and radiographic callus) and cleidocranial dysostosis (a bilateral inherited disorder of fetal membranous bone ossification, with clavicle, cranial, and pelvic dysplasia).

Occasionally the pseudarthrosis is so prominent that surgical removal and repair with internal fixation is indicated if the pseudarthrosis is very prominent or painful. Multiple complications of surgery have been reported, including sepsis, nonunion, and brachial plexus injury. Simple excision of the clavicular prominence without internal fixation or any attempt to obtain union is generally recommended in the postpubertal patient who wishes to improve appearance. In prepubertal children, most authors who advocate surgical treatment recommend excision of the pseudarthrosis, bone grafting, and plating.

CLASSIFICATIONS

There are no classification systems for congenital pseudarthrosis of the clavicle.

OPERATIVE TECHNIQUE

Pseudarthrosis Resection and Bone Grafting

- Position the patient supine, with a pad under the affected scapula.
- Incise the skin longitudinally along the inferior clavicular border, and expose the pseudarthrosis.
- Incise the periosteum longitudinally. Resect the pseudarthrosis subperiosteally. Measure the defect.
- Obtain autologous corticocancellous iliac crest bone graft to span the clavicular defect created by resection of the pseudarthrosis, if necessary.
- Internally fix the clavicle with a semitubular or small low-profile dynamic compression plate. Avoid inferior placement of the plate or graft, which could cause subclavian vessel or brachial plexus injury (the subclavian artery passes between the clavicle and first rib immediately deep to the clavicular defect).
- Close the incision in layers, and immobilize the arm in a sling.

Remove the sling 6 weeks after pseudarthrosis and grafting. The osteotomy sites are difficult to see on radiographs. If the plate or screws are prominent, they should be removed after osteosynthesis has occurred.

COMPLICATIONS

Many complications of pseudarthrosis resection, grafting, and plating have been described, including hypertrophic scar formation, infection, nonunion, neurovascular injury, and bone graft donor site morbidity. Steinmann pin fixation should never be used because it provides inadequate fixation and pins have been reported to migrate or cause neurologic injury. Simple excision of the pseudarthrosis without bone graft or internal fixation causes the affected shoulder to droop.

CONCLUSIONS

Surgical treatment of this condition is indicated only when the malformation is conspicuous and bothersome to the patient or the patient’s parents. As with any elective operation, the patient and the parents must fully understand the potential risks. Resection, grafting, and plating can improve the patient’s appearance considerably in this condition.

CONGENITAL PSEUDARTHROSIS OF THE ULNA

PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT

Congenital pseudarthrosis of the ulna is a very rare condition that is usually associated with neurofibromatosis. Pseudarthrosis may be present at birth, or it may develop spontaneously after a fracture or after osteotomy; it has been reported to occur in the tibia, ulna, femur, clavicle, radius, and humerus. Congenital pseudarthrosis is unknown; in the majority of cases, the pseudarthrosis contains fibrous tissue, not neurofibroma (see Chapter 185).

Congenital pseudarthrosis of the ulna causes a progressive forearm deformity. The forearm is short and bowed, and eventually the radial head dislocates (Fig. 165.33). The goal of treatment is to obtain union without sacrificing motion.
Figure 165.33. Congenital pseudarthrosis of the ulna.

ASSESSMENT, INDICATIONS, AND RELATIVE RESULTS

Pseudarthrosis of the ulna causes deformity, instability, weakness, and sometimes pain, although motion is usually not limited. Like the same condition in the tibia, union can be achieved with bone grafting and immobilization, but pseudarthrosis usually recurs. Historically, creation of a one-bone forearm was the only option available. This operation successfully restores forearm stability (169) but eliminates forearm rotation. Although the Ilizarov technique may successfully restore union in tibial pseudarthrosis (132), the use of prolonged immobilization and differential lengthening of the forearm bones is also likely to result in loss of forearm rotation.

Several authors (54, 114, 116, 183) have reported treating ulnar pseudarthrosis with free vascularized fibular graft; in most cases, union was achieved, length was maintained, and forearm rotation was diminished but not completely lost. The indications for vascularized fibular graft, including the optimal age of the patient, have not yet been established, but this technique is promising.

CLASSIFICATIONS

There is no classification system for congenital pseudarthrosis of the ulna.

PREOPERATIVE PLANNING

When a free vascularized fibular graft is planned, preoperative arteriograms of the donor and recipient sites help identify possible vascular abnormalities (54).

OPERATIVE TECHNIQUE

Free Vascularized Fibular Graft to the Ulnar Pseudarthrosis

Gerwin and Weiland (54) discuss this technique. See Chapter 36 for the surgical technique of harvesting a free fibular graft.

- Resect the pseudarthrosis and fix the graft in place using short plates at the proximal and distal ends, before performing vascular anastomoses. Avoid using intramedullary fixation or a long plate that spans both ends of the graft because these fixation methods interfere with graft vascularity.
- Use an end-to-side anastomosis in the forearm, if possible, to minimize reduction of hand perfusion.
- Use a supplemental cancellous bone graft at each end of the fibular graft to enhance union.

Allow ambulation 3 to 5 days after surgery in a short-leg walking cast, which can be removed after 3 to 4 weeks. Immobilize the arm with a long-arm cast and check radiographs out of plaster every 6 weeks. Continue immobilization until graft incorporation is seen on radiographs; the average time to graft incorporation is 3 to 6 months.

COMPLICATIONS

Union may be difficult to achieve, and subsequent regrafting with cancellous allograft may be necessary. Even after union is achieved, pseudarthrosis may recur. If painful pseudarthrosis recurs and regrafting fails, creation of a one-bone forearm is the only remaining surgical option.

CONCLUSIONS

Because this condition is so rare, the indications for vascularized fibula grafting are not well established, and follow-up to skeletal maturity is lacking. The best indications probably are pain and progressive deformity.

CONGENITAL PROXIMAL RADIOULNAR SYNOSTOSIS

PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT

Congenital proximal radioulnar synostosis (PRUS) is a malformation caused by failure of normal prenatal separation of the radius and ulna. The persistent connection between the two bones is nearly always proximal; distal radioulnar synostosis is extremely rare (15, 96, 144, 152, 173). The connection is initially cartilaginous, but it usually eventually ossifies, forming a bony synostosis (Fig. 165.34). The forearm is usually fixed in pronation, probably because this is the normal fetal position (96, 173).

Figure 165.34. Proximal radioulnar synostosis.

PRUS is usually an isolated malformation, but it may be associated with other malformations or syndromes in up to one third of affected children (152). Other malformations associated with PRUS include thumb hypoplasia, carpal coalition, symphalangism, and clubfoot (125); syndromes associated with PRUS include Apert's syndrome, arthrogryposis, fetal alcohol syndrome, and Klinefelter's syndrome (96, 152, 165, 166). Familial occurrence (37, 71) with autosomal dominant inheritance (141) has also been reported.
involved (long bones and from the pelvis, ribs, scapula, and vertebrae. Multiple hereditary exostoses (MHE) is a disorder of enchondral bone growth in which cartilaginous exostoses (also called osteochondromas) grow from the physes of

needed, obtain it in two stages. If either of these complications occur, remove the transfixion pin and return the forearm to its original position; if forearm compartment
The complication rate for forearm rotational osteotomy was 36% in one series (129,144,152). The optimal position of the forearm is controversial because the best position of rotation varies with the task. Some surgeons recommend placement of the dominant forearm in 10° to 20° of pronation, and the nondominant forearm in neutral rotation, if necessary; and for unilateral PRUS, placement in 0° to 15° of pronation (152). Other authors (157) consider fixed pronation between 15° and 60° a relative indication, and forearm fixation in greater than 60° pronation a definite indication for surgery, if functional limitations are significant.
Surgery to regain forearm rotation has nearly always been unsuccessful (136), although recently a free vascularized fascial flap placed between the separated forearm bones has been reported to successfully block postoperative recurrence of the synostosis (93). At present, however, the generally accepted surgical treatment is derotation osteotomy through the fusion mass, using K-wires or small Steinmann pins to fix the osteotomy (65,126,129,152). Others have described gradual correction to neutral following osteotomy, using the Ilizarov method (23), and two-stage osteoclasis without internal fixation (105).
The optimal position of the forearm is controversial because the best position of rotation varies with the task. Some surgeons recommend placement of the dominant forearm in 10° to 20° of pronation, and the nondominant forearm in neutral rotation, if necessary; and for unilateral PRUS, placement in 0° to 15° of pronation (152). Other authors (128) advocate placing the nondominant forearm in 20° to 35° of supination first, and the dominant forearm in 30° to 45° only, if necessary, for unilateral involvement, 0° to 20° supination.
CLASSIFICATION
Radiographic classification based on radial head position and the presence of a radoulnar synostosis does not predict function (37). PRUS is part of a spectrum of malformations ranging from radial head abnormalities to complete synostosis with marked forearm shortening and absence of the radial head (124,152), although these have not been formally divided into types.
PREOPERATIVE PLANNING
Preoperative evaluation by an occupational therapist helps determine the child’s functional deficits and optimal forearm position. If possible, surgery should be performed before school age (152), but this timing precludes considering the child’s future intended occupation to determine the optimal forearm position, as recommended by some surgeons (37).
OPERATIVE TECHNIQUE
Rotational Osteotomy
Green and Mital (65) discuss surgical treatment of congenital radioulnar synostosis. The general surgical technique follows:
- Perform the operation under general anesthesia and a tourniquet.
- Make a dorsal longitudinal incision just radial to the subcutaneous border of the ulna. Incise the fascia in the interval between the anconeous and extensor carpi ulnaris muscles (Kocher approach). Expose the fusion mass subperiosteally.
- Pass a smooth K-wire from the olecranon apophysis into the intramedullary canal of the ulna under fluoroscopic guidance. This wire helps maintain longitudinal position while allowing adjustment of rotation.
- Make a mark across the osteotomy site to determine rotation. Perform the osteotomy around the wire, using multiple drill holes and an osteotome or oscillating saw. The osteotomy should be distal to the coronoid and radial head (if present).
- Rotate the forearm to the desired position and transfix the osteotomy site with a K-wire, passing obliquely from proximal ulna to distal radius. Leave the end of this wire through the skin to facilitate urgent removal for postoperative derotation if vascular compromise occurs.
- If a large change in forearm rotation is necessary, consider resecting 5 mm of bone at the osteotomy site (129), prophylactic forearm fasciotomy (152), or two-stage derotation to decrease the risk of postoperative neurovascular traction or compartment syndrome.
- Close the subcutaneous tissues and skin, and place the arm in a splint or long-arm cast with the elbow flexed to 90°.

Keep the forearm elevated and monitor the patient’s neurovascular status closely for at least 48 hours postoperatively. If a long-arm splint was applied, change to a long-arm cast after 1 to 2 weeks. Remove the cast 6 weeks postoperatively to check forearm radiographs. Remove pins when the forearm bones show signs of healing. Therapy is not usually necessary.

COMPLICATIONS
The complication rate for forearm rotational osteotomy was 36% in one series (152), and the reoperation rate was 23% in another (65). The most serious complications are vascular compromise and compartment syndrome, which occur more frequently with rotational position change of greater than 60°. If this much correction is needed, obtain it in two stages. If either of these complications occur, remove the transfixion pin and return the forearm to its original position; if forearm compartment pressures are elevated, perform fasciotomies (see Chapter 13). Rotational correction can be achieved 5 to 10 days later (152). Other complications include nerve palsy (due to either intraoperative damage to the posterior interosseous nerve or traction from rotational change), wound infection, loss of correction, and nonunion (37,105,129,152).
CONCLUSIONS
In our experience, children with PRUS associated with fetal alcohol syndrome have more severe pronation contractures than most other children with PRUS. Children with fetal alcohol syndrome are often mentally retarded, and they may be unable to describe symptoms of nerve traction following rotational osteotomy.
ELBOW AND FOREARM DEFORMITY DUE TO MULTIPLE HEREDITARY EXOSTOSES
PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT
Multiple hereditary exostoses (MHE) is a disorder of enchondral bone growth in which cartilaginous exostoses (also called osteochondromas) grow from the physes of long bones and from the pelvis, ribs, scapula, and vertebrae (10,135). The exostoses may be sessile or pedunculated (Fig. 165.35). They grow until the patient is skeletally mature and eventually ossify. The forearm is affected in 30% to 67% of patients with this condition (22,88,145), and the proximal humerus is also commonly involved (Fig. 165.36).
Figure 165.35. Multiple hereditary exostoses. A: Forearm, with distal ulna growth arrest and radial head dislocation. B: Proximal humeral exostosis.

Figure 165.36. Multiple hereditary exostoses. Forearm deformity associated with radial head dislocation (same patient as in Fig. 165.35).

The prevalence of MHE is approximately 1 in 50,000 (145). MHE is inherited in an autosomal dominant pattern with high penetrance (145) and variable expressivity. Although MHE has an equal prevalence in both sexes, boys tend to have more severe involvement (120). Genetic studies of families with this condition have mapped the chromosomal abnormality to at least three different loci (119,120), indicating that the MHE phenotype can be subdivided into at least three different genotypes.

Multiple exostoses also occur in other conditions, such as metachondromatosis and the Langer–Giedion syndrome (120).

Estimates of the risk of malignant degeneration of osteochondromas (secondary chondrosarcoma) in MHE vary from 0.5% to 50% of patients; the lower incidence is most likely correct. Malignant degeneration is quite rare in the upper extremity; the pelvis and proximal femur are the most common locations of secondary chondrosarcoma (146). Malignant degeneration in children is also very rare (120,135).

Most exostoses are asymptomatic and do not need to be surgically removed; exostoses removed before skeletal maturity may recur. However, exostoses can cause local discomfort, nerve or tendon impingement, decreased range of motion, and longitudinal and angular growth abnormalities (136). Growth abnormalities may also occur in MHE in the absence of radiologically visible exostoses (23).

ASSESSMENT, INDICATIONS, AND RELATIVE RESULTS

The patient's history of local pain, crepitance, or decreased range of motion, combined with a clinical examination for bony bumps of the upper extremity, helps the physician determine which areas to radiograph. Most exostoses have a cartilage cap and, therefore, are larger than their radiograph appearance suggests.

Local pain, often due to nerve, tendon, or vessel impingement, is a frequent indication for exostosis removal. Subscapular exostoses are common but do not usually cause pain or require removal. Proximal humeral exostoses may impinge on muscle tissue, the brachial plexus, or the axillary nerve, causing pain, paresthesias, or paresis; exostoses of the distal radius and ulna may impinge on the dorsal radial sensory, median, or ulnar nerves or the radial or ulnar arteries. These are indications for surgical removal, which effectively relieves symptoms of impingement (135). An exostosis in the interosseous space that is blocking forearm rotation should also be removed. Recurrence is unlikely if the patient is near skeletal maturity.

The forearm deformities caused by growth arrest due to MHE are complex, and their interrelationships are not well understood. Distal ulnar growth arrest is a common sequela of MHE, even when osteochondromas of the distal ulna are not visible on radiographs. The radial articular angle may increase, and the carpus may “slip” ulnarward, but neither of these findings appears to be associated with negative ulnar variance (28). Radius bowing, radial head dislocation (179) (Fig. 165.35), and forearm shortening also occur, causing loss of forearm rotation.

Early osteochondroma removal may (113,135) or may not (51) retard these progressive growth disturbances. Hemiepiphyseal stapling of the radial side of the distal radius retards the growth of that side while allowing the ulnar side to continue to grow, which corrects the increased radial articular angle (179) (Fig. 165.37). This procedure may be performed in conjunction with ulnar lengthening (51,135). Resection of a dislocated radial head relieves pain and removes the associated prominence (10,113) but probably does not improve forearm rotation significantly. This procedure should be reserved for skeletally mature patients because removal of the radial head in the growing child may cause cubitus valgus or proximal radial overgrowth (95,97). Single-stage ulnar lengthening with or without radial ostectomy can be performed (179), or using the Ilizarov technique, the ulna and radius can be differentially lengthened, radial bowing corrected, and the dislocated radial head reduced (42) (Fig. 165.38). Differential lengthening requires several months of external fixation and may diminish forearm rotation. Finally, radioulnar fusion may be performed as a salvage procedure (143).

Figure 165.37. Correction of increased radial articulation angle (radial tilt) in multiple hereditary exostoses by hemiepiphyseal stapling. A: Forty-two degree radial tilt, immediately following distal radial stapling. B: Twenty-nine degree tilt, 2 years following distal radial stapling.
Two recent studies show that skeletally mature people with untreated forearm deformities due to MHE maintain function and are comfortable with their appearance. The authors of these studies recommend a less aggressive approach to surgical treatment of the forearm in MHE. They point out that relatively simple procedures, such as removal of symptomatic osteochondromas and dislocated radial heads, can improve appearance and relieve pain, but no surgical treatment has been shown to improve forearm function in MHE.

One final indication for surgery in MHE is an enlarging osteochondroma in a skeletally mature person because this condition may be a sign of malignant degeneration.

CLASSIFICATIONS AND TERMINOLOGY

Many different names have been used to describe MHE, including multiple cartilaginous exostoses, diaphyseal aclasis, dyschondroplasia, hereditary deforming chondrodysplasia, and osteochondromatosis. The individual tumors may be called exostoses or osteochondromas. MHE is frequently confused with multiple enchondromatosis (Ollier’s disease), an entirely different condition.

Two different classification systems have been described for forearm deformity caused by MHE. In the first, type I forearms are the most common type (Table 165.5).

OPERATIVE TECHNIQUES

Removal of Osteochondroma (Proximal Humerus or Distal Forearm)

- Perform the operation under a tourniquet, if possible.
- Approach the osteochondroma through a longitudinal incision, centered over the tumor.
- Use the most readily available anatomic interval. Usually the osteochondroma splits the surrounding structures, and approach is not difficult. Watch for nerves or vessels wrapped around the pedicle of the tumor, or a nerve flattened over its surface.
- Remove the entire tumor, leaving a smooth contour.

Postoperatively, a soft dressing and wrist splint for 2 to 3 weeks is adequate immobilization.

Distal Radius Hemiepiphyseal Stapling

- Perform the operation under a tourniquet, with fluoroscopic guidance.
- Approach the radial aspect of the distal radial physis through a longitudinal incision. Find and protect the dorsal radial sensory nerve.
- Under fluoroscopic guidance, place three extraperiosteal epiphyseal staples across the distal radial physis: one directly radial, one slightly palmar, and one slightly dorsal, all outside of the first dorsal compartment.

A soft dressing and wrist splint for 2 to 3 weeks postoperatively is adequate immobilization. Obtain radiographs of the distal radius twice a year, and remove the staples when the desired amount of radial tilt (usually 20°) is attained.
**Radial Head Excision (Posterolateral Dislocation)**

This technique is discussed in Chapter 16.

**Differential Forearm Lengthening**

This complex operation is rarely indicated and beyond the scope of this text. See Dahl (42) for a detailed description of planning osteotomies, designing fixation, ulnar lengthening and angular correction, and radial head reduction.

**COMPLICATIONS**

If the periosteum and physis are disrupted during insertion of hemiepiphyseal staples, permanent physeal arrest and overcorrection could occur. Hemiepiphyseal staples usually require removal at the end of growth, if not sooner, because of adequate correction or local irritation.

**CONCLUSIONS**

Hemiepiphyseal stapling and removal of osteochondromas and the radial head are simple operations with good results. We measure forearm rotation twice a year for children with MHE with forearm involvement, and consider progressive loss of forearm rotation an indication for osteochondroma removal.

Chapter References

Abnormalities in newborns or in children consisting of dysplasia of the acetabulum and subluxation or dislocation of the femoral head from the acetabulum, if present at birth, have been known in the past as dysplasia or dislocation of the hip. Westin et al. (30) reported on late dislocation of the hip in children with apparently normal neonatal clinical and radiographic examinations, which they termed developmental dysplasia of the hip (DDH). Since then, the term DDH has come to be used to describe all dysplasias of the hip, reflecting the uncertainty about the exact time of onset and detection of the condition. Many mechanisms for DDH have been proposed, including the following:

Mechanical factors including breech delivery and postnatal positioning of the hips in extension and adduction

Hormone-induced joint laxity
Genetic inheritance
Primary acetabular dysplasia

Dysplasia of the hip occurs in approximately 1 in 1,000 live births. Involvement of the left hip alone or bilateral involvement is more common than involvement of the right hip alone.

Risk factors increasing the incidence of DDH have been identified; examiners should be alert to the following:

Female sex (5:1 female-to-male ratio)
Breech delivery
First-born child
Positive family history
White or Navajo Indian race

Associated disorders such as metatarsus abductus, talipes calcaneovalgus, and congenital torticollis

Early detection of DDH in newborns with early initiation of treatment is important to avoid the severe disability that results in late diagnosis, particularly after 5 years of age. Physicians and other paraprofessionals involved in delivering children must be competent in routine clinical screening with Ortolani’s test and Barlow’s provocative maneuver.

Use of ultrasound screening of newborns has proven useful in the hands of experienced ultrasonographers (9,15). False-positive sonography is common in the first 10 weeks of life; practitioners should take this into account when making treatment decisions.

In children between 6 and 18 months of age in whom a dislocated hip was missed at birth or who subsequently dislocate a dysplastic hip, reduction of the hip or dislocation of the hip by Ortolani’s test and Barlow’s maneuver becomes impossible. Important clinical findings in this age group include asymmetry in abduction of the hip because of adductor muscle contractures, asymmetric skin folds with gathering on the dislocated side, and Galeazzi’s sign showing apparent shortening of the femur on the side of the dislocation. Bilateral dislocations are more difficult to detect because they are symmetrically abnormal. If affected children reach walking age, they will usually demonstrate a waddling (Trendelenburg) gait.

Radiographic findings are not reliable in newborns because the lack of ossification of the proximal femur makes detection difficult. Indications of DDH in newborns include the following:

Acetabular index of more than 30°
Decreased center–edge angle of Wiberg
Disruption of Shenton’s line

Location of the metaphyseal beak of the proximal femur outside the inner lower quadrant of the grid formed by the vertical line of Perkins and the horizontal line of Hilgenreiner (Fig. 166.1)
NONOPERATIVE TREATMENT

Most patients with DDH or dislocation can be treated by nonoperative methods if the condition is detected in the first 6 months of life. Pavlik harness treatment in this age group has a high rate of success, and I have been able to achieve reduction of hips in some children up to 9 months of age with this harness.

Pavlik-harness adjustment is critical to success. The shoulder harness portion should be tight enough to cover the chest at the nipple line. The anterior (medial) foot straps are tensioned enough so that the hips are flexed greater than 90°. The posterior (lateral) straps are tensioned enough so that the knees cannot touch in the midline; they must not be too tight.

The Pavlik harness should be worn full-time. I reexamine a child in 1–2 weeks and readjust the device, which is often necessary because it is confusing to parents. Thereafter, if it is accepted by the family and properly adjusted, the harness will rapidly produce a reduction of the hip if Pavlik treatment is going to be successful. If the hip is performed with relative safety in some children, but many surgeons (including myself) elect femoral shortening in a walking child because it allows prompt open reduction without preoperative traction and with an extremely low incidence of avascular necrosis. It also permits derotation of the anteverted femur, thus stabilizing the dysplasia.

When closed reduction fails, open reduction is indicated. Open reduction is a delicate, specialized operation with complications that can affect a patient for a lifetime, and it should not be undertaken by an inexperienced surgeon. Surgery for the residual dysplasia that can follow closed or open treatment of DDH also requires adequate follow-up and experienced judgment in its applications and execution. The techniques described in this chapter are those that I have found most effective in surgical management of this condition, but they are not exclusive and many alternatives can be found in the literature.

OPEN REDUCTION OF THE HIP

INDICATIONS

Open reduction of a dislocated or subluxated hip is indicated when closed reduction fails or when closed reduction would result in such extremes of position that avascular necrosis would be a likely consequence. It is also indicated in children older than 12–16 months, when it is frequently combined with femoral shortening to decrease the overall time of immobilization required to achieve remodeling of the hip. Open reduction is indicated in a subluxated hip when abduction fails to reposition the femoral head deeply into the true acetabulum; in this instance, osteotomy of the pelvis or proximal femur is usually performed simultaneously.

Failures of closed reduction under general anesthesia that obviously do not allow the femoral head to be centered in the acetabulum or that result in extremes of position are easy to detect and should be followed with prompt open reduction, preferably as a continuation under the same anesthesia. In children younger than 12 months, closed reduction that results in a reduction that is stable but not deep and concentric may be accepted initially. Follow these reductions by arthrography in 8–12 weeks; if soft-tissue remodeling has not occurred and the reduction is not congruent and deep, proceed with open reduction.

The use of preoperative traction and femoral shortening in 1–3-year-old children is somewhat controversial. Standard open reduction can be performed with relative safety in some children, but many surgeons (including myself) elect femoral shortening in a walking child because it allows prompt open reduction without preoperative traction and with an extremely low incidence of avascular necrosis. It also permits derotation of the anteverted femur, thus stabilizing the reduction. This allows early ambulation and may speed hip remodeling; both of these goals are admirable in a child who has never had a reduced hip joint before surgery. Open reduction is occasionally useful in diseases other than congenital hip dysplasia, such as cerebral palsy or reconstruction following trauma or infection.

PREOPERATIVE CONSIDERATIONS

The use of preoperative traction, once so universally accepted, has been widely questioned in recent years. I personally no longer use it. In general, open reduction and its variants should be done without the use of blood transfusions. This requires great care on the surgeon's part. The use of X or 3X loupes is valuable in the dissection, and electrocautery greatly facilitates dissection without excessive bleeding. All tissues must be handled extremely gently, and the surgeon should have a thorough knowledge of hip anatomy. For children younger than 2–3 years, attempt a closed reduction immediately before proceeding with an open procedure because occasionally a stable reduction can be achieved with good long-term prognosis for resolution of the dysplasia.

I prefer open reduction from an anterior approach because capsulolraphy and other reconstructive procedures can easily be accomplished. Open reduction from a medial (adductor) approach does not give sufficient exposure for these essential parts of the operation and is indicated only in very young children who will undergo prolonged casting to maintain reduction while the capsulotomy heals and remodels. The medial approach is not described here; see Chapter 3 and Ferguson's description for details.

Although the standard exposure is a classic Smith–Petersen approach, I prefer a skin incision that falls in, or is parallel and superior to, the inguinal crease. Inguinal incisions can be extended medially and laterally, and they allow excellent deep longitudinal exposure with a nearly undetectable scar that is hidden beneath standard clothing. If open reduction and femoral shortening are combined, the use of an inguinal incision for the open reduction and a lateral incision for the femoral shortening yields a more cosmetic appearance and permits simple removal of internal fixation devices later through the lateral incision.

CLOSED REDUCTION

With the patient under a deep general anesthetic, gently flex, lift, and abduct the femur with the knee flexed until reduction is felt. In older children, the reduction is usually either definite or unobtainable, but younger children may not have distinct stability. Arthrography and fluoroscopy greatly improve assessment of the reduction. Occasionally, percutaneous adductor-longus tenotomy enhances stability. If the hip is unstable in less than 55° of abduction, strongly consider open reduction. Full double-spica casting is safest in 90° to 100° of flexion, neutral rotation, and less than 55° of abduction, which is Saltzer's "human" position.

Change the cast every 6–8 weeks until fluoroscopy demonstrates stability in the weight-bearing position. Usually, 12–18 weeks in a spica cast is required. Abduction...
OPEN REDUCTION

- Drape the affected limb and hip free with the pelvis elevated on a small towel.
- Make a transverse inguinal incision directly in the most prominent flexion crease of the hip (Fig. 166.3A). After incising the skin, use electrocautery to expose the fascial layer.

- Dissect subcutaneously both proximally to the iliac crest and sufficiently distally to mobilize the skin and subcutaneous tissue and allow a longitudinal incision of the deeper layers of the wound.
- Identify the lateral femoral cutaneous nerve as it emerges from the sartorius. Isolate and protect it with Silastic tape (Fig. 166.3B).
- If an innominate osteotomy is to be done, now split the apophysis, but for standard open reduction, it is unnecessary to dissect the proximal iliac apophysis.
- Carefully develop the interval between the sartorius and the tensor fasciae latae. Retract the sartorius medially and the tensor laterally to expose the rectus femoris.
- Using a Kidner dissector, identify, tag, and transversely section the tendinous attachment of the rectus femoris to expose the reflected head of the rectus femoris, which is the key to the anterior capsule (Fig. 166.3C).
- Expose the capsule, using gentle blunt dissection with a periosteal elevator and a Kidner dissector. Use electrocautery for any bleeders. The capsule will be found to be large, redundant, and extending superiority and posteriorly.
- Carry the capsular exposure medially under the adherent iliopsoas muscle and distally until the lesser trochanter can be palpated with a fingertip.
- At the medial border of the capsule, identify the iliopsoas muscle, hook its tendon with a right-angle clamp, and bring it into the wound, where it is sectioned (Fig. 166.3D).
- Now, divide the capsule in a fashion, taking care to avoid damage to the underlying femoral head (Fig. 166.3E). The vertical limb of the lines parallel to the femoral neck, with the cross of the lying parallel and 0.5 cm distal to the labrum of the hip joint. Scissors may be used to extend the superior border of the cross part of the around to the upper and posterior portions of the hip capsule. At this point, place suture tags in the two corners of the capsulotomy for later use in repairing the capsule.
- Now inspect the hip joint (Fig. 166.3F). Unless the patient is older, the ligamentum teres will be seen as a large, hypertrophic, flattened structure. Carefully excise it sharply from its attachment on the femoral head. Leave its acetabular attachment intact, and follow the ligament into the acetabular fovea to locate the true acetabulum (Fig. 166.3G). With external rotation or flexion and abduction, the femoral head can be pulled out of the way to allow full exposure of the acetabulum. After the fovea has been clearly identified, cut the remaining stump of the ligamentum teres. Clean any fibro-fatty tissue from the acetabulum, using rongeurs and Kidner dissectors, being careful to avoid damage to the articular surface. Sometimes, the anterior capsule is adherent to the acetabulum and must be painstakingly dissected free to expose the entire “horseshoe” of the acetabular surface. In nearly every case, the transverse acetabular ligament (a capsular thickening that lies across the base of the horsehoe of the acetabular surface) will need to be sectioned. This ligament is hypertrophic and prevents the descent of the femoral head into the depths of the true acetabulum.

Management of the labrum is controversial. Occasionally, the labrum may actually be inverted, but more often it is rolled and hypertrophic. If an actual inversion can be demonstrated and it cannot be adequately dissected to allow placement of the femoral head, use axial (radial) incisions to allow part of the labrum to be teased out of the acetabulum. This is rarely necessary. Do not excise the labrum because it contributes to future growth of the acetabular rim.

- Now reduce the hip by traction, abduction, and internal rotation. The femoral head is often flattened on its medial border and somewhat bullet-shaped; this is usually not a problem if the hip is abducted and the apex of the femoral head can be brought inside the acetabular labrum. If any force is required to bring the femoral head into the acetabulum, perform a femoral shortening osteotomy. If the hip reduces but is stable only when the hip is flexed and abducted, consider performing an innominate osteotomy (usually Salter osteotomy), especially if the child is near 3 years of age. In addition, if severe internal rotation is required in an older child, consider a derotational osteotomy through a lateral incision.
- With the hip held in internal rotation, close the capsulotomy (Fig. 166.3F). Bring the superior flap corner (tagged A in Fig. 166.3F) into the intermedial portion of the capsule, at the lower end of the T. The redundant lower flap can then be either excised or sewn over the superior flap (tagged B in Fig. 166.3F). After additional capsular repair, the hip joint should be stable. Close the wound by reattaching the tendons of the rectus femoris and by subcutaneous and subcuticular skin closure with absorbable 5-0 synthetic suture. Drainage is usually unnecessary.

Immobilize the child in a double-hip spica cast with the legs in 30° of abduction, 20° of flexion, and gentle internal rotation (Fig. 166.3J). The position is safe if the femur has been shortened and the iliopsoas lengthened. After open reduction in older children, this extended internally rotated position is more appropriate than the flexed “human” position used after closed reduction.

Postoperative radiographs must show a reduced femoral head, although the small ossific nucleus is often seen to be somewhat inferior to its expected position. This results from the misshapen femoral head and the hypertrophic labrum, and will remodel (Fig. 166.3J). Casting for 6 weeks is usually sufficient to allow healing of any osteotomy and development of satisfactory joint stability after open reduction. Ambulation with or without abduction bracing, as the clinical situation dictates, may begin immediately.

**COMBINED OPEN REDUCTION AND FEMORAL SHORTENING**

Femoral shortening is done during open reduction of the hip to minimize the compressive force across the joint (thus decreasing the risk of avascular necrosis) and to avoid preoperative traction in older children. It is also done in combination with derotational osteotomy to stabilize the reduction in the weight-bearing position (Fig. 166.4D). This lateral approach is more cosmetic and facilitates plate removal, if desired. However, the proximal femoral shaft can, with more difficulty, also be reached anterolaterally through the lower arm of an extended standard Smith–Petersen incision.
A leg-length discrepancy after congenital hip dysplasia usually occurs as a result of vascular damage to the proximal femoral physis. This avoids denervation of the vastus lateralis, but take care to cauterize perforating vessels that enter the muscle posteriorly. Then reflect the entire muscle subperiosteally anteriorly to expose the proximal femoral shaft.

Select a small plate for internal fixation; I use a four-hole tubular small-fragment plate. Place the plate along the lateral shaft of the femur just below the trochanteric flare.

Drill, measure, and tap the two proximal screw holes (because the shaft is small, this is more easily done before the osteotomy).

After completion of the osteotomy, the proximal femur can easily be reduced into the hip joint through the anterior incision. Gently pull the thigh, and observe the bayonet overlap of the femoral fragments; this determines the amount of shortening to be done (usually 2 cm). Remove the selected length of shaft by a second transverse osteotomy of the distal fragment (Fig. 166.4D).

Secure the plate to the proximal femoral fragment, and temporarily fix the plate to the distal fragment with a small bone clamp. Adjust anteverision by putting the hip through the full range of motion while observing the joint through the anterior incision. Derotation should not be excessive; usually there should be 15° to 20° of residual anteverision after the osteotomy is fixed. I do not routinely increase varus; however, varus derotation osteotomy with shortening is an alternative at this point.

Once the three-dimensional position of the fragments is satisfactory, fix the distal two holes of the plate to the distal shaft with screws (Fig. 166.5).

Figure 166.5. A: Radiographic appearance of complete congenital dislocation of the hip treated with primary open reduction and femoral shortening using plate fixation of the osteotomy (B).

After a final check of hip coverage by the acetabulum during motion, close the lateral wound with fine, absorbable synthetic suture.

COMPLICATIONS

Infection

Infection is rare, but if it occurs, open all wounds, including a second lateral incision (if done), down to the skeletal structures. Leave the plate in place if a femoral shortening osteotomy was done. Thoroughly irrigate and debride the wound. The hip capsule may be opened if necessary to irrigate the joint, but it must be repaired in the same fashion as the original capsulorrhaphy. The wounds may be packed open or closed over suction drains, depending on the severity of infection and the surgeon's preference. Cast immobilization is mandatory. Administer appropriate antibiotic therapy.

Redislocation

Early redislocation is evidence that the capsulorrhaphy has failed. If it is detected early, simple manipulation under general anesthesia and application of a spica cast should suffice to restore reduction. Late redislocation is often associated with residual stiffness. It may occur because of insufficient immobilization, capsulorrhaphy failure, or excessive derotation. Rarely, it can be secondary to severe ligamentous laxity, even when appropriate surgery has been done, usually in an older child with a markedly dysplastic acetabulum. Management of late redislocation must be based on careful radiographic studies to determine the cause. Sometimes, fluoroscopy or arthrogramy is helpful. A proper diagnosis will suggest the most appropriate treatment.

Subluxation

Late subluxation of the hip following open reduction can occur, particularly in older children. Assessment is almost always radiographic. If subluxation is subtle and mild, I postpone additional surgical treatment for 6 months to allow complete rehabilitation of the hip girdle musculature and joint remodeling; abduction bracing during this period may be appropriate.

If a previous femoral shortening or derotation osteotomy was performed, subluxation is usually best treated by an innominate osteotomy. Repeat open reduction may be required. Unless the surgeon is extremely experienced in all aspects of congenital hip surgery, it is safer to perform such acetalubar procedures as secondary treatment, even if it is initially thought that both femoral and acetabular surgery will be necessary. If previous femoral surgery was not done, the surgeon may elect either pelvic or femoral osteotomy, especially if the child is younger than 5 years.

Stiffness

A hip that has been properly reduced should not be stiff, even if open reduction was required. Stiffness is almost always a sign of subluxation or avascular necrosis. Make every attempt to accurately diagnose the problem; fluoroscopy and arthrography can be helpful.

Avascular Necrosis

Avascular necrosis may be mild and subtle (e.g., delayed or irregular ossification in a clinically normal joint) and require observation only. More extensive avascular necrosis may lead to temporary subluxation, which should be managed by casting, ambulatory abduction bracing, or surgical treatment. Severe subluxation associated with avascular necrosis may require reorientation of the acetabulum by innominate osteotomy, but it is safe to wait and observe if the hip is reduced in an abduction brace. Arthrography to visualize cartilaginous structures is recommended before surgical treatment for avascular necrosis. Avascular necrosis is a potential complication of all additional treatment options for patients and reduces the success of reconstructive surgery. It can also lead to early osteoarthrosis of the hip.

Extensive avascular necrosis involving the growth plate will be followed by leg-length discrepancy and deformity of the proximal femur. These deformities (head deformity, coxa breva, coxa valga) may appear late. Initiate a regular program of leg-length evaluation and x-ray observation to detect these complications and plan long-term management (11,27).

Proximal Femoral Growth Arrest and Leg-Length Discrepancy

A leg-length discrepancy after congenital hip dysplasia usually occurs as a result of vascular damage to the proximal femoral physis (14). In most children (except very short ones), the appropriate management is properly timed epiphysiodysis of the contralateral limb, based on routine yearly leg-length measurements through childhood. Occasionally, femoral lengthening may be necessary (see Chapter 171). The slight temporary discrepancy that accompanies femoral shortening osteotomy is usually followed by slight femoral overgrowth, so treatment is unnecessary.
Surgery for Residual Dysplasia

After reduction has been achieved in DDH, treatment must be continued until remodeling has eliminated the secondary dysplastic features of the acetabulum and the proximal femur. Monitor dysplasia and residual subluxation both radiographically (acetabular index, center–edge angle) (12) and clinically (subtle loss of abduction, Trendelenburg gait). The use of casts, abduction braces, and surgery for residual dysplasia is somewhat arbitrary and should be based on the patient’s age, the parents’ wishes, and the surgeon’s experience. However, failure of significant remodeling of dysplasia by 5 years of age makes additional surgery worth considering because there is good evidence that excellent remodeling can occur if correction is achieved by that age. Obvious subluxation warrants a more aggressive surgical approach because prompt treatment improves the dysplasia and the prognosis. Both femoral and pelvic osteotomies can be done for residual dysplasia.

FEMORAL OSTEOTOMY

INDICATIONS

Proximal femoral derotation or varus osteotomy is indicated in subluxation or dysplasia of the hip when reorientation can stabilize a reduction, resolve mild subluxation, or stimulate remodeling of the joint (4, 5, 12, 22, 23). Often, it is used to achieve a congruent joint in the weight-bearing position after closed or open reduction to allow a child of walking age to ambulate with less risk of subluxation. When acetabular dysplasia persists after reduction, femoral osteotomy can stimulate remodeling of the acetabulum, if done by 5 years of age (12). The choice of femoral or pelvic osteotomy in this situation is often a matter of the surgeon’s personal preference; I prefer the pelvic procedure.

The usual deformity of the femur in congenital hip dysplasia is excessive anteversion. This contributes to anterolateral subluxation in the weight-bearing position and encourages superolateral subluxation in the sitting position. Femoral derotation alone is generally sufficient to correct the deformity. This becomes obvious when radiographs are taken with the legs internally rotated and a normal neck–shaft angle (135°) is seen. If abduction is also necessary to produce a congruent reduction, then varus can be added, as well. Take great care not to overcorrect the femoral deformity. Avoid retroversion; increased varus of greater than 20° is rarely indicated. If a varus osteotomy is done, the hip must have an adequate range of abduction to allow functional motion after surgery. In my opinion, the prerequisites for femoral osteotomy in hip dysplasia are critical and should be the same as those for innominate osteotomy: congruent reduction of the hip and a full range of motion.

Internal fixation is necessary for femoral osteotomy. Some have advocated single-screw fixation or multiple smooth pins, but I strongly prefer rigid fixation with a small plate (for derotation alone) or a pediatric blade plate (for a varus osteotomy in an older child). This allows more accurate control of position during healing.

INTERTROCHANTERIC VARUS DEROTATION OSTEOTOMY

- Perform the operation with the hip and leg draped free, the patient on a radiolucent table, and an image intensifier available positioned anteroposteriorly. This allows testing of range of motion and reduces the chance of overcorrection, compared to the more conventional fracture table.
- Make a longitudinal lateral incision from the greater trochanter to a point distant enough to accommodate the fixation device selected. Incise the fascia lata and reflect the vastus lateralis anteriorly from its posterior femoral insertion, taking care to cauterize perforating vessels. Expose the proximal femoral shaft subperiosteally to the apophysis of the greater trochanter.
- The osteotomy site is critical. It must be intertrochanteric because internal rotation of the proximal fragment would otherwise increase iliopsoas tension (12). If a subtrochanteric osteotomy is preferred, expose and release the tendinous portion of the iliopsoas insertion.

Figure 166.6. Proper intertrochanteric level for femoral derotation osteotomy. This allows relaxation rather than tightening of the iliopsoas muscle.

- Position the guide pins for a blade plate, using anteroposterior (AP) and frog-lateral image intensification. Use appropriatereamers or blade chisels according to the manufacturer’s directions, depending on the specific fixation system being used. Drill and tap any proximal fixation holes before cutting the femur.
- Perform the osteotomy with a saw, taking an appropriate wedge out medially if varus positioning is desired. Fix the plate to the proximal fragment, externally rotate the distal fragment, and temporarily clamp the plate to the shaft. Now put the hip through a full range of motion while studying the joint with fluoroscopy, making special note of anteversion (which should not be less than 15°). Readjust the position until you are satisfied that subluxation has been adequately treated, and fix the plate to the distal fragment. Close the wound with fine, absorbable suture, including the skin; I prefer 5-0 undyed polyglycolic acid subcuticular suture. Apply a double-spica cast. Remove the cast at 8 weeks postoperatively or after radiographic union. Allow ambulation as tolerated. Physical therapy is unnecessary. Warn the family that the perieneum will appear wide until the child grows and that a limp may persist for 2–3 months but will eventually disappear.

PELVIC OSTEOTOMY

INDICATIONS

Pelvic osteotomy is indicated when there is primary acetabular dysplasia, residual subluxation of the hip, or failure of gradual improvement of radiographic dysplasia following reduction of a dislocated hip. In general, pelvic osteotomy should be done when severe dysplasia is accompanied by significant radiographic changes (high acetabular index, failure of lateral acetabular ossification) on the acetabular side of the hip joint, as opposed to changes on the femoral side (e.g., marked anteversion), which are best treated by femoral osteotomy (5). Surgical treatment of definite hip subluxation by either pelvic or femoral osteotomy before age 4 years will be accompanied by at least partial remodeling and resolution of anatomic abnormalities on the opposite surface of the joint (12).

Pelvic osteotomy is ideal for treatment of dysplasia when remodeling has ceased (as assessed by serial radiographs) and dysplasia or subluxation persists (5). Often, after the hip is reduced, pelvic osteotomy can be postponed until 4 years of age to allow adequate time for remodeling.

Pelvic osteotomy is also indicated when necessary to stabilize reduction during or after open reduction of the hip.

PREREQUISITES AND SELECTION OF OSTEOTOMY SITE

The many osteotomies described for acetabular dysplasia may be categorized as indicated either for primary treatment of dysplasia (Salter innominate osteotomy, Pemberton osteotomy, triple innominate osteotomy) or for salvage of a poor result in the later stages of dysplasia when complete remodeling is not expected (Chiari osteotomy). The primary osteotomies are generally reorientation procedures for the acetabulum, although the Pemberton procedure allows actual diminution of acetabular volume at the expense of some acetabular congruity. The Salter and Pemberton osteotomies are the most common osteotomies performed in North America.

To be successful as a primary treatment of dysplasia, an osteotomy must be done only in the presence of a congruent reduction, satisfactory range of motion, and reasonable femoral sphericity. These prerequisites have been popularized primarily by Salter (18,19) for his innominate osteotomy, and they are appropriate preoperative goals for any primary osteotomy about the hip (acetabular or femoral).

The Salter and Pemberton osteotomies differ somewhat in concept, although both are designed to limit anterolateral subluxation by improving coverage in this area. The Salter osteotomy, because it goes completely through the pelvis, allows anterior and lateral rotation of the acetabulum through an axis formed by the sciatic notch and the pubic symphysis. There is a limit to the degree of correction that can be obtained, and the procedure does not change acetabular shape (17). Conversely, the Pemberton osteotomy is an incomplete osteotomy that hinges the anterolateral acetabular roof on the flexible triradiate cartilage for correction (16). This actually
changes the configuration of the acetabulum and introduces joint incongruence that must be corrected by remodeling during growth. For these reasons, the Pemberton procedure may be indicated when there is an elongated, dysplastic acetabulum, but it is most effectively done in children younger than 8 years, as there is still flexibility in the triadrate cartilage and growth remains for remodeling of the joint surfaces (29).

In older children with deficient, dysplastic acetabulae but a relatively congruent reduction, the Salter osteotomy does not provide sufficient angular correction to improve stability. When the triadrate cartilage is closed, the Ganz periacetabular osteotomy (see Chapter 104) can achieve the extremes of reorientation required. When the triadrate cartilage is open, the same freedom to reorient the acetabulum in space can be achieved by cutting the ischium and pubis in addition to the ilium (triple innominate osteotomy). Variations of this technique have been described by Steel (24), Tönnis et al. (25), and Tachdjian (26). All are complex operations that should not be attempted by an inexperienced surgeon.

In older children, salvage of a hip that is too deformed to remodel for the growth time remaining requires a different type of procedure. The Chiari osteotomy is the most commonly used operation. It is a displacement osteotomy that essentially provides a shelf or buttress to limit further proximal subluxation of the femoral head. The superior hip capsule provides an interpositional surface between the cancellous bone of the shelf and the femoral head, and the capsular tissue may undergo metaplasia into fibrocartilage. Thus, the functional size of the acetabulum can be increased by the operation. If done properly, the Chiari osteotomy also moves the hip joint center medially and improves the mechanical advantage of the abductor muscles, both of which tend to decrease the intra-articular resultant force across the hip joint. The Chiari osteotomy does not require a concentric reduction; it may be done above a subluxated hip. The chief indication for Chiari osteotomy is pain associated with a subluxated, dysplastic hip in an older child. It should not be performed if degenerative changes are present or the hip is stiff. Do not do a capsulotomy at the same time as a Chiari osteotomy.

The exact indications for salvage surgery in congenital hip dysplasia are controversial. The goal of surgery most often stated is to treat chronic hip pain in an adolescent who has significant dysplasia as seen on radiographs. For many surgeons, another appropriate indication is radiographically demonstrated progressive subluxation, often associated with increasing degenerative changes of the hip. Although it may be unwise to consider surgery in an adolescent who has no pain, regardless of the radiographic appearance of the hip, there are surgeons who are exploring the use of late reconstructive procedures (e.g., the Ganz osteotomy) in asymptomatic patients who have severe radiographic dysplasia (see Chapter 104).

SALTER INNOMINATE OSTEOTOMY

- Prepare and drape the affected hip and leg free. Use a transverse inguinal skin incision as described earlier in this chapter (Salter describes a slightly more oblique incision), and identify the lateral femoral cutaneous nerve where it exits at the upper border of the sartorius; protect it with Silastic tape. Develop the proximal interval between the sartorius and the tensor fasciae latae muscles and between the straight head of the rectus femoris and the tensor fasciae latae muscles.
- Split the iliac apophysis with a single longitudinal scapula cut from the anterosuperior spine to the mid crest (Fig. 166.7A), and carefully pull the cartilage away from the crest. Strip the inner and outer walls of the ilium subperiosteally. Strip the anteroinferior spine medially with its attached rectus femoris. Carry the subperiosteal dissection to the sciatic notch. The notch is best exposed by gently teasing the periosteum away from it both medially and laterally with right-angle clamps; the tip of the two clamps should touch when stripping is complete. Stay subperiosteal to avoid sciatic nerve injury.
- In the inferior wound, identify the hip capsule and the iliopsoas muscle anterior to it. Pull the tendinous portion of the muscle into the wound with a right-angle clamp and sever it.
- Pass a Gigli saw through the notch with right-angle clamps. Saw a straight osteotomy from the notch to the anteroinferior iliac spine (Fig. 166.7B), keeping the hands as far apart as possible to avoid binding; protect the skin with ribbon retractors. Incline the osteotomy slightly in the frontal plane so that the lateral edge is superior to the medial edge.
- Open the osteotomy by externally rotating, abducting, and extending the hip to place the extremity into a figure-four position while holding the posterior osteotomy site closed and slightly anteriorly with a tenaculum. Do not pull the proximal ilium upward; this tends to displace the proximal ilium rather than the distal fragment containing the acetabulum. Do not use a lamina spreader because damage to the fragile ilium may result.
- With an oscillating saw (my preference) or a large rib cutter, fashion a triangular graft with one angle of 30° from the anterior portion of the proximal fragment. Containing the acetabulum. Do not use a lamina spreader because damage to the fragile ilium may result.
- With an oscillating saw (my preference) or a large rib cutter, fashion a triangular graft with one angle of 30° from the anterior portion of the proximal fragment. Containing the acetabulum. Do not use a lamina spreader because damage to the fragile ilium may result.
- Place the graft into the osteotomy site, keeping the posterior osteotomy closed, and fix it with two threaded pins inserted from the proximal fragment, through the graft, and into the distal ischium posterior to the hip joint (Fig. 166.7C). Check the pin length carefully, and move the hip joint to feel for any crepitus, which might indicate pin protrusion into the joint. Temporarily leave the pin ends long.
- Irrigate the wound and reapproximate the apophysis over the pins with simple absorbable sutures passed directly around the cartilaginous apophysis. Cut the pins so they will be palpable beneath the skin, and close the subcutaneous tissue and skin with fine, absorbable suture.
- Apply a well-molded one-and-one-half spica cast with the hip in 25° of flexion, 25° of abduction, and slight internal rotation. Remove the cast and pins 8 weeks after surgery, when radiographic union has occurred, under a brief general anesthetic. The patient can then begin weight bearing as tolerated. Physical therapy is usually unnecessary.

PEMBERTON PERICAPSULAR OSTEOTOMY

- Perform the operation on a radiolucent table with image-intensifier control.
- Make a transverse skin incision in the inguinal crease, but use subcutaneous dissection to mobilize the proximal and distal flaps. Then use a standard Smith–Petersen exposure of the hip (see Chapter 3). Protect the lateral femoral cutaneous nerve.
- Develop the interval between the sartorius and tensor fasciae latae muscles, and incise the iliac apophysis longitudinally with a sharp scalpel.
- Expose the anterior two thirds of the inner and outer tables of the pelvis with a periosteous elevator. The subperiosteal stripping does not need to go behind the sciatic notch (as in the Salter osteotomy) but must proceed distally to the triadrate cartilage. This can be felt as a line of resistance to further stripping; facilitate a safe approach to the area by teasing subperiosteally with a right-angle clamp.
- Begin the osteotomy with a small, curved osteotome to make a cortical pericapsular osteotomy, starting at the anteroinferior iliac spine and continuing parallel to the joint. This osteotomy curves down to, but not into, the triadrate cartilage and must end anterior to the sciatic notch (Fig. 166.8).

Figure 166.7. Surgical technique for Salter innominate osteotomy. A: Split of the iliac apophysis and fascial incision. B: Exposure of the ilium and sites of the osteotomy. C: Completed osteotomy.
Tönnis Variation

Join the two osteotomies, using a curved or spherical osteotome and taking care to avoid penetration of the sciatic notch or the joint. Use the image intensifier at this point to confirm the safe position of the osteotome.

Carefully pry the anterolateral acetabular fragment distally with the osteotome and a smooth, broad lamina spreader, without too much force. When this is properly done, the triradiate cartilage should be visible in the depths of the osteotomy.

Cut a triangular graft from the proximal ilium; a saw helps to make this cut without crushing the bone (Fig. 166.6C). Flatten a notch in the faces of the pelvic osteotomy, as needed, to receive the graft and lock it in place. Carefully wedge the triangular graft into the osteotomy site, and remove the lamina spreader; the graft should be secure and require no fixation (Fig. 166.6D).

Close the wound with absorbable sutures, and apply a spica cast as described in the technique of Salter osteotomy.

Steel Variation

Remove the cast 8 weeks after surgery (Fig. 166.9). Allow weight bearing as tolerated. Physical therapy is unnecessary. Older children may exhibit transient stiffness of the hip joint because of changes in the acetabular surface configuration caused by the Pemberton osteotomy.

TRIPLE INNOMINATE OSTEOTOMY

General approaches to the variations in triple innominate osteotomy are presented here (24,26,28). These are highly specialized operations, and their powerful ability to reorient the acetabulum can lead to overcorrection (6). There is also significant potential risk of neural and vascular injury, these are not operations for the inexperienced. Of the operative approaches, I prefer Tachdjian's (29), but each has its proponents. For fully detailed descriptions, readers are referred to the originators of each approach (24,26,28).

Drape the patient on a radiolucent table with the leg free. The iliac portion of the osteotomy (usually performed last) is performed exactly as in the Salter osteotomy.

Steel Variation

Steel (24) makes the pubic cut through an inguinal incision and the ischial cut through the buttok (Fig. 166.10A).

Flex the hip 90° to expose the buttock and ischial tuberosity. Make the ischial cut first through a transverse incision positioned 1 cm proximal to the gluteal crease. Retract the gluteus maximus laterally, and sharply dissect the origin of the biceps femoris from the ischium. Identify the sciatic nerve, using a nerve stimulator if necessary, and protect it throughout the procedure.

Separate the origins of the semimembranosus and semitendinosus muscles, and pass a very curved hemostat subperiosteally along the ischium, starting from the obturator foramen and emerging posterior to the ischial ramus. Stay carefully on the bone to avoid vascular injury. Cut the ramus, using the clamp as protection, with an osteotome using the clamps posteriorly and laterally. Then close the wound. Steel recommended changing gloves, gowns, and instruments at this stage because of the risk of contamination in this area of the perineum.

Expose the anterior pelvis as for a Salter osteotomy (see above), continuing the dissection medially to identify the pectineus muscle. Detach the pectineus from the pubic ramus, clearing the pubis to about 1 cm medial to the pectineal tubercle. Pass a significantly curved hemostat subperiosteally from above the pubis and around the bone to emerge in the obturator foramen. Again using the instrument for protection, cut the pubic ramus by directing an osteotome posteriorly and medially.

Then make the iliac cut as described for the Salter osteotomy, and under image-intensifier control reposition the entire acetabular unit to its desired position. A towel clip or Steinmann pin (inserted as a “joystick”) can be helpful in controlling the fragment.

Position a triangular graft in the iliac osteotomy site, and fix the ilium with threaded pins directed either as in the Salter osteotomy or from the distal fragment upward into the wing of the ilium.

Close the wound, and immobilize the hip in a one-and-one-half hip spica cast for 8 weeks. Follow-up care is similar to that for Salter osteotomy.

Tönnis Variation

Tönnis (28) uses a posterior gluteal approach for the ischial cut (Fig. 166.10B). He felt that redirection should emphasize more lateral and less anterior coverage of the hip than advocated by Salter or Steel.

With the patient lying prone, expose the ischial tuberosity through an oblique incision in the direction of the fibers of the gluteus maximus, which are split bluntly and separated. Cut the obturator internus and the inferior and superior gemellus muscles to expose the ischial ramus. Protect the sciatic nerve and the gluteal vessels with a blunt retractor in the sciatic notch, and place special retractors around the ischial ramus, preserving the sacrotuberous and sacrospinalis ligaments for stability. Make the ischial cut as frontal as possible, from lateral to medial, connecting the ischial and obturator foramina. The osteotomy must be complete, without spikes remaining on the cut surfaces of the bone.

Close the wound and reposition the patient supine. Rather than using an extended inguinal incision (see the Steel technique above), make a small incision over the pubis where it is palpable just medial to the psoas. Insert two retractors above the pubis and through the obturator foramen, and make the osteotomy cut parallel with the hip joint.

The remaining procedure is performed similarly to the Steel osteotomy, except that in the frontal plane the iliac osteotomy is oriented from superolateral to...
interomedial, which allows easier lateral rotation of the fragment.

**Tachdjian Variation**

Tachdjian (26) performs the ischial cut anteromedially through a subinguinal incision between the adductor magnus and obturator externus (Fig. 166.10C).

- With the extremity in the frog-leg position, make a transverse adductor incision over and posterior to the adductor longus. Although Tachdjian (26) released the adductors, I have found that the ischiun can usually be exposed by bluntly developing the interval between adductor brevis and magnus and then carefully dissecting toward the ischial tuberosity on a line between the adductor magnus and obturator externus insertions. Expose the ischiun subperiosteally, and protect the soft tissues with Chandler retractors. The ischiun osteotomy is a laterally based about 1.5 cm wide wedge that allows moving the acetabulum medially.
- Expose the pubis through the same incision by retracting the iliopsoas muscle (which may be fractionally lengthened) laterally and elevating the pectineus to expose the iliopectineal eminence. Protect the pubis subperiosteally with two Chandler retractors. Make the pubic osteotomy parallel to the joint, 1.5 cm medial to the acetabulum as seen on image intensification, with the osteotomy directed 15° medially.
- Using a second incision (or an extension of the medial one), perform the iliac osteotomy in a similar fashion to that in the Steel osteotomy.

**CHIARI OSTEOTOMY**

Perform a Chiari (3) osteotomy on a radiolucent table with AP image-intensifier control.

- Drape the hip and leg free, with the affected side elevated on a small towel or sandbag.
- Make an extended transverse inguinal incision as previously, carrying it well lateral to the mid-lateral line. Undermine the subcutaneous tissue to expose the proximal crest of the ilium, and isolate and protect the lateral femoral cutaneous nerve.
- Detach and tag the straight head of the rectus femoris. Split the iliac apophysis longitudinally, and expose the inner and outer walls of the ilium by subperiosteal dissection down to the sciatic notch. Carefully cut the reflected head of the rectus femoris, and dissect it free to expose the edge of the capsule. Under the reflected head of the rectus femoris, identify the edge of the capsule where it attaches to the pelvis. Use an instrument and the image intensifier to confirm the position of the capsular attachment on the ilium. The correct spot will be several millimeters above the superior edge of the acetabulum as seen on the fluoroscope because of the thickness of the capsule.

The original osteotomy described by Chiari (3) was straight from the front to the back of the pelvis. Most surgeons (including myself) prefer a curved cut, which limits anteroposterior sliding of the osteotomy. However, if the cut is made as a conical rather than cylindric curve three-dimensionally, the fragments will not displace; therefore, accurate three-dimensional control is mandatory.

- Make the osteotomy just at the superior edge of the thickened hip capsule at a 15° upward angle as viewed in the AP plane with the image intensifier. Use two alternate ⅛ in (1.5–2.0 cm) straight osteotomes and frequent radiographs to make a slightly curved osteotomy from the front of the pelvis to near the notch. Both osteotomes must be kept absolutely parallel to each other (at 15° inclination); otherwise, the osteotomy will not slide properly. Although logic suggests that the entire osteotomy should follow the arc of the hip joint, there has never been any demonstrated advantage to such a cut, and it is unrealistic to expect perfect congruence with the hip capsule, except by the rapid remodeling that follows Chiari osteotomy.
- Protect the inner wall of the pelvis with malleable retractors. The cut must be smooth so there are no spikes of bone to catch during displacement.
- Complete the posterior part of the osteotomy with a Gigli saw passed behind the sciatic notch with right-angle clamps, as described above for Salter osteotomy.
- Displace the osteotomy by abducting the leg widely. The displacement should be one-half of the width of the ilium at the site of the cut; too much displacement reduces the contact area of the osteotomy surface and may lead to delayed union (Fig. 166.11). Do not pull the proximal ilium laterally in an attempt to move the fragments; if the cut will not displace, it is because the osteotomy is not complete or is irregular or conical or because spikes of medial cortex remain.

**Figure 166.11.** The Chiari osteotomy is made through a triangular section of the ilium. Avoid excessive displacement of the distal fragment, which reduces the contact area and may result in delayed union.

- If there is a large anterior defect over the capsule after displacement, it may be filled with corticocancellous graft from the proximal ilium.
- I prefer internal fixation with a long, 4.5 mm cancellous bone screw introduced from the lateral proximal ilium into the distal fragment. Use the image intensifier to ensure that the hip joint is not penetrated. Alternatively, threaded Steinmann pins may be used. Internal fixation is not absolutely necessary, but if it is not used, the leg must be immobilized in abduction (with a spica cast or traction) to maintain displacement until the pelvis begins healing in 2–3 weeks (Fig. 166.12).

**Figure 166.12.** An adolescent girl with a painful dysplastic hip was treated by Chiari osteotomy. A: Preoperative radiograph. B: Postoperative radiograph. Note the upward inclination of the osteotomy. Postoperative hip function was excellent, with complete relief of pain.

- Close the wound over a suction drain. If internal fixation was used and is stable, allow early touch-down crutch walking.

**CHAPTER REFERENCES**

Each reference is categorized according to the following scheme: *, classic article; #, review article; 1, basic research article; and +, clinical results/outcome study.

Foot deformities in children may be either congenital or acquired during childhood. Before starting a treatment program for congenital foot deformity, search for associated deformities that may also need treatment (e.g., congenital hip dysplasia, torticollis) and associated conditions that may require further evaluation and that might affect the prognosis of the foot deformity (e.g., arthrogryposis, spinal dysraphism, bone dysplasia). Deformities that develop during childhood are often manifestations of underlying neuromuscular disease that must be evaluated before intelligent treatment of the foot can be planned.

Primary treatment for congenital deformities often begins the first day of life and generally should be concluded by the time the child begins walking. Secondary treatment and treatment of recurrence are often necessary, because mild muscular imbalance and incomplete correction of deformities are common. The foot may require long-term bracing or repeated surgery to maintain adequate function. For these reasons, experience and judgment are as important as surgical skill in the long-term management of foot deformities. The surgeon with only occasional exposure to these problems should not undertake treatment.

CONGENITAL CLUBFOOT

Congenital clubfoot (talipes equinovarus) is a hereditary foot deformity of unproven etiology. It affects males more often than females and may be unilateral or bilateral. It is often associated with other conditions, such as myelodysplasia, arthrogryposis, and congenital hip dysplasia. Pathologic changes seen in clubfoot include bony deformity, particularly of the talus (short neck, mediolateral deviation of the neck, abnormal articular surface of the head), and soft-tissue contracture (muscle, tendon sheath, capsule, ligament, skin) (14). Externally, the clubfoot is smaller than the normal foot. There is equinus of the ankle, varus and internal rotation of the heel, accompanied by adduction, supination, and cavus of the midfoot. The calf is atrophic and smaller in circumference than the opposite calf. The leg lengths are generally equal.

Internally, the deformity is most clearly defined as a rotational subluxation of the talocalcaneonavicular joint complex, with the talus in plantar flexion and the talocalcaneonavicular (subtalar) complex in medial rotation and inversion (20). There is controversy over whether the soft tissue or bony changes are the primary cause of the disorder, although nonoperative and surgical treatment both address the soft-tissue portion of the deformity with the expectation that at least some of the bony abnormalities will remodel. Regardless of the form of treatment, the resultant foot will be smaller and less mobile, and the calf relatively atrophic, when compared with a normal limb.

Management of the congenital clubfoot is initially nonoperative and, if possible, should begin on the first day of life. Serial manipulation of clubfoot and maintenance of correction with casting is a skill that all orthopaedic surgeons dealing with children should develop (15,26). It is essential to correct the midfoot adductus and hindfoot varus in the casts before you make any attempt to address the equinus. We have concern that overly aggressive attempts at dorsiflexion may damage the talus, and we often abandon casting once progression of the correction into dorsiflexion stops.

When casting fails, surgical release is indicated. The need for and the exact timing of the surgery depends on the severity of the clubfoot. We normally make a decision to treat surgically by 3–4 months of age. Surgery, however, can be timed so that the postoperative casting is completed at about the time the child begins to bear weight on the foot. Some surgeons prefer operative treatment at a much younger age, but there is also literature support for postponing surgery up to 1 year of age or beyond, if the surgeon feels technically more able to operate on a larger foot (43). In children with syndromes, delay of surgery until a year of age or beyond is often desirable or necessary.

Stress dorsiflexion lateral radiographs of an incompletely corrected clubfoot reveal inadequate dorsiflexion of the os calcis or parallelism of the talar and calcaneal axes. Anteroposterior (AP) views show medial deviation of the first metatarsal axis relative to the talar axis, a function of subluxation of the talonavicular joint (the navicular ossification center itself does not appear for several years, and its position must be inferred); the axes of the talus and calcaneus likewise become parallel because the external rotation of the subtalar joint is lost. Most of the angles described for evaluation of clubfoot are based on radiographs of older children, and they date from an era when treatment was nonoperative and involved prolonged casting. We have not found radiographs to be helpful in determining which children should have early surgery; the decision is made more easily on clinical grounds.

The aim of surgical treatment is to release soft-tissue restraints on proper positioning of the tarsal bones. The exact surgical procedure can be tailored to the residual deformity of the foot at the completion of casting. The usual surgical release always includes posterior structures (tendo Achilles, posterior tibial tendon, calcaneofibular ligament, posterior ankle, subtalar capsulotomy, and, sometimes, long toe flexors). If significant midfoot deformity remains (medial talonavicular subluxation), release the tarsal sinus, tarsal sinus, and the tendon sheaths of posterior tibial, flexor digitorum longus (FDL), and flexor hallucis longus (FHL) muscles. Some clubfeet have significant medial subluxation of the calcaneocuboid joint, requiring capsular release (2,21). The medial subtalar capsule can be partially or completely released to correct hindfoot varus. These releases allow the talus to be dorsiflexed into neutral position, the navicular to be abducted and rotated onto the true axial head of the talus, and the os calcis to be brought out of varus and into lateral rotation under the talus to reduce the subtalar joint. Hold the reduction with pin fixation in a cast until the soft tissues heal.

Although surgeons have recognized for years that posterior and medial releases are necessary to correct clubfoot, recent attention to the posterolateral ankle structures (fibulocalcaneal ligament and peroneal sheaths) has emphasized the importance of correction of internal rotation of the subtalar joint if full correction of the clubfoot is to be achieved (26,21,22,28,29,32). The exact incision used may not be important, but it must provide adequate exposure of these structures or the correction is incomplete. We prefer the Cincinnati circumferential subtalar incision (or portions of it), because it gives the fullest visualization of the entire midfoot and hindfoot, including the posterolateral region; you can use portions of this incision for more limited releases (8). Because tarsal bones are largely cartilaginous in the small child, they are inevitably deformed at the time of reorientation, and the correction must be maintained for at least 3–4 months to allow remodeling. Many children...
require further bracing for a year or more to maintain position during walking.

Tailor the operative procedure to the deformity. If the releases performed are overly aggressive, the result may be an overcorrected clubfoot when the child becomes older. There are good methods that have been developed to later improve undercorrected feet or relapsed feet, but there are no good secondary procedures that adequately address the overcorrected clubfoot. Although our initial feeling was that complete correction of a clubfoot was necessary in most cases, the long-term follow-up of many of our earlier patients with clubfoot has led us to temper these beliefs. In the mild and moderate clubfoot, we now favor a more limited release of posterior structures, which generally leads to better foot function as the child matures.

**CLUBFOOT RELEASE**

- Perform clubfoot release with the patient prone or supine, using a pneumatic tourniquet.
- Make a full Cincinnati skin incision, extending it from the navicular tuberosity under the medial malleolus, arching slightly over the os calcis posteriorly, and extending obliquely around to the calcaneocuboid joint laterally (Fig. 167.1A). Portions of the incision may be used for less extensive releases.
  - Keep the knife at a 90° angle to the skin, and carry the incision sharply through the subcutaneous tissue with minimal retraction. Use caution as the knife crosses the Achilles tendon, which is deep in the subcutaneous tissue of the posterior wound.
  - Use a fine scissors for the remaining dissection.
  - Identify and mobilize the neurovascular bundle in the posteromedial wound both proximally and distally (to the point where the nerve branches into the calcaneocuboid branch and medial and lateral plantar nerves); retract it with a Silastic tape.
  - Posterolaterally, identify the sural nerve running with the lesser saphenous vein; mobilize and protect these structures with a Silastic tape.

**Posterior Release**

Perform the posterior release portion of the procedure first.

- Protecting the neurovascular bundle and the sural nerve, perform a Z-lengthening of the Achilles tendon, making the distal transverse cut in the medial half of the tendon (the lateral half is left attached to the calcaneus). Tag each end with #0 absorbable suture (Fig. 167.1C).
- Just posterior and lateral to the neurovascular bundle lies the FHL tendon; incise its sheath, identify it, and protect it during the next stage with a Silastic tape.
- If the midfoot deformity has been corrected by casting, the dissection just described may be enough to correct the deformity; in this case, the posterior talonavicular capsule usually requires Z-lengthening, as may the FHL and FDL tendons.
- If you are satisfied with the correction obtained after posterior release alone, manipulate the forefoot into corrected position and blindly pin it from back (talus) to front, bringing the pin out the dorsum of the foot; bend the tip to prevent migration (Fig. 167.1D).
- Close the wound as will be described later.

**Lateral Release**

Frequently, additional release may be required.

- In the posterolateral portion of the wound, identify and transect the heavy fibulocalcaneal ligament (Fig. 167.1D); this allows external rotation of the os calcis as it is dorsiflexed (Fig. 167.1F). Use a pair of scissors to cut the sheaths of the peroneal tendons circumferentially, taking care not to injure the tendons. Slide the scissors along the posterolateral subtalar joint capsule to incise it.

**Medial Release**

- Incise the posterior talonavicular joint and perform a Z-lengthening of the tendon, grasping the distal tendon stump with a small Kocher clamp.
- Follow the tendon stump as it inserts into the navicular, and transversely incise the deep posterior tibial sheath and the medial, dorsal, and plantar talonavicular capsules.
- Blending with the inferior capsule are the spring ligament (connecting the navicular with the sustentaculum tali) and Henry’s knot (where the flexor hallucis and flexor digitorum cross). While appearing in textbooks as discrete structures, these usually are difficult to separate and are released as the capsule is incised (Fig. 167.1B). One of us (GTR) separates the intact knot of Henry from the navicular, and one of us (PBS) incises it longitudinally, freeing the flexor tendons.
- Incise the anterior subtalar joint with scissors just above the sustentaculum. If the talus still does not mobilize, incise the remaining medial subtalar capsule. It is usually easiest to start from the posterior exposure of the subtalar joint at the site of the previous capsulectomy. Retract the FHL and the neurovascular bundle to cut the firm medial capsule, staying right at the joint level. It is very easy to inadvertently cut the FHL during this portion of the dissection.
- Incise the FDL tendon sheath transversely as you encounter it. Take care not to drift superiority out of the subtalar joint, or injury to the deep deltoid ligament may occur.
- Once the subtalar capsule has been circumferentially incised to the anterior end of the os calcis, open the joint by everting the os calcis. This exposes the subtalar interosseous ligament, which can be seen through either the medial or the posterior portions of the wound as a thick, ribbonlike band (Fig. 167.1F). You should not divide this ligament except in the most severe cases (usually arthrogryposis), because this can lead to significant overcorrection.
- If the lateral border of the foot is still convex, or if preoperative radiographs demonstrate significant medial subluxation of the calcaneocuboid joint, release that joint. We prefer to dissect the medial wound distal to the anterior os calcis, which is now well exposed. Cut the long plantar ligament and identify the medial calcaneocuboid capsule; incise its entire medial surface and use a fine scissors to incise the superior and inferior capsule as well. If that does not free the joint sufficiently, expose the calcaneocuboid joint in the distal part of the lateral incision and release the capsule there.
- If significant cavus is present, you may release the plantar fascia through the posteromedial wound. Identify the interval between the calcaneal sensory branch and the lateral plantar branch of the posterior tibial nerve, and gently retract the lateral branch anteriorly while dissecting down the medial and inferior side of the os calcis with scissors (Fig. 167.1C). Stay right on the bone, taking great care not to injure the neurovascular bundle, because after a Cincinnati incision it supplies the major vascularity to the heel pad. With a blunt scissors, cut the plantar fascia where it originates from the inferior os calcis; you will feel a palpable relaxation of the cavus.
- Reduce the talonavicular joint, being careful not to overreduce or to allow it to subluxate dorsally (the most common malreduction), and hold it with an 0.035 Kirschner wire (K-wire), inserted from the posterior talus through the joint and out the skin of the dorsum of the foot (Fig. 167.1H). Pull the pin flush with the posterior talus, and cut and bend it superficial to the dorsal skin to prevent migration.
- If you desire, insert a second pin through the heel pad longitudinally across the subtalar joint after it has been reduced into neutral varus–valgus and slight subtalar external rotation (Fig. 167.1I). Move the ankle to ensure that this pin stops before entering the ankle joint. Cut and bend the pin outside the heel skin.
- Hold the ankle at 90° and use the two suture tags coming from the ends of the Achilles tendon to hold tension on the tendon so that the structure is snug at a neutral ankle position. Repair the tendon in this position. Be careful not to overlengthen the Achilles tendon, or calcaneus gait can result. Small gaps in the tendon fill in spontaneously in a child under 4–6 months of age.
- Repair the Z-lengthened posterior talonavicular tendon, and perform sliding Z-lengthenings of the FDL (in the medial wound) and the FHL (in the posterior wound), if they are snug and prevent correction of the deformity.
The last-resort salvage procedure, a triple arthrodesis, is best postponed until the age of 10–12, when the foot is fully grown.

Recurrence may be a manifestation of muscle imbalance in a growing foot (or Lichtblau procedure) and an opening wedge osteotomy of the medial cuneiform are excellent alternatives (medial cuneiform, accompanied by shortening of the lateral column of the foot) and a combination of a closing lateral column shortening procedure (cuboid decancellation, Evans procedure, or Lichtblau osteotomy with a medial release). We use the Lichtblau procedure because it produces predictably good results.

In a child younger than 2 years, you may manage recurrence by repeating the posterior medial release. In our experience, however, this is usually not enough, especially when adequate initial surgery was performed. Lateral column shortening is often extremely helpful to accomplish secondary correction (cuboid decancellation, Evans procedure, or Lichtblau procedure) and an opening wedge osteotomy of the medial cuneiform are excellent alternatives (19,23). Osteotomy of the os calcis can be used to correct the hindfoot inversion and varus (11).

After the age of 5 years, the joint of the foot are sufficiently formed so that it is better to accept the malposition of the joints and perform secondary bony procedures to reorient the joint. Metatarsal or midfoot osteotomies (1) can be used to correct forefoot abduction, but they are of limited use since they do nothing for the main deformity in the hindfoot and midfoot. The soft-tissue alternative, mobilization of the tarsometatarsal joint by capsulotomies (Heyman-Herndon procedure), has been abandoned because it has been found to cause pain and midtarsal stiffness in an already stiff foot. The double tarsal osteotomy (opening wedge osteotomy of the medial cuneiform, accompanied by shortening of the lateral column of the foot) and a combination of a closing lateral column shortening procedure (cuboid osteotomy or Lichtblau procedure) and an opening wedge osteotomy of the medial cuneiform are excellent alternatives (19,23).

**LATERAL COLUMN SHORTENING PROCEDURES**

- Perform lateral column shortening procedures (16,17) under pneumatic tourniquet control. Use the medial and lateral arms of the Cincinnati incision described for congenital clubfoot; leave the posterior portion of the skin intact.
- On the medial side, expose the posterior tibial tendon sheath and incise it, exposing the tendon. Perform a Z-lengthening of the tendon and tag both free ends.
- Use a fine curved scissors to dissect deep to the distal posterior tibial tendon stump, and identify the talonavicular joint; incise its capsule superiorly, medially, and inferiorly.
- In the lateral wound, expose the calcaneocuboid joint and incise its capsule sufficiently to mobilize it. If performing a Lichtblau osteotomy (Fig. 167.2C), resect the distal portion of the os calcis to cancellous bone, using a small osteotome. This shortens the calcaneus at the same level as the talonavicul joint, allowing the midtarsal joint to translate easily to a corrected position.

**Figure 167.2. Lateral column shortening options for residual adduction deformity in clubfoot. A: Lichtblau osteotomy (resection distal os calcis). B: Cuboid decancellation. C: Evans procedure (calcaneocuboid fusion).**

- Abduct the midfoot to check correction. If the medial release has been performed fully and enough os calcis has been resected, the foot should appear corrected. If it does not, resect more of the os calcis or release the medial foot more until the correction is adequate. Although the articular surface has been removed from the calcaneus, the cuboid articular cartilage remains, and a painless synchondrosis will develop.
- If performing a cuboid decancellation (Fig. 167.2B), incise only enough of the capsule to identify the joint surface plane (10). Use either a small osteotome or a curet to remove a wedge of bone from the middle portion of the cuboid. In younger children, it is usually easiest to simply curet out the ossific nucleus, leaving a shell of the cartilaginous anlage.
- Compress the cuboid closed as the released talonavicul joint is reduced. Check correction as for the Lichtblau osteotomy, and adjust the medial release and bone resection accordingly.
- If performing a calcaneocuboid fusion (Evans procedure) (Fig. 167.2C), curet or resect with an osteotome the articular surfaces of both joints. Excessive resection is unnecessary, since the fusion resected lateral column growth potential and the midfoot will gradually abduct (10). Insert an 0.062 K-wire longitudinally across the corrected calcaneocuboid articulation. For the Evans and Lichtblau procedures, this is done most easily by adducting the forefoot and placing the pin at a 90° angle to the endosteum of the talus. This lengthening of the talonavicul joint with a second pin introduced from the dorsum of the foot. The pins are inserted to prevent migration. The calcaneocuboid fusion can be performed with the foot in a short-leg walking cast for an additional 4 weeks. If the pins are removed, Apply a second cast for an additional 6 weeks. If the child is of walking age, the first 6–9 weeks of immobilization should be in a long-leg cast with a 90° bend to control subtalar rotation and prevent ambulation, but the last 6 weeks may be in a short-leg cast with a walking heel. Some surgeons use orthotic devices for the first 12–24 months following clubfoot release, but we have generally found them unnecessary. An exception may be made if a mild clubfoot has required only posterior release; in these cases, maintaining alignment with an ankle–foot orthosis (AFO) while postural muscles develop seems to lessen the flexible midfoot deformity.

**MANAGEMENT OF RECURRENCE OR UNDERCORRECTION**

Recurrence, relapse, or undercorrection occurs in up to 15% of operated clubfeet. The most common residual finding is adduction and supination of the forefoot so that the first metatarsal does not touch the ground during walking, and callouses develop on the lateral border of the foot. This can be associated with hindfoot varus and internal rotation. When noted early, it may be treated with an AFO, or a Perlstein brace (straight-last shoe, medial upright, lateral T-strap, and 90° plantarflexion stop). If the deformity persists, however, the treatment is surgical.

In a child younger than 2 years, you may manage recurrence by repeating the posterior medial release. In our experience, however, this is usually not enough, especially when adequate initial surgery was performed. Lateral column shortening is often extremely helpful to accomplish secondary correction (cuboid decancellation, Evans procedure, or Lichtblau osteotomy with a medial release). We use the Lichtblau procedure because it produces predictably good results.

After the age of 5 years, the joint of the foot are sufficiently formed so that it is better to accept the malposition of the joints and perform secondary bony procedures to reorient the joint. Metatarsal or midfoot osteotomies (1) can be used to correct forefoot abduction, but they are of limited use since they do nothing for the main deformity in the hindfoot and midfoot. The soft-tissue alternative, mobilization of the tarsometatarsal joint by capsulotomies (Heyman-Herndon procedure), has been abandoned because it has been found to cause pain and midtarsal stiffness in an already stiff foot. The double tarsal osteotomy (opening wedge osteotomy of the medial cuneiform, accompanied by shortening of the lateral column of the foot) and a combination of a closing lateral column shortening procedure (cuboid osteotomy or Lichtblau procedure) and an opening wedge osteotomy of the medial cuneiform are excellent alternatives (19,23). Osteotomy of the os calcis can be used to correct the hindfoot inversion and varus (11).

Recurrence may be a manifestation of muscle imbalance in a growing foot (1). Regardless of the success of treatment, the clubfoot patient has an atrophic calf and a small foot on the affected side. Weakness of the peroneals or the peroneus tertius appears to contribute to the late tendency toward hindfoot varus, forefoot supination, and adduction. This can be improved with either lateral or split transfer of the anterior talibial tendon. The postorbital tendon transfer and FHL transfer have been described for residual anterior talibial muscle weakness in the clubfoot, but we have no personal experience with either procedure (22,34). Skeletal deformities should be corrected before the tendon transfers.

The last-resort salvage procedure, a triple arthrodesis, is best postponed until the age of 10–12, when the foot is fully grown.
Make a single osteotomy cut transversely in the cuneiform (Fig. 167.3A). After you complete this osteotomy, place an instrument such as a small lamina spreader across the osteotomy and open it.

Figure 167.3. Double tarsal osteotomy for residual adductus deformity. Wedge resected from cuboid (A) is inserted into opening osteotomy of medial cuneiform (B).

Insert the bone graft that was taken from the cuboid into the osteotomy of the medial cuneiform (Fig. 167.3B). Usually the bone graft is quite stable, but a small K-wire can be used to secure the graft in place. Place it through the base of the first metatarsal and across the two fragments of the cuneiform, securing the bone graft.

Close the cuboid osteotomy and hold it with K-wires. Close the wounds with 4-0 absorbable suture.

Place the patient in a long-leg, bent-knee cast to prevent weight bearing. At 6 weeks, exchange the cast for a weight-bearing short-leg cast, to be worn for an additional 4 weeks (19,23).

OS CALCIS OSTEOTOMY TO CORRECT HINDFOOT VARUS

When performing an os calcis osteotomy to correct hindfoot varus, make a curved lateral incision just inferior and parallel to the peroneal tendon sheaths, and dissect down to the os calcis (Fig. 167.4).

Figure 167.4. A: The lateral approach for osteotomy of the os calcis. B: Fixation with a small Steinmann pin inserted at a 45° upward angle from the tip of the os calcis.

Incise the periosteum parallel with the skin wound. Perform limited subperiosteal dissection to allow passage of a metatarsal (Hayes or Blount) retractor posteriorly between the Achilles tendon and bone, and inferiorly between the planter structures and the calcaneus.

After locating the site for the osteotomy, confirm the position with an image intensifier.

With an osteotome or oscillating saw, cut an oblique osteotomy through the lateral cortex and medullary bone of the os calcis. Carefully complete the cut through the medial cortex with controlled use of an osteotome and varus manipulation of the heel (to crack the medial cortex). The neurovascular bundle lies on the medial side and must not be injured.

Manipulate the heel to loosen the periosteum on the medial side, and slide the tuberosity of the os calcis laterally until the heel pad is positioned in the appropriate position.

Hold the osteotome with an oblique 0.065 K-wire or a small Steinmann pin inserted through the heel (Fig. 167.4B) and bent to prevent migration. Close the wound with subcuticular 4-0 synthetic absorbable suture.

Apply a long-leg cast with the knee bent 90° to prevent weight bearing. Change the cast at 4 weeks and remove the pin. Then use a weight-bearing short-leg cast until clinical and radiographic union is achieved, usually 6 weeks after surgery. An alternative method is to do a closing wedge osteotomy in the same location. This is generally recommended in the older child.

METATARSAL OSTEOTOMIES

The procedure for metatarsal osteotomies begins with three longitudinal incisions on the dorsum of the foot; the first is on the dorsomedial aspect of the proximal first metatarsal, and the remaining two are between the second and third metatarsals and the fourth and fifth metatarsals (Fig. 167.5). (An alternative is to use a curved transverse incision at the level of the tarsometatarsal joints.) Take care to protect the small dorsal veins, the superficial nerves, and the dorsalis pedis artery.

Figure 167.5. A: Preferred longitudinal incisions for metatarsal osteotomies. B: Supination of the forefoot relative to the heel must be corrected with the metatarsal osteotomies.

Expose the proximal shaft of the first metatarsal by medial longitudinal subperiosteal dissection. The periosteum is adherent proximally, where the physes of the first metatarsal is located. The physes must not be injured: Use a Keith needle or intraoperative radiograph, if necessary, to locate and protect it.

Use a small oscillating saw to perform a transverse osteotomy 1 cm distal to the physis, starting from the medial side. If possible, do not quite complete the cut through the dorsolateral cortex, but instead create a greenstick-type fracture to act as a hinge, or leave an intact sleeve of periosteum laterally.

Perform similar osteotomies of the remaining proximal four metatarsals using the saw; the physes of these bones are distal, so there is no risk of injury to them. Try not to injure the lateral periosteal sleeves.

Manipulate the metatarsals into corrected position. Hold them in place with two K-wires inserted obliquely through the first and fifth metatarsal shafts into the midtarsus. Be sure to correct any forefoot supination (Fig. 167.5B) and cavus that are present. These must be evaluated clinically because axial deformity in particular will not be evident on radiographs. The foot should appear fully corrected externally when lying relaxed on the table, and the entire sole should be plantar grade from heel to metatarsals.

Cut the wires outside the skin and bend them to prevent migration.

Check the position of the wires on a radiograph. Minor displacement of the middle metatarsals remodels easily if the lateral periosteum has not been violated (Fig. 167.6). Gross displacement of lesser metatarsals can lead to nonunion, which, although not always painful, should be corrected. If the hindfoot is in rigid varus, perform an os calcis osteotomy, or perform any desired tendon transfers at this time.
Close the wounds with subcuticular 4-0 absorbable synthetic suture.

Apply a well-padded short-leg cast. At 3–4 weeks, change the cast and remove the wires. Apply a new well-molded cast in the corrected position and allow weight bearing. Remove the cast 6–8 weeks after surgery.

ANTERIOR TIBIAL TENDON TRANSFER TO THE THIRD CUNEIFORM

Although Garceau (12) originally described anterior tibial tendon transfer to the cuboid, we have found that a less lateral position, to the third cuneiform, is more appropriate, especially when correction of fixed deformity is performed prior to the tendon transfer.

Make a small dorsal medial incision (Fig. 167.7). Detach the insertion of the anterior tibial tendon close to bone through the wound, leaving the tendon as long as possible. Place a Bunnell suture of #1 or #0 synthetic absorbable suture in the tendon.

Make a second, longitudinal incision over the anterior tibial muscle belly above the ankle, identify the muscle by pulling on the tendon, and pull the tendon into this incision.

Make a third incision over the third cuneiform bone. Pull on the periosteum in line with the selected transfer insertion site to dorsiflex the foot, observing inversion–eversion. Modify the insertion site to obtain balanced dorsiflexion.

Make a drill hole through the third cuneiform to the plantar surface. Pass the tendon through the subcutaneous tissue from the proximal wound to the third cuneiform (not beneath the ankle retinaculum). Thread the suture in the tendon through the hole in the cuneiform. Bring the Keith needles out the plantar surface, tying the suture over a button or dental roll on the plantar aspect of the foot.

Close the wounds with fine absorbable synthetic subcuticular suture.

Apply a short-leg cast, which is worn for 6 weeks. Allow weight bearing after 4 weeks.

SPLIT ANTERIOR TIBIAL TENDON TRANSFER

For a split anterior tibial tendon transfer (13), make a small medial incision (Fig. 167.8). Isolate the insertion of the anterior tibial tendon through the wound. There is usually a natural longitudinal division of the tendon. Split the tendon from proximal to distal. Do not attempt to split the tendon from below, because it is easy to rupture it. If rupture occurs, abandon the procedure and proceed with a standard anterior tibial transfer as described previously, using the remaining tendon stump. Free up the lateral half of the insertion into the navicular at this split, and place a suture of #1 or #0 synthetic absorbable suture in it using a crisscross Bunnell technique.

Make a second, longitudinal incision anteriorly above the ankle. Identify the anterior tibial muscle by pulling on the split tendon end, and pass a tendon passer from the proximal wound to distalward along the tendon, taking care to remain in the tendon sheath.

Grasp the Bunnell stitch, pull it back into the second wound, and deliver the lateral half of the split tendon up into the proximal wound.

Transfer the split portion of the tendon to the cuboid bone by the technique described previously for anterior tibial transfer. Adjust the tension so that the lateral arm of the transfer is just slightly tighter than the medial arm (observed through the superior wound). Anchor the transfer as described previously, or bring it through a hole in the cuboid and sew it back on itself.

Closure and postoperative care are the same as for anterior tibial tendon transfer.

CAVUS FOOT

Rarely, cavus foot is idiopathic and seen in infancy. Cavus is a common component or residuum of clubfoot. However, isolated cavus or cavovarus deformity usually develops insidiously with growth and is a sign of occult neuromuscular disease. Some of the more common associated disorders are listed in Table 167.1.
Table 167.1. Common Conditions Associated with Cavus or Cavovarus Feet

Because the orthopaedic surgeon is often the first physician to recognize the deformity, it is important to do a careful neurologic examination and initiate necessary ancillary studies (e.g., electromyography, muscle enzyme studies, spine radiographs, and spine magnetic resonance imaging) and obtain appropriate consultation before attempting treatment.

Cavus is generally progressive until growth stops. Orthotic management is never successful; the deformity is either accepted or treated surgically. The mainstay of treatment is triple arthrodesis (see Chapter 115), but dorsal wedge osteotomy may be appropriate in selected cases. There is usually associated hindfoot varus. Determine whether hindfoot varus is fixed by the Coleman block test (Fig. 167.9). This test differentiates between rigid varus, which must be surgically treated by triple arthrodesis, and varus secondary to first metatarsal depression, which is flexible and corrects once the medial column cavus has been corrected using midfoot dorsal wedge osteotomy.

If cavus is severe and disabling in a young child, plantar release and metatarsal osteotomies can successfully temporize while the foot matures. However, bony procedures at maturity (after age 11 or 12 years) almost always are required, even after earlier soft-tissue release.

DORSAL WEDGE OSTEOTOMY OF THE CUNEIFORMS

Dorsal wedge osteotomy of the cuneiforms is appropriate only if the hindfoot varus is flexible and fully correctable; otherwise, perform triple arthrodesis with appropriate wedge resection (see Chapter 115). Plan the osteotomy on a lateral radiographs of the foot so that the correction will bring the forefoot plantigrade when the hindfoot is in the weight-bearing position.

- Make a longitudinal midline dorsal incision from the mid talus to the base of the third metatarsal.
- Identify and protect the dorsal is pedis vessels, and incise the peristeum from the navicular to the cuneiform bones.
- Strip the periosteal and capsular structures medially and laterally to expose the cuneiforms dorsally, as far as the cuboid laterally and to the navicular medially.
- Under image intensification, insert two guide pins at the osteotomy edges, avoiding the talonavicular and cuneiform–metatarsal joints; converge the pins so that their tips meet at the plantar surface of the bones, producing a wedge large enough to correct the deformity (Fig. 167.10).

- Use an oscillating saw to cut the two faces of the wedge just inside the guide pins. Make the cut slowly, all in one pass, since the small bones shift and it is easy to lose the plane of the cut. Remove the wedge with an osteotome and a small rongeur.
- Close the wedge, correct for supination deformity, and carefully align the rotation of the forefoot with the hindfoot. Fix the osteotomy with dorsal staples, or crossed smooth Steinmann pins or K-wires inserted from medially and laterally through the metatarsal bases.
- Close the wound with absorbable sutures.
- Apply a padded splint or a short-leg cast in neutral dorsiflexion. It is usually necessary to split the cast.

Aftercare

Change to a cast in neutral position when swelling in the foot resolves. Allow, but do not force, weight bearing as tolerated. Continue casting until union occurs, which is usually 6–8 weeks.

POLYDACTYLY

Polydactyly is a hereditary foot deformity inherited with an autosomal dominant pattern. The most common form is postaxial duplication of the fifth digit. Less common is preaxial duplication of the great toe. Rarest is middle toe duplication. Both preaxial and postaxial polydactyly may be associated with syndromes, which you should look for. The hand is often involved as well; when this is the case, the foot deformities are usually more severe than the hand deformities in that the duplications are more proximal. Generally, it is desirable to treat polydactyly of the toes because untreated patients experience difficulty with fitting shoes. In addition, extra digits, even
though asymptomatic, can subject a child to ridicule from peers (25,35).

**POSTAXIAL POLYDACTYLY**

In most postaxial (lesser toe) deformities, it is generally easiest and most effective to remove the peripheral (lateral) toes. The metatarsal is nearly always abnormal, ranging from a widened lateral metatarsal, through Y- or T-shaped distal metatarsals, to duplication of the entire bone. You must shave a widened or prominent metatarsal to reduce the width of the foot, or a bunionette will result. Preoperative radiographs are important for planning, because occasionally there is an obvious internal (central) duplication that requires more complex reconstruction. In such a case, it is desirable to preserve the toe that is more functional and has the best axial alignment. A risk of removing the intercalary digit may be the development of an angular deformity of the lateral toe. It may therefore be necessary to create a partial syndactyly between the remaining lateral toe and the fourth toe to prevent this from occurring. If the metatarsal is duplicated, you must remove this as well (Fig. 167.11).

![Figure 167.11. Examples of resection required (shaded area) for postaxial toe duplication correction. Trim the metatarsal so there is no lateral prominence.](image)

**RESECTION OF A SIXTH TOE**

- To resect a sixth toe, make a dorsal curvilinear incision over the base of the toe (Fig. 167.12). Make a longitudinal dorsal cut down the middle of the digit to be excised, and filet it out.

![Figure 167.12. Excision of sixth digit. A: Curved dorsal incision and longitudinal sixth toe incision. B: Dorsal exposure of sixth toe allows complete excision and any necessary metatarsal trimming. C: Filleted skin flap is pulled dorsally, shaped, and closed. The resulting scar is dorsal and does not rub against shoe wear.](image)

- If the proximal phalanges of toes five and six are joined, cut the cartilaginous portion cleanly with a scalpel. Trim the metatarsal head to the size of a normal bone, using a sharp scalpel and osteotome; growth arrest will not occur. Wrap up the plantar flap dorsally, trim it, and stitch it with fine absorbable suture.
- Resect a fifth toe as a wedge, including the digit and any rudimentary metatarsal.
- Bring the fourth and sixth digits together, closing this wedge.
- Perform syndactylization if appropriate when drifting of the remaining toes is likely.
- A short-leg cast can be used for 3 or 4 weeks to allow the wounds to heal and the toes to stabilize.

**HINTS AND TRICKS**

If the postaxial digits are congenitally syndactylized, the principles of reconstruction remain the same. Preserve the most functional digits. A duplication of the nail frequently exists. It is important to carefully resect the nail and its matrix with the digit to be sacrificed to prevent recurrence of an abnormal nail. Plan skin flaps carefully.

**PREAXIAL POLYDACTYLY**

Preaxial duplications present a much more complex problem in reconstruction than postaxial duplications. Each of these reconstructions must be planned individually. The first metatarsal may be shortened and have a longitudinal epiphyseal bracket epiphysis that has an L or a C shape and acts as a medial tether to the growth of the toe (Fig. 167.13) (18,24). The hallux itself may be in varus. If a longitudinal epiphyseal bracket is present, central physeal lysis has been reported to be successful. The results of reconstruction of preaxial polydactyly can be disappointing. Residual or recurrent hallux varus occurs frequently and difficulties with shoe wear are common complications. Consider syndactylization of the first and second toes in the more difficult cases, especially if there is a recurrent deformity.

![Figure 167.13. Duplicated first toe is frequently associated with a short, rounded first metatarsal with an epiphysis that surrounds both ends and the medial side of the bone—a longitudinal epiphyseal bracket. Excision (shaded area) at the time of toe removal may allow more normal longitudinal growth of the first metatarsal; failure to recognize this may lead to a very short first ray at maturity.](image)

We recommend excising the toe that will allow the foot and remaining toes to assume the most normal contour. In most cases, this is the most medial or tibial toe in patients with duplication of the hallux. Sometimes it is appropriate to excise the tibial toe even if the second toe is more hypoplastic, since the risk of hallux varus is less. If a longitudinal epiphyseal bracket is present, excise the central portion of the bracket epiphysis. Because hallux varus has been the most common and most symptomatic long-term problem following surgery on duplicated great toes, make an effort to reinsert the adductor hallucis muscle into the proximal phalanx of the great
toe. In addition, consider a partial syndactyly of the great and second toes. Syndactylization may be necessary at a separate procedure if extensive dissection would be necessary on both sides of the toe, resulting in an endangered blood supply. This combination of reconstructive procedures leads to an acceptable result for shoe wear. The cosmetic result is often less than satisfactory.

**JUVENILE HALLUX VALGUS**

Bunions, or hallux valgus deformities, are relatively common problems in children and adolescents (6, 7, 31). The incidence is unknown. It occurs much more commonly in girls than boys. Ill-fitting shoes have been implicated as a causative factor in adult hallux valgus, but the association of shoe wear with juvenile hallux valgus is unclear. There is often a positive family history. The deformity is usually bilateral. The age of onset may be as young as 10 years of age.

The general indications for surgical intervention are problems with shoe wear and dissatisfaction with the cosmetic appearance of the foot. Despite the fact that surgical intervention is noted to have a high failure rate, most reports on the correction of juvenile hallux valgus have presented the results of a single, specific technique of surgical reconstruction. We agree with Coughlin (6) that the operative procedure to correct juvenile hallux valgus must be customized to the specific deformities in the foot. Surgical correction prior to epiphyseal closure is controversial. Whereas there is rarely a rush to perform surgery to correct the deformities of juvenile hallux valgus, the notion that surgery performed on a patient with an open epiphysis is contraindicated has not been substantiated.

In assessing the patient with juvenile hallux valgus, obtain an AP weight-bearing radiograph of the foot. Measure the following: (a) the hallux valgus angle, (b) the first-to-second intermetatarsal angle, (c) the distal metatarsal articular angle, and (d) the first metatarsophalangeal joint congruency (the relationship of the articular surface of the base of the proximal phalanx to the articular surface of the 1st metatarsal) (Fig. 167.14, Fig. 167.15).

![Figure 167.14](image1.png)
**Figure 167.14.** Lines used for assessing patient with juvenile hallux valgus. Normal values are in parentheses. **A:** Hallux valgus angle (<15°). **B:** First-to-second intermetatarsal angle (<9°). **C:** Distal metatarsal articular angle (useful for assessing subluxation and congruency).

![Figure 167.15](image2.png)
**Figure 167.15.** The first metatarsal phalangeal joint may be incongruent (A) with lateral subluxation of the joint, or congruent (B) with a tilted distal metatarsal articular surface.

Operative procedures to correct juvenile hallux valgus can be grouped into four categories:

1. Distal soft-tissue procedures, such as the McBride operation. In most series, this has been associated with a high recurrence rate.
2. Distal metatarsal osteotomies, such as a chevron osteotomy or a Mitchell osteotomy. These procedures have a relatively high rate of patient satisfaction. They should be used for patients with less severe deformities and a relatively normal distal metatarsal articular angle. These procedures can be modified if the distal metatarsal articular angle is abnormal (see the fourth category).
3. A proximal metatarsal osteotomy with a distal soft-tissue procedure. These procedures can be used successfully in moderate hallux valgus deformities with fibular valgus subluxation of the metatarsophalangeal joint but are less successful in correcting a patient with a congruent joint and an increased distal metatarsal articular angle.
4. Double metatarsal osteotomies. We believe that this is the best method of correction in a patient with an increased first-to-second intermetatarsal angle and an increased distal metatarsal articular angle with a congruent joint. The proximal osteotomy corrects the first-to-second intermetatarsal angle (Fig. 167.16A), and the distal osteotomy corrects the hallux valgus and the increased distal metatarsal articular angle (Fig. 167.16B). The distal osteotomy can be a chevron or Mitchell type, with more bone resected on the tibial side of the osteotomy than on the fibular side.

![Figure 167.16](image3.png)
**Figure 167.16.** Double metatarsal osteotomy is used when a patient with hallux valgus has an increase of both the first-to-second intermetatarsal angle and the distal metatarsal angle. The proximal cut can be as shown or crescentic. The distal cut may also be a chevron type, with more resection on the tibial side of the osteotomy. **A:** The osteotomies. **B:** Completion of osteotomies and fixation with a longitudinal Kirschner wire.

These procedures are covered in more detail in Chapter 112. No one standard operation is suited for all juvenile patients with hallux valgus. Versatility is the surgeon’s most important asset when treating the juvenile bunion. It is important not to stretch the indications for a particular technique to correct the deformity.

**TARSAL COALITION**

Tarsal coalition (9, 23) is a congenital fusion between two or more of the tarsal bones. The coalition can be a true bony fusion, or a cartilaginous or fibrous connection.
The overall incidence of tarsal coalitions is unknown, but many are inherited with an autosomal dominant pattern. Many tarsal coalitions are not symptomatic and therefore go unrecognized. The most common symptomatic tarsal coalitions occur between the calcaneus and the talus, and between the calcaneus and the navicular. Complex coalitions also accompany fibular hemimelia and proximal femoral focal deficiency, but these rarely require treatment.

Pain is the principal presenting symptom, occurring when the coalition or bar begins to ossify. The usual age of onset is the second decade of life. The most common clinical finding is restriction of subtalar motion. The hindfoot is in valgus, and the patient may experience peroneal muscle spasm exhibiting in a rigid flatfoot. An attempt to invert the hindfoot, especially as a rapid maneuver, causes an increase in pain.

For radiographic evaluation, take AP, lateral, and oblique radiographs of the foot. The best radiographic view to detect a calcaneonavicular bar is the 45° oblique view (Fig. 167.17A). A lateral radiograph of the foot or of the ankle will usually demonstrate the so-called anteater nose sign, which is elongation of the anterosuperior aspect of the calcaneus as it is directed toward the navicular.

A talocalcaneal bar is much more difficult to demonstrate on plain radiographs. Oblique subtalar (Harris) views can be helpful, but often the best study to demonstrate a medial subtalar coalition is a computerized tomographic examination. When done in the coronal plane, this study usually successfully demonstrates talocalcaneal coalition.

The treatment of a symptomatic tarsal coalition is initially conservative. Start with 4–6 weeks of immobilization in a short-leg walking cast. If this and other conservative measures fail, consider resection of the tarsal coalition if the child is still young, particularly when some subtalar motion is present. Results are generally favorable with resection of calcaneonavicular tarsal coalitions. The results are less predictable with tarsal coalitions between the talus and calcaneus. The presence of symptoms for many years and advanced degenerative changes on midfoot radiographs are contraindications for resection of the coalition. In such cases, triple arthrodesis may be appropriate.

RESECTION OF CALCANEONAVICULAR TARSAL COALITION

- Using a thigh tourniquet, make an oblique incision across the sinus tarsi from near the heel to the head of the talus, or use a horizontal incision (Fig. 167.17B). Protect the branches of the sural nerve.
- Identify the fat of the sinus tarsi and the extensor digitorum brevis muscle, and reflect them distally from their origins on the calcaneus, exposing the sinus tarsi. Lesions attached distally.
- Identify the calcaneonavicular coalition. Remove the coalition as a large rectangle of bone, using an osteotome and a rongeur. The removed bone is larger than one would expect when looking at the radiograph, and it must be rectangular in shape so that there is no bony impingement in the depths of the resection.
- Demonstrate motion between the calcaneus and the navicular, and between the talus and the calcaneus after the resection is complete. Apply bone wax to the cut bony surfaces.
- Place a Bunnell suture through the origin of the extensor digitorum brevis muscle. Pass the sutures through the coalition with Keith needles, and bring them out on the medial aspect of the midfoot.
- Pull the distally based pedicle flap of fat and the extensor digitorum brevis into the space created by resection of the coalition, and tie the sutures on the medial aspect of the foot over a dental roll.
- Close the wound with absorbable sutures.
- Place the patient in a non-weight-bearing cast for 3–4 weeks until soft tissues are healed. Generally, motion is regained over the following 6 weeks.

RESECTION OF MEDIAL SUBTALAR COALITIONS

Surgical resection of talocalcaneal tarsal coalitions is more controversial. In our opinion, it seems reasonable to attempt resection of the subtalar coalition when there are no associated degenerative changes in the joints of the foot. It has been observed that resection of even the more sizable subtalar coalitions can be successful. If the operation fails, a subtalar or triple arthrodesis can be a satisfactory salvage procedure. The technique involves a medial approach to the medial facet of the subtalar joint. Determine the exact location and size of the coalition preoperatively with coronal plane computerized tomography.

- Under pneumatic tourniquet, make a horizontal incision over the sustentaculum tali.
- Retract the muntanward and divide the flexor retinaculum over the sustentaculum.
- Identify the FHL (which is just beneath the sustentaculum tali) and retract it plantarward.
- Retract the posterior tibial tendon, above the sustentaculum, dorsally.
- Reflect the peristome off the sustentaculum. Do this with care so that you can later approximate it to hold a fat graft in place.
- Identify the anterior and posterior boundaries of the coalition. We excise the coalition using a high-speed burr, gradually taking away bone until we identify the normal posterior facet of the subtalar joint. You must visualize the joint cartilage anteriorly, posteriorly, and laterally through the site of the excision. Once the excision is completed, subtalar motion should improve.
- The final step is to interpose fat between the two bony surfaces. You can obtain the fat locally, through a small incision at the ankle, or from a separate incision made in the suprapubic area, which gives a cosmetically invisible scar when the patient becomes more mature. Seal the resected bony surfaces with bone wax, and carefully push the fat graft into the defect created by the excision. Hold it in place by approximating the peristome with sutures.
- Close the wound.
- Place the patient in a short-leg, non-weight-bearing cast for 4 weeks, and then allow progressive weight bearing as tolerated.

TRIPLE ARTHRODESIS

If resection of the tarsal coalition fails to relieve the patient’s symptoms, triple arthrodesis is a successful salvage procedure. You can use it as a secondary procedure after a failed attempt at coalition resection, or as a primary procedure when the coalition is extremely large, symptoms have extended for years, or degenerative changes are present. This procedure is generally successful in relieving the pain associated with tarsal coalition. Techniques of triple arthrodesis are described in Chapter 115.

CONGENITAL VERTICAL TALUS

Congenital vertical talus (CVT), also known as congenital convex pes valgus, is a complex, rare, foot deformity that is resistant to conservative treatment. There is a continuum from a relatively mild, flexible form (oblique talus) to a rigid, severe deformity characterized by a plantar-flexed talus, hindfoot equinus, and dorsal dislocation of the tibial plafond and subtalar joints. The heel is always in rigid valgus. There are contractures of the Achilles tendon, peroneus tertius, long-toe extensors, and tibialis anterior muscle (Fig. 167.18). Lateral roentgenographs taken in full dorsi- and plantarflexion differentiate the more flexible oblique talus from the severe variety; oblique talus exhibits severe deformity in dorsiflexion but a relatively normal relation between the talus and calcaneus in full plantar flexion (16).
In more than 80% of cases, CVT is associated with other anomalies and syndromes (Marfan's syndrome, arthrogryposis, multiple pterygium syndrome), genetic abnormalities (trisomy 13–15, trisomy 18), or neuromuscular defects (myelomeningocele) (16). Unless the cause of the anomaly is clear, perform a thorough neuromuscular and genetic workup. Many children with CVT who would otherwise be candidates for surgery are wheelchair bound and can be treated by protecting the foot with a soft tennis shoe.

When indicated, treatment of rigid CVT is always surgical. Most experts recommend preliminary casting to mobilize the skin, but casting does not correct the bony deformity. Single-stage correction usually involves mobilization and reduction of all subluxed joints, internal fixation, and appropriate soft-tissue repair with transfer of the anterior tibial tendon to the neck of the talus to maintain dorsiflexion of the talus and minimize heel valgus (15,30).

The other commonly used approach is a two-stage method, with the procedures spaced 6–8 weeks apart (5). In this approach, first reduce the dorsally dislocated midfoot through an anterior incision, and lengthen contracted toe extensors and anterior tibialis muscles. Stabilize the subtalar joint in appropriate position with a subtalar bone block. Six weeks later, release the posterior ankle and subtalar joints, lengthen the heel cord, and reconstruct the anteriorly displaced posterior tibial muscle to support the talar head and neck. Whereas many surgeons attempt correction by soft-tissue means, this approach (using a subtalar fusion) can be highly effective in difficult cases.

Seimon (27) has described correction of deformities in CVT with a single dorsolateral longitudinal incision and a percutaneous posterior release. This procedure has been used with excellent success in patients under the age of 2 years.

Surgery is ideally done at 4–6 months of age, although accompanying anomalies and illnesses often require postponement to age 1 year or later. After the age of 2 to 5 years, reduction is difficult unless the foot is decompressed by navicular excision (3). Partial takedown and decancellation of the tarsal bones may be required. Triple arthrodesis may be necessary in neglected or severe cases, and it may be necessary in maturity even when surgery early in life has corrected the gross deformity. This is especially true when tarsal bones are excised, leading to late degenerative arthritis.

**DORSOLATERAL APPROACH**

- Approach the dorsolateral aspect of the foot with either an oblique incision or a longitudinal incision over the mid-dorsum of the foot (27).
- Lengthen the extensor digitorum longus and peroneus tertius tendons. Accomplish digital extensor lengthening by dividing a portion of the tendons proximally and a portion distally, and suturing the long proximal stumps to the long distal stumps in the elongated position.
- Identify the neurovascular bundle. Retract the tibialis anterior and extensor hallucis longus tendons medially.
- Generally, the peroneal tendons are contracted and lengthening is necessary.
- Divide the dorsal and lateral talonavicular joint capsule. This allows the navicular to be readily reduced onto the head of the talus. The dorsal and lateral calcaneocuboid capsule may require release as well. You can elongate the tibialis anterior and extensor hallucis longus tendons if they are obstacles to an easy reduction.
- Transfix the talonavicular joint with a smooth K-wire. If the calcaneocuboid joint is released (or subluxated), transfix it as well. Take care to correct midfoot supination when fixing these joints.
- Lengthen the Achilles tendon percutaneously.
- You may perform posterior capsulotomies of the ankle and subtalar joint to come to equinus, but usually this is not required.
- Once the hindfoot has been corrected, pass a second K-wire from the plantar aspect of the heel through the calcaneus and talus into the tibia.
- Apply an above-knee cast to be worn for 6 weeks. After 6 weeks, remove the two K-wires and apply a below-knee cast to be worn for a further 6 weeks.

**SINGLE-_STAGE REPAIR**

- Make three incisions (Fig. 167.19): The first is concave downward over the medial talonavicular joint; the second is oblique over the sinus tarsi to expose the calcaneocuboid joint and peroneal and extensor tendons; the third is along the lateral border of the Achilles tendon to allow posterior release.

- Begin laterally and make the dorsolateral approach already described. Inspect the calcaneocuboid joint, and release its capsule as necessary to correct lateral column alignment.
- In the medial wound, divide the dorsal talonavicular (deltoid) ligament and open the capsule of the dorsolateral talonavicular joint.
- Subluxate the posterior tibial tendon superiorly; divide it and tag it for later repair.
- The navicular is riding on the anterior talar neck; continue mobilizing the joint capsules dorsally through both incisions until the midfoot can be brought into plantar flexion, with reduction of the talonavicular and calcaneocuboid joints.
- Through the posterior incision, perform Z-lengthening of the Achilles tendon with the distal transverse cut directed laterally; tag the ends with #0 absorbable synthetic suture.
- Incise or excise the posterior capsules of the ankle and subtalar joints, and release the contracted fibulocalcaneal ligament and tendon sheaths of the peroneals by cutting circumferentially with small scissors. In severe cases, the interosseous subtalar ligament may require full or partial release.
- Reduce the talonavicular joint and pin it with a K-wire directed from the posterior tuberosity of the talus through the center of the joint. Bring the pin out anteriorly and bend it to prevent migration.
- Check the ankle to be sure there is adequate dorsiflexion and slight heel varus. Obtain an intraoperative lateral radiograph. The first metatarsal axis should line up exactly with the long axis of the talus; if it does not, repeat the preceding steps until it is correct.
- Repair the talonavicular joint capsule by reeling the elongated plantar calcaneonavicular ligament and remaining capsule, and repair the posterior tibial tendon, sewing it beneath the talar head and neck to assist in support.
- Release the origin of the anterior tibial tendon and transfer it to the midtalar neck; using a drill hole and sewing it to itself, to prevent abnormal plantar flexion of the talus; in the young child, make a small gutter in the medial cartilage of the talar neck and sew the tendon over this and into the soft tissues below the neck (Fig. 167.20).

---

Figure 167.18. Contractures involved in severe congenital vertical talus.

Figure 167.19. Preferred incisions for single-stage repair of congenital vertical talus (medial and lateral views).
 Repair the Achilles tendon with the heel in neutral position.

Close the skin with fine interrupted absorbable synthetic suture.

Apply a long-leg cast, molded in the arch. Change the cast at 3-week intervals; it is worn for 4 months. Often a reverse Peristeen brace or AFO is necessary for 1–2 years.

Feet with CVT are invariably somewhat stiff after surgery; a normal foot never can be obtained. Persevere to obtain a plantigrade foot that fits easily into normal shoes and that has no pain or pressure sores. Late subtalar or triple arthrodesis may be required. The vertical talus associated with myelomeningocele or cerebral palsy may require modifications of the surgical treatment and individualized tendon transfer to achieve a balanced foot.

**PITFALLS AND COMPLICATIONS**

Do not miss associated anomalies and conditions. Misdiagnosis can lead to a poor outcome or, worse, a serious complication when there is serious associated systemic disease or other disorders.

Precise, careful surgical technique is necessary to avoid neuromas from inadvertently cutting superficial sensory nerves, more serious injury to the main neurovascular bundles and tendons, and skin sloughs. In small feet, magnifying loupes are quite helpful.

Avoid incomplete correction or overcorrection, particularly the latter as it is more difficult to correct, by careful preoperative planning.

SURGICAL MANAGEMENT OF TORSIONAL DEFORMITIES OF THE LOWER EXTREMITIES

Vincent S. Mosca and Lynn T. Staheli

The most common reason for children to seek orthopaedic evaluation, except perhaps for trauma, is for suspected torsional or angular deformities of the lower extremities. Most of these children are normal. Studies have shown that measurements of torsion and angulation in children have wide ranges of normal values and that these values change spontaneously with age until they reach the narrower adult normal ranges (3,15,17,21,22).

Values within two standard deviations of the mean are termed physiologic variations. Those beyond two standard deviations are called deformities.

It is the role of the orthopaedist to identify the few true torsional or angular deformities, as well as to identify disease entities that mimic or resemble these deformities. Do this with a careful history and clinical assessment. Perform the torsional profile examination and document it for all children who are referred for evaluation of their lower extremities or gait abnormalities (19). Clinical photographs are helpful for documentation, especially for serial evaluations. Accurate anatomic diagnosis can be made by routine radiographs for angular deformities and biplane radiographs or computed tomography (CT) scan for torsional deformities. These studies are reserved for severe deformities and for preoperative planning.

Having ruled out true deformities and other disease entities, convince the parents (and grandparents) that the apparent deformity is a normal finding, although it may not represent the average value. Point out that the apparent deformity will probably become “more normal” with time. There is no convincing evidence that orthotic management of torsional or angular variations or deformities has any beneficial effect over simple observation of the natural history alone (4,19). Therefore, the management decision is between observation with parent education, and surgery.

The parents’ main concern is usually the child’s appearance. Education about natural history, the uselessness and expense of orthotic devices, and the cost–benefit ratio of surgery establishes a rational basis for the observational approach. If the parents are not convinced, see their child yearly and review the torsional or angular profile with them. Clinical photographs are most helpful in this setting. Also stress that even if full spontaneous correction of torsional variations does not occur, the child may be able to voluntarily change the foot-progression angle when self-appearance takes on increased meaning during adolescence.

Function is frequently the family’s second concern. One study has shown that severe medial femoral torsion appears to adversely affect running, but a moderate amount of torsion does not (23). Marked genu valgum appears to adversely affect running performances as well, but this has not been documented.

Although secondary deformities have been attributed to some variations, only the concurrence of lateral tibial torsion with medial femoral torsion in late childhood has been documented (3). Likewise, genu valgum is often associated with foot pronation, but a cause-and-effect relationship has not been documented.

A final concern about torsional or angular variations or deformities is the development of arthritis (6,8,9,11,12,24,25). No documentation to date proves a cause-and-effect relationship between such variations or deformities and arthritis of the hip or patellofemoral joint.

It follows from the foregoing that indications for surgery for torsional or angular variations or deformities are extremely narrow. Because of the natural tendency for rotational deformities to remodel and improve with growth, surgical treatment is not indicated in children under 10–12 years of age. The decision hinges primarily on cosmetic concerns in the adolescent.

In most cases, variations or deformities are bilateral and often at more than one level; for example, medial femoral torsion often accompanies lateral tibial torsion. Surgical correction at one level frequently necessitates surgical correction at the other level. Staged unilateral surgery prolongs the period of temporary disability. Simultaneous bilateral surgery increases the temporary disability.

The risk of complications from surgery is quite high. A 15% complication rate was found in a review of operative treatment for medial femoral torsion alone (20). In another study, a 13% incidence of peroneal nerve palsy was reported following proximal tibial rotational osteotomies if the fibula was not osteotomized (16).

Indications for surgery are subjective and must be individualized. The patient’s general body habitus, the torsional and angular profile at all levels, the patient’s emotional and psychologic makeup, and the torsional and angular variations of other family members must be considered. With these parameters carefully evaluated and in perspective, consider surgical correction when (a) femoral rotation values are more than three standard deviations from the mean, (b) tibial rotation values are more than four standard deviations from the mean, or (c) there is more than 25° of genu valgum in a child older than 8 years. A busy, full-time pediatric orthopaedist may find one or two torsional or angular variations or deformities per year that require surgery. The operations to be described are used much more frequently to correct the antversion and coxa valga in cerebral palsy, the lateral tibial torsion with ankle valgus in myelodysplasia, and the angular deformities from old infection, partial physeal arrest, metabolic disorders, ischemia, ionizing irradiation, or genetic conditions.

FEMORAL ROTATIONAL OSTEOTOMIES

Femoral rotational osteotomies can be carried out proximally, in the mid shaft, or distally. The intertrochanteric region of the femur is the preferred site for proximal osteotomies (19). Osteotomy at this level is safe, heals rapidly, and leaves an acceptable cosmetic scar. The intertrochanteric region is usually the site of the pathology and is easily accessible. The essence of the problem is torsional malalignment of the femoral neck and shaft, and it is in the intertrochanteric region that these two anatomic structures meet. If proximal femoral angulation is a problem in addition to torsion, simultaneous corrections can be made with osteotomy at this level. The technique and instrumentation for intertrochanteric osteotomy are simple and no special training or equipment is required. Early partial weight bearing is possible when rigid internal fixation is used.

Closed, mid-shaft, intramedullary rotational osteotomy of the femur is an alternative for the older adolescent in whom there is adequate intramedullary shaft diameter and little concern about iatrogenic arrest of the greater trochanter (26,27). The utility of this operation in the immature child, however, is limited both by its complexity and by the small but real risk of avascular necrosis of the femoral head related to the proximal insertion site for the nail. The scar is acceptable cosmetically and the patient may bear weight immediately. Special expertise and equipment are required, and after surgery the femur may tend to derotate around the rod unless a locked nail is used. Some angular deformities can be corrected simultaneously (see Chapter 30).

Distal femoral osteotomy in the supracondylar region gives the least acceptable scar, runs the highest risk of potential injury to growth plates, is more likely to leave residual angulation, and is farthest from the site of pathology, unless there is an associated marked patella-tracking problem (7).
OPERATIVE TECHNIQUES

Proximal Femoral Rotational Osteotomy

Use preoperative planning with radiographs and templates to determine which blade-plate angle will permit entrance of the blade just distal to the greater trochanteric apophysis, and to determine seating of the tip of the blade in the inferior proximal femoral neck.

- Place the patient supine on a radiolucent operating table extension to permit use of the image intensifier. Place folded towels under the buttocks in such a way as to allow the lateral soft tissues of the buttocks and thigh to overhang the edge of the towels. Isolate the perineum with an adherent plastic drape. Prepare both lower extremities from the iliac crests over most of the hemipelvis down to the toes.
- Make a straight lateral longitudinal incision extending distally from the greater trochanter. Incise the fascia lata longitudinally. Incise the vastus lateralis transversely just distal to the vastus ridge, and then longitudinally just anterior to the linea aspera. Bring the transverse cut in the vastus lateralis anteromedially, sufficient to see the base of the femoral neck. This creates an L-shaped flap of the muscle that can be easily reattached at the completion of the procedure.
- Expose the femur subperiosteally. Carefully incise the linea aspera with a scalpel at the proposed level of the osteotomy. Attempts at blunt elevation are difficult and may result in plunging into highly vascularized soft tissues. Using image intensification, internally rotate the extremity until the femoral neck is in the horizontal plane. Place a Steinmann pin along the anterior femoral neck in the proposed position of the blade and use the image intensifier to confirm the appropriateness of the chosen angle (Fig. 168.1).

![Figure 168.1. Proximal femoral rotational osteotomy with blade plate. A: Steinmann pin confirms appropriateness of 100° blade plate. Notice placement of distal femoral alignment pin. B: Initial position of distal pin and chisel. Angle represents degree of desired correction. C: Pin and chisel (which is actually the plate holder) aligned parallel after osteotomy. Note residual average amount of torsion. D: Final position with blade-plate fixation after intertrochanteric osteotomy.]

- Introduce the seating chisel (13), mounted on the seating chisel guide, distal to the vastus ridge and in the anterior half of the greater trochanter when viewed laterally. Hold the chisel in the horizontal plane (which is the plane of the femoral neck as positioned earlier) and angled away from the femoral shaft by 180° minus the predetermined blade-plate angle. Most importantly, rotate the chisel until the flap of the seating chisel guide is exactly in line with the long axis of the femur. Incorrect alignment of this position will result in flexion or extension at the osteotomy site when fixing the plate to the shaft. The proximal femoral shaft must be well exposed to make this alignment possible. Insert the chisel to the desired depth under image intensifier control. Check the frog-leg lateral view as well as the anteroposterior view to guide your chisel correctly.
- Insert a smooth Steinmann pin in the distal femoral metaphysis perpendicular to the long axis of the femur and rotated away from the chisel (in the direction of the rotational deformity) by the desired degree of correction. Perform the osteotomy with an oscillating saw beginning 5–10 mm distal to the entrance point of the chisel and perpendicular to the long axis of the femur.
- Use a bone-holding clamp to stabilize the proximal fragment as the chisel is removed. Carefully insert the blade plate on the plate holder. It is vital to maintain your attention and orientation during this maneuver or the blade plate could easily find a new seat in the femoral neck. Confirm the position in two planes with the image intensifier.
- Rotate the femoral shaft until the Steinmann pin and plate holder are aligned parallel. Then clamp the plate firmly on the shaft and rotate the extremity with a finger on the osteotomy site to ensure that there is no false rotation at this level. If the arc of rotation of the extremity is as desired, the side plate can be attached to the shaft with cortical screws in the usual fashion. Make sure that the side plate sits squarely on the shaft prior to making drill holes. An oblique orientation will create undesired and uncalculated additional rotation as the screws are tightened. It is better to accept a few millimeters of translation than to accept an oblique plate. Once again, check rotation and confirm final position of instrumentation by image intensification.
- Reattach the vastus lateralis with 0 Vicryl sutures. Repair the fascia lata with the same suture material. Use an absorbable subcuticular suture for the skin.
- A soft sterile dressing is all that is required. Rigid external immobilization is not needed. The child may begin touch-down weight bearing with crutches when comfortable, usually within several days of surgery. If both femurs have been osteotomized, weight bearing is not permitted. Continue this for 6–8 weeks, at which time healing should be sufficient for full weight bearing. Remove the blade plate 1 year after surgery, with 6 weeks of protected weight bearing after plate removal.

Closed Intramedullary Femoral Rotational Osteotomy

Closed intramedullary femoral rotational osteotomy is described in detail in Chapter 30. A brief description follows:

- The patient can be either lateral or supine on a fracture table. Make a longitudinal incision just proximal to the greater trochanter. Incise the abductors in the direction of their fibers to expose the trochanteric recess just medial to the greater trochanter. Open the medullary canal and then pass a bulb-tipped guide down the canal. Ream the canal up to the desired diameter.
- Place a smooth Steinmann pin percutaneously in the lateral cortical proximal femur. Place a second pin through the lateral cortex of the distal femur rotated internally from the plane of the first pin by the desired amount of rotational correction.
- Introduce the intramedullary saw down to the mid diaphysis under image intensifier control and make the osteotomy (Fig. 168.2). Rotate the distal fragment until the two Steinmann pins are parallel; then drive the intramedullary nail. Statically lock the intramedullary nail with the osteotomy in compression. This guarantees that rotational correction will not be lost. Immediate weight bearing with assistive devices is usually possible.

![Figure 168.2. Closed femoral rotational osteotomy with an intramedullary saw. (From Winquist RA. Closed Shortening of the Femur: Utilizing a New Type of Intramedullary Saw. In: Hempel D, Fischer S, eds. Intramedullary Nailing. New York: Thieme-Stratton, 1982;214.)]

- Begin crutch-assisted weight bearing when tolerated and continued for 6 weeks. Remove the nail approximately 1 year after the operation or when healing is solid (see Chapter 30).

Distal Femoral Rotational Osteotomy

- Prep the entire leg and hip area free so the limb is free to move in space. Make a longitudinal incision over the posterolateral distal femur, but do not extend distally beyond the lateral epicondyle of the femur. Lift the vastus lateralis fibers from the posterior fascia lata, and incise the muscle along its femoral insertion. Take time to carefully identify and cauterize the two or three perforating vessels before dividing or tearing them.
- Strip the peristeum and retract it using a Bennett or Hohmann retractor. As the peristeum is gently stripped distally, a point of resistance will be felt; this is the region just above the physis, and dissection should not be carried more distally. An image intensifier may be used to confirm this position.
OPERATIVE TECHNIQUES

For pure rotational deformity in the tibia, the advantages of distal osteotomy over proximal or mid-shaft osteotomy are overwhelming. We therefore feel there are no tibial apophysis. There is a greater risk of compartment syndrome. Scars at the knee are perhaps less cosmetically acceptable than scars at the ankle.

Proximal tibial osteotomy has the disadvantages of potential injury to the common peroneal nerve and the popliteal artery at its trifurcation, as well as damage to the foot. Preoperatively, the angle of the transmalleolar axis and the thigh–foot angle must be assessed to determine that the rotational problem is in the tibia and not in the foot.

Distal tibial rotational osteotomy is preferred for its accessibility, simplicity, safety, rapid healing, and cosmetically acceptable scar. It is also versatile in cases where femoral osteotomies in the case of medial femoral torsion with lateral tibial torsion. Cosmesis is the prime indication.

Indications for tibial rotational osteotomies are even narrower than for femoral rotational osteotomies. They are perhaps most commonly performed in conjunction with femoral osteotomies in the intertrochanteric region is extremely rare. However, this could result from failure to achieve reasonable apposition of bone, or from distraction of the osteotomy by the hardware. In cases of delayed union, prolonged external immobilization or prolonged partial weight bearing is usually all that is necessary to achieve union.

TIBIAL ROTATIONAL OSTEOTOMIES

Indications for tibial rotational osteotomies are even narrower than for femoral rotational osteotomies. They are perhaps most commonly performed in conjunction with femoral osteotomies in the case of medial femoral torsion with lateral tibial torsion. Cosmesis is the prime indication.

Preoperatively, the angle of the transmalleolar axis and the thigh–foot angle must be assessed to determine that the rotational problem is in the tibia and not in the foot. Distal rotational osteotomy is reserved for tibial torsion problems. Transverse or coronal plane deformities of the foot should be managed by appropriate surgery on the foot.

Distal tibial rotational osteotomy is preferred for its accessibility, simplicity, safety, rapid healing, and cosmetically acceptable scar. It is also versatile in cases where rotational abnormalities are accompanied by distal angular abnormalities.

Proximal tibial osteotomy has the disadvantages of potential injury to the common peroneal nerve and the popliteal artery at its trifurcation, as well as damage to the tibial apophysis. There is a greater risk of compartment syndrome. Scars at the knee are perhaps less cosmetically acceptable than scars at the ankle.

Mid-shaft osteotomies have the disadvantages of potential for compartment syndrome and delayed union or nonunion.

For pure rotational deformity in the tibia, the advantages of distal osteotomy over proximal or mid-shaft osteotomy are overwhelming. We therefore feel there are no reasonable alternatives.

OPERATIVE TECHNIQUES

Distal Tibial Rotational Osteotomy

- Position the patient supine on a radiolucent operating table extension. Prepare both limbs from the toes to the tourniquets on the proximal thighs (Fig. 168.3). The distal thigh and knee must be exposed in the surgical field. In the skeletally immature child, identify the distal tibial physis with the image intensifier and mark its level on the skin.

![Figure 168.3. Distal tibial rotational osteotomy. A: Both limbs prepped and exposed up to tourniquets. B: Initial axial rotation between alignment pins checked with goniometer. C: Pins aligned parallel after osteotomy. Fixation pins enter malleoli and cross osteotomy. D: Final thigh–foot angle checked with hip and knee flexed 90° and also with joints in extension. E: Good early healing. Notice Tibular osteotomy.](image)

- Make a 5 cm longitudinal incision 1–2 cm lateral and parallel to the tibial crest ending at the physial line. Retract the anterior compartment tendons laterally and protect the anterior tibial neurovascular bundle. Incise the periosteum longitudinally down to, but not across, the physis, and expose the tibial metaphysis subperiosteally.
- Through the same skin incision, make an extrafascial approach to the fibula between the lateral and anterior compartments. Expose the fibula subperiosteally at a level 1–2 cm proximal to the anticipated osteotomy of the tibia. Make a long oblique osteotomy with the image intensifier.
- Drill a smooth 1/32-inch Steinmann pins into the anterior proximal tibia in the sagittal plane. Drill a second smooth pin into the distal metaphysis just proximal to the physis. This pin should be perpendicular to the long axis of the tibia and axially rotated away from the first pin (in the direction of the deformity) by the amount to be corrected. The goal is a transmalleolar axis of +20° and a corresponding thigh–foot angle of + 10°.
- Perform the osteotomy 1–1.5 cm proximal to and parallel with the physis using an oscillating saw. Then rotate the distal fragment until the two Steinmann pins are aligned parallel. Fix the osteotomy with crossed smooth 1/32-inch Steinmann pins that enter each malleolus, cross the osteotomy, and engage the tibial cortex of the proximal fragment. Occasionally a third Steinmann pin will be needed for fixation across the osteotomy. Check fixation and bone apposition with the image intensifier. Check the angle of the transmalleolar axis and the thigh–foot angle with the hip and knee flexed 90° and again with these joints in extension.
- Perform a blind, prophylactic, subcutaneous fasciotomy of the anterior and lateral compartments with Metzenbaum scissors. Be certain that the fascia is cut.
- Loosely reapproximate the tibial periosteal edges with 2-0 Vicryl sutures. Following irrigation and hemostasis, approximate the subcutaneous tissues with 3-0 absorbable sutures and subcuticular technique.

Fabry G. Torsion of the Femur.

Angular deformities of the lower extremities in children are common and are a frequent reason for orthopaedic referral. They predominantly occur in the tibia; the femur is much less frequently involved. Angulation may occur in the frontal plane (varus and valgus), the sagittal plane (anterior and posterior), or a combination of both (anterolateral or posteromedial). Torsion may also be involved. It is important to understand the various physiologic and pathologic causes of angular deformities, the methods of evaluation, and the natural histories of the abnormalities to determine appropriate treatment (50,115,287). The classification for the differential diagnoses of genu varum (bowleg), genu valgum (knock-knee), and congenital angular deformities of the tibia and fibula are presented in Table 169.1, Table 169.2 and Table 169.3.

Table 169.1. Classification of Genu Varum or Bowleg Deformities of the Lower Extremities in Children

Table 169.2. Classification of Genu Valgum or Knock-knee Deformities of the Lower Extremities in Children

Table 169.3. Differential Diagnosis of Congenital Angular Deformities of the Tibia and Fibula

NORMAL DEVELOPMENTAL ALIGNMENT OF THE LOWER EXTREMITY

Mild to moderate bowing of the lower extremities is a common finding in infants and young children. It is the result of molding of the lower extremities in utero. The bowed appearance of the lower extremities is actually a combination of external or lateral rotation of the hip (tight posterior capsule) and internal or medial tibial torsion. This physiologic genu varum tends to persist during the first year of life with only minimal improvement. After a child begins to walk, the bowing corrects spontaneously. Complete correction may require up to 36 months of ambulation.

Physiologic genu valgum may appear by 3–4 years of age. This is true genu valgum, not the result of a torsional combination from in utero positioning. This deformity also undergoes spontaneous correction with normal adult knee alignment of mild genu valgum obtained by 5–8 years of age. Cahuzac et al. (65) demonstrated that girls have a consistent genu valgum alignment by 10 years of age that remains constant as they finish musculoskeletal growth. Boys, however, tend to have a decreasing valgus alignment until approximately 16 years of age. Thus, men have less valgus at maturity than do women.
Salenius and Vanikka (242) analyzed the femoro-tibial angles clinically and radiographically in 1,279 children between birth and 16 years of age (Fig. 169.1). They found a mean varus alignment of 15° in newborns. This decreased to approximately 10° of varus alignment by age 1 year. Neutral alignment occurred between 18 and 20 months of age. The maximum valgus of approximately 12° was achieved by 3–4 years of age. The results were similar for boys and girls. By age 7 years, the children’s valgus alignments had corrected to those of normal adults (8° in women, 7° in men). The researchers estimated that in approximately 95% of the children physiologic genu varum or valgum alignments resolved spontaneously with growth. In a follow-up study of 20 children between 1 and 4 years of age with pronounced physiologic varus (16° to 33°) or valgus (15° to 20°) deformities of the knees, Vanikka and Salenius (229) found that even these pronounced deformities resolved during growth, although some did not completely correct until adolescence. They recommended that surgical correction be cautiously considered for children between 10 and 13 years of age, when corrective osteotomies are usually performed.

![Figure 169.1. Normal development of knee alignment from infancy through childhood. (Adapted from Salenius P, Vanikka E. The Development of the Tibio-femoral Angle in Children. J Bone Joint Surg Am 1975;57:259.)](image)

**GENU VARUM**

Genu varum, or bowleg, is a common childhood deformity and one of the most common causes of parental concern. In the majority of cases, it will be physiologic in origin and will correct with normal growth and development. However, there are pathologic genu varum disorders that may progress and produce functional impairment (Table 169.1).

The evaluation of a child with genu varum consists of a careful history and physical examination. The history will frequently distinguish physiologic from pathologic genu varum. Obtain a birth history, family history, the age at which developmental milestones occurred, a nutritional history, and the previous percentiles for height and weight. A family history of short stature or varus alignment or progression of the deformity may indicate a pathologic process.

On physical examination, measure height and weight, and determine the percentile for age. Shortening of the extremities relative to the trunk may indicate a skeletal dysplasia. In ambulatory children, the appearance to the lower extremities during standing and gait can provide important information. Determine the location of the deformity, as well as whether there is a lateral knee thrust while walking. Measure the range of motion of the hips, knees, and ankles. Assess the presence of ligamentous laxity. Measure the degree of genu varum in the standing and the supine positions. Measure and record the distance between the medial femoral condyles in centimeters. In addition, measure the torsional profile as described by Mosca and Staheli (see Chapter 168). This includes the foot progression angle, hip range of motion in extension, the thigh–foot angle, and the shape of the foot. Torsional changes in the femur and tibia are common in angular deformities of the lower extremities. Obtain serial photographs, if possible, and place them in the child’s chart as an aid in documentation of improvement or worsening over time.

Radiographs are not routinely necessary in genu varum. However, if the child is short, the deformity is asymmetric, there is a history of progression, or the child is older than 3 years, obtain radiographs consisting of a standing anteroposterior (AP) projection of the lower extremities, including the hips, knees, and ankles. Position the patellae pointing forward. Measure the femoro-tibial angle, the mechanical axis, and the metaphyseal–diaphyseal angles. Assess the physeal of the femur and tibia, especially those about the knee. Metaphyseal and physeal widening suggest an underlying metabolic disorder.

The history, physical examination, and radiographic evaluation then provide the basis for an accurate assessment of whether the child has a physiologic or pathologic genu varum deformity. The specifics of further evaluation and treatment are based on the diagnosis.

**PHYSIOLOGIC GENU VARUM**

**Pathophysiology**

Physiologic genu varum due to in utero positioning is a common finding in children between birth and 2 years of age. It is usually associated with a toe-in gait due to medial tibial torsion.

While the child is standing, the lower extremities appear bowed. However, physical examination demonstrates excessive lateral rotation of the extended hip and medial tibial torsion (Fig. 169.2). Contracture of the posterior capsule is a normal finding in children up to 1 year of age. It tends to improve during the first 3 years of life, and ultimately medial rotation slightly exceeds lateral rotation (222). Medial tibial torsion is the major component of physiologic genu varum. The knees are normal, except for possibly a slight residual knee-flexion contracture. A lateral knee thrust during gait is uncommon and indicates a pathologic genu varum deformity (161, 163). The degree of varus can be measured by a goniometer (femoro-tibial angle) or the distance between the medial femoral condyles (55, 65, 120).

![Figure 169.2. A: Physical examination of a 9-month-old boy with physiologic genu varum. The infant may still comfortably assume the in utero position with the hips flexed, abducted, and laterally rotated. The knees are flexed, with the lower legs and feet medially rotated. B: When the lower extremities are extended, the posterior hip capsule contracture results in increased lateral rotation (80° to 90°) and limited medial rotation (0° to 10°). When the patellae point laterally, the medial tibial torsion is not readily apparent. C: When the hips are maximally rotated medially and the patellae are directed anteriorly, the medial tibial torsion is more apparent. The medial tibial torsion can be measured by the thigh–foot angle or the transmalleolar axis. The medial tibial torsion may also produce in-toeing during ambulation. This can be assessed by measuring the foot progression angle.](image)

On radiographs, the typical features of physiologic genu varum include the following (268):

Transverse planes of the knees and the ankle joints are tilted medially.

Tibia is slightly bowed laterally at the junction of its proximal and middle thirds and the femur at its distal third.
Medial cortices of the tibia and femur are thickened and sclerotic. Epiphyses, physes, and metaphyses have normal appearances, and there is no evidence of intrinsic bone disease. Involvement is usually symmetric.

It can be difficult to differentiate radiographically between physiologic genu varum and tibia vara (Blount’s disease) in children younger than 3 years of age. Levine and Drennan (176) developed the metaphyseal–diaphyseal angle to aid in differentiating these two disorders (Fig. 169.3). An angle of 11° or less indicates physiologic genu varum, and angles greater than 11° suggest that progressive tibia vara is likely (Fig. 169.4). However, a later study by Feldman and Schoenecker (101) indicated that angles greater than 16° are predictive of tibia vara, whereas angles of 9° or less suggest physiologic genu varum and angles between 10° and 15° are indeterminate. The metaphyseal–diaphyseal angle has been shown to have good interobserver and intraobserver reproducibility (104). However, it is important that standing radiographs be obtained with the knees in a neutral position, as rotational changes can alter measurements (265).

**Figure 169.3.** Metaphyseal–diaphyseal angle. Draw a line between the radiographic corners of the medial and the lateral metaphyses of the proximal tibia, and another line parallel to the longitudinal axis of the tibial diaphysis. Then construct a line perpendicular to the diaphyseal line at the intersection of the metaphyseal and diaphyseal lines, and measure the angle between the right-angle line and the metaphyseal line. (Adapted from Levine AM, Drennan JC. Physiologic Bowing and Tibia Vara: The Metaphyseal–Diaphyseal Angle in the Measurement of Bowleg Deformities. *J Bone Joint Surg Am* 1982;64:1158.)

**Figure 169.4.** Standing AP radiograph of an 18-month-old girl with asymmetric bowing of the lower extremities. The metaphyseal–diaphyseal angle is 14° on the right, indicating infantile tibia vara; it is 10° on the left, representing physiologic genu varum. There is already medial metaphyseal irregularity and beaking, as well as mild medial epiphyseal flattening on the right.

If a metabolic disorder is suspected, obtain serum calcium, phosphorus, and alkaline phosphatase levels. Obtain a pediatric endocrinology evaluation to assist in diagnosis and management.

Physiologic genu varum resolves spontaneously with normal growth and development (94,124,161,163,190,242,252,268,279). Operative treatment is rarely indicated. Orthoses or corrective shoes are not recommended because there is no evidence that they improve alignment of the extremity. Follow infants and young children with physiologic genu varum at 6-month intervals (Fig. 169.5). Recording accurate clinical measurements is useful in reassuring anxious parents that improvement is occurring.

**Figure 169.5.** A: A 16-month-old girl with physiologic genu varum. Observe the lateral rotation of the thighs and knees and the medial tibial torsion. B: One year later, with no treatment, there has been complete resolution of the physiologic genu varum.

**Operative Techniques**

The techniques for correction of genu varum are listed in Table 169.4. The usual procedures for physiologic genu varum include a proximal tibial valgus derotation and diaphyseal fibular osteotomies, proximal tibial hemiepiphyseal stapling, or proximal tibial hemiepiphysiodesis. The latter two procedures are based on adequate remaining growth to achieve complete correction (39). The graph developed by Bowen et al. (38) can be helpful in determining proper timing.
**Proximal Tibial Valgus Osteotomy and Diaphyseal Fibular Osteotomy** This is the most common procedure in persistent physiologic genu varum because it addresses both the varus and the medial tibial torsion. A variety of techniques can be used, including closing-wedge, opening-wedge, oblique, or dome osteotomies. These are essentially the same procedures as for tibia vara or Blount’s disease. A diaphyseal fibular osteotomy is performed concomitantly because the fibula is usually too long and may be contributing to the deformity. The technique of a closing-wedge proximal tibial and diaphyseal fibular osteotomy is discussed in the section on *tibia vara* (see below). Internal or external fixation to maintain alignment is necessary and usually supplemented by a long-leg cast until complete healing has occurred.

**Proximal Tibial Hemiepiphyseal Stapling** Temporary retardation of growth in the lateral aspect of the proximal tibial epiphysis with staples is an effective method for correction of persistent physiologic genu varum. If the deformity is severe or there is limited remaining growth, a combined lateral distal femoral and the proximal tibial epiphyses may need to be performed. This procedure will not correct any coexistent medial tibial torsion.

**Proximal Tibial Hemiepiphysiodosis** Percutaneous closure of the lateral aspect of the proximal tibial epiphysis can be effective in correcting persistent physiologic genu varum in adolescents. The indications are essentially the same as for stapling. However, once complete correction has been achieved, a second procedure may be necessary on the medial side to prevent overcorrection. The proximal fibular epiphysis is usually closed concomitantly. This procedure will not correct any medial tibial torsion.

**Rehabilitation and Postoperative Principles**

In general, children treated with a proximal tibial valgus derotation and diaphyseal fibular osteotomies are managed similar to patients undergoing the same procedure for tibia vara. In children treated with a proximal tibial hemiepiphysodial stapling or hemiepiphysiodosis, apply a knee immobilizer postoperatively for approximately 2 weeks. This allows healing of the skin incision and minimizes discomfort. Then begin active range of motion exercises, and allow return to normal activities, typically at 4–6 weeks postoperatively.

**Pitfalls and Complications**

Complications of proximal tibial osteotomies have been well described in the orthopaedic literature (103,148,187,202,204,205). There is a risk for injury to the peroneal nerve as it passes around the lateral aspect of the proximal fibula, and to the anterior tibial artery as it passes into the anterior compartment through the hiatus between the proximal tibia and fibula. Compartment syndromes have been described, and a child must be carefully evaluated for the first 24–48 hours postoperatively. Perform prophylactic anterior compartment fasciotomies at the time of surgery.

Complications of hemiepiphysodial stapling or epiphysiodosis occur much less frequently. Physeal damage with asymmetric closure and complete secondary to prolonged compression are the most common problems but are fortunately rare.

**Conclusion**

Physiologic genu varum rarely persists to such a degree that surgical intervention is necessary. There is a relationship between this disorder and tibia vara (Blount’s disease). Persistent varus deformity may progress to the latter disorder. It has been my experience that the most common residual abnormality of physiologic genu varum is persistent medial tibial torsion. This is a more common indication for surgical treatment (see Chapter 168).

**PATHOLOGIC GENU VARUM DEFORMITIES**

**Tibia Vara**

Idiopathic tibia vara (Blount’s disease) is the most common pathologic genu varum deformity. It is characterized by abnormal growth of the medial aspect of the proximal tibial epiphysis that results in progressive varus angulation beneath the knee. This disorder was first described by Erlacher (95) in 1922 and further analyzed by Blount (35) in 1937.

**Classifications**

Tibia vara may occur at any age in a growing child. It was initially classified into two broad groups, depending on the age at clinical onset: infantile, with onset between 1 and 3 years of age; and adolescent, with onset inconsistently described as occurring after 6–8 years of age or just before puberty (33,35,97,110,111,116,151,157,158,260). In 1964, Thompson et al. (275) proposed a three-group classification based on the age at onset: infantile (1–3 years), juvenile (4–10 years), and adolescent (11 years or older). The juvenile and adolescent forms are commonly combined as late-onset tibia vara. However, the incidence of recurrent deformity after a corrective valgus osteotomy of the proximal tibia is much higher in the juvenile group, justifying a three-group classification. All three groups share relatively common clinical characteristics, although the radiographic changes in the late-onset groups are less pronounced. Although the exact cause of tibia vara remains unknown, it appears to be secondary to growth suppression from increased compressive forces across the medial aspect of the knee (22,23,33,35,59,60,69,111,167,168,171,172,274,275,276,286).

Familial cases have been reported (23,111,173,250,253).

The natural history of tibia vara is one of progressive varus deformity. Infantile tibia vara can produce the greatest degree of deformity because of the greater amount of growth time remaining. In 1952, Langenskiöld (172) described six stages of progressive deformity in infantile tibia vara. Each grade advanced the degree of physeal growth inhibition (Fig. 169.6). It is possible to restore normal growth and development of the proximal tibial physis in grades I and II and probable grades III and IV. Grades V and VI represent severe damage to the medial proximal tibial physis and probable premature or asymmetric closure. The rate of deformity in grades V and VI is rapid, resulting in severe deformity and articular malformation. There is relatively good interobserver agreement with the use of this classification, especially for the early and late stages (284).

**Assessment, Indications, Relative Results**

Comparison of the clinical characteristics of the infantile (22,23,33,35,46,90,91,95,97,103,110,111,116,151,167,168,169,172,173,180,181,223,248,260) and late-onset (juvenile and adolescent) (29,46,129,167,274,275,286) forms of tibia vara shows similarities as well as distinct differences (Table 169.5). The infantile form is the most common (Fig. 169.7). However, the late-onset forms also occur frequently (Fig. 169.8). Anterior cruciate ligament incompetence may occur in severe deformities (28).

![Figure 169.6. Six grades of radiographic changes in infantile tibia vara as described by Langenskiöld (172). These represent a continuum of progressing deformity over time.](image-url)
resulted in asymmetric compression with subsequent suppression of posteromedial physeal growth and ultimate formation of an osseous bridge, producing a normal endochondral ossification, producing tibia vara. This concept, which reflects the Heuter–Volkmann law, has been confirmed experimentally by Arkin and Katz. The histopathologic abnormalities indicate that asymmetric compression and shear forces acting across the proximal tibial physis result in suppression and deviation of the epiphyseal plate. Two patients with late-onset tibia vara associated with slipped capital femoral epiphysis described similar changes, which are remarkably similar to the changes observed in infantile tibia vara and in slipped capital femoral epiphysis, suggesting a common cause. The extension of noncalcified cartilaginous bars into the proximal and distal metaphyses of the tibia is a characteristic feature of tibia vara. Chondrocytes at the apex of the vascular invasion front, which has increased width and length, have increased necrotic chondrocytes throughout the proliferative and hypertrophic zones. Intraphyseal ossification centers, transphyseal canals of capillaries, multidirectional clefts and fissures, cystic degeneration and necrosis, and abnormal histochemical staining and excess of hypocellular matrix are all characteristic features of tibia vara. Disorganization and misalignment of the physeal zones are also common. These changes are found uniformly throughout the medial and lateral aspects of the physis, although they are quantitatively greater on the medial side. They are remarkably similar to the changes observed in infantile tibia vara and in slipped capital femoral epiphysis, suggesting a common cause. Lovejoy and Lovell described two patients with late-onset tibia vara associated with slipped capital femoral epiphysis. The histopathologic abnormalities indicate that asymmetric compression and shear forces acting across the proximal tibial physis result in suppression and deviation of normal endochondral ossification, producing tibia vara. This concept, which reflects the Heuter–Volkmann law, has been confirmed experimentally by Arkin and Katz. Golding and McNeil-Smith concluded that children who had significant physiologic varus deformity, walked early and stretched their knee ligaments. This Pathophysiology Histopathologic studies indicate a similar pathologic process for all three groups. Only a few biopsies of the proximal medial tibial condyle have been obtained from patients with infantile tibia vara. Histopathologic abnormalities included islands of densely packed chondrocytes exhibiting a greater degree of hypertrophy than would be expected from their topographic position, areas of almost acellular cartilage, and abnormal groups of capillaries. Langenskiöld and Golding and McNeil-Smith, in studies of nine and six biopsies, respectively, concluded that the abnormalities were localized principally to the physes and that there was no evidence of avascularity. More extensive histopathologic data are available for the late-onset forms of tibia vara. The major histologic aberrations include the following:

- Disorganization and misalignment of the physeal zones
- Abnormal histochemical staining and excess of hypocellular matrix
- Cystic degeneration and necrosis
- Multidirectional clefts and fissures
- Transphyseal canals of capillaries
- Intraphyseal ossification centers
- Increased necrotic chondrocytes throughout the proliferative and hypertrophic zones
- Abnormal collagen fibrils in the cartilage matrix
- Chondrocytes at the apex of the vascular invasion front, which has increased width and length
- Extension of noncalcified cartilaginous bars into the proximal and distal metaphyses

These changes are found uniformly throughout the medial and lateral aspects of the physis, although they are quantitatively greater on the medial side. They are remarkably similar to the changes observed in infantile tibia vara and in slipped capital femoral epiphysis, suggesting a common cause. Lovejoy and Lovell described two patients with late-onset tibia vara associated with slipped capital femoral epiphysis. The histopathologic abnormalities indicate that asymmetric compression and shear forces acting across the proximal tibial physis result in suppression and deviation of normal endochondral ossification, producing tibia vara. This concept, which reflects the Heuter–Volkmann law, has been confirmed experimentally by Arkin and Katz. Golding and McNeil-Smith concluded that children who had significant physiologic varus deformity, walked early and stretched their knee ligaments. This resulted in asymmetric compression with subsequent suppression of posteromedial physeal growth and ultimate formation of an osseous bridge, producing a

**Figure 169.7.** A: Clinical photograph of a 5-year-old African-American girl with left infantile tibia vara. Observe the obesity, the unilateral left genu varum deformity, and the associated medial tibial torsion. B: Standing radiograph of the left knee demonstrates Langenskiöld grade III changes in the medial aspect of the proximal tibial epiphysis and metaphysis. Notice the metaphyseal beaking.

**Figure 169.8.** A: Standing preoperative photograph of a 13-year-old African-American boy with bilateral adolescent or late-onset tibia vara. A previous proximal tibial osteotomy was performed on the right, producing only partial correction. Observe the marked obesity and the untreated left genu varum deformity and its medial tibial torsion. The patient subsequently underwent a laterally based closing-wedge proximal tibial osteotomy, including the physis, and a diaphyseal fibular osteotomy for correction of this deformity. B: On a standing AP radiograph of the left knee, the radiographic changes in adolescent tibia vara are less striking than in the infantile form. There is narrowing of the medial aspect of the proximal tibial epiphysis, physeal irregularity, and increased height of the lateral aspect of the epiphysis.
permanent and progressive varus deformity. This pathogenesis is consistent with Blount’s (23,35) initial observations that infantile tibia vara is first recognized when there is an increase of physiologic bowing during the first 3 years of life. Langenskiöld (172-173) emphasized that necrosis of the physeal cartilage is the principal cause of growth disturbance, leading to varus deformity; he attributed the abnormal cartilage to abnormal pressure or shear in overweight children with physiologic bowleg. Others agreed that abnormal pressure is probably the primary etiologic factor in infantile tibia vara (22-35,46,111,157,162).

In predisposed older children or adolescents with minimal residual deformity after physiologic bowleg, rapid growth and weight gain repetitively injure the postero medial portion of the proximal tibial physis, resulting in a cycle of varus-growth suppression similar to the cycle described by Golding and McNeil-Smith (111) for the infantile form (127,150,274,275,286). Progressive genu varum deformity is not due to an osseous bridge but is caused by suppression of normal endochondral growth after repetitive local injury (28,162,260,274,275,286). The concept of physeal growth suppression in tibia vara has been confirmed biomechanically by Cook et al. (69) in a finite element analysis. As varus increases, the forces in the proximal medial tibial physis increase. Obesity and mild varus (10°) in older children create enough force to suppress growth. However, Henderson and Green (127) reported a case of late-onset tibia vara in an adolescent with previously documented neutral mechanical alignment, suggesting that, at least in some cases, preexisting varus alignment is not a prerequisite.

Preoperative Management and Planning
If radiographic findings confirm the diagnosis of infantile tibia vara, begin treatment immediately. Orthotic management may be considered for children 3 years of age or younger with Langenskiöld’s grade II and possibly grade III involvement. Approximately 50% to 65% of these in children can be corrected with an orthosis (151,180,232,248). Children with suspected infantile tibia vara with metaphysyal-diaphyseal angles of 10° to 15° are more likely to benefit from orthotic management (232). Use a knee–ankle–foot orthosis with a single medial upright without a knee hinge. Place pads, straps, or elastic webbing over the distal femur and proximal tibia to apply a varus force. The orthosis should be worn for 22–23 hours each day. Tighten the straps at 1–2-month intervals to provide progressive correction. Obtain standing radiographs at 3-month intervals to document correction of the tibia vara deformity. The metaphyseal–diaphyseal angle should decrease (122). After obtaining an absolute valgus mechanical axis, begin weaning from the orthosis. Follow the child carefully thereafter to ensure maintenance of correction.

A maximum trial of 1 year of orthotic management is currently recommended. If correction is not obtained after 1 year of bracing, corrective osteotomy is indicated. Orthotic treatment is not indicated after 3 years of age or for severe deformities. Bracing children older than 3 years risks delaying performance of a corrective osteotomy.

Loder and Johnston (130) showed that delay in performing corrective osteotomy, even by a few months, beyond 4 years of age risks failure to achieve lasting reversal of the physeal inhibition of the proximal tibia. This predisposes a child to repeated operative procedures to maintain a satisfactory result.

Conservative management in the late-onset forms of tibia vara is contraindicated. The children are too large and the remaining growth is too small to allow adequate correction. Compliance with an orthosis in this age group is difficult to achieve.

The indications for surgical treatment in infantile tibia vara include age 4 years or less, failure of orthotic management, and Langenskiöld grade III or higher. The possible procedures are presented in Table 169-4. Proximal tibial valgus osteotomy with fibular diaphyseal osteotomy is usually the procedure of choice. Perform an anterior compartment fasciotomy concomitantly. Tibial osteotomy techniques include closing-wedge, opening-wedge, dome, and oblique osteotomies. The procedure selected must correct the valgus deformity and any associated medial tibial torsion. Tibial length is usually not a problem in infantile tibia vara. It is important that the selected osteotomy overcorrect the mechanical axis of the knee to 5° or more of valgus. This ensures that the supine correction obtained in the operating room is adequate. Overcorrection compensates for the tendency of the knee to fall back into varus after a patient resumes weight bearing because of the depression in the posteriorarticular surface and the ligamentous relaxation laterally. The goal is to transfer the line of weight bearing to the lateral compartment of the knee.

Schoenecker et al. (248) reported that correction within 5° of neutral usually proves satisfactory. However, others recommend overcorrection (168,173,180,229). Considering the physeal inhibition phenomena as proposed by Cook et al. (69), overcorrection to absolute valgus alignment is necessary to relieve the excessive compressive forces medially.

Rab (229) described an oblique osteotomy of the proximal tibia for tibia vara. It is a single-plane osteotomy that allows simultaneous correction of the varus and medial tibial torsion deformities and permits postoperative cast wedging, if necessary, to improve position. This ability to adjust the osteotomy postoperatively is important because of the difficulty in achieving satisfactory alignment intraoperatively.

In older children with infantile tibia vara, especially those with Langenskiöld grade IV lesions or higher, a single osteotomy of the proximal tibia is usually insufficient to restore normal alignment and physeal growth. Langenskiöld grades IV and V act effectively as medial physeal arrests. Possible procedures for these children include the following (25,47,65,67,103,117,130,152,158,156,166,177,195,217,229,245,246,247 and 248,255,261,274,275):

- Multiple proximal tibial metaphyseal osteotomies and fibular diaphyseal osteotomies
- Proximal tibial osteotomy with physeal resection
- Intraepiphysyal osteotomy to elevate the medial tibial articular surface (elevation of the medial tibia plateau)
- Physeal bridge resection and replacement with interposition material such as fat or Silastic
- Hemiepiphysiodesis of the lateral portion of the proximal tibial epiphysis
- Obligui proximal tibial osteotomy
- Ilizarov ring fixation system and callotasis technique

In the juvenile and adolescent forms of tibia vara, surgical correction is necessary to restore the mechanical axis of the knee. The same surgical options as those for older children with infantile tibia vara are applicable in these groups. Correction to physiologic genu valgum with careful preoperative biotrigonometric planning for the tibial osteotomy is the goal (47,130) reported that distal femoral varus is a part of the deformity in late-onset tibia vara. Evaluate this possibility, and perhaps consider it in the treatment plan.

Obtain intraoperative radiographs with the knee in extension and with slight varus stress to ensure contact between the medial femoral condyle and the postero medial articular depression of the proximal tibia. This technique can help minimize undercorrection of the deformity. Aim to achieve at least 5° of valgus at the time of correction. The recurrence rate for the juvenile-onset group approaches 25% overall and is even higher in boys (274,275). Evaluate all juvenile-onset patients with tomography or magnetic resonance imaging (MRI) before surgery for evidence of premature closure or impending closure of the proximal medial tibial physis. If premature closure is not present, a simple closing-wedge metaphyseal tibial osteotomy or oblique proximal tibial osteotomy with correction to physiologic valgus may be considered (229). Correction using the Ilizarov ring fixation system and callotasis may be applicable, especially if there is a significant lower-extremity length discrepancy (227).

If the deformity recurs, indicating significant physeal inhibition, then additional surgery is necessary; techniques include physeal bridge resection and interposition graft, intraepiphysyal osteotomy, elevation of the medial tibia plateau, and physeal excision (117,152,174,177,188,245,246,255,289). Internal or external fixation is usually necessary to maintain alignment until satisfactory healing occurs. Physeal distraction with an external fixator has also been used in Europe (86,88), but it is not widely used. The procedure selected depends on the patient’s age, the amount of growth remaining, and the severity of the deformity. Proximal tibial physeal excision with proximal fibular epiphysiodesis is usually recommended for recurrent deformities with premature medial tibial physeal closure or for patients 12 years of age or older (274). Healing is rapid and the correction permanent. Measure any residual lower-extremity length discrepancy with scanograms, and manage by contralateral epiphysiodesis, when necessary.

Henderson et al. (128) reported results in nine children with late-onset tibia vara treated by hemiepiphysiodesis of the lateral aspect of the proximal tibial epiphysis. The average correction achieved was 13° (range, 3° to 25°). They found a correction rate of 7° per year. Three patients required a proximal tibial osteotomy because of incomplete correction. The authors thought that hemiepiphysiodesis was an effective procedure with less morbidity for managing varus deformities of the extremities of obese children. Similar results can probably be anticipated with staples, although they were not used in this study.

Operative Techniques

Proximal Tibial Valgus Osteotomy and Fibular Diaphyseal Osteotomy

- Make a 5 cm horizontal or transverse skin incision below the level of the tibial tubercle (Flp. 169.9).
Tibia vara secondary to focal fibrocartilaginous dysplasia involving the medial aspect of the proximal tibial metaphysis was first reported by Bell et al. (Tibia Vara Caused by Focal Fibrocartilaginous Dysplasia). Timed contralateral epiphysiodesis will be necessary to achieve relatively equal leg lengths at skeletal maturity.

In children with recurrent deformities in whom a physeal bridge is suspected, I would suggest excision of the physis with concomitant correction of both the residual be accomplished using an Ilizarov frame and callotasis. This allows precise correction of the deformity. Weight-bearing radiographs may be obtained during treatment. Even if the physis appears open, it may still be abnormal and not respond to normalization of the compressive forces postoperatively. Correction in these children can even if the physis appears open, it may still be abnormal and not respond to normalization of the compressive forces postoperatively. Correction in these children can

In older children with infantile or late-onset tibia vara, especially the juvenile type, a preoperative MRI may be helpful in assessing the integrity of the physis. However, in most cases, the degree of lower-extremity length discrepancy is followed scanographically, and any residual leg-length discrepancy is corrected by a contralateral distal femoral epiphysiodesis at the appropriate time.

Oblique Tibial Osteotomy

Expose the proximal tibia subperiosteally.

Release the fascia of the anterior compartment. The fibers of the patellar tendon insertion are usually visible in the proximal portion of the incision.

Perform a fibular diaphyseal osteotomy through a 3 cm vertical incision at the junction of the middle and proximal thirds of the fibula.

Identify the muscles of the lateral compartment, and retract them anteriorly. Split the periosteum of the fibula longitudinally, and reflect it circumferentially.

Make an oblique osteotomy with a small oscillating saw.

Place a smooth Steinmann pin through the epiphyseal plate of the proximal tibial osteotomy. This may be a closing-wedge, opening-wedge, or dome osteotomy. The procedure should allow correction of the medial tibial torsion and the varus deformity. I prefer a closing-wedge osteotomy. It is important to correct the medial tibial torsion first and then perform the laterally based, closing-wedge osteotomy. Excessive correction and unnecessary bone excision may occur if the torsion is not corrected first.

Fix the osteotomy with crossed Steinmann pins, compression plate and screws, or an external fixation device. I prefer the latter because the pins can be removed in the outpatient clinic without a separate operative procedure.

Obtain intraoperative radiographs with the knee in flexion in extension to confirm that approximately 5° of valgus alignment have been obtained.

After closure, immobilize the leg in a long-leg cast with the knee in extension and a slight valgus stress.

Excision of the Proximal Tibial Physis If the deformity recurs in an older child with the adolescent form of tibia vara, excision of the proximal tibial physis may be advantageous.

This procedure is similar to the proximal tibia osteotomy previously described. Make a similar incision, although more proximally.

Mobilize the patellar tendon on its medial and lateral sides.

Place a smooth Steinmann pin through the epiphyseal plate just below the articular surface.

Excise the entire physis in a closing-wedge osteotomy. Insert a second pin distally, and apply an external fixator.

Always perform a fibular diaphyseal osteotomy. The advantage of this procedure is that it is performed at the site of the deformity and therefore allows maximal correction and physiologic realignment of the tibia. Healing is usually rapid, and there is no risk of recurrent deformity. A contralateral proximal tibia epiphysiodesis may be performed at the same time. However, in most cases, the degree of lower-extremity length discrepancy is followed scanographically, and any residual leg-length discrepancy is corrected by a contralateral distal femoral epiphysiodesis at the appropriate time.

Other Techniques In the late-onset form of the disease, a callotasis technique may be beneficial with either a cantilever or ilizarov ring fixation system. The advantage of this procedure is that it allows slow, progressive correction. Because the patient is bearing weight, the precise degree of desired correction can be achieved. This procedure is being used more frequently today (see Chapter 171).

General Rehabilitation and Postoperative Principles The postoperative management of children is similar after any corrective osteotomy of the proximal tibia.

Continue immobilization until healing is complete; then place the children on a physical therapy program at home for approximately 2 weeks. After complete rehabilitation, allow them to return to normal activities. Because of associated obesity, these children frequently benefit from a dietary consultation.

Complications Complications during and after a proximal tibial osteotomy are common. They include peroneal nerve palsy, injuries to the anterior tibial artery, and compartment syndromes (88,103,146,187,202,204,249,263). Occurrence of a compartment syndrome may be minimized by performing an anterior compartment fasciotomy at the time of surgery. If a compartment syndrome occurs, temporarily reduce the correction, and perform a four-compartment fasciotomy. Children with the infantile form of tibia vara require long-term follow-up to assess the results of surgery. The deformity may recur, especially in older children and those with advanced Langenskiöld deformities. Deformity persisting after skeletal maturity predisposes to degenerative osteoarthritis (137,251).

Conclusion I prefer a proximal tibial valgus derotation and fibular diaphyseal osteotomy to correct infantile tibia vara. This allows simultaneous correction of both components of the deformity. It is important that the deformity be slightly overcorrected so that the mechanical axis passes medial to the ankle joint. It can be difficult to assess the degree of correction intraoperatively because radiographs on a long cassette cannot be obtained. A helpful hint is to visualize the iliac crest on the involved side. The cord from the electrocautery knife can be used to measure the mechanical axis on the fluoroscope. This can be stretched between the anterosuperior iliac spine and the middle of the patella. Its distal extension can then be judged with respect to the ankle joint. Undercorrection is a common problem that prevents adequate alignment. Radiographic contrast material in the knee joint at the time of surgery may also be helpful. Manually manipulate the knee into varus after the osteotomy is internally stabilized, as this gives a more realistic feeling for the alignment of the extremity during weight bearing.

In older children with infantile or late-onset tibia vara, especially the juvenile type, a preoperative MRI may be helpful in assessing the integrity of the physes. However, even if the physes appear open, it may still be abnormal and not respond to normalization of the compressive forces postoperatively. Correction in these children can be accomplished using an ilizarov frame and callotasis. This allows precise correction of the deformity. Weight-bearing radiographs may be obtained during treatment.

In children with recurrent deformities in whom a physeal bridge is suspected, I would suggest excision of the physes with concomitant correction of both the residual tibia vara deformity and any medial tibial torsion. Postoperatively, patients will need to be evaluated for residual lower-extremity length discrepancy. An appropriately timed contralateral epiphysiodesis will be necessary to achieve relatively equal leg lengths at skeletal maturity.

Tibia Vara Caused by Focal Fibrocartilaginous Dysplasia

Tibia vara secondary to focal fibrocartilaginous dysplasia involving the medial aspect of the proximal tibial metaphysis was first reported by Bell et al. (28) in 1985.
Since then, additional cases have been reported (345, 114, 122, 148, 149). Tibia vara may also involve other areas of the body. Lincoln and Birch (178) reported upper-extremity involvement. It is an uncommon cause of pathologic genu varum but one that must be differentiated from Blount's disease because the natural histories of the two disorders are distinctly different.

**Pathophysiology**  
Biopsy of the lesion at the time of corrective osteotomy or for diagnostic purposes has shown consistent histopathologic features. Grossly, there is a white cartilaginous lesion with well defined margins deep to the insertion of the pes anserinus. Histopathologic findings include acellular or sparsely cellular collagenous tissue, inactivated fibroblasts, plump cells resembling chondrocytes in lacunae, and dense, nondescript fibrous tissue (234, 145, 192, 208). No giant cells, osteoid, or bone are found within these lesions. The lesions suggest fibrocartilage centrally and tendinous tissues peripherally. They do not involve the physeal or epiphyseal cartilage. Bell et al. (26) observed that the tissue resembles that normally found at the site of the insertion of tendons into cortical bone, as described by Cooper and Misol (70) in 1970. They suggested that these children had abnormal development of fibrocartilage at the insertion of the pes anserinus. The exact mechanism of this abnormal growth is unknown. The defect may be congenital.

**Assessment**  
All children with tibia vara caused by focal fibrocartilaginous dysplasia present with unilateral bowing. There is no apparent sex or side predilection. The onset is usually before age 1 year, and the deformity progresses until approximately age 2 years and then begins to resolve. During the time of progression, the deformity may become quite prominent, reaching 25° to 30° of varus. Medial tibial torsion and mild tibial length discrepancy (0.5–1.0 cm) are common associated findings (28, 45). The lesions are characteristically not tender to palpation, and there is no prominence of the proximal medial metaphysis, as seen in infantile tibia vara.

Radiographically, there is a cortical defect in the medial metaphyseal region of the proximal tibia with an area of surrounding sclerosis (Fig. 169.10). MRI will demonstrate dense fibrocartilaginous tissue (192). Computed tomography shows similar findings, with an ellipsoid fibrous cortical defect but no soft-tissue mass (131–133). On the basis of reported cases, it appears that the metaphyseal lesion resolves spontaneously after age 2 years, followed by correction of the tibia vara deformity. Significant improvement is usually evident by 4 years of age (28, 45). Use of an orthosis does not increase the rate of improvement.

Figure 169.10. A: Standing AP radiograph of a 2-year-old Caucasian boy shows asymmetric genu varum involving the left lower extremity. B: Observe the typical radiographic features of focal fibrocartilaginous dysplasia of the proximal tibia. There is a cortical defect involving the medial aspect of the proximal tibial metaphysis. There is associated sclerosis, as well as the mild tibia vara deformity. C: The lateral radiograph is relatively normal.

**Preoperative Planning**  
Although data are limited, it appears that only children with no evidence of spontaneous correction by 4 years of age are candidates for corrective osteotomy (290). This typically involves a proximal tibial osteotomy distal to the apophysis of the tibial tubercle and a diaphyseal fibular osteotomy. Because of the associated medial tibial torsion, the procedure of choice is a laterally based closing derotation osteotomy or an oblique proximal tibial osteotomy as described by Rab (229).

**Operative Techniques**  
The procedures for focal fibrocartilaginous dysplasia are the same as those for tibia vara. There is no intrinsic osseous pathology that interferes with bone healing. Immobilization in a long-leg cast or a one-and-one-half spica cast is necessary, depending on the child's age. A spica cast is usually advised for younger children. After healing, there is usually rapid rehabilitation and return to normal activities. Prolonged follow-up is necessary to assess resolution of the lesion and subsequent growth and development of the proximal tibia. Periodic scanograms are necessary to assess the length of the extremities.

**Complications**  
A peroneal nerve palsy and persistent valgus deformity into adolescence were reported by Bradish et al. (45) after corrective osteotomy. This appears to have been a technical problem. No other complications have been reported for operative treatment of this lesion.

**Other Pathologic Genu Varum Deformities**

**Vitamin D–Resistant and Nutritional Rickets**  
Persistent or progressive genu varum deformities are common in children with metabolic disorders such as vitamin D–resistant rickets (hypophosphatemic rickets) or nutritional rickets. Vitamin D–resistant rickets is an X-linked dominant disorder due to vitamin D resistance that results in defective bone mineralization. Affected children typically have bilateral symmetric genu varum; they are relatively short, usually being in the tenth percentile. The varus deformity is due to a combination of bowing and involvement of the distal femur and the proximal tibia. Hematologic studies reveal normal serum calcium and decreased phosphate values. In nutritional rickets, the child has been receiving an unusual diet from the parents.

Radiographically, the features are widening of the metaphyses, widening of the physes, and a cup-shaped relationship between the physis and the metaphysis. The bowing is usually symmetric throughout the femur and the tibia. Marked osteopenia and thinning of the cortices are also common. Obtain serum calcium, phosphorus, and alkaline phosphatase levels, as well as a pediatric endocrinology consultation to confirm the diagnosis.

Medical treatment is important before any form of orthopaedic intervention is considered (86, 239). This typically includes oral phosphate supplementation and high doses of vitamin D for vitamin D–resistant rickets, and dietary changes for nutritional rickets. Surgical measures to correct genu varum deformities are usually unsuccessful unless adequate medical control has been obtained preoperatively. If such control cannot be obtained, it is usually best to wait until skeletal maturity before attempting to realign the mechanical axes.

If metabolic control can be obtained and a child is young, observation is appropriate. Spontaneous improvement may occur in children younger than 5 years. However, in older children or those who are not improving spontaneously, surgical treatment is necessary (96, 239). This may consist of osteotomies of the distal femur, proximal tibia, or both. If involvement is extensive, proximal femoral and distal tibial osteotomies may be necessary to adequately realign the lower extremities. Cast immobilization postoperatively may result in immobilization-induced hypercalcemia and may require modification of medical management. When osteotomies are done, healing time may be twice normal. It is often advantageous to postpone major alignment procedures until adolescence to minimize the recurrence that is common in younger children.

**Renal Osteodystrophy**  
Children who have end-stage renal disease may manifest renal osteodystrophy. The physes in these children show the same pathologic changes found in tibia vara and slipped capital femoral epiphysis. These include disorganized enchondral ossification at the physeal–metaphyseal junctions. Because end-stage renal failure occurs more commonly in older children who have achieved physiologic valgus alignment, valgus deformities are more common. Varus is more likely when renal failure occurs at 3 years of age or younger. Renal osteodystrophy has many of the same radiographic features as vitamin D–resistant and nutritional rickets. There is physearl cupping and widening at both the distal femoral and proximal tibial physis. Marked osteopenia and thinning of the cortical bone are also present.

Treatment of genu varum deformities secondary to renal osteodystrophy is similar to that for vitamin D–resistant and nutritional rickets. Surgical treatment is usually postponed until the renal status has stabilized in response to medical treatment, hemodialysis, or kidney transplantation. There will be a rapid recurrence of the deformity if the underlying metabolic bone disease is not corrected first.

**Skeletal Dysplasias**  
Many skeletal dysplasias may result in a progressive genu varum deformity (Table 169.1). Metaphyseal chondrodysplasia (both Jansen and Schmid types), which results in abnormal chondroblast function and chondroid production, is a common cause. Occasionally, these may be difficult to distinguish from rickets. Although the physes are widened and cupped in the Schmid type, the epiphyses are normal, and the presence of short stature may be helpful in making the correct diagnosis.

Genu varum frequently occurs in achondroplasia. This rhizomelic dwarfing condition is due to abnormal enchondral bone formation. Affected children have short
stature and characteristic craniofacial features. The genu varum deformity is due to asymmetric growth of the proximal tibial epiphysis and overgrowth of the fibula. These children rarely have knee pain.

For some surgeons, the treatment options for genu varum deformities secondary to achondroplasia must be surgical because orthotic management historically has not been effective. Their usual procedure is a proximal tibial valgus osteotomy and proximal fibular epiphysiodesis (Fig. 169.11). The latter must be done early in childhood to prevent recurrence and progression of the genu varum deformity. Others feel that genu varum in achondroplasia is not associated with functional difficulty or increased risk of osteoarthritis, and surgery may not be recommended (see Chapter 180).

Figure 169.11. A: Standing preoperative radiographs of a 6-year-old Caucasian boy with achondroplasia genu varum demonstrating the typical epiphyseal and metaphyseal changes, as well as overgrowth of the fibula. B: Postoperative radiograph after proximal tibial and fibular diaphyseal valgus derotation osteotomies of the right leg shows that internal fixation was achieved with percutaneous smooth Steinmann pins. C: Postoperative radiograph of the left lower leg. D: Standing radiographs 6 months postoperatively demonstrates satisfactory healing and excellent correction of the genu varum deformities.

Osteoepiphysiosis imperfecta results from a defect in type I collagen and produces varying degrees of skeletal fragility. Repeated fractures often lead to bowing and torsional malalignment of the lower extremities. The distal third of the femur is a common location for these fractures, which frequently result in anterolateral angulation. Residual deformities after fractures are common, and the varus angulation often increases as a result of repeated fractures. Occasionally, in the more severe cases, osteotomies with intramedullary fixation may be beneficial (see Chapter 180).

Other Causes Any condition, such as infection or trauma, that damages the physis may result in asymmetric growth and deformity. The distal femur is the most common site of growth disturbance following a physeal fracture. Physeal fractures of the proximal tibia occur much less commonly. The management of genu varum deformities secondary to physeal growth disturbance is complex. If an asymmetric physeal bar is present, it may be resected and grafted with fat or Silastic. The deformity is corrected concomitantly by an osteotomy. If the physeal damage is extensive, complete physeal closure and management of the associated leg-length discrepancy may need to be considered (see Chapter 164).

GENU VALGUM

Genu valgum, or knock-knee, is a common condition affecting the lower limbs in children and adolescents. Physiologic genu valgum is the most common form, but pathologic genu valgum disorders occur and may require treatment (Table 169.2). The most common pathologic causes of genu valgum are posttraumatic and renal osteodystrophy.

Evaluation of a child with genu valgum is similar to that for genu varum and includes a careful history and physical examination. In the majority of children with genu valgum, the femoro-tibial angles are within the physiologic range of two standard deviations above or below the mean. Only those with an angle greater than two standard deviations from the mean are considered to have a deformity. Fat thighs, ligamentous laxity, and flat feet are often the results of associated out-toeing, and this can accentuate the appearance of the knock-knee, making physiologic genu valgum appear more severe. Measurements of the femoro-tibial angle (with a goniometer) and the intermalleolar distance are methods for assessing and following genu valgum (Fig. 169.12). The latter must be done early in childhood (Fig. 169.13). The maximal deformity occurs between 3 and 4 years of age. However, the intermalleolar distance may be misleading. The same intermalleolar distance in an individual of short stature may be more significant than the same distance in a taller individual. Torsional malalignment is less common in genu valgum, but the combination of femoral anteversion or torsion and compensatory external tibial torsion gives the appearance of a valgus knee.

The indications for radiographs for genu valgum are similar to those for genu varum. Short stature, asymmetry, history of injury, or history of progression are indications. Standing AP radiographs of the lower extremities, including the hip, knee, and ankle, are the best method (Fig. 169.12). The majority of children with genu valgum have physiologic genu valgum or its persistence into later childhood and early adolescence. However, there are other pathologic genu valgum disorders that may progress and cause functional impairment.

Figure 169.12. Standing AP radiographs of the lower extremities of a 3-year-old boy with physiologic genu valgum show no radiographic abnormalities of the distal femoral or proximal tibial epiphyses or metaphyses.

PHYSIOLOGIC GENU VALGUM

Pathophysiology

Physiologic genu valgum is a normal finding in children between 2 and 6 years of age (Fig. 169.13). The maximal deformity occurs between 3 and 4 years of age. It rarely causes symptoms or disability unless the deformity is severe. In these cases, the knees may rub, and the child walks and runs with a circumduction gait. With severe genu valgum deformities, the feet are pronated. In older children or adolescents, malalignment of the quadriceps mechanism may occur, resulting in patellar subluxation or dislocation. Severe genu valgum occurs more frequently in obese children. The abnormal weight may produce a medial thrust that can result in laxity of the medial collateral ligament and possibly early degenerative osteoarthritis.
Preoperative Management and Planning

In 95% of cases, physiologic genu valgum resolves spontaneously with normal growth (94, 161, 163, 190, 197, 207, 242, 268, 279). Use of an orthosis is controversial and is not recommended. Even significant deformities persisting into adolescence can be expected to improve or resolve if slow, steady improvement can be documented. Persistent deformities that are not improving may benefit from surgical treatment.

The major indication for surgical intervention in physiologic genu valgum is a persistent, severe deformity (>15°) in the immediate preadolescent years (ages 11 years in girls and 12 years in boys). After this age, significant spontaneous improvement is not likely to occur (141).

The methods for surgical correction of genu valgum are presented in Table 169.6. Three methods are usually employed for physiologic genu valgum:

These procedures are applicable in the distal femur, proximal tibia, or both, depending on the patient's age and the severity and location of the deformity.

Operative Techniques

Medial Physeal Stapling of the Distal Femur or Proximal Tibia

Retardation of growth about the medial aspect of the distal femur or proximal tibia by medial physeal stapling is a relatively easy, reliable method of correcting a genu valgum deformity if there is sufficient remaining growth to produce satisfactory alignment (Fig. 169.14) (36, 105, 141, 193, 221, 282, 294). If the deformity is pronounced or there is insufficient remaining skeletal growth, a combined stapling of the medial aspect of the distal femoral and proximal tibial physis may be necessary (105, 221).

The medial aspect of the distal femoral epiphysis is palpable at the junction of the maximal metaphyseal flare and the medial femoral condyle. Stapling of the distal femoral and proximal tibial epiphyses proceeds as follows.

- Approach the physis through a 4–5 cm longitudinal incision between the anterior and posterior margins of the medial femoral condyle. Begin the incision approximately 1–1.5 cm distal to the physes, and extend it proximally.

- Divide the subcutaneous tissues, deep fascia, and patellar retinaculum. If necessary, resect the medial margin of the vastus medialis anteriorly. Identify the physis plate with a straight Keith needle or by fluoroscopy. Identification of the physis and insertion of the staples occur more quickly and more accurately with fluoroscopy. If the physis plate is identified by probing with a Keith needle, the plate is softer than the adjacent cancellous bone.

- Select Blount staples that are rectangular or oblique, depending on the shape of the medial femoral condyle and metaphysis. Vitallium staples cause less reaction, are stronger, and are less likely to be extruded than stainless steel staples.

- Avoid subperiosteal stripping to protect the perichondrial ring and the physis plate.

- With a staple holder, partially insert three staples. Insert one directly medially and one each in the anteromedial and the posteromedial aspects of the distal femur. Before completely setting the staples, confirm their location and orientation with radiographs or fluoroscopy. The physis should be in the mid portion of each staple. Insert the ends of the staple parallel to the physis to avoid phsyseal injury. If position and orientation are satisfactory, drive the staples flush with the
periosteum. Do not bury the staples into the bone to avoid injury to the perichondrial ring.

- Close the patellar retinaculum and the deep fascia separately. It is important that the patellar retinaculum not be bound down by the staples because it can cause loss of knee motion, local swelling, and pain.

- Close the subcutaneous tissues and skin with absorbable sutures. A subcuticular closure of the skin gives the best cosmesis. Reinforce the incision with adhesive closure strips, and apply sterile dressings and a knee immobilizer.

If the proximal tibial physis is selected for stapling, the procedure is similar to that for the distal femur.

- Make a 4–5 cm longitudinal incision directly over the medial aspect of the knee. The incision usually begins just distal to the joint line and proceeds distally.

- Identify and retract anteriorly the medial border of the pes anserinus, if possible. Occasionally, the pes anserinus must be split. After the periosseous of the bone is incised, identify the pes anserinus with a Keith needle or by fluoroscopy.

- Insert one staple directly medially and one each in the anteromedial and the posteromedial aspects of the proximal tibia. The oblique or angulated Vitalium Blount staples are quite useful in this location because they conform to the flare of the medial aspect of the proximal tibia. Insert the staples parallel to the physis and the articular surface. Center the staples over the physis. Before setting the staples, confirm the position radiographically.

- Close the wound in layers. If the pes anserinus is split, repair it with absorbable sutures. Close the subcutaneous tissues and skin in a similar manner, and apply sterile dressings.

Postoperatively, use a knee immobilizer for approximately 2 weeks. Follow up at 2–3-month intervals, and assess radiographically for correction. After the desired amount of correction has been achieved, remove the staples. However, there is frequently rebound overgrowth and slight recurrence of the deformity. Zeuge et al. (105) found that the amount of rebound overgrowth was minimal and unpredictable. They also advised against leaving the staples in place for longer than 1 year because of possible premature closure of the physis. The amount of correction can be calculated mathematically on the basis of the width of the physis and the amount of remaining growth (38).

**Medial Hemiepiphysiodesis of the Distal Femur or Proximal Tibia** Partial or hemiepiphysiodesis of the medial aspect of the distal femur or proximal tibia has been proposed as a method for gradual correction of genu valgum deformity. The table devised by Bowen et al. (39) can be used to determine the appropriate time for epiphysiodesis. However, because of the variability in the data necessary to make these determinations, a second operative procedure is often required to close the remaining lateral portion of the epiphysis.

Rotational bone blocks, as described by Phemister (219), were once popular. However, the percutaneous techniques of epiphysiodesis using curet, drills, burrs, or a combination of these are now preferred (37, 39, 58, 207, 279). These are as accurate and much more cosmetic than the open bone graft epiphysiodesis techniques. Although this technique is most commonly used for lower-extremity length discrepancies, it can also be used successfully in the correction of persistent angular deformities such as genu valgum and genu varum (39).

**Percutaneous Epiphysiodesis**

- Position the patient supine on a fluoroscopy table. Identify and mark the mid portion of the medial aspect of the distal femoral physis.

- Make a 2–3 mm incision directly over the physeal plate.

- Enter the medial aspect of the physis with a small curet or drill, and remove the medial portion of the physis. This allows the formation of a medial bone bridge. Do not extend the epiphysiodesis across the midline of the physis to avoid symmetric closure.

- Only a single subcutaneous suture is usually necessary to close the wound.

A similar procedure may be performed on the medial aspect of the proximal tibial epiphysis, if necessary.

After epiphysiodesis of the distal femur or proximal tibia, use a knee immobilizer for approximately 2 weeks. This allows skin and soft-tissue healing. The physis after epiphysiodesis is weak and must be protected for a short period to prevent complete physeal separation. At the end of 2 weeks, discontinue the knee immobilizer and allow partial weight bearing. Continue restriction of activities until 6 weeks postoperatively. Institute quadriceps and hamstring strengthening exercises at that time, with a gradual return to normal activities. After the desired correction has been achieved with medial epiphysiodesis, a lateral epiphysiodesis of the distal femur or proximal tibia is necessary to prevent overcorrection if the lateral physis remains open.

**Osteotomy of the Distal Femur or Proximal Tibia** Correction of a genu valgum deformity by distal femoral or proximal tibial and fibular diaphyseal osteotomies allows full correction of the deformity with a single operative procedure. However, both procedures are extensive and require internal or external fixation to maintain alignment until healing has occurred. In the correction of a valgus deformity, attention must be given to the peroneal nerve because neuroapraxia or partial paralysis may occur if the nerve is stretched. The osteotomy may be performed in early adolescence or after skeletal maturity. Several techniques are available, including opening-wedge, closing-wedge, and dome osteotomies. The choice of technique is frequently based on the length of the lower extremity and the individual bones. An opening-wedge or dome-shaped osteotomy adds length to the extremity. DePablos et al. (47) described a progressive opening-wedge osteotomy using an external fixator, a fixator for the osteotomy is not required, and the osteotomy allows progressive and adjustable correction. Both lower extremities can be corrected simultaneously. Ordinarily, osteotomies are considered for boys age 14 years or older and girls age 12 years or older.

Varus osteotomy of the proximal tibia and diaphyseal osteotomy of the fibula are indicated if the deformity is in the proximal tibia below the knee joint and there is no associated lateral tilt to the articular surface. The osteotomy is usually performed at the junction of the metaphysis and the diaphysis, just distal to the tibial tubercle. If there is associated lateral torsion of the tibia, derotation may also be accomplished. If a closing-wedge osteotomy is to be performed, perform the derotation initially because it frequently decreases the amount of bone requiring resection to correct the angular deformity. After satisfactory correction has been achieved, internal or external fixation is required. Compression plate and screws, crossed Steinmann wires, or an external fixator are suitable. In some cases, the lizarov ringfixation technique may be used, and a cannulated screw is inserted across the physis. This method allows slow correction of the valgus and the derotation. Hemichondrodistasis, or asynchronous phyeal lengthening, has been recommended by some, but it is not popular in the United States. This procedure allows simultaneous correction of limb-length inequality and correction of the genu valgum deformity. Because the physis stops closing after the osteotomy, it is best performed for patients in late adolescence.

Treat a genu valgum deformity associated with a valgus alignment of the distal femur with an osteotomy of the distal femur. Deformities in this area are associated with a lateral tilt to the joint line that cannot be corrected by a proximal tibial osteotomy. The osteotomy may be performed through a medial or a lateral approach to the distal femur. The medial approach is more complex because of the proximity of the femoral artery, but it allows easier visualization of the operative site. The lateral approach is simpler, and there is less risk to the femoral artery as it passes posteriorly at the upper margin of a medial incision. Opening- or closing-wedge osteotomies are commonly performed because it is difficult to perform a dome osteotomy of the distal femur. After the osteotomy is complete, internal or external fixation is performed with a compression plate and screws, crossed threaded Steinmann pins, or an external fixation device. See Chapter 36 and Chapter 37 for additional information on osteotomies of the femur and the tibia, respectively.

**General Rehabilitation and Postoperative Principles**

After an osteotomy has been performed, postoperative management depends on the type of internal or external fixation. If rigid internal fixation has been achieved with a compression plate and screws, immobilization is usually unnecessary, other than perhaps a knee immobilizer for 1–2 weeks for comfort. Allow only toe-touch weight bearing until early callus formation; then increase weight bearing, although not to full weight bearing, until the osteotomy site is completely healed. Remove the compression plate and screws 12–16 months postoperatively.

If simple external fixation is used, supplement it with a long-leg cast. Have the patient avoid weight bearing for 3–4 weeks, until there is early radiographic callus formation. When the patient can bear weight, gradually increase the amount to 4–6 weeks, followed by a graduated return to full weight bearing. If rigid internal fixation has been achieved, remove the external fixation device in the clinic. Apply a cylinder cast for an additional 2 weeks to allow solid union. After this has been accomplished, institute range-of-motion exercises. Failure to obtain a full range of motion at the end of 2 weeks is an indication for a referral to physical therapy. After full motion has been regained, begin strengthening exercises of the quadriceps and hamstring muscles. Return the patient to full activities after rehabilitation of the leg is complete.

**Complications**

The problems of asymmetric growth retardation associated with physeal stapling were outlined by Tachdjian (268): unpredictability of growth after the staples have been removed, possibility of asymmetric medial physeal closure, widening or loosening of the staples with eventual extrusion requiring revision, irregular patterns of initial growth retardation after stapling, the need for a second surgical procedure to remove the staples or to perform a lateral epiphysiodesis, and long and frequently wide operative scars due to stretching with knee motion. In 49 patients with genu valgum treated with stapling by Pistevos and Duckworth (261), there were no
complications other than scar, although six patients did not obtain complete correction. Staples may be painful; however, this resolves after removal.

Osteotomies of the distal femur or proximal tibia may result in peroneal nerve palsy, injury to the femoral or anterior tibial arteries, and anterior compartment syndrome (148,187,202,204,249,263,265). These severe complications are more common after proximal tibial osteotomies. Monitor patients closely postoperatively so that immediate intervention can be taken if a complication occurs. Postoperative wound infection, delayed union, nonunion, overcorrection, and undercorrection may occur after corrective osteotomies.

Conclusion

Because physiologic valgus genu valgum does not usually have a rotational component, medial physeal stapling is my procedure of choice. This is usually performed on the proximal tibial epiphysis. In severe deformities, however, the distal femur may be included. I have not used the chart described by Bowen et al. (15). Once slight overcorrection is achieved, I remove the staples, and I have not encountered a case of premature physeal closure. This procedure is simple and effective and requires minimal postoperative immobilization.

PATHOLOGIC GENU VALGUM DEFORMITIES

Genu Valgum after Fractures of the Proximal Tibial Metaphysis

Fractures of the proximal tibial metaphysis are relatively common and tend to occur most frequently in children between 3 and 6 years of age (range, 1–12 years) (79,146,150,205,237). Three times as many boys are affected as girls, which is typical for all tibial fractures (123). Skak et al. (258) reported an incidence of 5.6 fractures per 100,000 children per year. The fractures are usually the result of direct injury to the lateral aspect of the extended knee. The primary injury pattern is compression (i.e., torus fracture), incomplete tension–compression (i.e., greenstick fracture), or complete fractures (235). The fibula is typically intact but may be fractured or have a plastic deformation. The incomplete tension–compression or greenstick fracture is the most common pattern. The medial cortex on the tension side fractures, whereas the lateral cortex on the compression side remains intact or slightly hinges. The distal fragment may angulate into a slight valgus deformity, but there is no displacement and the apposition remains normal. However, most fractures are nondisplaced and without angulation.

The most common sequelae of the fracture of the proximal tibial metaphysis are valgus deformity and overgrowth of the tibia. In 1953, Cozen (72) reported on four patients with valgus deformities after nondisplaced or minimally angulated fractures of the proximal tibial metaphysis. Many other reports of this complication have been published (18,18,21,27,30,44,51,66,71,76,79,109,113,133,146,147,150,153,163,184,226,258,273,281,283,292,283). Similar valgus deformities were observed after other insults to the immature proximal tibial metaphysis, such as osteomyelitis, bone-graft harvest, osteochondroma excision, and osteotomy (18,243,280).

The incidence of genu valgum deformity after proximal tibial metaphyseal fractures varies. It appears to occur in approximately 50% of cases. Saltzer and Best (244) reported on 21 patients with proximal tibial metaphyseal fractures, observing the development of a valgus deformity of 11° to 22° in 13 (62%) of them. Robert et al. (235) reported the development of a genu valgum deformity in 12 (48%) of 25 patients. However, Skak et al. (258) reviewed 40 consecutive patients and found the development of deformity in only 4 (10%). Boyer et al. (44) reported no valgus deformity in seven children 2–5 years of age who sustained fractures while jumping on a trampoline with a heavier child or adult. Valgus deformities occur predominantly in association with greenstick or complete fractures and are uncommon after a torus fracture (235,258).

Theories about the cause of valgus deformity include injury to the lateral aspect of the proximal tibia physis, inadequate reduction, premature weight bearing, hypertrophic callus formation, dynamic muscle action, soft-tissue interposition, tethering from the intact fibula, and asymmetric physeal growth stimulation (14,18,18,19,21,27,30,44,51,66,71,76,79,109,113,133,138,139,146,147,150,153,163,184,201,205,206,226,230,237,243,244,247,273,281,283,292,293). The fibula is typically intact but may be fractured or have a plastic deformation. The incomplete tension–compression or greenstick fracture is the most common pattern. The medial cortex on the tension side fractures, whereas the lateral cortex on the compression side remains intact or slightly hinges. The distal fragment may angulate into a slight valgus deformity, but there is no displacement and the apposition remains normal. However, most fractures are nondisplaced and without angulation.

Assessment, Indications, and Relative Results

Valgus deformity usually develops within 5 months of injury, reaches its maximum in 1–2 years, stabilizes, and then begins to improve by longitudinal growth through the proximal and distal physes (Eq. 169.15) (215). Unfortunately, there are no data indicating how much improvement can be anticipated. Saltzer and Best (244) found no improvement in 21 patients, and 13 later required proximal tibial varus osteotomies. Visser and Veldhuizen (281) reported no spontaneous improvement in the valgus deformity from the proximal tibial physis but observed some correction in alignment from the distal tibial epiphysis. Taylor (273) found improvement in some patients but not all. Of the 12 children with valgus deformity described by Jordan et al. (153), 11 had documented improvement, although four subsequently required corrective osteotomies. Two of these children had their deformities recur, and two had compartment syndromes. Six children had complete correction of their deformities.

Jackson and Cozen (147) and later Ippolito and Pentamalli (146) observed that deformities of 15° or less usually remodeled completely, especially in young children. The more severe deformities, however, did not completely correct. Bahnson and Lovell (15) found some improvement in the valgus deformities in five children followed for a minimum of 3 years after injury. Balthazar and Pappas (13) reported that two of nine patients who were treated nonoperatively had resolution of their valgus deformity in 1–3 years. Skak et al. (258) found that valgus deformities tended to increase during the first year after injury and then remained constant for 1–2 years and finally improved. Only one of their six patients had residual deformity at final follow-up.

MacEwen and Zions (183,293) followed seven children with posttraumatic tibial valgus deformities for a mean of 39 months after injury. These children were 11 months to 6 years of age. The valgus deformities progressed most rapidly during the first year after injury and then continued at a slower rate for as long as 17 months. Overgrowth of the tibia accompanied the valgus deformities. The mean overgrowth was 1 cm (range, 0.2–1.7 cm). Clinical correction with subsequent growth occurred in six of their seven patients. They recommended that the alignment of the lower extremities be measured by the mechanical femoro-tibial angle as described by Visser and Veldhuizen (281) rather than the metaphyseal–diaphyseal angle of Levine and Drennan (170). The latter measured only the alignment of the proximal tibia. Much of the late correction of the deformity is due to distal realignment (183,259,281). The distal epiphysis tends to realign itself perpendicular to the applied forces, resulting in asymmetric growth and an S-shaped appearance of the tibia radiographically (216).

Preoperatively Management and Planning

The treatment of proximal tibial metaphyseal fractures must consist of correction of any associated valgus angulation by manipulative reduction and immobilization in a long-leg cast with the knee in extension for 4–6 weeks or until the fracture is well healed (238). If closed reduction is required, it is best performed under general anesthesia. Radiographic evaluation of fracture alignment may be difficult unless radiographs of both lower extremities with the knee in extension are obtained on a long cassette. Greenstick fractures with slight valgus angulation may require that the intact tibial lateral cortex be manually fractured. This usually allows correction of the deformity. Slight overcorrection is desirable (205).

Displaced fractures also require correction of any residual angulation. However, normal apposition is not always necessary. There are limited indications for open reduction of these fractures. Inability to correct a significant valgus deformity by manipulation under general anesthesia rather than failure to close the medial fracture

Figure 169.15. A: Standing AP radiograph of a 5-year-old boy after treatment for a greenstick fracture of the right proximal tibial metaphysis. At the time of cast removal, there was already 22° of genu valgum on the right but only 5° on the left. B: One year later, there was increased genu valgum deformity.
gap is currently the major indication. Most angulated displaced fractures are amenable to reduction by nonoperative methods.

The final step in initial management is to advise the family that although anatomic alignment of the fracture has been obtained, the possibility of valgus angulation and tibial overgrowth exist as a natural consequence of this fracture. This information prepares the family for complications if they occur.

Assess fracture alignment radiographically at least weekly during the first 3 weeks after injury. Correct any loss of alignment. During this initial period, children should avoid bearing weight to minimize compression forces and the possibility of valgus angulation within the cast.

Treatment of valgus deformities after proximal tibial metaphyseal fractures is predominantly nonoperative with prolonged observation. The use of orthoses has been suggested, but there is no evidence to substantiate the efficacy of this method (89,133,146). MacEwen and Zions (183) recommended observation until early adolescence. If spontaneous improvement fails to provide sufficient clinical correction, surgical intervention may be necessary. McCarthy et al. (188) reported no difference in the long-term results between 10 patients treated nonoperatively and five managed operatively.

The major indications for surgical intervention include severe valgus deformities (>25°) and failure to achieve satisfactory correction by the immediate preadolescent years. All children should be allowed 2–4 years of growth after injury to allow spontaneous correction to occur. Most deformities of 15° or less resolve, and those that are 25° or more may not. Deformities between 15° and 25° must be carefully followed. The development of a medial thrust during this observation period is an indication for surgical intervention to prevent laxity in the medial collateral ligament.

Operative Techniques The operative procedures to correct genu valgum deformities after proximal tibial metaphyseal fractures are similar to those for other valgus deformities and include the following:

- **Medical physial stapling**
- **Medial physial epiphysiodesis**
- **Osteotomy with internal or external fixation**

Because the deformity is usually restricted to the tibia, these procedures are most commonly applicable to the proximal tibia. They are described in the section on physiologic genu valgum. If surgical intervention is contemplated, it is important to assess the degree of tibial-length inequality. Surgery must address the valgus deformity and residual tibial overgrowth. In young children with severe genu valgum deformities that are not improving with spontaneous growth and development, a corrective osteotomy may be indicated. This should include shortening of the tibia by approximately 5 mm to allow recurrent overgrowth. Similar consideration is necessary in the early adolescent years when surgical intervention is planned.

**Recurrence of Deformity** Recurrence has been attributed to the same overgrowth phenomenon that led to the initial valgus deformity. Balthazar and Pappas (18) reported that the valgus deformity recurred, although lesser in magnitude, in six children undergoing a proximal tibial varus osteotomy. Four of the six also had further longitudinal overgrowth of the tibia. DallMonte et al. (89) reported recurrent valgus deformities in 7 (44%) of 16 patients after proximal tibial osteotomies. The recurrence rate for children younger than 5 years was 60%, and for those between 5 and 10 years of age, it was 36%. The authors concluded that the osteotomy is essentially a second fracture and therefore has the same risks of deformity. If surgery is undertaken, families should be advised that the deformity can recur and that prolonged follow-up is required.

**Conclusion** With the recent demonstration that the majority of children with genu valgum following a proximal tibial metaphyseal fracture will undergo spontaneous correction during growth, I now feel that these children should be observed for as long as possible. Only a severe disabling deformity should be considered for early surgical correction. Deformities persisting into adolescence can be corrected with a proximal tibial or distal femoral medial hemiepiphyseal stapling (or both). Typically, this allows for rapid correction of any residual deformity. I try to avoid corrective osteotomy because this may induce the same genu valgum deformity that followed the initial fracture.

**Other Pathologic Genu Valgum Deformities**

**Metabolic Disorders** Metabolic causes of pathologic genu valgum include vitamin D–resistant rickets, nutritional rickets, and renal osteodystrophy. These disorders are more likely to produce genu valgum rather than genu varum. This is due to their later onset, at which time the physiologic valgus alignment of the knee has already been achieved. Renal osteodystrophy is the most common metabolic disorder producing genu valgum (12,19,32,62,75,81,132,143,210). Oppenheim et al. (210) described changes in the lateral proximal tibial epiphysis and metaphysis in children with renal osteodystrophy similar to those seen in the medial proximal tibia in Blount's disease.

Treatment is generally initiated after correction of the underlying metabolic disorder. Treatment before that time has a high incidence of recurrence. After the metabolic condition has been controlled, treatment may be by either osteotomy or physial stapling of the distal femur or proximal tibia. The latter is a particularly effective method, provided there is sufficient remaining growth (Fig. 169.16).

![Figure 169.16. A: Preoperative standing radiograph of a 15-year-old boy 2 years after renal transplantation. His genu valgum has not been improving, although the physes now appear normal. B: Postoperative radiograph after insertion of staples about the medial aspect of the distal femoral epiphyses. C: Standing radiograph at 18 months postoperatively and 9 months after staple removal demonstrates physiologic alignment and no evidence of growth disturbance.](image-url)

**Trauma** Injuries to and about the distal femoral or proximal tibial epiphyses is a common cause of genu valgum (142,233). The deformities are progressive and require surgical treatment if there is an asymmetric physial bar or bridge. The extent of the bar can be assessed by tomography or, preferably, MRI. Treatment options consist of physial bar excision and grafting with fat or Silastic (Langenskiöld [169] procedure), together with a corrective osteotomy. If the bar is extensive, then complete physial closure and corrective osteotomy may be performed, with delayed management of the leg-length discrepancy (see Chapter 164).

**Neuromuscular** Ambulatory children with neuromuscular disorders, such as cerebral palsy, often have a pes valgus and excessive external tibial torsion that may produce a progressive genu valgum. This is more likely to be a torsional malalignment than a true genu valgum deformity. Treatment may involve soft-tissue releases to restore muscle balance and osteotomies to correct torsional and angular deformities (see Chapter 172).

**Infection/Osteomyelitis** Osteomyelitis may cause genu valgum directly by damaging the physis or producing a reactive hyperemia and asymmetric growth stimulation. Asymmetric physial arrest is managed similarly to trauma (see Chapter 176).

**Skeletal Dysplasia** Genu valgum will occur in children with skeletal dysplasia, including multiple epiphyseal dysplasia, spondyloepiphyseal dysplasia, metaphyseal dysplasia, and pseudoachondroplasia. Treatment is based on the diagnosis. Orthotic management is usually ineffective in skeletal dysplasia. Surgery with either stapling or corrective osteotomies is usually necessary (Fig. 169.17) (see Chapter 189).
Inflammatory Disorders. Juvenile rheumatoid arthritis may produce a progressive genu valgum deformity, but this is uncommon. Correction can be achieved by physeal stapling (240). In older children and adolescents, an osteotomy may be necessary.

CONGENITAL ANGULATION DEFORMITIES OF THE TIBIA AND FIBULA

Congenital angular deformities of the tibia and fibula are uncommon (Table 169.3). Anterior and anterolateral angulation or bowing is the most common form and is usually associated with other congenital anomalies, such as congenital pseudarthrosis (6,11,15,120,125,135,165,200,212,231). Congenital posteromedial angulation is less common, resolves spontaneously, and is not associated with significant osseous pathology other than residual lower-extremity length inequality.

CONGENITAL ANTEROLATERAL BOWING OF THE TIBIA: CONGENITAL PSEUDARTHROSIS

Anterolateral bowing of the tibia is usually associated with significant pathologic disorders (Table 169.3). The most common are congenital pseudarthrosis of the tibia, congenital longitudinal deficiency of the tibia (paraxial tibial hemimelia), and congenital longitudinal deficiency of the fibula (paraxial fibular hemimelia) (see Chapter 174).

Congenital pseudarthrosis of the tibia is a rare congenital malformation that includes all congenital fractures of the tibia and pseudarthrosis of the tibia arising after pathologic fracture in a tibia with congenital anterolateral angulation (4). Usually, anterior or anterolateral bowing of the tibia is recognized shortly after birth. Only occasionally are the fracture and pseudarthrosis present at birth, and the pseudarthrosis is therefore not truly congenital. Its incidence has been estimated to be 1 in 130,000 live births (140). The left side is affected slightly more often than the right (270); bilateral involvement is rare. Beals and Fraser (24,106) reported cases with bilateral and familial involvement. Congenital pseudarthrosis of the tibia is one of the most difficult and challenging deformities confronting orthopaedic surgeons (120,213,270).

Pathophysiology

The exact cause of congenital pseudarthrosis of the tibia is unknown (43,49,52). Between 40% and 80% of children with this disorder are ultimately diagnosed with neurofibromatosis (5,49,52,66,74,186,203,213,214,262). Others have fibrous dysplasia or no associated disorders. Brown et al. (52), in a study of 17 children with a congenital pseudarthrosis, found that eight had neurofibromatosis, three had fibrous dysplasia, and six had no apparent disorder. Despite the clinical association with neurofibromatosis, the cause remains obscure.

Biopsy material removed from the tibia in the area of the pseudarthrosis shows a dense, cellular, fibrous connective tissue with variable areas of cartilage formation (43,49,52,114). Electron microscopy reveals the lack of a basement membrane, and the cells resemble fibroblasts rather than Schwann cells or perineural cells, even in children with known neurofibromatosis (49). Only rarely is neurofibromatosis tissue observed in these specimens, and these samples are usually from intraosseous neurofibromas (114). In some cases, the tissue does resemble fibrous dysplasia (42). This dense, fibrous connective tissue with fibrocortilage and occasional bone trabeculae fills a poorly vascularized gap between the sclerotic bone ends to create the nonunion. This is not a true pseudarthrosis. The defective tissue occurs within the bone itself, the periosteum, the surrounding soft tissue, and possibly in the nerve and vascular supply to the involved area.

Assessment, Indications, and Relative Results

An infant predisposed to congenital pseudarthrosis of the tibia characteristically presents with anterior or anterolateral bowing of the tibia (Fig. 169.18). This rarely occurs in conjunction with an acute fracture. The bowing is rarely anteromedial. The angular deformity of the tibia is congenital. Unless there is a fracture, the area is not tender, and a bony prominence is palpable. With an acute fracture, the area is unstable and is usually painful.

Because of the high incidence of neurofibromatosis in these patients, the hallmarks of this disease must be sought. The criteria used by Crawford (73) for diagnosis required at least two of the following:

- Multiple café-au-lait spots
- Positive family history
- Definitive biopsy

Characteristic bony lesions, such as pseudarthrosis of the tibia, hemihypertrophy, or a short, sharply angulated spinal curvature

Café-au-lait spots are typically smooth-edged. The presence of at least five spots measuring more than 0.5 cm in diameter is considered diagnostic. The number of spots increases with the patient’s age. Subcutaneous nodules (i.e., fibroma molluscum) are uncommon until adolescence and are typical of chronic disease. Although other bones may be involved in neurofibromatosis, involvement of more than one bone is extremely rare. Isolated cases of congenital pseudarthrosis of the fibula with an intact tibia have been reported (79,82,170). They were usually associated with anterior bowing of the tibia and ankle valgus. Curly and overlapping toes have been
reported, as well as congenital constriction bands (201,271).

In children younger than 2 years presenting with anterior or anterolateral bowing of the tibia, there may be no clinical evidence of neurofibromatosis. The clinical features of neurofibromatosis usually become more apparent with growth and development. Radiographs of the tibia before the establishment of a pseudarthrosis may show an intact bowed tibia exhibiting sclerosis in the area of angulation without a medullary canal. After a fracture has occurred and a pseudarthrosis has been established, the proximal and the distal ends of the fracture site become tapered. Both tapered bone ends remain sclerotic.

Classification

Many classifications of pseudarthrosis have been based on the prognosis for various radiographic types (6,7,15,20,40,73,125,186,270). The classification by Boyd (40) is one of the most commonly used methods of assessment (Table 169.7). Crawford (73) proposed a four-group functional classification:

<table>
<thead>
<tr>
<th>Classification</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Type I</td>
<td>Anterolateral bow with a normal medullary canal</td>
</tr>
<tr>
<td>Type II</td>
<td>Anterolateral bow with a narrow, sclerotic medullary canal (Fig. 169.19)</td>
</tr>
<tr>
<td>Type III</td>
<td>Anterior bow with a cystic lesion</td>
</tr>
<tr>
<td>Type IV</td>
<td>Anterolateral bow with a fracture, cyst, or frank pseudarthrosis (Fig. 169.20)</td>
</tr>
</tbody>
</table>

Table 169.7. Boyd Classification of Congenital Pseudarthrosis

The type of radiographic deformity is related to the recommended treatment. In Crawford’s classification, a type I lesion has the best prognosis, and the remaining three types have progressively worse prognoses. However, the relation between the type of pseudarthrosis and the clinical result is not always predictable (4,73,183,196). The presence or absence of established neurofibromatosis makes no difference in the classification and is not a factor in determining treatment or prognosis. Cases in which bone-end resorption and sclerosis are evident radiographically and bone graft rapidly resorbs postoperatively have a poor prognosis. Those with a cystic lesion have a more favorable prognosis (198).

The natural history of anterior or anterolateral bowing of the tibia secondary to neurofibromatosis or fibrous dysplasia is a fracture with the establishment of a pseudarthrosis. The treatment of anterior and anterolateral bowing with an intact tibia is directed toward prevention of the fracture and pseudarthrosis. Congenital pseudarthrosis of the tibia is more than a mechanical problem (199); it represents a complex biologic problem because the established pseudarthrosis is extremely difficult to manage.

Preoperative Management and Planning

Patients with anterior or anterolateral bowing of the tibia without pseudarthrosis are best treated initially with a total-contact plastic orthosis. This is usually an ankle–foot orthosis. Prophylactic treatment may delay or prevent a fracture and subsequent pseudarthrosis. These orthoses are worn for years. With growth and in the absence of a fracture, the tibial bowing usually improves. There is typically some residual shortening within the bone. The medullary canal develops slowly over 5–10 years. It is possible, although unlikely, that a fracture and pseudarthrosis can be avoided with the use of an orthosis alone. If the tibia has straightened sufficiently, the medullary canal has reconstituted, and there is adequate cortical thickness, the orthosis may be discontinued as skeletal maturity is approached. Vigorous physical activities should be avoided. There are no long-term reports of successful orthotic management in adolescents or adults.

After a pathologic fracture and pseudarthrosis have occurred, the treatment is usually surgical. Casting alone rarely results in healing. However, Roach et al. (234) demonstrated that a late-onset fracture in a dysplastic tibia may heal with prolonged immobilization. Six of 11 fractures healed, but four of the six had a residual anterior bow susceptible to a stress fracture.

Operative Techniques
The indication for surgical management is an established pseudarthrosis. The goals of treatment include obtaining union at the pseudarthrosis site, maintaining union throughout growth and development, and obtaining an acceptable limb length at maturity (213,279). Previously, surgery was advised only for children age 4 years or older (6,125,203). Most physicians now recommend early surgical intervention and revision if the first procedure does not result in union of the pseudarthrosis (86,199,213,214). Morrissey et al. (199) reported that a good result did not occur in any child whose tibia was not united by 6 years of age. Masserman et al. (186) reported that union was more related to the pathologic process than the age at surgery. Earlier union produces more normal growth of the distal tibial epiphysis and less lower-extremity length discrepancy.

The current methods of surgical treatment include bone grafting alone, bone grafting and internal fixation, electrical stimulation, microvascular bone grafting, lizarov external fixation methods, and amputation.

**Bone Grafting Alone** Prophylactic bone grafting has been used for the deformed tibia before a pathologic fracture occurs (179,191,266,270). This was thought to strengthen the deformed area and decrease the risk for pathologic fracture. The technique described by McFarland (191) is the most common procedure. A long corticocancellous graft from the opposite tibia is placed posteriorly, spanning the deformity in the normal biomechanical longitudinal axis of weight bearing. Lloyd-Roberts and Shaw (179), however, reported success in only three of their seven patients, while Tachdjian (270) reported success in all five children. Recently, Strong and Wong-Chung (266) prevented fracture in six of nine children with a pseudarthrosis secondary to neurofibromatosis. Paterson (213), however, felt that the procedure was indicated primarily for cystic pseudarthrosis. Tachdjian (270) suggested concomitant curettage and bone grafting of any cystic lesions.

Many possible bone-grafting procedures have been used to treat an established congenital pseudarthrosis of the tibia (41,42 and 43,98,100,191,225,228). Morrissey et al. (199) reviewed 167 operations performed in 40 patients. The Farmer procedure, using a composite bone graft from the opposite tibia, demonstrated the best result, with a success rate of 52% (100). Other procedures had lower success rates, including only grafts (123), bypass grafts (7%), Soffield procedure (25%), sliding grafts (33%), bone alloilgraft (17%), and autogenous grafts (10%).

**Bone Grafting and Internal Fixation** Surgical excision of the pseudarthrosis, correction of the angular deformity of the tibia, and rigid internal fixation in addition to bone grafting have improved the rate of primary union. Stabilization has been achieved with compression plates and intramedullary rods. The former is rarely used because of difficulties involved in achieving adequate fixation (6,213). The most common methods at this time are tibial or dual tibial and fibular intramedullary rods. These techniques usually transfixed the ankle and subtalar joints to adequately stabilize the distal tibial segment (4,9,17,83,109,279). These joints are progressively freed with growth of the tibia and proximal incorporation of the rod. This method does not result in significant stiffness of the joints. Postoperatively, immobilize with a unilateral hip spica cast followed by a long-leg cast and then a knee–ankle–foot orthosis. Anderson et al. (9) reported that 10 of 13 pseudarthroses healed with an intramedullary rod technique. However, their mean follow-up time was short (6.9 years).

Several researchers used extending intramedullary rods and bone grafting (e.g., double cortical onlay, cancellous) (93,102). These rods extended with growth, decreasing the need for revision surgery and protecting the union until skeletal maturity. They were not inserted across the ankle or subtalar joint. Bilan et al. (21) recommended extending the length of the rods in four of seven patients when these rods were used in revision surgery after primary union. Fern et al. (102) recommended that the outer sleeve of an extendable rod be inserted across the pseudarthrosis site to provide more strength and decrease the risk of fracture. They reported primary union in all five patients in whom extendable rods and bone grafting were used. All rods expanded with growth up to a maximum of 6.4 cm.

The use of intramedullary rods, especially those that stabilize the hind foot, and cancellous bone grafting increases the rate of primary union. The correction of anterior or anterolateral bowing undoubtedly enhances healing by allowing compression across the pseudarthrosis. These rods are not removed until after skeletal maturity because the tibia may undergo progressive bowing or refracture.

**Electrical Stimulation** Electrical stimulation has been used in the treatment of congenital pseudarthrosis of the tibia for the past two decades (20,48,164,214,215,251,267). The various techniques include implanted direct-current bone growth stimulators and external stimulation devices with pulsating electromagnetic fields. The use of electrical stimulation has improved success rates after bone-grafting procedures (213,214). Most reports recommend that electrical stimulation be used in conjunction with internal fixation and bone grafting. In 1982, Kort et al. (164) observed that the most important variable in healing was the radiographic morphology of the nonunion. Patients with spindled bone ends, a large gap, and gross mobility had a poor prognosis, whereas those with a cystic or sclerotic transverse fracture and a gap of less than 5 mm had better responses.

Paterson and Simonis (214) described a technique of excision of the pseudarthrosis and abnormal tissue, fibular osteotomy, intramedullary rod fixation (i.e., large Steinmann pin or Kuntscher nail), cancellous bone grafting, and an implanted direct-current electrical bone growth stimulator. The leg was protected in a long-leg plaster cast until clinical and radiographic healing was achieved. Weight bearing was allowed and encouraged. They reported primary union in 20 (74%) of 27 patients. The average time for union was 7.2 months (range, 3–18 months). During a mean follow-up period of 3.8 years (range, 6 months to 10 years), no refractions were reported. The reasons for failure in seven patients included inadequate correction of the anterior tibial bowing, poor internal fixation, incorrect placement of the cathode, and extensively diseased bone. Brighton et al. (48) reported that only one of four patients with congenital pseudarthrosis of the tibia healed with direct-current stimulation from an implanted single cathode. However, they did not excise abnormal tissue, provide internal fixation, or use bone grafting. The extremities were immobilized in a plaster cast, and weight bearing was not allowed. They thought that the results did not prove the efficacy of this technique for congenital pseudarthrosis of the tibia.

In 1981, Bassett et al. (20) reported the results in 34 patients with congenital pseudarthrosis of the tibia treated with pulsed electromagnetic fields (PEMFs) by way of external coils. They reported that 17 of 34 patients achieved complete healing with reconstitution of the medullary canal. An additional seven (21%) patients achieved union with function but required continued protection with an orthosis. Healing of the pseudarthrosis occurred in 24 (71%) of 34 patients. Analysis of the failures demonstrated that most occurred in males (90%). For most (93%), the history of pseudarthrosis exceeded 1 year (i.e., pseudarthrosis of length greater than 1 year) and with cortical hypertrophy (164). The researchers did not employ any additional surgical procedures in the initial treatment. However, after early healing was demonstrated radiographically, surgical realignment, immobilization, and bone grafting were combined with the PEMFs. This did not have an adverse affect on the ultimate outcome. In 1982, Sutcliffe and Goldberg (213) reported the results of 48 patients treated for congenital pseudarthrosis of the tibia with PEMFs. The definitive end point of treatment was reached in 37 patients, and in 26 (70%) of them there was a successful outcome. Fifteen pseudarthroses healed with PEMFs alone. The remaining 11 patients required subsequent surgery, usually cancellous bone grafting, and a second course of PEMFs before healing was obtained.

It appears that electrical stimulation may help induce bone formation in the area of a pseudarthrosis and abnormal tissue. Electrical stimulation alone is effective in approximately 50% of the successful cases. In the remainder, additional procedures are necessary before primary union can be achieved, including excision of the pseudarthrosis and abnormal tissue, correction of existing deformity, intramedullary fixation, and cancellous bone grafting. However, in approximately 30% of cases, electrical stimulation with or without surgical intervention results in failure. The incidence of refracture appears to be low.

**Microvascular Bone Graft** Free vascularized bone grafts represent another popular procedure for congenital pseudarthrosis of the tibia (64,68,84,85,93,108,112,121,154,175,196,219,220,259,272,277,284,285,286). Vascularized rib, iliac crest, and fibula grafts have been used, and the latter appears to be superior in congenital pseudarthrosis of the tibia (64,68,84,85,92,108,121,154,175,219,220,284,285). The graft can be isilateral if it is of sufficient size (68,186,259,269). The procedure consists of transferring the contralateral fibular diaphysis on its vascular pedicle with a cuff of muscle to maintain the peristial blood supply into a defect created by resecting the pseudarthrosis and abnormal soft tissue on the involved side (Fig. 169.21). Supplemental cancellous bone grafting may be included to facilitate bone formation. The vascularized graft is advantageous because it is straight, a long segment can be harvested, and it tends to hypertrophy after healing. Leung (175) reported three successful microvascularized iliac crest grafts in congenital pseudarthrosis of the tibia. He thought that it was easier to harvest the iliac crest in comparison to a more rigid healing bone. The corticocancellous bone rather than corticocancellous bone was used. These corticocancellous bone grafts ranging from 3 to 10 cm may be obtained in children age 4 years or older. Rib grafts are less advantageous because of their curvature. Hagan and Buncke (121) reported that this curvature does not tend to correct with growth after satisfactory incorporation and the curvature may increase. Use of extensive corticocancellous grafting may prevent progressive bowing of the vascularized rib graft. Donor site problems after vascularized fibula transfers have been reported (269).
CONGENITAL POSTEROMEDIAL ANGULATION OF THE TIBIA AND FIBULA

In 1990, Weiland et al. (285) reported on the long-term results in 19 consecutive children with congenital pseudarthrosis of the tibia treated with a vascularized fibula graft. The mean age at surgery was 5.1 years (range, 1.4–11.4 years). The mean follow-up was 6.3 years (range, 2–11 years). They reported that 18 (95%) of the 19 pseudarthroses healed. The lower-extremity length discrepancy at follow-up was a mean of 1.6 cm (range, 0–4 cm). Sixteen of the children had been treated with electrical stimulation techniques, which failed, for at least 1 year before surgery. However, the fibular graft hypertrophied rapidly, and no graft fractured during follow-up. Five patients required secondary procedures for nonunion and angulation. Only one child failed and subsequently required an amputation. Four patients ultimately achieved healing, although they required nine bone-grafting procedures. Two children had fractures through normal bone distal to the vascularized bone graft; they also required bone-grafting procedures to achieve union. Morbidity of the donor site was minimal, but one patient sustained a nondisplaced fracture of the tibia through a screw hole, and a 20° valgus deformity requiring osteotomy developed in another. Thirteen tibiae had residual deformity: valgus deformity (five patients); anterior angulation (two patients), or both (six patients). The mean valgus deformity was 25° (range, 5° to 45°), and the mean anterior angulation was 24° (range, 10° to 30°). Two patients with a valgus deformity required correction with an osteotomy. Four patients had anterior bowing of more than 20°, but none required additional surgery. All children were treated with orthoses until skeletal maturity was achieved.

The five basic steps of free vascularized bone grafts are applicable whether iliac crest or fibula graft is used (220):

- Harvest of the vascularized bone with an intact vascular pedicle
- Excision of the tibial pseudarthrosis and abnormal tissue
- Fixation of the vascularized bone in situ
- Microvascular anastomosis
- Skin closure

The procedure is usually performed with two surgical teams. One team harvests the vascularized bone, and the second prepares the recipient site. Some form of internal fixation is usually necessary to maintain the alignment of the extremity. One advantage of microvascularized bone grafts is the simultaneous correction of any resulting bone deformity, which facilitates fracture healing. Prolonged immobilization is necessary until healing occurs, with protected weight bearing allowed thereafter. Weiland et al. (285) maintain their children in hip spica casts for 2–3 months to allow healing. After healing occurs, protected weight bearing with a knee–ankle–foot orthosis is allowed. The orthosis is worn until skeletal maturity (see Chapter 36).

Ilizarov Fixation System The Ilizarov method has been shown to be effective in achieving union at the pseudarthrosis site and in simultaneously correcting any associated angular deformity and lengthening of the tibia to restore length (85,99,119,144,211,224). The apparatus can be used in four ways: compression of the pseudarthrosis, compression with metaphyseal tibial lengthening, compression followed by distraction for hypertrophic nonunion, and distraction alone for hypertrophic nonunion. Excellent short-term results for union were reported. Whether the union is maintained in the long term remains uncertain.

Amputation In children with persistent congenital pseudarthrosis of the tibia after previous surgical procedures, an amputation may be advised. This should be a Boyd or Symes ankle-disarticulation amputation of the foot (82,134,149,185). See Chapter 175 on principles of pediatric amputation and Chapter 120 and Chapter 132 on lower-extremity amputations and prostheses. Amputation with appropriate prosthetic fitting allows rapid rehabilitation and return to normal function. McCarthy (189) recommended amputation for several criteria: failure to achieve bony union after three surgical attempts, a significant lower-extremity length inequality (usually 5 cm or greater), development of a deformed foot, undue functional loss from prolonged hospitalizations, and high medical costs.

The Boyd or Symes amputation is usually the procedure of choice. It preserves the heel pad and distal tibial epiphysis, which allows end bearing on the stump. The bone and skin are lengthened as a unit to avoid problems with overgrowth (82). A below-knee amputation through the pseudarthrosis produces a poor end-bearing stump for ambulation. The abnormal tissue and previous surgical scar provides poor skin coverage and predisposes to breakdown. There are also the problems of overgrowth and frequent revision. Amputation above the pseudarthrosis site provides better skin coverage, but there are problems with bony overgrowth.

Jacobsen et al. (149) reported the results of Symes amputation in eight children with pseudarthrosis of the tibia. The average age at amputation was 8.2 years, and the mean follow-up was 5.9 years. These children had a mean of 3.8 surgical procedures performed before amputation. None of the pseudarthroses healed, but with an appropriate Symes prosthesis, the children were able to engage in normal activities, including sports. The lower-extremity length inequality and some of the angular deformity were corrected within the prosthesis. Herrling et al. (134a) reported that 21 children (none with congenital pseudarthrosis) who had 23 Symes amputations had better psychological functioning than children undergoing multiple corrective surgical procedures. The better psychological function correlated with their better orthopaedic function. The level of family stress influenced the child's behavior, self-perception, and intelligence. The physicians thought that an early Symes amputation in the young patient was compatible with good athletic and psychological functioning, which closely approached that of a nonhandicapped child of the same age. Similar results were reported by Davidson and Bohne (82) for 23 children, including one with a congenital pseudarthrosis of the tibia that did not heal.

Because of the complexities associated with the treatment of pseudarthrosis of the tibia, it is recommended that Symes amputation be discussed as an alternative method of treatment with the parents and the child from the outset. Discussion should not be delayed until later in the treatment. Tell the family of the difficulties that will be encountered in attempting to obtain primary tibial union and satisfactory function.

General Rehabilitation and Postoperative Principles Each surgical procedure has its specific postoperative regimen, but all share long-term orthotic management. The extremity needs to be protected with a plastic ankle–foot orthosis. This helps prevent recurrent fracture. Protection is required at least until skeletal maturity and perhaps even longer. This decision is based on the radiographic appearance of the tibia, the degree of residual deformity, and the presence or absence of a reconstituted medullary canal.

Rehabilitation to restore maximum strength and function after healing of a congenital pseudarthrosis of the tibia is very important. Karol et al. (156) recently performed gait analysis on 12 patients with healed lesions and four patients treated by amputation. Gait and muscle strength were markedly disturbed. Early onset of fracture, early surgery, and transknee fixation lead to an inefficient gait compared with that of amputees.

Complications Congenital pseudarthrosis of the tibia is a difficult and challenging deformity. Refracture, tibial and lower-extremity length discrepancy, stiffness of the ankle and subtalar joints, progressive anterior angulation of the tibia, and ankle valgus are the major complications (270,285). Surgical complications are also common. Most children have had multiple surgical procedures and are at risk for infection and neurovascular injury. Because of these problems, the true outcome of a congenital pseudarthrosis cannot be fully assessed until skeletal maturity. Crosett et al. (73) found that the clinical results for their patients remained stable after skeletal maturity. Neurofibromatosis does not increase the incidence of complications or adversely affect the final clinical result (158).

Conclusion Probably, the most important aspect of the management of children with congenital pseudarthrosis of the tibia is to minimize the number of operative procedures and to maintain as normal function as possible. Prevention of fractures in children with pseudarthrosis lesions is critically important. This can sometimes be achieved with a clavshell ankle–foot orthosis. After a pseudarthrosis is established, the best results with respect to union are achieved with a vascularized fibula graft or intramedullary rod. I feel that the initial surgical procedure should be the latter. This allows strengthening of the tibia, with weight bearing providing compression across the pseudarthrosis. The results of a vascularized fibula transfer are also good, but I am concerned about a major operative procedure on the uninvolved extremity. Once it is apparent that a pseudarthrosis cannot be satisfactorily healed, Symes amputation and prosthetic replacement permit restoration of relatively normal function.

Figure 169.21. A: AP radiograph of the right lower leg of a 6-month-old boy with neurofibromatosis and a congenital pseudarthrosis of the distal tibia. B: Lateral radiograph. C: A procedure using a vascularized fibula graft from the left leg was performed at 17 months of age. Internal fixation was not used, and the ends of the fibula graft were inserted into the medullary canal proximally and into the metaphysis distally. D: Lateral radiograph. E: Two months after vascularized-fibula grafting, there is extensive subperiosteal new bone formation and hypertrophy of the graft. F: Lateral radiograph. G: Twenty-two months later, the tibia is healed, but the leg is protected in a knee–ankle–foot orthosis. H: Thirty-three months postoperatively, the tibia has healed well, and the medullary canal is reforming in the area of the vascularized fibula.
Pathophysiology

The cause of congenital posteromedial angulation of the tibia and fibula is unknown. There is some evidence to indicate a primary chondro-osseous defect in the embryologic development of the distal tibia and fibular epiphyses (138,212). Pappas (212) demonstrated delayed development of the secondary center of ossification of the distal tibia and a relative reduction in the height of the distal epiphysis. Other possibilities include intrauterine fracture of the tibia and fibula with malunion, restriction of growth from soft-tissue contractures, or intrauterine malpositioning with the affected leg molded under the buttock (15,83,107,165).

Assessment, Indications, and Relative Results

Congenital posteromedial angulation of the tibia and fibula has three associated clinical problems (210,135,136,194,212,231,236):

Angular deformity
Calcaneovalgus foot
Lower-extremity length inequality

The tibia and fibula are shortened and bowed posteriorly and medially at the junction of the middle and distal thirds of their shafts. The deformity, which is obvious at birth, is usually unilateral. The right and left sides are equally affected, and there is no sex predilection (138). Infants are typically normal, and there is no increased incidence of other congenital anomalies (288). Hofmann and Wenger (138) reported on a child who had a contralateral talipes equinovarus (clubfoot) deformity. Angulation can vary from 25° to 65°, with the magnitude of deformity in the posterior and medial directions being almost equal (221). The foot is hyperdorsiflexed and has a marked calcaneovalgus posture. It appears to fit into the anterior cavity of the lower leg. The anterior compartment muscles appear shortened and limit plantar flexion of the foot. The posterior bow of the shaft causes the distal portion of the tibia and fibula at the ankle to angulate anteriorly. This makes the limitation of plantar flexion seem even more severe. There is no true bone deformity of the ankle or foot. The calf musculature is usually slightly atrophic, and the foot is smaller than on the opposite, normal side (6,138). There may be a dimple at the apex of the posteromedial angulation (8,53,135,138,212). Occasionally, an extra skin crease is associated with the dimple (212).

Anteroposterior and lateral radiographs of the lower extremities of an affected child are necessary for complete assessment. The proximal aspects of the tibia and fibula, including their epiphyses, are normal. The degree of posteromedial angulation of the distal aspect of the tibia and fibula can be measured directly from the radiographs. The cortices in the concave aspect of the posterior and medial bones are thickened, and the distal aspects of the tibia and fibula are broader than the opposite, unaffected side (212). The intramedullary cavities at the apex of the bowing are usually poorly developed or obliterated by sclerotic bone. The alignment of the tarsal and metatarsal bones is relatively normal, although occasionally there may be a slight valgus orientation. Radiographs of the femora and pelvis should be obtained for thorough assessment of the lower extremities. Special diagnostic studies, such as MRI, are rarely indicated.

The posteromedial angulation or bowing resolves with growth, especially during the first 3 years of life (Fig. 169.22). The posterior bowing resolves more quickly than the medial bowing, which may not resolve until 5 years of age (120-212). However, the associated shortening of the tibia and fibula, which is unrelated to the bowing, persists and progresses during growth (8,138,212,288). The fibula is frequently slightly shorter than the tibia; there is usually no shortening in the femur. The mean growth inhibition in the involved tibia and fibula averages 12% to 13% (range, 5% to 27%). This percentage of growth inhibition persists throughout growth and development. There appears to be a direct correlation between the degree of tibial shortening and the degree of posteromedial angulation. The greater the angulation, the more severe the lower-extremity length discrepancy (135,136,138,165). The mean tibial length difference is approximately 1.2 cm in the first 2 months of life, 2.4 cm by 5 years of age, 3.3 cm at 10 years, and 4.1 cm (range, 3.3–6.9 cm) at maturity (138,212). It is possible to determine the percentage of inhibition and the ultimate leg-length inequality by annual scanographic evaluation and bone-age determination after the posteromedial angulation has resolved. During the first 6 months of life, correction of the bowing is rapid, and by 2 years of age approximately 50% of the angulation has undergone spontaneous correction. After 3 years of age, improvement in the deformity occurs at a much slower rate.

Figure 169.22. A: Clinical photograph of a 1-month-old boy with congenital posteromedial bowing of the left tibia. Observe the medial bowing of the distal aspect of the tibia. B: The posterior bow of the distal tibia produces a calcaneovalgus appearance of the left foot. C: AP radiograph of the left leg confirms the severe medial bowing of the distal third of the tibia and fibula. D: Lateral radiograph demonstrates the posterior bowing and the calcaneovalgus appearance to the foot. The alignment of the foot is due to the dorsal angulation of the distal tibia and ankle. E: AP radiograph obtained at 1 year demonstrates decreased medial angulation of the distal tibia. F: Lateral radiograph shows a significant decrease in the posterior bowing of the tibia and improved alignment of the ankle joint. G: Clinical photograph at 2 years of age shows marked improvement in the appearance of the left lower leg. H: There is only slight residual posterior angulation of the tibia in the sagittal plane. I: AP radiograph at 2 years of age shows further improvement in the medial angulation of the distal tibia. J: Lateral radiograph confirms further improvement in posterior angulation.

The appearance of the foot gradually improves with growth and development. As the posterior bowing decreases, the degree of planar flexion improves. A pes planovalgus appearance of the foot may persist. Hofmann and Wenger (138) found mild loss of ankle dorsiflexion in older children. They thought that this was due to mild equinus contracture from toe-walking to compensate for the length discrepancy. It may also be due to the slightly shorter fibula.

Preoperative Management

Because posteromedial angulation of the tibia and fibula in children undergoes spontaneous resolution, treatment is predominantly conservative. In newborn and young infants, passive stretching exercises of the hyperdorsiflexed foot may be performed to stretch the anterior compartment muscles and improve plantar flexion. It is important to assess maximal plantar flexion of the foot on a lateral radiograph because of the anterior angulation of the distal tibia, fibula, and ankle joint. What appears to be limited plantar flexion may only be secondary to the anterior tilt to the articular surface of the distal tibia. The talus may be in full plantar flexion in the ankle mortise, but the foot still may not appear plantigrade.

In selected cases, use serial short-leg casts to hold the foot in maximal plantar flexion and inversion (63,194,231,288). In 3–6 weeks, maximal stretching of the anterior compartment musculature and anterior ankle capsule is usually achieved. Yadav and Thomas (288) reported that six children with unilateral posteromedial bow of the tibia did well with serial casting, although one patient underwent an anterior soft-tissue release before initiation of casting. After complete correction has been obtained, passive exercises may be continued to maintain alignment. In severe cases, Tachdjian (288) recommended the use of night splints to hold the foot in plantar flexion and inversion. After 2–3 years of age, a University of California Biomechanics Laboratory or similar foot orthosis may be worn to support the plantigrade foot deformity. However, in view of the natural history and management of congenital bowing, the use of casts and orthoses is probably not indicated. Heyman and Herndon (135) initially thought that an orthosis was necessary to reduce the posterior thrust at the apex of the deformity during weight bearing. However, in their later report, they stated that the use of an orthosis was unnecessary (138).

Follow children with posteromedial angulation of the tibia and fibula with annual scanograms and bone-age determinations (10,118,200) (see Chapter 170 on leg-length inequality).

Operative Techniques
Typically, there are only two operative procedures utilized in this disorder:

- Osteotomy to correct severe or persistent angulation
- Equalization of lower-extremity length inequality

**Tibia and Fibula Osteotomy**
Osteotomy to correct posteroomedial bowing of the tibia is rarely indicated. If severe medial bowing persists after 3 or 4 years of age, corrective osteotomy may be considered. Bone healing is not a problem after a corrective osteotomy or a fracture because there is no underlying bone disorder affecting healing. Hofmann and Wenger (138) suggested corrective osteotomy in cases of severe bowing with progressive shortening during the first 5 years of life. They thought that an osteotomy would add length by correcting the deformity and realigning the physes perpendicular to the axis of weight bearing, stimulating growth. These concepts were not confirmed clinically. Osteotomy can realign the tibia, but it has a minimal effect on the ultimate lower-extremity length inequality. Kruda (165) reported that all three patients treated by corrective osteotomies had significant residual leg-length discrepancies.

**Leg-length Equalization**
Lower-extremity length discrepancy is the most common sequela of posteroomedial angulation of the tibia and fibula. Most affected children have enough inequality (2 cm) to require equalization. The procedure performed to equalize the leg length depends on the estimated tibial length inequality at maturity and the predicted normal height of the child (see Chapter 170).

**Conclusion**
In patients with posteroemedial angulation of the tibia, I prefer prolonged observation. Casting of the foot is rarely indicated, as the limitation of dorsiflexion is due primarily to the alignment of the ankle. This will correct with growth. The associated lower-extremity length inequality is followed by scanograms at 1- to 2-year intervals. An appropriately timed contralateral percutaneous proximal tibial and fibular epiphysiodesis is the procedure of choice for most patients. Leg-lengthening techniques are usually not necessary, unless the discrepancy is severe or the patient has short stature.

**CHAPTER REFERENCES**

INTRODUCTION

Limb-length discrepancy problems are challenging because growth complicates the longitudinal evaluation of each patient. Therefore, the orthopaedic surgeon must have an understanding of growth and the methods by which to analyze and predict future changes; this is particularly important before considering any surgery to correct limb-length discrepancy.

Human height is the combined total of limbs, pelvis, torso, and head. The limbs constitute approximately half of this total height, and they are the most kinetic component of the body during gait. Length abnormalities of the limbs have the potential to affect both height and efficiency of gait.

INCIDENCE

The incidence of limb-length discrepancy is relatively common. Reports have suggested some level of discrepancy in up to 70% of adult males (72). In a review of more than 100 Swedish laborers, 30% had a limb-length discrepancy of 1.0 to 1.5 cm, 4% had 2.0 to 2.5 cm, and 0.7% had more than a 2.5 cm discrepancy (33). Estimates are especially difficult in the changing pediatric population, but for individual congenital conditions, the incidence could be predicted more reliably.

NATURAL HISTORY

SPINE

Most important to the treating physician, as in many pediatric orthopaedic conditions, is the natural history of the condition. Parents are commonly concerned about the long-term effects of a limb-length discrepancy on the spine, but cause-and-effect relationships are unknown. Low back pain in the child is rare, even for a child with a limb-length discrepancy. Given the high rate of back pain in the normal adult population, we may assume that this rate of back pain must also exist for the same reasons in the population with limb-length discrepancies. Changes in adult spine radiographs, such as vertebral wedging and traction spurs, have been associated with limb-length differences of more than 9 mm, but these findings have not been correlated with symptoms (22, 26, 27, 79). Reviews of adults with minor discrepancies have suggested a relatively low association with low back pain (62, 77, 92). Other studies confirm that adult patients presenting with low back pain associated with limb-length discrepancy appear to have symptomatic relief after equalization surgery (71, 84).

An increased incidence of structural scoliosis over the general population is associated with limb-length discrepancies (66). However, the causative effects of one deformity on the other are unknown. Lumbar facet orientation does not correlate well with asymmetric changes in limb length (24). The direction of the curve is not always in the direction expected based on the limb-length difference (33). This makes it more difficult to postulate that the limb-length difference is the causative factor.

HIP

As limb-length discrepancy increases, so does the amount of uncoverage by the acetabulum of the high-side femoral head hip (59). Theoretically, this problem should result in force concentration on the lateral edge of the acetabulum, with resultant early arthritis. Gait lab studies, however, suggest the possibility that high-side hip forces may actually decrease during stance phase (13). Little long-term clinical information exists on the subject.

KNEE AND FOOT

Knee problems secondary to leg-length differences do not seem to be common in children. A report has been made of increased incidence of knee pain in athletes (47). The most common associated problem in the foot is equinus on the short side. When the problem is not followed closely, a contracture may result from years of compensation in this position.

GAIT

Children tend to be better able than adults to compensate for differences in limb length. Their increased joint flexibility and higher strength-to-weight ratio may result in adjustments that produce a smooth, even gait. With greater discrepancies between the two legs, compensation becomes more difficult. Coronal plane pelvic tilt may increase the energy consumption of gait.

Data from gait lab studies of children with length discrepancies have suggested a quite variable pattern of compensation among individuals (44, 51, 76). Those with less than 3% discrepancy do not require compensatory strategies. Compensation for greater discrepancies results in greater work and greater vertical displacement of the center of body mass. Each child applies compensatory mechanisms differently; the most common are walking with the short-side ankle in equinus or the long-side knee in flexion. Energy consumption studies have yet to be completed to confirm the meaning of these changes to gait efficiency.

GROWTH
LONGITUDINAL DATA

Growth of the limbs results from the combination of physeal new bone production and actual epiphyseal size increase. Epiphyseal size increase usually accounts for only about 5% of the total growth of the limb, but for calculation purposes, this increase is usually ignored (Fig. 170.1). The growth plates at the knee contribute the most to total limb length, whereas the distal tibial and proximal femoral physes add lesser amounts.

**Figure 170.1.** The distal femoral and proximal tibial physes contribute constant proportions to the growth of the leg. (From Moseley CF. Leg-Length Discrepancy. In: Morrissy RT, Weinstein SL, eds. Lovell & Winter's Pediatric Orthopaedics. Philadelphia: J.B. Lippincott, 1996:655, with permission.)

Difficulty with measurement has prevented us from understanding patterns of growth in the short term. One study suggests that children have week-to-week variability in limb growth, with pulsatile patterns of miniature growth spurts every 30 to 55 days, alternating with periods of slower growth (32). In the longer term, however, the growth pattern evens out.

Data for growth calculation have come mainly from two studies by Anderson and colleagues (4,6). In one, data were collected instantaneously on children between 5 years of age and maturity. In the other, a group was followed longitudinally until maturity. Their data were reported in tabular and graphic forms as total limb length as a function of skeletal age (Fig. 170.2). These were converted into the growth-remaining charts for the distal femur and proximal tibia (Fig. 170.3).

**Figure 170.2.** Graph of total limb length (femur plus tibia only) for boys. An individual boy may be plotted instantaneously and projected into the future based on his current situation. (From Anderson M, Messner MB, Green WT. Distribution of Lengths of the Normal Femur and Tibia in Children from One to Eighteen Years of Age. *J Bone Joint Surg* 1964;46A:1197, with permission.)

**Figure 170.3.** Green-Anderson growth-remaining graph for girls and boys. This plots the amount of remaining growth from each of the distal femoral and proximal tibial epiphyses as functions of the skeletal age. The mean is in the center, whereas one and two standard deviations in each direction are represented by the other lines. This enables the calculation of results if an epiphysiodesis is done. (From Anderson M, Green WT, Messner MB. Growth and Predictions of Growth in the Lower Extremities. *J Bone Joint Surg* 45A:1963, with permission.)

SKELETAL AGE

The study of limb-length discrepancy problems involves the interaction of patient age, maturity, and limb length. Growth rate is maximal at the time of birth, both in percentage gain and in absolute terms. The absolute rate of growth relative to chronologic years drops slightly between 3 years of age and the adolescent growth spurt. During the adolescent growth spurt, the absolute rate of growth increases. Cessation of growth occurs in boys at 16 to 17 years of age, and in girls at 14 to 15 years of age. When we compare different people, it becomes quickly evident that their times of maturation, as measured in chronologic years, vary considerably. One child who may appear to be tall may just be going through the process of maturation at an earlier time. In fact, this “temporarily” tall child may then end up shorter than a second child who, although shorter initially, matures at a later time as measured by chronologic age.

The best method we have to measure level of maturity appears to be radiographs of the bones. The standard radiograph has become the anteroposterior view of the left wrist, although other x-ray techniques are available (81). The skeletal age of a patient is defined as the age at which the general population, on average, reaches the same level of bony development as that patient. This skeletal age correlates more closely than chronological age with other signs of maturation, including menarche, secondary sexual characteristics, height, and limb length. Measurement of skeletal age with the anteroposterior view of the wrist, however, remains the weak point in predicting limb-length discrepancy, both because of reliability of readings and because of more variability in children with limb-length discrepancy (15,18).

For any large group of normal children at the same chronologic age, the average skeletal age should equal chronologic age. However, time of maturation varies greatly between people; thus, for any given child, the skeletal age does not necessarily equal the chronologic age. A child who matures earlier than his peers appears to go through a maturation spurt in which the skeletal age years are changing more quickly than the chronologic years. The other milestones of maturity (secondary sexual characteristics, menarche, and limb growth) are moving forward at a similar, early rate.

DIFFERENT GROWTH PATTERNS

Based on the change in discrepancy over time, Shapiro (74) has previously divided growth patterns in children with limb-length discrepancy into five types (Fig. 170.4).
Three phases are used to describe the change over time: In the initial phase, the discrepancy develops; in the middle phase, a pattern of difference is established during further growth; and the final phase is the period of time before growth cessation. Patient age is plotted against the limb-length discrepancy on a graph. By definition, the initial phase results in an increase in discrepancy. During the middle phase, the discrepancies are variable; some continue to increase (e.g., a traumatic physeal closure), whereas others plateau (e.g., a patient being treated for juvenile rheumatoid arthritis). The final phase is also variable in that a discrepancy may increase, plateau, or decrease. Again, conditions that cause permanent physeal damage tend to cause a steady increase in discrepancy, whereas other conditions are associated with a plateau in differences (e.g., improvement in functional level in a paralytic limb, as with a brace). The most common scenario for an actual decrease in limb-length discrepancy is that of a treated juvenile rheumatoid arthritis patient (75,88).

A discussion of patterns of change in limb-length discrepancy by Shapiro's technique are useful for large groups of patients, but it may be less useful for the individual patient. This is because patterns are plotted to age 13 rather than maturity, and the differences are related to chronologic age rather than the skeletal age. This technique also does not compare the pattern of the limb-length difference curve with the normal growth curve or take into account lengthening of either leg with growth, whether it is normal or not.

ANATOMIC SITES OF LENGTH INEQUALITY

The femur and tibia are not the only components of the limbs that make up the leg's effective length. Variable heights of the two sides of the pelvis and pelvic obliquity to the floor result in a functional difference in limb lengths. Scoliosis and hip abduction and adduction contractures are common situations in which resultant changes in the orientation of the pelvis to the ground create apparent changes in the limb length. The other commonly overlooked source of difference between limb lengths is the foot. Some loss of height may be expected from either varus or valgus collapse of the foot, and the operated hindfoot may lose a portion of its vertical height.

CAUSES OF LIMB-LENGTH DISCREPANCY

Limb-length discrepancy may be due to factors that change length directly or from an alteration in growth. Fractures, dislocations, and surgery are the only mechanisms by which length is changed acutely.

INHIBITION OF GROWTH

A physeal may be slowed by several mechanisms. The congenitally short limb is genetically programmed to be shorter via slower physeal growth. A growth plate injury may result in slowing or complete cessation of growth. External influences such as disuse, as may occur in polio or hemiplegia, may also cause slowing of growth. Experimental denervation of sciatic nerves in animal models suggest a slowed rate of maturation in denervated bone (29).

Congenital

Children with limbs of different lengths may be either hemihypertrophic or hemiatropic, although distinguishing between the two may be difficult (7). Typically, the shortening involves all parts of the involved limb. It is probably best to consider each limb as being genetically programmed at a different rate of growth. Plotting sequential growth on the straight-line graph should confirm this.

Congenitally short bones may occur in conjunction with anomalies of other bones or independently. The congenital short femur is considered to be a variant of proximal focal femoral deficiency (43). The spectrum of the presentation includes anterior cruciate ligament deficiency, absence of the fibula, progressive ankle valgus deformity, absence of the lateral ray or rays of the foot, and tarsal coalitions. Congenitally short tibiae are commonly associated with both posterior and anterior bowing deformities.

Trauma

Fractures through the growth plate tend to occur through the zone of hypertrophy. Fortunately, this weak area of the physes is not responsible for the continued generation of growth cells, which occurs closer to the epiphysis. Thus in the Salter-Harris classification of epiphyseal fracture type I and II injuries (see Chapter 164) tend not to result in long-term growth disturbances, with a few exceptions. The type V crush injury, however, may permanently damage cells at all levels of the physes. Type III and IV fractures do cross the growth zone of the physes; thus, they are most prone to formation of a bridge of bone or physeal closure. Anatomic reduction of type III and IV fractures helps prevent physeal abnormalities. When physeal bars form or partial closure occurs, angular malalignment occurs because of asymmetric involvement of the growth plate. Physeal closure has also been recognized as a complication of diaphyseal fractures of the ipsilateral limb (8).

Infection

Disturbance of growth from infections tends to have more severe results because of the young age at which this occurs. Direct invasion of the physeal cells occurs in hemogenous osteomyelitis, sometimes in conjunction with a septic joint. The bridges that result tend to be broader and more central than those that result from fractures, and thus, they are more difficult to resect successfully. A so-called sick physes may develop when an infection has a global effect on a physeal. The cellular effects of the infection on the physes then either slow the rate of growth or create a delayed complete or partial arrest. Meningococcemia is one of the more common infectious processes that create this delayed growth arrest.

Paralysis

The cause of limb-length differences in paralysis is not completely clear. Theories have included decreased blood flow, poor venous return, decreased neurogenic input to the physes, and disuse atrophy. Polio commonly results in significant differences in limb lengths. Hemiplegic cerebral palsy patients may have small differences in length, which seldom require surgical correction. Hemiplegic patients often appear to have more of a discrepancy because of asymmetric muscle tone and other joint contractures that result in pelvic obliquity.

Tumors

Tumors may directly invade the growth plate, having a destructive effect similar to infection. Abnormal cartilage emanating from the physeal cells may also disturb normal growth patterns. In enchondromatosis and Ollier's disease, abnormal physeal cells produce tumor cartilage rather than cartilage for longitudinal growth. Osteochondromata may have more of a mechanical effect on growth plates that may disturb growth, such as at the distal tibia. This is more commonly angular than longitudinal.
Avascular Necrosis

The proximal femur is the most common location for clinical problems arising secondary to avascular necrosis. Fortunately, the proximal femur is responsible for only about 15% of limb length. Clinical presentations include the treated developmental hip dislocation, traumatic hip dislocations and fractures, slipped capital femoral epiphysis, and Legg-Calvé-Perthes disease. A common situation with avascular necrosis of the proximal femur is a severe adduction contracture secondary to femoral head collapse. This results in a large apparent length discrepancy, which is actually due to a marked coronal plane pelvic obliquity.

STIMULATION OF GROWTH

A physis may be stimulated to increase growth by arteriovenous malformation, inflammation, fracture, and tumor. From a clinical standpoint, surgical creation of a situation that mimics these conditions has failed to provide reproducible increases in growth.

Tumor

Vascular malformations such as hemangiomias may result in growth stimulation, presumably via increased blood flow. Other nonvascular growths such as neurofibromatosis, fibrous dysplasia, and Wilms’ tumor may result in overgrowth, usually of focal areas of bones.

Fracture

Overgrowth from fractures commonly occurs in the femur in children younger than 10 years of age (2,34). Studies of the factors most responsible for femoral overgrowth have been contradictory (45,52,54,67). The proximal tibia also has a tendency toward overgrowth following fracture (52,67). If the fibula is not also fractured, a relative increase in tibial length results in progressive valgus deformity at the knee.

Inflammation

Infection may damage the growth plate, but in some cases, chronic osteomyelitis may actually result in physeal stimulation. Another common example is pauciarticular juvenile rheumatoid arthritis, in which overgrowth of the involved limb is common, particularly before 3 years of age (75,86).

EVALUATION

CLINICAL EXAMINATION

The physical exam remains the central tool for clinical assessment in limb-length differences. Physicians may tend to focus on radiographic findings; however, radiographic methods can have inherent artifacts from patient movement or from poor conversion of an angular deformity to two-plane measurement. In addition, many other clinical factors not measured by radiographs are important in making treatment decisions. Once the complete historical and physical evidence has been obtained, radiographs may be used to fine-tune data and to follow the condition precisely.

The most useful clinical tool is to place blocks beneath the foot of the short side of the patient in the standing position. The height can be adjusted until the pelvis is level, as judged by the anterior superior iliac spines from the front or the posterior iliac crests from the back (Fig. 170.5). This technique is generally the most reliable and provides the most comprehensive information, because it allows the clinician to take into account pelvic obliquity, contractures, angular deformities, and differences in foot height. To use the technique even more effectively, shoe lifts of variable heights may be used; this allows evaluation of gait and dynamic events, with partial to complete correction of differences (Fig. 170.17).

Figure 170.5. The standing technique of limb-length measurement is done with the patient standing on blocks on the short side until the anterior superior iliac spines are at the same level. It may also be visualized from behind the patient, using the top of the iliac crests as the measure of level.

Figure 170.17. Variable sizes of lifts are attached to the bottom of the shoe with hook-and-pile strips. These allow trials of differing amounts, which are particularly helpful in deciding how much to shorten a limb.

A traditional method of determining the limb length has been to measure from the anterior superior iliac spine to the medial malleolus, in the supine or standing position, using a tape measure. (Fig. 170.6). This method has some value, but reproducibility may be poor because of poorly palpable landmarks, tenting of the tape, angular deformity at the knee, and differences in the height of the pelvis (49). In addition, this measurement does not take into account angular deformity (i.e., obliquity) about the pelvis.
The supine technique of limb-length measurement is done with the tape measure from the anterior superior iliac spine to the medial malleolus with the knee straight. Because of difficulties in reproducing accurate measurements, the standing technique is generally preferred.

RADIOGRAPHIC EVALUATION

Scanogram

Radiographic techniques may be inherently more accurate than clinical methods in measuring limb lengths, and thus, they may be more valuable over the long term for evaluating growth trends. All of the radiographic techniques used have variability between readings because of differences in technician techniques, changes in patient position, and differences in techniques and landmarks of people reading the films. The orthopaedic surgeon must review all of the data derived from radiographs before considering surgery, check for consistency, and correlate the data with clinical findings.

Confusion exists over the terminology used for radiographic measurement techniques. The original scanogram was done with a collimated x-ray beam directed through a transverse slit that exposed a film beneath the patient as the x-ray tube was moved from one end of the limb to the other. The teleoradiograph is a single-exposure x-ray shot from a 2 m (6 ft) distance with a radiopaque ruler placed on the film cassette. It can reveal an angular deformity but has the disadvantage of increasing distortion through parallax of the x-ray beam (Fig. 170.7). The orthoradiograph avoids the parallax problem by taking three separate exposures on the same ruled cassette. Like the teleoradiograph, the large film size can be cumbersome (Fig. 170.8). The current scanogram technique uses three exposures, but the cassette is moved beneath the patient between each image. The ruler must be fixed to the x-ray table, which is not a necessity with the single exposure techniques (Fig. 170.9). The patient must be able to remain still between exposures with the teleoradiograph and the scanogram. For children younger than 5 or 6 years of age, the teleoradiograph is more appropriate.

The current standard of radiographic assessment for most situations is the scanogram. The images are captured on one film of relatively convenient size. As long as the patient does not move between exposures and no joint contractures are present, this provides an accurate and relatively reproducible methodology (3,29). When knee contractures are present, the bones may be measured individually by placing the patient prone for a ruled radiograph of the femur, and in the lateral position for the film of the tibia.
The scanogram is most ideally taken with the patient semierect, with the short side blocked up beneath the foot to level the pelvis. Separate images are then taken of the hips, knees, and ankles, including the plantar portion of the foot (Fig. 170.10). The semierect position has the advantage of mimicking the upright weight-bearing position, leveling the pelvis for more accurate measurement, limiting patient motion between exposures, and allowing evaluation of the contribution of the foot to the discrepancy. The only disadvantage is that a tilting x-ray table is required.

**Figure 170.10.** The semierect scanogram method. The tilt table allows for placement of lifts for leveling the pelvis, and will give more accurate information about joint and length changes with weight bearing. The three images of the hips, knees, and ankles are taken in the same way as with the supine technique shown in Figure 170.7.

The standard landmarks used from the orthoroentgenogram are the tops of the femoral head and the middle of the “saddle” formed by the subchondral bone of the distal tibial plafond. If separation into femoral and tibial components is required, use the medial femoral condyle. Then draw a horizontal line from the chosen points to the ruled area on the film. Each of these lines should be parallel to the edge of the film. (This assumes that the edge of the cassette is close to being perpendicular to the orientation of the leg.) By subtracting these numbers, the lengths of both legs and the femoral and tibial components may be calculated (Fig. 170.11).

**Figure 170.11.** Sample orthoroentgenogram. Results may be analyzed on one film of convenient size, but this film does not allow accurate calculation of mechanical or anatomical axis.

**Other Methods**

The computerized axial tomogram may be used in place of the orthoroentgenogram. It offers the advantage of being more accurate and delivering less radiation, but for many centers, the technique is more cumbersome and it is expensive to obtain (1,36). A decision should be made on the basis of cost and availability because the accuracy of the two techniques appears to be comparable.

Recently, real-time ultrasonography has been reported as an effective screening tool, although slightly less accurate than radiography, for limb-length determination (42,82).

**Skeletal Age**

Determining skeletal age is done by comparing radiographic landmarks of maturity with standards. The Greulich-Pyle atlas is the most commonly used standard today (30). The left hand and wrist are imaged in the anteroposterior plane; separate standards are used for boys and girls. The standard radiograph in the atlas represents the median level of bony maturity for the chronologic age. Given a random sampling of children at the same chronologic age, half of the left hand and wrist radiographs would appear more mature and half would appear less mature than the standard. For any given child, then, the skeletal age is that which corresponds with the best radiographic match from the atlas (Fig. 170.12).

**Figure 170.12.** Left hand and wrist anteroposterior radiograph taken for bone age estimation.

Unfortunately, the skeletal age determination is the weakest link in the process of limb-length calculations. Differences between children in the order of bone maturation around the wrist, extrapolation between ages in the atlas, and congenital anomalies of wrist bones may result in different interpretations of the radiograph for skeletal age (15,18). Other methods have been used to determine skeletal age and are probably more exacting, but they are also more cumbersome. In addition, all of the predictive growth data derived by Green and Anderson are based on the Greulich-Pyle atlas. Other methods of skeletal age determination do not necessarily correlate with the Greulich-Pyle skeletal age and, thus, should not be used with Green and Anderson’s data for surgical calculations.

**ANALYZING THE DATA**

After skeletal maturity, limb-length differences do not change without surgical intervention. The growing child, on the other hand, is continuously changing. The goal of the orthopaedic surgeon must be to predict the situation at maturity. In most cases, this means analyzing the data from a young age to predict the limb-length difference at maturity. Treatment should be based on this prediction, so careful analysis of the data is crucial (10). At present, three general methods are used widely...
for data analysis—the arithmetic method, the growth-remaining method, and the straight-line graph method. They all use roughly the same steps of analysis but with different techniques. The first step is evaluation of past growth, the second step is prediction of future growth, and the third step is evaluation of what the results of surgical correction would be.

**Arithmetic Method**

The arithmetic method is based on the following assumptions of growth patterns (*Fig. 170.13*):

- Girls stop growing at chronologic age 14.
- Boys stop growing at chronologic age 16.
- The distal femur grows at a rate of $\frac{3}{8}$ inch (10 mm) per year.
- The proximal tibia grows at a rate of $\frac{1}{4}$ inch (6 mm) per year.

This technique is convenient but has some inherent inaccuracies. The estimations of growth are most accurate during the last few years of growth, but are relatively inaccurate in younger children. In addition, the chronologic age is the basis for the measurements and determinations. As discussed earlier, the patient's chronologic age and bone age may vary considerably, but the bone age is a more reliable indicator of skeletal maturity for individual patients.

This technique should be used as a tool for estimation well before surgery is being considered. As the time for surgery nears, other, more precise methods should be used to minimize errors and make correction as exacting as possible.

**Growth-Remaining Method**

The growth-remaining method is based on the data and tables of Green and Anderson (*4, 5*). The percentage of growth inhibition of the short leg is first calculated. Using these data, the lengths of long and short legs at maturity can be predicted. The graphs of the growth remaining from the distal femoral and proximal tibial physes are used to determine appropriate times for epiphysiodesis (*Fig. 170.14*).

**Straight-Line Graph Method**

The straight-line graph method was conceived as a way of graphically representing the growth of the two limbs (*6, 7*). It incorporates the data of Green and Anderson (*5*), and is used as a method of recording, analyzing, and predicting both growth and the results of treatment. The method is based on two principles: First, the growth of each leg can be graphically represented as a straight line, and second, a nomogram can be used to determine the growth percentile, based on skeletal age and limb length (*Fig. 170.15*).

Green and Anderson's graphs have a curved pattern at each end, representing the high rate of growth during infancy and the slowing rate before skeletal maturity. By
manipulation of the scale of the x-axis at each end of the growth curve, the length of the limb can be graphically represented as a straight line. The long limb is thus assigned the graphic slope of 1.00, representing 100% of normal growth. If no variable disease process or treatment is changing the short limb, it will also follow a straight line on the graph over time. The discrepancy between the two limbs is thus represented by the vertical distance between the two growth lines, and the inhibition by the difference in the lines’ slopes.

The nomogram for skeletal age has been set up on the graph to allow the long limb length to be compared with that of the Green-anderson population. If a child grew such that the bone age and limb lengths progressed together exactly as the Green and Anderson data would suggest, the points on the nomogram would describe a perfect horizontal line. This rarely happens, both because of the inherent differences in the reading of bone ages and differences in growth of individual children. As an increasing number of estimates of bone age are obtained, these differences tend to diminish such that a more accurate best horizontal line estimate through the points can be obtained. Generally, heavier weighting is given to the most recent bone age readings when making a best horizontal line estimate.

Predictions of surgical results may be made with the graph as well. Changes in the growth rate of either leg result in a change in slope of the line representing that leg. Lengthening a limb results in simple upward vertical displacement of the line; shortening results in downward vertical displacement. When an epiphysiodesis is performed on a long limb, the slope of the line representing that leg decreases by an exact amount. This is because each epiphysis contributes a known amount to the length of the leg. Reference slopes placed on the graph include slopes of lines representing a normal (long) limb after proximal tibial epiphysiodesis, after distal femoral epiphysiodesis, and after both epiphysiodeses done simultaneously. Figure 170.16 shows a sample calculation using the straight-line graph.

Note that with the straight-line graph, the left edge represents the time of birth, and the long limb begins at 35 cm, not zero. If calculations depend on inhibition from the time of conception (such as congenitally short limbs), the long limb and the short-limb lines will converge off the graph to the left, where the limb length is zero. If the growth inhibition begins at a later date after birth (such as early physeseal closure from infection), then convergence of lines will occur at a later date on the graph.

This technique uses skeletal age for determination, takes into account growth percentile in prediction of future growth and results of surgery, decreases the inherent error of single skeletal age measurements, eliminates the need for cumbersome arithmetic, and spots values that appear to be out of line with others in longitudinal assessment. It also allows all data to be accumulated sequentially at a single place in the medical record.

Other Techniques

Recently, two additional graphic techniques have been described for limb-length inequality evaluation. One is based on data from Dutch children between 1979 and 1994. It suggests that children today have longer bones than the children in the study of Green and Anderson from the 1940s and 1950s (6). The technique uses principles similar to those of the straight-line graph. In the second technique, a graphic display is made based on plotting limb-length discrepancy versus chronologic age. This is a graphic variation of the arithmetic technique (21).

EVALUATION OF EFFICACY

In evaluating the various techniques used to assess limb-length discrepancy, studies vary with respect to interpretation of success. Theoretically, the Green and Anderson method and the straight-line graph methods should give the same prediction because they are derived from the same growth data. General success has been reported with both of these methods (19,48,61,69,78). Another recent review reported disappointing results with all three commonly used methods (50). Continued study and refinement are needed.

TREATMENT

GOALS

The goal in treatment of a patient with a limb-length discrepancy is based on a thorough assessment of the patient's problems, both clinically and radiographically. Each patient may have differing goals, reflecting a unique combination of associated problems. In general, it is best to consider correcting coexisting conditions before addressing the limb-length difference. Correcting a spinal deformity affects pelvic obliquity. Correcting angular deformity in the lower limb, whether it is at the level of a malunion or a contracture at a joint, usually has the effect of lengthening that limb.

Ideally, correction would result in limbs of exactly the same length, but this may not always be the best goal. In the patient with polio residuals, it is usually desirable to leave a weak extremity slightly short, which allows it to function better in the swing phase of gait. In the neuromuscularly normal child, it is best to plan for a limb-length difference of between 5 mm and 1 cm at maturity when considering epiphysiodesis. This allows for slight changes in growth patterns after the epiphysiodesis and inaccuracies in the preoperative assessment while not compromising adult height any more than necessary.

Many factors will influence the decision on the exact level in the limb at which to correct a discrepancy. The ideal situation would be to lengthen the short bone or shorten the long bone to a normal length. A general goal is to keep the legs symmetric so that knee height is equal. However, in some cases, a well-timed epiphysiodesis at one level (for instance, the distal femur) will eliminate the need for a later procedure involving two growth plates (distal femur and proximal tibia), even though it may leave the knee heights at slightly different levels. During lengthening procedures, this may be of even more concern, because differences made up are often greater than with epiphysiodesis. If lengthening is proceeding well, it may be more desirable to continue lengthening the segment past the predicted length at maturity of that segment on the opposite side so as to avoid the necessity of another segment lengthening as well. Asymmetry of knee height is generally of little functional significance but is of some cosmetic concern.

Much of the prior discussion of the workup and assessment of limb-length discrepancy has focused on the magnitude of discrepancy at maturity. This is because the predicted amount of difference at maturity helps determine the exact amount to correct and the treatment group likely to be best for equalization. These treatment groups with their suggested approaches, given a normal height range, are as follows:

- Difference of 0 to 2 cm: no treatment
- Difference of 2 to 6 cm: shoe lift, epiphysiodesis, shortening
- Difference of 4 to 15 cm: lengthening procedure
- Difference of more than 15 cm: prostatic fitting

Discrepancies of less than 2 cm, although quite common, do not have functional significance for the majority of adults of normal stature, and therefore do not need treatment (31,72). For those patients who feel unbalanced, a shoe lift can be tried.

In the 2 to 6 cm range, shortening procedures are generally the first choice for treatment. For greater levels of discrepancy, shortening procedures are usually not considered because of disproportionate appearance in the shortened segment and loss of stature. Also, if the limb is shortened acutely, the normal-sized muscle-tendon units also have difficulty adapting to the shortened bone, and consequently they become weaker. Correction of a difference of greater than 6 cm with...
epiphysiodesis may be considered when the long limb is clearly the abnormal side, because loss of stature and disproportionate appearance are not a concern.

For discrepancies of more than 4 cm, lengthening may be considered. In the 4 to 6 cm range, patient and family preference may be taken into consideration as the complications and long-term goals of lengthening versus shortening are weighed. For discrepancies greater than 6 cm, lengthening becomes the preferred treatment option. The total length possible from a single osteotomy procedure is variable. Generally the maximum length attainable at a single lengthening is 20% of the bone's length. Thus, if both the femur and tibia are lengthened (usually done in a staged manner), this may total more than 15 cm length gained. A complete assessment of patient needs and psychosocial situation are crucial before beginning any lengthening procedure, but the entire lengthening team must pay particularly close attention to these factors for the longer lengthenings. Consideration can be given to staged lengthenings of the same bones, spaced apart by several years for joint and soft-tissue recovery. An epiphysiodesis may also be used in combination with an opposite-side lengthening procedure as a method of limiting the amount of length required.

For discrepancies of more than 15 cm, or 20% of limb length, prosthetic fitting is the usual choice of treatment. Often, this is combined with an amputation, fusion of a joint, or rotationplasty for more functional prosthetic wear. Common clinical situations include the severe end of the spectrum of fibular hemimelia and proximal focal femoral deficiency. In many cases, discussion with the family centers on how quickly the child can return to normal function. The prosthetic option often allows a relatively fast return to a high functional level. If a lengthening device is used, much more time is required to attain the same functional level as that using a prosthetic device.

Shoe Lift
In a discrepancy of 2 to 5 cm, a shoe lift may be an acceptable method of treatment, particularly when the patient will not consider or is not an appropriate candidate for surgery. A lift becomes more unwieldy and thus a less viable alternative as more height is added. The weight of the lift and ankle instability are the chief problems with larger lifts. In addition, patients find them cosmetically unappealing. Lifts can be used as a trial in the preoperative period to determine the most comfortable or functional amount of lengthening or shortening (Fig. 170.17).

Limb Shortening
Epiphysiodesis
Epiphysiodesis slows the rate of growth of the long limb to allow the short side to catch up. It is simple, effective, and predictable; is done in one stage; and has a low complication rate. It is the usual procedure of choice when predicted discrepancy at maturity is 2 to 6 cm. When the procedure is completed, the growth at that physis is assumed to be completely stopped. Loss of percentage contribution to limb length will be 38% for the distal femur, 27% for the proximal tibia, and 65% for the two combined. The distal tibia contributes 18% of leg length and occasionally is also considered for closure. The exact amount of shortening desired can be achieved only by completing the epiphysiodesis at exactly the correct time. Usually, this choice of timing comes down to three different options that correspond to the surgical site: femur only, tibia only, or both femur and tibia. Because proper timing is so important, close preoperative follow-up of patients is necessary for prediction of growth. In one review of 67 epiphysiodeses, more than half were deemed failures due solely to improper interpretation of growth data.

Many techniques of epiphysiodesis have been used. The goal of all of them is production of symmetric physal closure to prevent future growth. The traditional Phemister technique uses removal of a rectangular block of bone medially and laterally at the level of the physis that is then replaced in a 18° rotated position (Fig. 170.18). The rectangular window is also used to remove remaining bits of physal with a curet. White and Stubbs (63) described removal of a square block at the level of the lateral physal, which is then rotated 90° and replaced. Epiphysiodesis by stapling was originally thought to be a good technique to stop physal growth temporarily, but problems developed with asymmetric and complete physal closure; thus it should be considered a permanent form of growth arrest. Stapling has fallen out of favor but may be appropriate in less developed areas of the world without routine access to fluoroscopy.

We recommend use of the percutaneous technique for most cases.

- Make longitudinal incisions medially and laterally. Use separate incisions for both the femur and tibia as necessary. If the tibia has been chosen, make an incision posterolaterally as well as laterally for the fibula. Incisions can be limited to approximately 1 cm in length or may be made longer if a rotated block is to be used.
- Under image control use a 2 mm wide curet to locate the medial and lateral borders of the physal. Then bore the curet into the physal both medially and laterally, using a turning motion with the curet. Sweeping from anteriorly to posteriorly with the curet scrambles the physal cartilage.
- The lateral side of the femur and tibia can be completed through lateral incisions, and the medial side can be completed through the medial incisions. The curet tip can be crossed to the opposite side of the bone to allow more surface area to be reached. Close 50% to 75% of the area of the growth plate using this method. The remaining amount ensures that strength remains for ambulation without immobilization.
- Complete the approach to the physis in the same manner, but with a wide enough exposure to allow direct visualization of the edge of the physal. This extra exposure allows the common peroneal nerve to be protected.
- The technique can be modified slightly in the femur and tibia by using a power drill to complete the physal closure. A drill bit or straight Steinmann pin with a slightly bent tip damages the growth plate enough to cause closure.

Follow-up care involves the use of a compressive bandage until the wound is healed. Allow the patient to have full range of motion about the knee postoperatively and to bear weight as tolerated with the aid of crutches. A knee immobilizer may be added for 2 to 3 weeks for pain relief. Full activities can usually be resumed in 6 to 8 weeks. Bony fusion across the physal occurs within 8 weeks.

Epiphysiodesis is a mainstay in the treatment of limb-length discrepancies. However, it is compensatory in that a normal leg is made abnormal and usually involves decreasing the patient's stature. For these reasons, other procedures are also considered.

Acute Shortening Procedures
Shortening procedures are considered for patients with the same amounts of discrepancy as those for epiphysiodesis but who are too old for full correction with physal closure. In the patient who has matured, it has a distinct advantage in that the exact amount of discrepancy is known and no future growth predictions are necessary. In general, femoral shortening is preferred to tibial shortening. The amount of shortening tolerable in the femur is approximately 5 cm. Greater shortening results in ineffective recovery of muscle-tendon units. The tibia may also be shortened but to a lesser degree. Maximum shortening in the tibia should be 3 cm because of shorter muscle-tendon unit lengths. Also, tibial shortening by intramedullary technique is less feasible because the bone is subcutaneous. Thus, the femur is strongly preferred.

In the past, femoral shortening used step-cut osteotomies with interfragmentary screws for fixation, but better implants have made these procedures obsolete. Current techniques include open shortening with plate fixation or proximal femoral shortening with blade plate fixation. The plating technique offers the advantage of ease of fixation but requires hardware removal and may result in scarring and stiffness of the quadriceps mechanism. Blade plate fixation offers the advantage of being
proximal to most of the quadriceps origin but has the disadvantage of a more involved operation.

More recently, closed femoral shortening has become popular (11,12). A standard closed intramedullary femoral nailing technique is used with the addition of a special eccentric canal saw. See Chapter 30 and Chapter 174 for more details. The intramedullary saw is used to make two transverse cuts in the femur. The segment of bone is then split vertically and then displaced to the sides, and the femur is then shortened over an intramedullary femoral nail and locked proximally and distally. The technique is demanding technically and requires experience with closed intramedullary nailing techniques. Malrotation can be a problem; assess this before awakening the patient. In children, the nail is removed after complete healing has occurred. The procedure is cosmetic and allows secure intramedullary fixation with its inherent healing capabilities. Implant removal is less involved than plating techniques. However, this procedure causes temporary quadriceps weakness similar to that of femoral plating. Complications in the young patient have been reported, including intraoperative or postoperative fat embolus syndrome; one center reported that 4 out of 100 patients had this complication (63).

**Growth Stimulation**

Multiple techniques for stimulation of the short extremity have been tried, including electrical stimulation, sympathectomy, surgical construction of arteriovenous fistulae, placement of foreign bodies next to the physis, and packing bone beneath the periosteum near the physis. None of these techniques have produced reproducible or clinically significant results. At present, growth stimulation through the physis is not a realistic option.

**Limb Lengthening**

Lengthening the short limb initially appears to be the most desirable approach because it allows correction of the abnormal extremity to a normal length while not changing the normal limb. However, lengthening is generally reserved for those patients with the most severe deformities. This is because lengthening techniques are associated with multiple complications and a prolonged treatment time.

Usually, the patient who is considered for lengthening has a projected discrepancy of between 4 and 20 cm. Relatively stable joints above and below the level to be lengthened are a prerequisite. Rotational or angular malalignment usually decreases the total length attainable through lengthening procedures. The patient should be emotionally mature. The youngest child we generally consider for a lengthening is 8 to 9 years of age so that the patient can cooperate with physical therapy. Occasionally, a younger child is considered for lengthening when two different stages of lengthening are required. A decision is made preoperatively for a target goal of length.

Lengthening procedures have been widely used in the past with varying degrees of success, as described by Codivilla (17), Millis and Hall (57), Anderson and colleagues (5,6), Wagner (67,88), Ilizarov and colleagues (67,88,39), Wasserstein and colleagues (69), Monticelli and Spinelli (68), and Paley (64). Specific techniques are described in Chapter 32 and Chapter 37.

The use of the ring fixator with thin wires, as described by Ilizarov, has focused interest on the biology of lengthening. Lengthening success has been clearly related to the emphasis on the exact rate of small incremental growth of bone. Others have modified the technique of using only thin wires by adding thicker half pins for stability (16). In addition, lengthening with the uniplane frame over an intramedullary nail, which allows significantly reduced external fixator time, is gaining popularity (65). The uniplane frame alone also has a place in pure length correction when angular correction at the same time is not needed. In all of these techniques, the rate of lengthening should be the same whichever external frame is used because the recent successes have been based on a biology that is highly dependent on technique.

The biology of osteogenesis during distraction begins in the intramedullary area as multipotential cells differentiate into osteoblasts. Their bone formation resembles intramembranous growth because no cartilage matrix is laid down. Cells appear to lay down in a longitudinal direction of the retreating bone end (49). Patients are allowed to bear weight fully immediately postoperatively and participate vigorously in exercise to prevent joint contractures.

One of the most difficult decisions after bone is lengthened is when to remove the fixator. The actual length of time that the fixator is left on will vary because the amount of length gained and the bone quality laid down differs among patients.

There are several complications that result from lengthening techniques. Most series have reported more than one major complication per patient. Pin-track infection or inflammation is almost universally expected. Joint contractures are a persistent problem as well, particularly flexion or extension contracture of the knee and equinus position of the ankle. Joint subluxation or dislocation at the hip or knee are relatively common complications (41,60). In addition, nonunion, malunion, and device failures have been reported.

Growth after lengthening is completely removed. One review suggested normal or even accelerated growth after moderate external fixator frame lengthening, whereas longer amounts of time and length may actually diminish later growth (70).

**Prosthetic Fitting**

Prosthetic fitting generally is the least desirable form of treatment, but it may be the best choice when a large discrepancy or severe deformity exists. When predicted discrepancy at maturity exceeds 15 to 20 cm, or 20% of the long side, this approach should be considered. A single operation can be performed during one hospitalization, so that multiple procedures during one hospitalization can be avoided.

A typical patient with fibular hemimelia, either with or without associated femoral shortening, has a large predicted discrepancy at maturity as well as progressive valgus in the foot. A Syme amputation followed by prosthetic fitting results in a functional below-knee amputation that results in a near-normal gait and activity level. This procedure is best performed when the child is younger than 1 year old. Waiting until a later age often results in a great emotional attachment of the family and the patient to saving the foot.

For the patient who has severe proximal focal femoral deficiency, Syme amputation with or without a knee fusion may be the best option. This is followed with fitting for the patient. In children, the nail is removed after complete healing has occurred. The procedure is cosmetic and allows secure intramedullary fixation with its inherent healing capabilities. Implant removal is less involved than plating techniques. However, this procedure causes temporary quadriceps weakness similar to that of femoral plating. Complications in the young patient have been reported, including intraoperative or postoperative fat embolus syndrome; one center reported that 4 out of 100 patients had this complication (63).

Over the past decade, external fixation has gained increasing acceptance as a surgical technique in children. The most common applications include incidences of trauma, correction of limb deformity, and limb-length equalization.

The numerous fixators available fall into two general categories: circular fixators and cantilever external fixators. Biomechanical studies have demonstrated that bone formation is enhanced by cyclic axial micromotion and, perhaps, by limited-bending micromotion (23). Torsion, on the other hand, is generally deleterious to bone formation. The Ilizarov-type of circular external fixator, which is less stable to axial loading than are most cantilever systems but relatively resistant to torsion, provides an excellent biomechanical environment for bone formation (42).

Another advantage of circular external fixation is that it is applicable to patients of virtually any size from toddler to large child, obese adolescent, or adult. The system provides three-dimensional adjustability, allowing angulation, translation, rotation, and lengthening when necessary. The Taylor Spatial Frame (5) now allows these parameters to be corrected simultaneously but currently has some ring-size limitations (Fig. 171.1). The traditional Ilizarov external fixator can be constructed with hinges to correct existing limb deformity (Fig. 171.2). Circular external fixation can be used to span adjacent limb segments, to protect potentially unstable joints, or to treat joint contractures (Fig. 171.3).

Figure 171.1. The Taylor Spatial frame allows simultaneous correction of angulation, rotation, length, and translation through the use of six struts and universal ball joints.

Figure 171.2. Preconstructed Ilizarov tibial fixator mimics the deformity and allows gradual correction through hinges placed at the level of the deformity.

Figure 171.3. A: Preoperative photograph of a 3-year-old patient with arthrogryposis and a nearly 90° flexion deformity of the knee. B: Appearance of Ilizarov fixator affixed to the femur and tibia, spanning the knee joint with corrective hinges.
The disadvantages of the traditional circular external fixator are its bulk, the fact that it is difficult to apply and adjust, and that it requires multiple sites for transfixed wires. The traditional Ilizarov external fixator uses 1.5 or 1.6 mm transfixed tensioned wires for bone fixation, with half-pin fixation in the proximal femur. Over the last 5 to 6 years, a number of surgeons have modified the originally described techniques, substituting half-pins for some of the wires. Specifically, in children, the traditional "medial face" tibial wire (parallel to the medial face of the tibia) has been eliminated in favor of an anteroposterior directed half-pin. Affixing half-pins to a circular fixator permits 360° adjustability at the same time it avoids some of the soft-tissue problems of transfixed wires.

Unilateral external fixators by contrast are easy to apply, require a limited number of pin sites, and are less bulky (33). They are applied to only one side of the limb and require usually no more than four to six half-pins per limb segment depending on the type of application. Cantilever systems have some disadvantages. They can be used only on limbs of a certain size, they have less stability to shear stress than circular fixators, they cannot span joints easily, and their ability to correct angulation, rotation, and translation gradually is limited. With many current systems, significant adjustments such as device and pin clamp exchange must be made under general anesthesia. Some systems, including the Heidelberg (5), Orthofix (5), and EBI (5) systems, have gradual but limited correction capabilities.

In this chapter, I provide specific application recommendations. I have had more than a decade of experience with both types of devices. The Ilizarov type of fixator remains the more versatile device, but patient acceptance and comfort clearly favor the monolateral fixator.

LARGE PIN AND CANTILEVER SYSTEMS

A number of cantilever devices are available in North America for trauma or limb reconstruction applications, including the Orthofix device (Orthofix, Winston-Salem, NC), EBI Dynafix (EBI Corp., Parsippany, NJ), Smith and Nephew Heidelberg fixator (Smith and Nephew, Memphis, TN), the Hex-Fix (Smith and Nephew, Memphis, TN), and the Synthes External Fixator (Synthes USA, Philadelphia, PA). In each case, application requires pin clamps or pin clamp templates through which half-pins are inserted. The choice of fixator is usually determined by the problem to be addressed and size of the patient. The most commonly used limb reconstruction systems are the Orthofix and EBI, with the Heidelberg system having been recently introduced. These fixators are lightweight devices with the ability to telescope. The technique for insertion of the half-pins, and application of these types of fixators is discussed in detail in Chapter 11 and specifically for the tibia in Chapter 24.

ORTHOFIX UNIT

The Orthofix, available in pediatric and adult sizes, has variable body lengths (Fig. 171.4). The short or standard length devices are used most often on children. Orthofix has two articulating ball joints and uses tapered predrilled half-pin fixation. The telescoping body can be unlocked once fracture or osteotomy callus formation is evident radiographically. This capacity theoretically allows axial loading or dynamization of the bone facilitating callus formation and bone healing. The standard articulated device is used for fracture management and osteotomies (16,35,40,50,53). Its ball-and-joint articulation permits approximately 30° to 35° of angulation; it can be freely rotated.

Use the straight slide-type device or LRS (5) (Limb Reconstruction System) for lengthening (Fig. 171.5). It allows placement of more than two pin clamps when necessary for situations such as bone transport. A swivel clamp can be substituted for straight clamps at one or both ends of the bone (Fig. 171.6); this technique may be useful for bifocal osteotomies with acute deformity correction or to eliminate deformity that may develop during lengthening. A variety of angulation and rotation template clamps are now available for more accurate multiplanar corrections (Fig. 171.7). Do not use the standard swivel clamps for lengthening; they are less stable than the standard pin clamps. With either the standard articulated body fixator or LRS, insert tapered predrilled half-pins through the clamp templates. Then replace the template with the standard pin clamps and tighten them. For fractures and osteotomies, generally two half-pins above and below the fracture or osteotomy are adequate. The widest pin spread in the clamp provides the best stability. For limb lengthening, use three pins proximal to the lengthening site in the femur and tibia. Two or three are adequate distally, depending on the size of the patient and amount of anticipated lengthening (Fig. 171.8) (1,22,25,46,47,48).

Figure 171.4: Several lengths of the Orthofix pediatric (top two) and adult (bottom 3) fixators are available.

Figure 171.5: A: Orthofix LRS slide lengtheners are available in various lengths, as well as pediatric and adult sizes for limb lengthening. B: Template clamps are placed directly on the lengthening device for parallel pin placement. C: LRS system with pin clamps in place and distraction device above the fixator.

Figure 171.6: Swivel template clamps and swivel pin clamps are available for angular correction.
A new rotation template clamp is now available to allow accurate planning and pin insertion for acute rotational corrections. The new angulation template clamp can be affixed to the end of the slide for planned acute angular correction 90° orthogonal to the plane of the swivel clamp.

Clinical appearance of a patient with Ollier's disease after tibial lengthening with residual varus deformity of the femur and shortening. AP and lateral radiographs following application of LRS system and acute correction of femoral deformity. Clinical and radiographic appearance at the conclusion of lengthening and bone consolidation.

The T-Garches device (Orthofix) is useful for gradual correction of frontal plane deformity in the tibia—for example, in adolescent Blount's disease. Small lengthenings can also be achieved with this device. A new template clamp allows correction of acute sagittal plane deformity before application of the device following osteotomy. It is not recommended for large lengthenings; the hinge may not withstand large lengthening forces, and the device, for the most part, accommodates only two proximal tibial pins.

The T-Garches external fixator is ideal for correction of proximal tibial frontal plane deformity. Clinical and radiographic appearance of a 12-year-old boy with adolescent Blount's disease and varus deformity of both the tibia and the femur. Radiographic appearance following osteotomy of the femur and tibia, and application of an Orthofix external fixator to the femur and T-Garches external fixator to the tibia. Radiograph following fixator removal with restoration of normal limb mechanical axis.

The new T-Garches template clamp allows accurate pin placement for simultaneous sagittal and frontal plane deformity correction.

Only two pins can be placed in the proximal T-Garches fixator. This potentially limits its use, particularly for significant lengthenings.
In applying the LRS systems, standard ball-joint fixators, and the T-Garches, it is important to note the length of the device and the pin spread for the particular application. Be certain, for example, in a limb lengthening, that the device is long enough. At least 10% extra length is needed for the tibia and 20% for the femur. The bone-to-fixator distance is relatively large, particularly in the femur. Thus, there is not always a 1:1 ratio between the amount of lengthening the device can achieve (i.e., number of turns) and the actual distraction achieved in the limb. Start with some extra length in the device to avoid running out of space.

ORTHOFIX TECHNIQUE FOR FRACTURE AND OSTEOTOMIES

- In the case of fracture reduction or osteotomy, anticipate whether the device will need to be lengthened or shortened to achieve the correct bone position before determining pin placement. Add a supplemental pin to the fixator body if necessary for segmental fracture stabilization.
- Once pins are in place, remove the template. Obtain provisional reduction of a fracture or positioning of the bone ends following osteotomy before applying the fixator.
- Apply the fixator and tighten the pin clamps. Attach the reduction forceps to the clamps and fine-tune the bone position under image intensifier control.

Dynafix

The major generic difference between the Orthofix and the Dynafix (manufactured by EBI Medical Systems) is that the Dynafix itself is used as its own template. Tissue protectors and drill guides are placed directly through the pin clamps. The Dynafix articulated body fixator has mobile joints that allow angulation in the frontal and sagittal plane and rotation through the center of the fixator ([Fig. 171.12](#)). The snakelike configuration of the device and the multiple fixator body joints permit translation and rotational corrections as well as approximately 30° of angulation at each joint. As with the standard Orthofix unit, these corrections need to be completed during surgery.

![Figure 171.12](image) The EBI Dynafix external fixator allows angulation, translation, and rotation through its “snake-like” configuration.

HINTS AND TRICKS

- With the articulated body fixator, always secure the ball joints with methylmethacrylate to avoid slippage during weight bearing, which can lead to loss of position in fractures or after osteotomy.
- Small articulated fixators are available for specialized application in the pediatric forearm, humerus, and tibia ([5](#)).
- In general, an adult-size fixator is recommended for the femur of all except the smallest children (those weighing less than 50 to 60 lb); it can also be applied to the tibia in older children.
- Use the larger 6.0 to 5.0 mm tapered pins when possible except in the forearm or in bones smaller than 15 mm in diameter. Two pin sizes are available for small bones.

The lengthening system is similar in concept to the Orthofix LRS ([Fig. 171.13](#) and [Fig. 171.14](#)). Both systems use pins with an external shaft diameter of 6.0 mm. The pin clamp spacing and configuration are different between the two devices; thus, it is impossible to exchange devices without changing pin locations.

![Figure 171.13](image) The EBI lengthening system is similar to the Orthofix LRS system.

![Figure 171.14](image) Swivel clamps are available for the Dynafix lengthening system.

A device similar to the Orthofix T-Garches is also available for correction of proximal tibial deformities ([Fig. 171.15](#)). Because the pin clamps are applied to the T portion of the device, more than two pins can be inserted if desired. The pins may also be applied either proximal or distal to the T allowing some longitudinal spread of the proximal metaphyseal pins.
Like the T-Garches, the EBI T-fixator allows gradual angular correction in the proximal tibia and lengthening.

**Heidelberg Fixator**

Used in Europe for approximately 5 years, the Heidelberg fixator, designed by Dr. Joachim Pfeil, has recently been introduced to North America (**Fig. 171.16**). This device is yet another cantilever system. Its proposed benefit, however, is the ability to achieve gradual angular correction through a device called the angulator (**Fig. 171.17**). Pins are inserted through a drill guide template (**Fig. 171.18**), which can be applied to the fixator in any plane and allows correction of oblique plane deformity or correction of deformity that may arise during limb lengthening such as procurvatum and valgus in the tibia. The surgeon can also apply supplemental bone screws when necessary to enhance stability. A special clamp is also available to allow fixation to the Ilizarov ring system (**Fig. 171.19**). Experience thus far in North America is limited, but the device has some potentially significant advantages, particularly when gradual deformity correction is desirable. Translational correction must nonetheless be obtained intraoperatively.

**Figure 171.15.** Like the T-Garches, the EBI T-fixator allows gradual angular correction in the proximal tibia and lengthening.

**Heidelberg Fixator**

**Figure 171.16.** The Heidelberg fixator has been recently introduced to North America. Similar to other systems, it has several pin clamp types. Lengthening occurs through the body of the fixator itself.

**Figure 171.17.** The Heidelberg “angulator” allows gradual deformity correction following lengthening.

**Figure 171.18.** Pins are introduced through a hand-held template that matches the pin clamp.

**Figure 171.19.** A special Heidelberg clamp allows fixator attachment to the Ilizarov ring system.
**Hex-Fix**

The Hex-Fix can be used to stabilize pediatric long-bone fractures definitively and in osteotomies in small children or children with particularly small bones, as in the skeletal dysplasias. I prefer to use it for proximal femoral fractures or fractures in very small children (those younger than 4 to 5 years of age) in whom stable fracture fixation is desired. The device can accommodate predrilled or self-drilling (eg, Schanz) half-pins of 4, 5, or 6 mm. There are several types of pin clamps available that accommodate one or two bone pins (Fig. 171.20). The single pin clamps permit flexible pin spacing. The clamps also allow some angulation and rotation, enabling multiplanar half-pin fixation on a cantilever device.

*Figure 171.20.* The Hex-Fix is particularly useful for fracture fixation in small children. Four, five, or six millimeter pins may be introduced through the pin clamps, which act as their own template. They are available as single or double clamps as shown. Pins and pin clamps are secured using the universal tool.

Generally, insert two pins proximally and distally to the fracture or osteotomy; pin spacing is dependent on the individual situation. There is no limit to the number of pins that can be used other than the ability to put the pin clamps on the bar. The actual bar on which the pin clamps are assembled is available in several lengths, the shortest being 8 inches. Although a distractor unit is available for lengthening, I have no experience using this device for limb lengthening.

**Circular External Fixation**

The most commonly used circular external fixator is the Ilizarov apparatus. This device is applicable to all limb segments in both the upper and the lower extremities and can be used for deformity correction of both bone and soft tissue, and for limb lengthening (3, 5, 6, 8, 9, 10, 11 and 12, 15, 17, 19, 20 and 21, 24, 27, 29, 30 and 31, 32, 38 and 39, 41, 42, 43, 44, 51, 56, 57 and 58, 61, 62 and 63). Acute trauma applications in the child are limited. It is used most commonly for segmental bone loss, in which it can be used for bone transport (13).

In children, the Ilizarov device is applied most commonly to the femur or the tibia. The standard tibial fixator consists of one or two rings proximally and distally depending on the size of the patient. The standard tibial wire “formula” calls for the insertion of four wires proximally and distally (Fig. 171.21) (26). These wires are either 1.5 or 1.8 mm in diameter. Use 1.5 mm wires in the tibia of smaller children, and 1.8 mm wires in the femur and the tibia of heavier children. At each end of the bone, place two “olive” wires and two smooth wires. Generally, place the olive wires transversely in the frontal plane, one olive from the medial and one from the lateral aspect of the bone. Transfix the fibula and tibia with a smooth wire, both proximally and distally. Finally, place two wires from anterolateral to posterolateral (one proximal and one distal), parallel to the medial border of the tibia. When bifocal—proximal and distal tibial osteotomies—are planned, use another ring fixed to the mid-diaphysis by two wires (Fig. 171.22). These wires are often two olive wires, or an olive wire and plain wire, depending on the direction or nature of the deformity.

*Figure 171.21.* A and B: Transverse “Olive” wires are first placed on the most proximal and distal rings. C and D: Two additional olive wires are placed from the opposite direction on the two middle rings. E and F: Smooth wires are placed from the lateral aspect of the leg, parallel to the medial face of the tibia both proximally and distally. G and H: Two smooth wires are placed through the proximal and distal fibula, transfixing the tibia.

*Figure 171.22.* Bifocal treatment for deformity or lengthening requires an additional middle ring with two-wire or wire and half-pin fixation.

Many modifications have been made to this standard wire “formula” in recent years, generally the substitution of half-pins for wires (discussed in Chapter 32).

In children, I prefer a largely “wired-based” circular fixator. Because the standard medial face tibial wire can often interfere with the pes anserinus tendons, I substitute a half-pin for this wire, leaving the remaining wires as described earlier (Fig. 171.23). In the tibia, the addition of an extra ring in the diaphysis allows bifocal treatment. It is useful for patients with deformities at more than one level (Fig. 171.24), when extensive lengthening is necessary, and in bone transport (Fig. 171.25).
For femoral fixation I prefer an Italian modification using partial rings proximally, as compared with the original Russian technique, which uses full rings for both the proximal and distal thigh. My technique is as follows.

- Generally, I use four wires distally—two 1.8 mm olive wires and two plain wires fixed to one or two rings (Fig. 171.26).

- Connect these rings to an empty diaphyseal ring via lengthening rods or hinges depending on the application.
- Achieve proximal fixation by half-pin, rather than by wire fixation. Determine the diameter of the half-pin by the size of the child.
- Connect the distal rings to the proximal thigh fixation through oblique supports.
- Attach the proximal half-pins to one or two “arches,” depending on the size of the patient.
- Introduce wires or half-pins on the diaphyseal ring for bifocal application to the femur. Although bifocal lengthening is not recommended, proximal angular or rotational osteotomy can be performed acutely (Fig. 171.27), combined with distal deformity correction and lengthening.

- Radiographs at the conclusion of bone transport.
Circular fixation allows almost limitless modification of the fixator. During lengthening, adjacent joints are at risk for progressive contracture, subluxation, or dislocation. The risk of dislocation is particularly significant in the case of congenitally short limbs, such as the ankles associated with fibular hemimelia, knees or hips in the congenital short femur, and proximal femoral focal deficiency (PFFD). Pre-existing contracture due to trauma, burn, or infection may warrant use of circular fixation for gradual correction of deformity with combined femoral and tibial lengthening. Consider prophylactic incorporation of the foot or tibia in tibial or femoral lengthening, respectively, at the beginning or if there is any indication of subluxation or progressive contracture as lengthening proceeds. Consider extending the fixator to the pelvis when the hip is at risk for subluxation (Fig. 171.28). I recommend fixation of the foot at the initial surgery in any patient undergoing tibial lengthening who has fibular hemimelia or a pre-existing equinus contracture. Comprehensive release of the foot can be maintained with foot fixation and combined with tibial lengthening (Fig. 171.29).
closed distraction alone may be unacceptably painful and, owing to the scar stiffness, may result in wire cut-out thorough osteopenic bone. In this situation, perform a conventional comprehensive release first, followed by fixation of the foot and tibia with appropriate hinge placement and subsequent gradual correction (Fig. 171.31). This surgery avoids the problem of wire migration.

**Figure 171.31.** A and B: Clinical and radiographic appearance of a girl with fibular hemimelia and a four-ray equinovarus foot following two previous attempts to correct her foot deformity. C: Comprehensive foot release was combined with gradual independent correction of the forefoot and hindfoot deformities and tibial lengthening.

Apply this technique only to stiff feet in poor position, the goal being to produce a plantigrade foot.

The distraction rate in soft-tissue corrections is limited by patient discomfort, skin tension, and the tolerance of neurovascular structures. Slight overcorrection is recommended due to soft-tissue elasticity which can cause rebound following apparatus removal. Once correction has been achieved, maintain the fixation an additional 6 to 8 weeks. Use orthotics after the removal of the fixator to maintain the correction.

Tibial fixation should span the leg with two rings. A total of four wires, or two wires and two half-pins, are adequate fixation in the tibia because there is no tibial osteotomy. The number of wires in the foot and complexity of the apparatus depends entirely on the nature of the deformity.

With bony deformity in the older child, osteotomy is usually necessary (Fig. 171.32). The nature of the deformity determines the location of the osteotomy. If the hindfoot is neutral and the problem is midfoot cavus or supination, use a midtarsal osteotomy. Hindfoot fixation can be neutral with respect to the tibial fixation. Place hinges between the hindfoot and forefoot, centered over the apex of the deformity. A hindfoot that is not in neutral may be addressed in one of two ways. If cavus exists with hindfoot deformity, use a V-shaped osteotomy to address the hindfoot and midfoot independently. Additional fulcrum wires are necessary, usually in the midfoot and talus to ensure that correction occurs through the osteotomy and not through joint distraction. If the midfoot and forefoot are relatively neutral with respect to one another and the hindfoot is the problem, use a crescent-shaped osteotomy. Perform the osteotomy from the lateral side through the calcaneus and neck of the talus. Place wires superior and inferior to the osteotomy with appropriate hinge location to avoid translation of the foot during correction.

**Figure 171.32.** A and B: This nearly skeletally mature boy with fibular hemimelia has a fixed deformity of his foot and limb shortening. C: An open crescentic osteotomy was performed through the talus and calcaneus with resection of the deforming tight fibular anlage. D: Lateral foot radiograph at the conclusion of correction. E: Radiographs following fixator removal.

**JOINT CONTRACTURES**

Circular external fixation can be used to correct joint contractures in children due to trauma (Fig. 171.33), infection, and burns. Unfortunately, to date, most surgeons' long-term experience has been disappointing. As with conventional soft-tissue and capsular release, the recurrence rate is high despite prolonged periods of posttreatment bracing. Furthermore, as with conventional surgery, depending on the duration of the deformity and the nature of the articular cartilage, the surgeon's goal may be limited to reorienting rather than increasing the arc of motion. The joints most commonly involved in the pediatric patient are the knee and ankle. The usual deformities are knee flexion and ankle equinus contractures.

**Figure 171.33.** A: A lawnmower accident resulted in a severe flexion deformity of this knee. Open posterior release achieved no improvement in knee position, and the Ilizarov external fixator was applied to the femur and tibia with hinges at the approximate center of rotation of the knee. B: Appearance at the conclusion of correction.

In the knee, the rate of correction is usually limited by the neurovascular bundles, in particular the sciatic nerve. Apply circular fixation to span the adjacent femur and tibia to provide an efficient lever arm. Hinges must be located as close to the center of rotation of the knee joint as possible to avoid joint compression or subluxation. After obtaining correction, depending on the preoperative range of motion, use the hinges to assist in moving the knee during physical therapy. At the ankle, center the hinge placement over the center of the talar dome to avoid anterior subluxation of the talus in the ankle mortise.

**UPPER EXTREMITY**

In general, it is easier to apply cantilever fixation than circular fixation to the upper extremity. At present, circular fixation is optimal for complex deformities that cannot
be corrected acutely (Fig. 171.34). It is also useful if the wrist needs to be spanned, for example, in lengthening of radial or ulnar club hand (12,37). Metacarpal wires can be fixed to a half-ring and attached to the forearm fixation (10,12,37,49,64).

Figure 171.34. A and B: Clinical and radiographic appearance of 6-year-old girl with a right radial club hand and no history of prior intervention. C: The ulna was centralized through an open procedure and the wrist stabilized with a transfixing Kirschner wire. Lengthening of forearm was then undertaken. D: The ulna was lengthened by more than 89%.

Cantilever fixation can be combined with circular fixation of the forearm, and the two methods can be used independently for deformities such as those associated with multiple hereditary exostosis (Fig. 171.35). In general, half-pin fixation is easier and safer to apply to the forearm than transfixing wires. The fact that the ulna is subcutaneous throughout its length makes half-pin fixation attractive. Half-pins can be attached in a multidirectional fashion to rings if desired. Two half-pins proximal and distal to the osteotomy site are enough for deformity correction or lengthening.

Figure 171.35. A and B: Radiographs and clinical appearance of a 16-year-old girl with multiple hereditary exostoses with forearm shortening and deformity. C and D: Circular fixation was applied to the radius around a small Orthofix LRS fixator for gradual correction of radial deformity and ulnar lengthening. E and F: Clinical and radiographic appearance of the forearm at the conclusion of treatment.

The humerus is the most easily lengthened long bone (Fig. 171.36) (10). Perform osteotomy distal to the deltoid insertion. Two half-pins proximal and distal to the osteotomy or lengthening site are adequate in the arm. Insert the most distal pin just proximal to the olecranon fossa. The next most proximal pin must avoid the path of the radial nerve. Place it with open technique.

Figure 171.36. A and B: Clinical appearance and radiographs of 13-year-old boy with 10 cm of right humeral shortening due to septic growth arrest of the proximal humerus at the age of 2 years. C and D: Radiographs at the conclusion of distraction and following consolidation.

### TRAUMA APPLICATIONS

#### OPEN FRACTURES

At present, open fracture is the most clear-cut indication for external fixation of pediatric long-bone fractures (4,14,16,34,35,47,50,53,65,66). Depending on the size of the limb segment, apply a four-pin fixator (Hex-Fix, Orthofix, Dynafix) after irrigation and debridement of the open wound. Locate the fixator to minimize interference with subsequent wound management such as local or free flaps and skin grafts. In the case of segmental bone loss, circular fixation can be used to transport bone for definitive bone reconstruction of bone loss.

#### MULTIPLE TRAUMA

Multiple trauma, particularly if combined with a concurrent severe closed head injury, is a strong indication for fixation of major long bone fractures in the pediatric patient. Those patients who require frequent computed tomography (CT) scans, magnetic resonance imaging (MRI) studies, or the operations for treatment of their associated injuries are more easily managed with stable fracture fixation. Traction or spica casts make this difficult, and spica casts may interfere with management of abdominal or chest trauma. Patients who experience spasticity or who are uncooperative following head injury are best managed with rigid stabilization of their long-bone fractures. Even in the very young child, small cantilever unilateral external fixators, such as the Hex-Fix, can be adapted to long-bone fractures, particularly of the femur and tibia.

#### FEMORAL SHAFT FRACTURES

Operative management of isolated femoral diaphyseal fractures using external fixation has become accepted in patients older than 5 to 6 years of age (14,22,34,35,50,62,65). Immediate spica treatment is still preferred in small children, and older adolescents may be treated with intramedullary rodding. Current literature supports operative treatment of this intermediate age group between age 5 and 11 to 12 years, reporting excellent results with external fixation decreasing hospitalization, promoting early patient mobilization and return to school, decreasing psychosocial family stress, with an acceptable complication rate (2,4,14,16,34,50,52,53,65). A recent report (18) also demonstrated a clear cost savings when compared with traditional skeletal traction followed by spica-cast
immobilization. The major concern when using external fixation in these fractures is the risk of refracture. The incidence of refracture can be minimized by early weight bearing, early fixator dynamization, and mobilization of the knee. Anecdotal reference is made by some to suggest that the most common fracture pattern susceptible to refracture is a transverse diaphyseal fracture. In my experience, the most important factors in refracture are a stiff knee and lack of weight bearing during fracture healing.

FLOTTING KNEE

Ipsilateral concomitant fracture of both the femur and the tibia produces a floating knee. Operative stabilization of both the tibia and the femur are indicated. Depending on the skeletal maturity of the patient, intramedullary fixation of the femur, using either reamed or flexible implants, can be combined with external fixation of the tibia. In the younger child, external fixation can be applied to both the femur and the tibia. It allows rapid mobilization of the patient, motion of the knee and ankle, and normal shoe wear. Weight bearing can be initiated as soon as patient can tolerate it in most cases.

PELVIC FRACTURES

Although they are relatively rare in children, unstable pelvic fractures, particularly open-book type fractures of the pelvis, can be treated with external fixation as in the adult (52). Posterior disruptions can be addressed by internal fixation and combined with an anterior fixator (see Chapter 17). For more details on the treatment of pediatric fractures, see Chapter 164.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and *, clinical results/outcome study.

PATHOPHYSIOLOGY

Slipped capital femoral epiphysis (SCFE) is the most common adolescent hip disorder (39). It is defined as a posterior and inferior slippage of the proximal femoral epiphysis relative to the metaphysis; it occurs through the hypertrophic physeal zone. In actuality, the relationship of the epiphysis and its articular surface relative to the acetabulum does not change, and the slippage is better defined as an anterior inferior slippage of the proximal femoral epiphysis. Familiarity with this concept makes the surgical techniques much easier to visualize.

The cause of idiopathic SCFE is unknown, and it is probably multifactorial (60). Because it occurs during the adolescent growth spurt, a subtle endocrine influence is likely. Physeal shear strength decreases during that period (17), probably reflecting the increased physeal width in response to growth hormone. However, circulating hormone levels are usually normal when standard assays are used. The majority of children with SCFE are obese, typically above the 95th percentile for body weight for age (69). In an adolescent child who is above the 95th percentile for body weight, biomechanical studies have shown that the shear stress across the proximal femoral physis from simple running is enough to create an SCFE (17,66). This stress is further increased with femoral retroversion, an associated finding in obese children and in the contralateral “normal” hips of children with SCFE (26,29). In addition, children with SCFE demonstrate a more vertical physis, further increasing the susceptibility to slip (61).

PRINCIPLES OF TREATMENT

The goals of treatment are to (a) prevent further slipping until physeal closure; (b) avoid complications, primarily those of avascular necrosis (AVN) and chondrolysis; and (c) maintain adequate hip function. Four main treatments are described: (a) internal fixation, (b) epiphysiodesis, (c) proximal femoral osteotomy, and (d) spica cast immobilization.

ASSESSMENT, INDICATIONS, AND RELATIVE RESULTS

CLASSIFICATION AND ASSESSMENT

The traditional classifications of SCFE are acute, chronic, and acute-on-chronic (1,23). An acute SCFE is one with a symptom duration of less than 3 weeks; a chronic SCFE, greater than 3 weeks; and an acute-on-chronic SCFE is one with chronic symptoms for more than 3 weeks but with a sudden exacerbation of symptoms for less than 3 weeks. This classification scheme is unreliable because many children and parents cannot remember the exact duration of symptoms. It also gives no information regarding hip prognosis.

Newer classification systems account for SCFE stability, are easier to use, and impart prognostic information (37,52). A child with a stable SCFE is able to walk, with or without crutches; a child with an unstable SCFE is unable to walk, with or without crutches. The prognosis for a child with a stable SCFE is very good, with an incidence of AVN approaching zero. The prognosis for a child with an unstable SCFE is guarded because of the increased risk of AVN, which may be up to 50%. The vast majority (>95%) of SCFEs are stable.

A child with a stable SCFE has a history of intermittent limp for several weeks to months that may or may not be associated with thigh, knee, or groin pain. Hip pain is variably present, often resulting in diagnostic delay. Physical examination demonstrates loss of internal rotation and spontaneous external rotation with hip flexion. Abduction and flexion are usually decreased, especially in the more severe cases. In longstanding cases, shortening of the lower extremity with varying degrees of thigh atrophy is noted; the parents usually also describe a gradually increasing external rotation gait and limb-length discrepancy.

A child with an unstable SCFE presents with sudden, severe pain; there is often a history of a minor fall, such as tripping off a curb. The child lies perfectly still with the lower extremity in a position of flexion, abduction, and external rotation. The hip is extremely irritable, and any attempts toward active or passive hip motion are resisted. These SCFEs are analogous to an acute Salter Harris I fracture, which explains their painful nature and high AVN rate.

In a stable SCFE, the diagnosis is confirmed with anteroposterior (AP) and lateral pelvis radiographs; both views are needed because an early SCFE often is seen only on the lateral view. Always view both hips because the incidence of simultaneous bilateral may approach 20%. Either frog-lateral or cross-table lateral radiographs may be used. Proponents of the cross-table lateral view argue that the variability with the frog positioning resulting from limitation of hip motion inaccurately represents the SCFE, and that the frog view can also theoretically convert a stable SCFE to an unstable SCFE. Proponents of the frog-lateral view argue that the lateral
epiphyseal–shaft angle, a commonly used method to assess slip magnitude, is measured on the frog-lateral view. It is also the view many of the preoperative osteotomy plans depend on. Comparisons with the literature findings are also possible with this view because of its common use.

In an unstable SCFE, only an AP pelvis radiograph can be obtained, and the diagnosis is readily made. A cross-table lateral radiograph can be attempted, but clearly a frog-lateral radiograph should not be attempted, because of both the severe discomfort for the child and the risk of further slippage. A frog-lateral view of the opposite hip should be obtained; it is easy to forget this in the excitement of assessing the unstable side.

Slip magnitude is commonly measured using two methods. The first involves the amount of epiphyseal displacement relative to the metaphysis (16) (Fig. 172.1A). A mild SCFE is one with less than 33% displacement; moderate, 33% to 50%; and severe, greater than 50%. This can be measured on both the AP and the lateral radiographs. In the case of a stable SCFE of many months’ duration, remodeling of the femoral neck makes this measurement less reliable, underestimating the true magnitude of slip.

**Figure 172.1.** Two common methods of magnitude measurement for slipped capital femoral epiphysis (SCFE). A: Measurement of the amount of displacement of the epiphysis relative to the metaphyseal width. The SCFE is considered mild if the measured tip is less than 33%, moderate if it is 33% to 50%, and severe if it is more than 50%. B: The head–shaft angle is measured on the frog-lateral pelvis radiograph of the pelvis to determine the degree of the slip, which is calculated by subtraction of the angle on the normal side from the angle of the affected hip: 49° – 12° = 37°. (From Aronson DD, Carlson WE. Slipped Capital Femoral Epiphysis: A Prospective Study of Fixation with a Single Screw. J Bone Joint Surg Am 1992;74:810, with permission.)

Because of these concerns with the displacement method, the epiphyseal–shaft angle, which more accurately reflects the true slip magnitude, is used (78) (Fig. 172.1B). This angle is measured on the frog-lateral pelvis radiograph by the following method:

- Draw a line between the anterior and posterior tips of the epiphyseal at the physeal level.
- Then draw a line perpendicular to this epiphyseal line.
- Finally, draw a line along the mid axis of the femoral shaft.
- The epiphyseal–shaft angle is the angle formed by the intersection of the perpendicular line and the femoral shaft line.
- Measure this angle for both hips; the magnitude of slip displacement is the angle of the involved hip minus the angle of the contralateral normal hip.
- By using this angle, SCFEs can be classified as mild (<30°), moderate (30° to 50°), or severe (>50°).
- In the case of bilateral SCFEs, 10° to 12° is used as the normal hip angle.

Other imaging techniques are rarely needed. Computed tomography (CT) scans are useful when doubt exists regarding the status of physeal closure or when the postoperative screw position is not adequately determined with plain radiographs. Bone scans are helpful in the rare occasion when AVN or chondrolysis is suspected but not yet visualized on plain radiographs. Magnetic resonance imaging is unnecessary in either the diagnosis or treatment of SCFE.

**INDICATIONS FOR TREATMENT**

Any child with an SCFE and open physis needs treatment; without stabilization, progression is inevitable. Most authors advocate an in situ technique (either internal fixation or epiphysodesis) for any mild or moderate SCFE. The treatment to use for severe SCFE is more controversial. Primary osteotomy has been advocated to improve joint mechanics, motion, and hip function. However, the incidence of complications is much higher with osteotomy than in situ fixation, and thus most surgeons recommend in situ fixation as the primary treatment of a severe SCFE. In situ fixation allows the synovitis to subside, which will in itself result in improved motion (77).

After complete physeal closure (usually 1 or 2 years later), the child’s functional limitations, gait pattern, and pain can be more leisurely assessed (36,44). A decision regarding the need for osteotomy can then be made after a thorough discussion of the risks and benefits with both child and parents.

In a patient with closed physes, only the surgical treatment in the absence of severe degenerative changes is proximal femoral osteotomy. Indications are functional limitations, unacceptable gait, or cosmetic deformity. Here again, a thorough discussion of the risks and benefits is needed before performing the procedure.

**RESULTS OF TREATMENT**

When selecting treatment, the results should be better than the natural history of the disease. The natural history of SCFE is one of gradual degenerative arthritis of the hip (19). The more severe the SCFE at diagnosis, the sooner the degenerative changes appear.

**Stable SCFE**

Proximal femoral osteotomy makes the most “orthopaedic sense” for stable SCFE (Table 172.1, Table 172.2). Although some of the literature demonstrates low complication rates with osteotomy, the majority document a higher complication rate than with in situ stabilization. The complications, primarily AVN (13% with cuneiform osteotomy) and chondrolysis (23% with intertrochanteric osteotomy, 16% with cuneiform osteotomy, 7% with basilar neck osteotomy), result in poor long-term outcomes. No long-term study has demonstrated an improved outcome in severe SCFEs treated by osteotomy compared to in situ fixation (18,72).

**Table 172.1. Results of Various Treatment Methods for Stable Slipped Capital Femoral Epiphysis (SCFE)**
Spica cast immobilization is difficult because of the typical body habitus of a child with SCFE, and it has an unacceptably high rate of chondrolysis (18%) and slip progression (8%) (9,59). Difficulties in mobility are encountered in these very large children in spica casts and with prolonged bed rest.

The best long-term results are with in situ treatment. The results of in situ fixation with a single central screw using today's intraoperative imaging technology are uniformly excellent (0% AVN and chondrolysis, 1% slip progression), as long as attention to technical details is maintained. The use of two screws does not double the biomechanical strength of the physeal–screw construct, and it increases the risk of complications (e.g., joint penetration) (88,41). In situ epiphysiodesis does not give comparable results (2% AVN, 1% chondrolysis, 7% slip progression, 1% nonunion) and is also plagued with increased morbidity [e.g., blood loss, wound problems (hematoma/seroma, infection), longer operative time, larger incisions, failure of fixation, and further slippage]. For all these reasons, most surgeons presently recommend in situ fixation with a single central screw for all stable SCFEs (30).

Unstable SCFE

The results in the population of unstable SCFE are much worse, primarily because of the increased risk of AVN, up to 47% (52,82). If AVN does not occur, then the outcomes and results are similar to those of the stable SCFE.

PREOPERATIVE MANAGEMENT

STABLE SCFE

Once the diagnosis is made, do not allow the child to bear weight on the involved limb. The ideal treatment is immediate hospital admission, enforced bed rest, and next-day surgery. There is no need or role for preoperative traction. The goal is to obtain epiphyseal fixation before the SCFE can become unstable. However, it is often difficult to convince the family, and especially insurance companies, that this is a medical urgency. If such immediate procedures cannot be done, keep the child strictly non-weight-bearing; strongly counsel regarding the concerns of walking, running, or falls that might create an unstable SCFE; and rapidly schedule stabilization in the next few days. Wailing several weeks for an opening on an elective surgical schedule is inappropriate management.

UNSTABLE SCFE

The controversies with unstable SCFEs concern the timing of surgical stabilization and the use of preoperative traction (5,83). If an unstable SCFE resembles a displaced femoral neck fracture in a young adult in terms of concerns about AVN, then an immediate anatomic reduction should be obtained (closed, or open if necessary), and the hip joint decompressed to relieve intracapsular pressure, all in the hopes of reducing the risk of AVN. However, the present data are inadequate to either support or refute this approach. My approach is to admit the child and schedule surgery within the next 24 hours. Some advocate keeping the child at bed rest for 1 or 2 weeks; this allows the joint to quiet down, early healing to occur, and a more stable situation to develop (3). Here again, the data are lacking to either support or refute this approach.

If surgery is scheduled within the next few days, the next question concerns preoperative traction (either skin or skeletal) (21). The proponents of gentle preoperative traction argue that it allows a gradual reduction in the hopes of reducing the risk of AVN. Again, the data are inadequate to answer the question. If traction is used, the hip should be flexed. Extension decreases intracapsular volume, makes the child more uncomfortable, and theoretically increases the risk of AVN. My approach is to keep the child comfortably positioned in bed with pillows and other supports until surgery.

PREOPERATIVE PLANNING

Take adequate AP and lateral radiographs of both hips to ensure that a contralateral SCFE is not missed. This is especially important when in situ fixation with a single screw is the selected treatment, because both hips should be treated under one anesthetic.

IN SITU FIXATION

No further special preoperative planning is needed for in situ fixation. The position and length of the cannulated screw is determined intraoperatively.

EPIPHYSIODESIS

Only adequate preoperative radiographs are needed.

PROXIMAL FEMORAL OSTEOTOMY

Proximal femoral osteotomy can be performed at several locations: (a) physis (Fish or Dunn cuneiform osteotomy); (b) basilar neck (e.g., Abraham); and (c) intertrochanteric/subtrochanteric level (Southwick, Müller osteotomy) (Fig. 172.2). The physeal osteotomy is at the level of pathology and allows for maximal correction (20,25,65). Its serious disadvantage is a high rate of AVN. The few studies with low AVN rates indicate that its success depends on the individual surgeon (15,48). The object of the basilar neck osteotomy is to reduce the risk of AVN by operating immediately distal to the entry site of the epiphyseal blood supply, yet close enough to the deformity for adequate correction (2,49). The intertrochanteric/subtrochanteric osteotomies are compensatory and introduce a distal reverse deformity (89,79). Their advantage is a low risk of AVN. However, they do not allow as much correction and are complicated by chondrolysis and fixation problems. Later joint replacement arthroplasty is more difficult because of the distorted proximal femoral anatomy (19).

Figure 172.2. The three osteotomy locations for proximal femoral osteotomy for slipped capital femoral epiphysis as shown in both anterior and posterior views. These locations are subcapital, basilar neck, and trochanteric. The wedges of bone necessary for removal are different in shape anteriorly and posteriorly. On the posterior view it is noted that the vascular supply to the proximal femoral epiphysis enters the femur just proximal to the basilar neck osteotomy, whereas with the subcapital
ostectomy the entry point of the vascularity is distal to the osteotomy which increases the risk of avascular necrosis with that osteotomy. The trochanteric osteotomy is safely distal to the entry point of the vessels into the femoral neck.

If proximal femoral osteotomy is selected as the treatment, accurate preoperative planning is mandatory. Use paper tracing cut-outs and implant templates to ensure that the osteotomy is properly performed and that the necessary internal fixation is available. In certain circumstances, the fixation device can be preoperatively bent and only fine adjustments need to be made intraoperatively.

The surgical technique for the intertrochanteric osteotomy (Southwick osteotomy) is as follows:

- Use a standard technique to obtain AP and frog-lateral radiographs of the pelvis incorporating the proximal femurs. Maintain the pelvis flat on the x-ray table and center the beam midline between the hips. For the AP film, maintain the hips in as neutral a position as possible by keeping the patellae pointing as straight up as possible. For the frog-lateral film, place the hips in maximal abduction and external rotation, with the knees flexed, the plantar surface of the feet facing each other, and their lateral surfaces resting on the table. Determine the osteotomy angles by marking the angular relationships of the femoral head to the shaft on the radiographs; use the opposite normal side for comparison.
- The AP measurement determines the amount of varus deformity, and the frog-lateral measurement determines the amount of posterior epiphyseal tilting (Figs. 172.3A, 172.3B). The difference in the epiphyseal–shaft angle on the AP view determines the anterior osteotomy. If there is bilateral involvement, use 145° as the normal angle. The difference in the epiphyseal–shaft angle on the frog-lateral view determines the lateral osteotomy. If there is bilateral involvement, use 10° as the normal angle of retroversion.) Mark the wedges of bone to be removed on both radiographs, and fabricate templates for intraoperative use (Figs. 172.3C, 172.3D). Southwick initially used tin for the templates, but any malleable material that can be safely sterilized can be used; I have found metallic suture wrappers to be helpful (Fig. 172.3E). The template outlines the size and shape of the bone wedge to be removed. Typical angles are 20° to 30° anteriorly and 45° laterally. A wedge of 25° typically cuts through two thirds of the femoral shaft, and a wedge of 50° typically cuts through one half of the femoral shaft. Never exceed 45° anterior and 60° lateral.

![Figure 172.3](https://example.com/f172.3.png)

**Figure 172.3.** Preoperative planning for the Southwick intertrochanteric osteotomy. AP and frog-pelvis radiographs of a 14-year-old boy with a left SCFE. A: The epiphyseal–shaft angle on the AP view is 150° on the normal side and 125° on the affected side; thus a 25° wedge is needed. B: The epiphyseal–shaft angle on the frog-lateral view is 20° on the normal side and 80° on the affected side; thus a 60° wedge is needed. C: The AP wedge is marked on the radiograph. The lateral wedge is similarly marked. D: The proposed osteotomy is made by using paper cut-outs from the radiographic markings. E: After the angles that give the desired correction have been determined, life-size paper templates are obtained from the original Southwick manuscript and traced onto a malleable, autoclavable material (e.g., tin or a metallic suture wrapper). This template is then sterilized at the time of surgery.

- Next, plan the internal fixation. After obtaining paper tracings of the proximal femurs in both AP and lateral projections, draw the intended osteotomy on paper. Use overlay templates of the selected internal fixation device(s) to plan their appropriate position and length (e.g., length and angle of side plate and lag screw if using a hip compression screw system, or the length and angle of the blade plate if using a blade-plate system). Take care to ensure that the tips of the lag screws or blade plates may be special orders. After osteotomy, the femoral head should appear erect in the acetabulum in the AP view, and at a right angle to the long axis of the femoral shaft in the lateral view.

![Figure 172.4](https://example.com/f172.4.png)

**Figure 172.4.** Technique of in situ single-screw fixation for SCFE. Preoperative AP (A) and frog-lateral (B) radiographs of both hips in a 14-year-2-month-old boy. There is an SCFE of 40° on the right; the left hip is normal. A guide pin is placed onto the skin overlying the hip so that the pin is positioned in the center of the epiphysis and is perpendicular to the physis in both AP (C) and lateral (D) images. Skin lines are drawn to record the position of the guide pin on both the AP (E) and lateral (F) projections. The incision is made at the intersection of the skin lines (G). After draping, multiple Kocher clamps are placed on the base of the drape to act as weights, which allows for movement of the image between AP (H) and lateral (I) images without violating surgical field sterility. The guide pin is advanced onto the anterolateral cortex of the femur so that the pin will enter the center of the epiphysis perpendicular to the physis. The guide pin is then advanced across the physis, and its tip is advanced no deeper than 5 mm from the subchondral bone [AP (J) and lateral (K) views]. The appropriate depth of the pin tip is checked using the lateral image. A cannulated screw is inserted in routine fashion after drilling and tapping the hole (L,M). Postoperative radiographs demonstrate ideal screw position in the center of the epiphysis perpendicular to the physis in both AP (N) and lateral (O) projections.

- Position the patient supine on a fracture table, moving the image intensifier rather than the lower extremity. Take care when transporting the patient onto the fracture table; no reduction maneuvers are performed and forced fracture is not applied to the lower extremity. I use the fracture table only as a positioning device, allowing the involved limb to lie comfortably in its natural position of rotation.
- Place the opposite limb into abduction with the hip extended, and move the image intensifier into position between the two lower extremities.
- Prior to surgical draping, confirm the ability to obtain adequate AP and cross-table lateral images.
- Place a guide pin onto the skin overlying the proximal femur and obtain an AP image (48). Position the pin in the center of the epiphysis and perpendicular to the

**SURGICAL TECHNIQUES**

**STABLE SLIPPED CAPITAL FEMORAL EPIPHYSIS**

**IN SITU FIXATION**

The most common stable SCFE surgical technique uses a cannulated screw system (3,48,62,67) (Fig. 172.4). In this technique, a single screw is placed into the center of the epiphysis in both AP and lateral planes.
Percutaneous Allograft Technique

Slipped Capital Femoral Epiphysiodesis.

With an SCFE, the epiphysis is posteriorly displaced relative to the femoral neck, and the guide pin in the lateral projection angles from anterior to posterior. Thus the two skin lines intersect on the anterolateral aspect of the thigh, and as the slip becomes more severe, the intersection point becomes more anterior. Because of the retroversion in the posteriorly displaced epiphysis in SCFE, the osseous entry point of the guide pin is on the anterior aspect of the femur. In mild SCFEs, it is often at the anterior intertrochanteric line; in severe SCFEs, it moves up onto the anterior femoral neck.

- Prepare and drape the anterolateral portion of the thigh. I prefer to use a transparent shower-curtain-type of isolation drape with multiple Kocher clamps on the base of the drape as weights; this allows movement of the image intensifier in both AP (Fig. 172.4A) and lateral (Fig. 172.4B) projections without violating surgical field sterility.
- Introduce the guide pin through the skin at the intersection of the skin lines; it may be introduced through either a stab wound or a small, 1–2 cm incision.
- Advance the guide pin into the anterolateral cortex of the femur, keeping the drill and guide pin aligned according to the skin lines. Once the guide pin contacts the femoral cortex, its point of entry and angular direction is confirmed in both AP and lateral projections.
- When you are satisfied that the entry point and direction of the guide pin are correct, carefully advance the guide pin into the femoral neck, frequently checking the angle of entry on both AP and lateral images. Ideally, there should only be one entry point into the femoral cortex; extra holes act as stress risers and increase the risk of postoperative fracture. Do not advance the guide pin across the physis until you are certain that the pin will enter the center of the epiphysis perpendicular to the physis in both AP and lateral projections.
- After the pin has crossed the physis, advance the tip to the proper depth (no closer than 5 mm from the subchondral bone; any permanent pin position less than 5 mm from the subchondral bone increases the risk of joint penetration). This depth is determined on the lateral projection. Take care to ensure that the pin is not in the superior quadrant of the femoral head, because this position may jeopardize the epiphyseal blood supply.
- When the pin is in the appropriate position, determine screw length by placing another guide wire of identical length along the introsseous guide wire and measuring the difference.
- Insert a cannulated screw in routine fashion after drilling and tapping. The screw should be at least 6.5 mm in diameter.
- While drilling and tapping, closely monitor the guide pin to ensure that if (a) does not break, (b) does not penetrate the joint and enter the abdominal cavity, or (c) does not withdraw from the femoral neck.
- After inserting the screw, remove the guide pin and confirm that the screw tip does not penetrate the joint. This can be done by one of several techniques: (a) move the limb in multiple directions in both AP and lateral views to confirm that it does not penetrate the joint, (b) use the approach-withdraw phenomenon, or (c) use intraoperative arthrography through the cannulated screw. My approach is a variation of the first technique. I obtain images of the hip every 10° to 15° while moving from a lateral to an AP projection, ensuring that the screw tip is no closer than 5 mm to the subchondral bone of the epiphysis. If it is closer than 5 mm, use a shorter screw.
- After confirmation of appropriate screw position and depth, close the incision.

EPIPHYSIODESIS

Open Autograft Technique with an Anterolateral Approach

The following technique is the Weiner (69) modification of the Hoyt-Heyman-Herndon procedure. The anterolateral approach (61) (Fig. 172.5) is now used instead of the older anterior iliofemoral approach (32). The advantages of this approach compared to the anterior approach are shorter operating time, less blood loss, easier instrument insertion, avoidance of lateral femoral cutaneous nerve injury, and fewer wound complications.

- Position the patient supine on a radiolucent table.
- Bump up the affected hip, and be sure you can obtain adequate AP and lateral images prior to surgical draping.
- Prepare and drape free the entire lower extremity, hip, and iliac crest, as for a total hip arthroplasty.
- Make a mid-lateral incision starting 4 inches below the level of the greater trochanter in the lateral midline of the upper thigh, continue the incision proximally to the greater trochanter, and then angle it obliquely to the anterior superior iliac spine.
- Split the tensor fascia lata proximally to the level of the anterior superior iliac spine.
- Retract the anterolateral muscles of the gluteus medius posteriorly, exposing the underlying gluteus musculature.
- Retract the anteriormost fibers of the gluteus medius posteriorly to view the capsule.
- Perform an H capsulotomy (Fig. 172.5A) and use retractors (large Cobra type) to expose the femoral head and neck; the area of slipping is now directly in view.
- Make a rectangular or square window in the femoral neck and insert a large hollow mill drill through this window. Under image control, drill the hollow mill across the physis into the epiphysis (Fig. 172.5B).
- Introduce the cylindrical core consisting of metaphyseal bone, physis, and epiphyseal bone.
- Enlarge the cylindrical tunnel further by curettage, removing more of the physis (Fig. 172.5C).
- Expose the outer table of the ilium, removing sections of corticocancellous bone, which are packaged together in sandwich fashion and driven into the epiphysis as a composite peg (Fig. 172.5D).
- Perform routine closure.
- In unstable cases, apply a bilateral hip spica cast with the epiphysis in the reduced position.

Percutaneous Allograft Technique

This technique, known as the Schmidt procedure, is similar to that of in situ fixation using a single central screw (78).

- Position the patient supine on a fracture table with the involved hip in the neutral position and the knee extended.
- Determine stability of the SCFE radiographically before sterile draping.
- Gently mobilize the hip through internal rotation under the image intensifier. If the epiphysis moves relative to the metaphysis, the slip is considered to be unstable.
- At this point, gently position the involved hip in 10° to 15° of abduction and with internal rotation such that the femoral neck is parallel to the floor. This position allows for a true anterior and lateral view with the image intensifier. A forced reduction maneuver is never performed.
- After prepping and draping using an isolation drape, determine the guide pin entry point by the intersection of two skin lines using the same technique as in situ single-screw fixation.
- Introduce the guide pin through a stab incision at the intersection of the skin lines, and advance it onto the anterolateral cortex of the femur. The ideal bone entry position for the guide pin is just below the greater trochanteric physis and above the thick cortical bone of the femoral shaft to avoid creating a stress riser in the subtrochanteric region.
- Confirm the point of entry and angular direction of the guide pin in both AP and lateral views.
Cuneiform Osteotomy (Fish Procedure)

the metaphysis.

more than one-third the diameter of the physis, or an acute-on-chronic SCFE radiographically demonstrated by the presence of new bone along the posterior aspect of

AVN with these procedures.

I have had no experience with any of the physeal osteotomies, but two procedures are included here for the sake of completeness. With either the open reduction

PROXIMAL FEMORAL OSTEOTOMY

I have had no experience with any of the physeal osteotomies, but two procedures are included here for the sake of completeness. With either the open reduction

Physeal Osteotomy

Dunn Procedure The Dunn procedure, an open reduction of the severe SCFE, is popular in the United Kingdom and other countries with a British orthopaedic influence (13,22). An absolute prerequisite for this procedure is an open physis. The indications for this procedure in Dunn's original paper were a chronic SCFE of more than one-third the diameter of the physis, or an acute-on-chronic SCFE radiographically demonstrated by the presence of new bone along the posterior aspect of the metaphysis.

Place the patient in the lateral decubitus position with the involved extremity up.

Prepare and drape free the entire lower extremity, hip, and iliac crest area as for a total hip arthroplasty.

At this point, drill three threaded pins up the metaphysis, so that when the epiphysis is reduced they will engage the epiphysis in different parts

Figure 172.6 Dunn procedure. See text above for a description of the technique. (From Dunn DM, Angel JC. Replacement of the Femoral Head by Open Operation in Severe Adolescent Slipping of the Upper Femoral Epiphysis. J Bone Joint Surg Br 1978;60:394, with permission.)

Cuneiform Osteotomy (Fish Procedure) The indications for this procedure according to Fish (24,25) are an SCFE greater than 30° with an open physis.

Position the patient on a radiolucent table in the supine position with a small bump under the involved hemipelvis.

Drape the entire limb, hip, and iliac crest area as for a total hip arthroplasty.

Approach the hip through an anterolateral exposure. Dissect between the sartorius and tensor fascia femoris muscles, exposing the anterior capsule. The capsule must be generously exposed proximal to the acetabular rim for adequate visualization (Fig. 172.7A).
Figure 172.7. Cuneiform osteotomy of Fish. A: Exposure of the femoral metaphysis. Note the minimal amount of the epiphysis that is initially seen. B: Location of the physis using a small curved osteotome. C: The osteotomy is made by removing small pieces of bone with a sharp osteotome and mallet. The fragments are wiped away while being removed to ensure continuous identification of the physis. C: Further removal of the physisal cartilage with a curet, and then reduction of the epiphysis on the metaphysis. The diameter of the head is larger than that of the neck after removal of the bone wedge; thus the epiphysis overlaps the neck. D: After reduction of the epiphysis, it is fixed with three or four threaded pins. Note how much more of the articular surface is now visible compared to the preoperative situation (A). (From Fish JB. Cuneiform Osteotomy of the Femoral Neck in the Treatment of Slipped Capital Femoral Epiphysis. J Bone Joint Surg Am 1984;66:1153, with permission.)

- Make a longitudinal incision in the anterior capsule, and extend it in an H fashion both proximally and distally. Carefully retract the capsule; no retractors should be placed around the femoral neck either medially or laterally.
- Identify the proximal femoral epiphysis; it usually is barely visible at the acetabular rim. The anterior projection of the metaphysis is quite obvious and can be mistaken for the capital femoral epiphysis. In a very severe SCFE, it may be necessary to remove a portion of the metaphysis to visualize the epiphysis.
- Next, identify the location of the physis and determine its plane by gentle probing with a Keith needle.
- Determine the size of wedge to be removed by the degree of the slip and position of the epiphysis (Fig. 172.7B).
- Remove enough bone to allow an anatomic reduction of the epiphysis on the metaphysis. A large bone wedge is needed in a more severe SCFE. The base of the wedge must be in the plane of anticipated correction of the epiphysis, and the curved contour of the physis should match the corresponding curved metaphyseal neck.
- Gently remove the wedge in small pieces with an osteotome and mallet. Maintain continuous identification of the physis.
- Use extreme caution when approaching the posterior aspect of the neck. The posterior periosteum must be protected and preserved to avoid vascular damage.
- Remove the posterior bone (a curet is usually used), and use a large curet to remove any remaining physis (Fig. 172.7C). Once sufficient posterior bone has been removed, the epiphysis will effortlessly reduce with flexion, abduction, and internal rotation of the limb. If inadequate posterior bone has been removed, undue tension will be placed on the posterior periosteum, potentially compromising epiphyseal vascularity.
- Once an anatomic reduction has been obtained, achieve fixation with three or four threaded pins directed toward the center of the femoral head and only deep enough to obtain firm epiphyseal fixation (Figs. 172.7B-D).
- Confirm the position of the pins and epiphysis radiographically and perform routine closure.

Basilar Neck Osteotomy

The basilar neck osteotomy is theoretically safer than at the physis because it is performed just distal to the entry of the posterior retinacular vessels. It may be either intracapsular (the Kramer technique) (65) or extracapsular (the Barmada/Abraham technique) (2,6). The maximum amount of correction is less than with a physeal osteotomy, usually no more than 50°.

Intracapsular Osteotomy (Kramer Technique)

Kramer’s indications are an SCFE greater than 40° on either the AP or the lateral radiographic view.

- Approach the hip laterally with an incision starting 2 cm distal and lateral to the anterosuperior iliac spine, curving distally and posteriorly over the greater trochanter and lateral shaft of the femur to a point 10 cm distal to the base of the greater trochanter.
- Incise the fascia lata longitudinally and develop the space between the gluteus medius and the tensor fascia lata. This dissection should be carried proximally to the anterior branch of the superior gluteal nerve, which innervates the tensor fascia lata.
- Open the hip capsule anteriorly along the anterosuperior surface of the femoral neck, and widely release it anteriorly into the intertrochanteric line.
- Reflect the vastus lateralis distally, exposing the base of the greater trochanter and the proximal femoral shaft.
- The margin between the articular cartilage of the femoral neck and the epiphysis, as well as the junction of the two with the normal cortex of the femoral neck, can now be seen. Compare the distance between these two junctions with the amount calculated preoperatively from the radiographs. The widest part of the wedge will be in line with the widest portion of the slipped epiphysis, in the anterior and superior aspects of the neck. The most common mistake is to make the superior part of the wedge too small, resulting in incomplete correction of the varus; if the anterior wedge is too wide, overcorrection of retroversion occurs.
- Make the distal osteotomy first, perpendicular to the femoral neck and following the anterior intertrochanteric line from proximal to distal. The cut should reach the posterior cortex but leave it intact.
- Direct the second osteotomy obliquely so that the cutting edge of the osteotome remains distal to the posterior retinacular blood supply. Anteriorly the capsule reaches the intertrochanteric line, but posteriorly the lateral third of the femoral neck is extracapsular; thus an osteotomy done at this level does not violate the posterior cortex and its retinacular supply.
- Before completing the osteotomy, drill one or two 5 mm, threaded Steinmann pins into the proximal fragment to ensure control of the osteotomy. The osteotomy is completed without penetrating the posterior cortex.
- Remove the bone wedge, and “greenstick” the posterior cortex, closing the osteotomy.
- Insert several 5-mm-diameter Steinmann pins from the outer cortex of the femoral shaft through the neck, across the osteotomy and into the epiphysis.
- Cut the pins to the appropriate length after radiographic confirmation of the osteotomy position and fixation.
- Close the wound in routine fashion.

Extracapsular Osteotomy (Barmada/Abraham Technique)

The indication for an extracapsular osteotomy, according to Abraham, is an SCFE greater than 50°.

- Position the patient supine on the fracture table.
- Rotate the involved limb maximally internally by gently positioning the foot plate; abduct it approximately 5°.
- Widely abduct the contralateral limb, and place the image intensifier between the two lower extremities.
- Rotate the involved limb maximally internally by gently positioning the foot plate; abduct it approximately 5°.
- Position the patient supine on the fracture table.
- Make the distal osteotomy first, perpendicular to the femoral neck and following the anterior intertrochanteric line from proximal to distal. The cut should reach the posterior cortex but leave it intact.
- Place the periosteal elevator around the femoral neck either medially or laterally.
- Make a longitudinal incision in the anterior capsule, and extend it in an H fashion both proximally and distally. Carefully retract the capsule; no retractors should be placed around the femoral neck either medially or laterally.
- Identify the proximal femoral epiphysis; it usually is barely visible at the acetabular rim. The anterior projection of the metaphysis is quite obvious and can be mistaken for the capital femoral epiphysis. In a very severe SCFE, it may be necessary to remove a portion of the metaphysis to visualize the epiphysis.
- Next, identify the location of the physis and determine its plane by gentle probing with a Keith needle.
- Determine the size of wedge to be removed by the degree of the slip and position of the epiphysis (Fig. 172.7B).
- Remove enough bone to allow an anatomic reduction of the epiphysis on the metaphysis. A large bone wedge is needed in a more severe SCFE. The base of the wedge must be in the plane of anticipated correction of the epiphysis, and the curved contour of the physis should match the corresponding curved metaphyseal neck.
- Gently remove the wedge in small pieces with an osteotome and mallet. Maintain continuous identification of the physis.
- Use extreme caution when approaching the posterior aspect of the neck. The posterior periosteum must be protected and preserved to avoid vascular damage.
- Remove the posterior bone (a curet is usually used), and use a large curet to remove any remaining physis (Fig. 172.7C). Once sufficient posterior bone has been removed, the epiphysis will effortlessly reduce with flexion, abduction, and internal rotation of the limb. If inadequate posterior bone has been removed, undue tension will be placed on the posterior periosteum, potentially compromising epiphyseal vascularity.
- Once an anatomic reduction has been obtained, achieve fixation with three or four threaded pins directed toward the center of the femoral head and only deep enough to obtain firm epiphyseal fixation (Figs. 172.7B-D).
- Confirm the position of the pins and epiphysis radiographically and perform routine closure.

Figure 172.8. Extracapsular basilar neck osteotomy of Barmada and Abraham. A: A periosseous elevator is used to elevate the anterior iliofemoral ligament. Inset: The incision of the anterolateral exposure. B: The proximal osteotomy cut is determined by placing a 3 cm K-wire along the base of the neck. The correct site is scored with an osteotome after fluoroscopic confirmation. A vertically placed K-wire is drifted vertical to the femoral neck at the scored line. C: The distal osteotomy starts at the base of the neck inferiorly and extends obliquely along the intertrochanteric line to the greater trochanter. The proximal osteotomy starts at the same position distally and extends proximally so that a proximally based triangle is formed. D: The bone wedge is removed. E: The lower extremity is internally rotated and abducted to close the osteotomy site. Fix with three to four screws. (From Abraham E, Garst J, Barmada R. Treatment of Moderate to Severe Slipped Capital Femoral Epiphysis with Extracapsular Base of Neck Osteotomy. J Pediatr Orthop 1993;13:294, with permission.)

- Longitudinally incise the fascia lata and develop the interval between the gluteus medius and tensor fascia lata.
- Locate the anterior joint capsule at the intertrochanteric line between the gluteus medius and the vastus lateralis.
- Using a periosteal elevator, elevate the anterior iliofemoral ligament from the anterior aspect of the femoral cortex (Fig. 172.8A).
- Gently place a narrow-tip Hohmann retractor around the superior aspect of the femoral neck superior and deep to the iliofemoral ligament; place another deep to the iliofemoral ligament proximal to the lesser trochanter.
- Reflect the vastus lateralis distally, exposing the base of the greater trochanter and the proximal femoral shaft.
- Incise the fascia lata longitudinally and develop the interval between the gluteus medius and the tensor fascia lata. This dissection should be carried proximally to the anterior branch of the superior gluteal nerve, which innervates the tensor fascia lata.
- Insert several 5-mm-diameter Steinmann pins from the outer cortex of the femoral shaft through the neck, across the osteotomy and into the epiphysis.
- Cut the pins to the appropriate length after radiographic confirmation of the osteotomy position and fixation.
- Close the wound in routine fashion.

Position the patient supine on the fracture table with the affected limb draped free. Mark a lateral incision 15-20 cm long along the posterior border of the greater trochanter. Incise the tensor fascia lata and vastus lateralis, and expose the femoral shaft subperiosteally.

Identify the lesser trochanter; it can be brought into prominence by abduction and external rotation of the hip. Detach the psoas insertion from the lesser trochanter, taking care not to injure the nearby vessels or sciatic nerve. Detach the previously made template, which consists of two right angles, at 90° and superimpose it on the femur, with the hypotenuse of each triangle based proximally; they intersect at the longitudinal orientation mark.

Identify the junction between the flat anterior surface and the slightly curved lateral surface of the femur; make a longitudinal mark along this junction using a sharp osteotome or oscillating saw. This mark identifies the anterolateral edge of the femur. It corresponds to the lateral (AP radiograph) and anterior edge of the femur (frog-lateral radiograph) used to make the intraoperative template.

Next, make a transverse mark at the level of the lesser trochanter (Fig. 172.9A).

Figure 172.9. Operative technique of the Southwick intertrochanteric osteotomy. A: The osteotomy site is marked as shown. B: The osteotomy is made and the bone wedge removed. C: The remainder of the medial and posterior transverse cut is made and, while controlling the proximal fragment with the pin attached to a T-handle chuck, the distal fragment is abducted and flexed, bringing the osteotomy surfaces together. The osteotomy is then internally fixed. Postoperative radiographs (D,E) of the child in Figure 172.2 demonstrate fixation with a Southwick plate. The AP radiograph (D) demonstrates equal epiphysial-shaft angles of 147°; the lateral radiograph (E) demonstrates a residual epiphysial-shaft angle on the left of 17° (34°–17°). Radiographs at last follow-up (F,G) (child now 16 years old) demonstrate union of the osteotomy; note the remodeling at the osteotomy seen on the lateral views. Fixation of a Southwick osteotomy with the more customary intertrochanteric lag/compression hip screw system (H–M). This 20-year-old man presented with a longstanding SCFE as shown on the AP (H) and lateral (I) views. The old SCFE deformity measured 82° using the lateral epiphysial–shaft angle (94°–12°). Immediate postoperative radiographs [AP (J) and lateral (K) views] demonstrate fixation with a hip screw system using a 95° dynamic compression plate. Note the short lag screw. It does not penetrate into the femoral head but rather into the proximal femoral metaphysis and neck, stopping just short of the calcar. The amount of correction achieved was 34°, with a final lateral epiphysial–shaft angle of 48°. The radiographs at last follow-up, at age 22.7 years, demonstrate osteotomy union [AP (L) and lateral (M) views]; again note the remodeling of the osteotomy in the lateral view. (Parts A–C from Tachdjian MO. Pediatric Orthopaedics, vol. 2, 2nd ed. Philadelphia: Saunders, 1990:1057, plate 37, with permission.)
Dunn Procedure
Proximal Femoral Osteotomy

Allow the child out of bed 48–96 hours after epiphysiodesis surgery and keep the child non-weight-bearing until physeal closure ensues. Full weight bearing is usually not advised until complete physeal closure. Counsel the child and parents to return immediately if there is any pain or loss of motion in either hip. Otherwise, return visits occur every 3 or 4 months, with repeat AP and frog-lateral radiographs of the pelvis, until complete physeal closure. After this time, allow normal activities except for running, jumping, and contact sports.

Toe-touch weight bearing is allowed immediately after

Surgical Techniques

UNSTABLE SLIPPED CAPITAL FEMORAL EPIPHYSIS

INTERNAL FIXATION

Gently transfer the child from the bed to the fracture table after anesthesia induction. The induction of anesthesia removes the child's muscle spasm and guarding. This often results in a spontaneous, unintentional reduction of the slip with simple positioning of the child on the fracture table. I do not employ any intentional reduction maneuver unless the deformity is so severe that adequate internal fixation is not possible because of inadequate osseous contact between the epiphysis and metaphysis.

Then proceed with cannulated screw fixation in the usual fashion. Place the first screw just as you would for a stable SCFE. The use of a second screw is controversial. Some authors advocate a second screw to control rotation and increase stability. Biomechanical studies do not show a two-fold increase in strength, and any screw off center axis has a much higher chance of joint penetration. Therefore, if a second screw is used, place it inferior to the first screw and with the final tip position at least 1 cm from the subchondral bone to reduce the risk of intraarticular penetration.

EPIPHYSIODESIS

The surgical technique is the same as that for a stable SCFE; the only difference is the application of a spica cast.

INTERTROCHANTERIC AND BASILAR NECK OSTEOTOMY

Intertrochanteric and basilar neck osteotomy procedures are contraindicated in the unstable SCFE.

CUNEIFORM OSTEOTOMY

Both Fish (24,25) and Dunn (22) will undertake their procedures in an acute-on-chronic SCFE as long as the other operative indications are met. There is no difference in the operative technique from that for a stable SCFE.

PROPHYLACTIC FIXATION OF THE OPPOSITE HIP

Prophylactic fixation of the opposite hip is controversial in North America, although it is more commonly accepted in Europe (31). In children with underlying endocrine or metabolic disorders (e.g., renal failure), prophylactic fixation of the uninvolved hip should be strongly considered (30,41). Therefore, if a second screw is used, place it inferior to the first screw and with the final tip position at least 1 cm from the subchondral bone to reduce the risk of intraarticular penetration.

REHABILITATION AND POSTOPERATIVE PRINCIPLES

STABLE SLIPPED CAPITAL FEMORAL EPIPHYSIS

In Situ Fixation

Toe-touch weight bearing is allowed immediately after in situ fixation with stable SCFE (3,87). Discharge is often the same evening for a morning surgery, or the next day for an afternoon surgery. I recommend toe-touch weight bearing for 4–6 weeks; however, many children have no postoperative discomfort and it is not uncommon to see them return for their first postoperative visit 1–2 weeks later carrying their crutches! At the first postoperative visit, check the incision and obtain radiographs to ensure no change in fixation. The next visit is 4–6 weeks after surgery; obtain radiographs then also. Obtain both AP and frog-lateral radiographs of the pelvis so as to follow the opposite hip. After this time, allow normal activities except for running, jumping, and contact sports.

Counsel the child and parents to return immediately if there is any pain or loss of motion in either hip. Otherwise, return visits occur every 3 or 4 months, with repeat AP and frog-lateral radiographs of the pelvis, until complete physical closure. After physical closure, all physical activities are allowed. Screw removal is controversial. The morbidity and complications (incision, operative time, blood loss, fracture risk) for screw removal are much greater than for insertion.

Epiplhysiodesis

Allow the child out of bed 48–96 hours after epiplhysiodesis surgery and keep the child non-weight-bearing until physal closure ensues. Full weight bearing is usually achieved by the tenth postoperative week (70,76,91).

Proximal Femoral Osteotomy

Dunn Procedure Dunn (22) originally recommended 4 weeks of postoperative skin traction, with active range of motion exercises starting on the first postoperative
day. Hip flexion to 90° should be achieved by 4 weeks. Then mobilize the patient with crutches; do not allow full weight bearing until radiographic union of the osteotomy, usually 2–3 months after surgery.

**Fish Cuneiform Osteotomy** Keep the child in bed until comfortable and then allow the child up with crutches, with toe-touch weight bearing (25). Permit full weight bearing when there is radiographic evidence of osteotomy union, at an average of 5 months. Fish recommends pin removal; allow full activity 2 months after pin removal.

**Basilar Neck Osteotomy** Kramer et al. (45) recommend partial weight bearing with crutches starting in the eighth postoperative week. Progression to full weight bearing varies according to the patient’s weight, reliability, and generalized hip osteopenia.

Abraham et al. (2) recommend partial weight bearing with crutches for 6 to 8 weeks. Full weight bearing is allowed at 8 weeks. In the case of bilateral osteotomies, permit weight bearing as tolerated.

**Intertrochanteric Osteotomy** Southwick (78) recommends bed rest with the limb in balanced suspension for 2 to 4 weeks. Keep the hip at 30° flexion. On the second or third postoperative day, allow the patient to sit at the bedside with support. Encourage mild active flexion of the hip and knee; when this flexion is comfortable and the wound is healed, allow non-weight-bearing with crutches.

Rao et al. (68) allow the patient to get out of bed on the first postoperative day and to walk with crutches without bearing weight on the third postoperative day. Start active range of motion exercises of the hip and knee on the seventh postoperative day. Permit full weight bearing when there is radiographic evidence of osteotomy union; physeal closure is not necessary for full weight bearing.

Müller (64) keeps the patient at bed rest for the first postoperative week. The limbs are held in abduction and internal rotation with the aid of boots and bars. On the tenth postoperative day, allow crutch walking with minimal weight bearing. Allow full weight bearing after 6 months.

**UNSTABLE SLIPPED CAPITAL FEMORAL EPIPHYSIS**

**Screw Fixation** Allow the child to get up with crutches once she is comfortable (6,82). If there is any question regarding compliance or stability of fixation, I recommend the use of a wheelchair for the first 6 weeks. Maintain non-weight-bearing until early callus is seen at the slip. Once there is evidence of early healing, allow gradual and progressive weight bearing. This typically begins at 8–12 weeks. Progression to full weight bearing is usually achieved by 3–4 months after fixation. These children must be closely observed for the development of AVN; it will usually occur within the first 12 months after the slip. The remainder of the postoperative rehabilitation is no different from that of a stable SCFE.

**Epiphysiodesis** In epiphysiodesis, a spica cast is applied, usually for 6–8 weeks. After cast removal, recommend non-weight-bearing until there is physeal closure. Full weight bearing is usually achieved 10 weeks after surgery (76,81,82).

**Proximal Femoral Osteotomy**

**Dunn Procedure and Fish Cuneiform Osteotomy** The postoperative protocol is the same as for the stable SCFE.

### PITFALLS AND COMPLICATIONS

Table 172.1 shows the results, including complications, of treatment methods for SCFE.

### AVASCULAR NECROSIS

Avascular necrosis usually occurs within the first year after an SCFE (52). AVN has not been reported in an untreated chronic stable SCFE. Its iatrogenic occurrence may be due to either realignment procedures (either closed reduction or proximal femoral osteotomy) or intraosseous vascular injury from internal fixation. Fixation that posteriorly exits the neck and reenters the epiphysis may damage the posterior retinacular vessels (Fig. 172.11) (71). Also, the superior weight-bearing quadrant of the femoral head is supplied by an artery that can be potentially injured by fixation devices (12). This may explain the high incidence of AVN when the fixation device is in this portion of the femoral head (Fig. 172.12). In the unstable SCFE, AVN is common and a result of the disease itself.

**Figure 172.11.** Diagram illustrating the potential for vascular injury when internal fixation is placed posteriorly through the neck in an SCFE. (From Riley PM, Weiner DS, Gillespie R, Werner SD. Hazards of Internal Fixation in the Treatment of Slipped Capital Femoral Epiphysis. *J Bone Joint Surg Am* 1990;72:1500, with permission.)

**Figure 172.12.** The radiographs of a 12-year-old girl with avascular necrosis after pinning of a left SCFE. Note cluster of pins placed anteriorly.

The long-term prognosis for AVN from SCFE is variable; many patients do reasonably well for some time. Degenerative changes gradually develop, but reconstructive surgery can usually be delayed until adulthood (44). In one series of 24 hips with AVN after an SCFE at 31 year follow-up, reconstructive surgery was required in four
hips during adolescence and in five during adulthood. The remainder had not required reconstructive surgery but did show degenerative changes on recent radiographs. AVN from an acute unstable SCFE appears to be worse than that from a stable SCFE.

Avascular necrosis may either be segmental or complete (55). Treatment is difficult and there is no perfect solution. The first goals are to maintain joint motion and, as much as possible, to prevent further collapse. Relief from weight bearing is initially recommended. Unfortunately, healing of the necrotic areas may require a prolonged time, and most adolescents will not be compliant with prolonged non-weight-bearing.

Internal fixation may penetrate the joint and require removal if the collapse is in the area of the pin (Fig. 172.13). If the physis is still open, the epiphysis needs to be restabilized with appropriately redirected internal fixation. Further progression of a slip with concomitant AVN after hardware removal is a difficult problem that should be avoided.

![Figure 172.13.](image)

After healing of the necrotic area, hip motion may be reasonably good if the AVN is segmental with no gross joint deformity present. With more extensive involvement, poor motion and pain may persist. In this case, there are multiple options to consider when medical therapy fails (e.g., nonsteroidal anti-inflammatory drugs (NSAIDs), range-of-motion exercises, activity modification). If hip motion can be improved by redirecting a noninvolved area of the femoral head to a more congruent weight-bearing position, then proximal femoral osteotomy may be considered. Another alternative is bone grafting the collapsed area to improve joint congruity (42,75) and to provide further containment by femoral and/or pelvic osteotomy. Arthrodesis or total joint arthroplasty are considered if the hip is not salvageable. It must be remembered that these patients are young and heavy, which is a concern regarding the longevity of a total hip arthroplasty.

CHONDROLYSIS

Chondrolysis is an acute loss of articular cartilage in association with increasing joint pain and stiffness (54,58,89). Unlike AVN, chondrolysis can occur in the untreated stable SCFE. It may be aggravated by persistent intraarticular fixation or with spica casts. In the past, it was thought that black children and those of Hawaiian ancestry were more susceptible to its development (58,85); recent reports question this view (4,40,80). The exact etiology is unknown, although it may be an autoimmune process aggravated by the persistent pin penetration and secondary mechanical joint damage (63). Chondrolysis does not occur in all joints with pin penetration; however, its incidence is higher as the number of pins increases or they become closer to the subchondral bone (10). Transient intraoperative pin penetration that is corrected at surgery does not increase the risk of chondrolysis (86).

Chondrolysis usually appears within 1 year after diagnosis of the SCFE. Its clinical hallmark is severe loss of motion and pain in relation to slip magnitude. It is radiographically defined as a loss of more than 50% of the width of the weight-bearing portion of the articular space in children with unilateral SCFE (Fig. 172.14), or less than 3 mm width of the articular space in children with bilateral SCFE. When the diagnosis is suspected but there is no plain radiographic evidence, a technetium-99 methylene-diphosphonate bone scan may be helpful (57). Marked periarticular uptake and premature closure of the greater trochanteric physis are highly predictive of future chondrolysis.

![Figure 172.14.](image)

Once chondrolysis is diagnosed, it is incumbent on the surgeon to prove that there is no intraarticular hardware penetration (Fig. 172.15). If there is, the fixation must be removed and repositioned if the physis is still open. Occult sepsis must also be ruled out. The initial treatment for chondrolysis is rest, NSAIDs, and maintenance of joint motion by physiotherapy, traction, and protected weight bearing. In the refractory case, aggressive capsulotomy has been advocated (73).

![Figure 172.15.](image)
The long-term outcome is variable. Up to 60% may do well with at least partial reconstitution of the articular cartilage and restoration of a clinically useful range of motion. In other cases, spontaneous ankylosis may occur. If spontaneous ankylosis occurs in an acceptable position, nothing further needs to be done. If spontaneous ankylosis occurs in an unacceptable position, then a femoral osteotomy below the ankylosis may be necessary to appropriately reposition the lower extremity in space. A painful, malpositioned hip often requires a formal hip arthrodesis (Fig. 172.14).

OTHER Complications

Other complications include slip progression, hardware complications beside joint penetration, femoral fracture, nerve palsy/injury, and nonunion or delayed union of an osteotomy or epiphysiodesis (71).

The incidence of slip progression in the stable SCFE is approximately 1% with in situ single-screw fixation; the incidence after epiphysiodesis is approximately 7% (Table 172.1, Table 172.2). If the internal fixation is left prominent from the cortical bone entry point, loosening of the screw due to a "windshield-wiper effect" can occur (56). A false aneurysm has also been reported with retained prominent hardware (33). Because of this, the screw head should not be more than 1.5 cm from the cortical surface. Sciatic nerve injury and septic arthritis are rare but described complications with internal fixation of SCFE.

Hardware breakage before removal was more common when smaller, multiple pins were used, especially when they entered the femoral neck posteriorly and reentered the epiphysis (Fig. 172.16). It is less common with the single-cannulated screw and anterolateral placement. The hardware may also strip or break during removal, making complete removal impossible. This is much more common with titanium cannulated screws; in the young child with SCFE and hard bone, no titanium implants should be used (47,88).

Figure 172.16. Broken pins in SCFE. A: Diagram showing how pins can break when they exit the femoral neck and then reenter the femoral head. B: The AP radiograph of the pelvis of a 23-year-old man who had an SCFE treated as a teenager with multiple-threaded Steinmann pins. Note the broken pin. C: The CT scan demonstrates the pin exiting the femoral neck and then reentering the femoral head. (Part A from Riley PM, Weiner DS, Gillespie R, Werner SD. Hazards of Internal Fixation in the Treatment of Slipped Capital Femoral Epiphysis. J Bone Joint Surg Am 1990;72:1500, with permission.)

Fracture of the femur may occur at the subtrochanteric, intertrochanteric, or neck level. Holes after hardware removal act as a stress riser and may lead to an intertrochanteric or subtrochanteric fracture. Fracture may also occur immediately after internal fixation if multiple starting points are made on the femur, even in the region of the femoral neck (7).

The Southwick osteotomy has a slight risk of delayed union or nonunion (69,74,79). This is not surprising when considering the low intertrochanteric position of the osteotomy in these obese children. With bone graft epiphysiodesis, there is a low but persistent incidence of epiphysiodesis failure.

SALVAGE PROCEDURES

Most salvage procedures are adequately discussed elsewhere [e.g., hip arthrodesis (8,11,14,67,81), total hip arthroplasty (19)]. Also see Chapter 105 and Chapter 106. For the rare case in which a trap door or other bone grafting procedure is needed for AVN, the reader is referred to the original manuscripts (42,75).

There are certain considerations regarding these procedures peculiar to children with SCFE. The most important is their young age and obesity. Union of an arthrodesis is more difficult because of obesity; a postoperative hip spica cast is recommended, even if rigid internal fixation is used. Arthrodesis after AVN is also more difficult, because of the lack of blood supply. If possible, both an intra-and an extraarticular arthrodesis should be performed. The difficulties with arthrodesis in this patient population makes arthroplasty more appealing. However, the risk of loosening and need for revision arthroplasty is likely to be quite high in these patients. Unfortunately, there are no published series specifically addressing the outcomes of total hip arthroplasty as the treatment for associated complications of SCFE.

LEGG-CALVÉ-PERTHES DISEASE

INTRODUCTION

Legg-Calvé-Perthes disease is a form of idiopathic avascular necrosis of the femoral head. Although the exact etiology of the disorder is not known, the association of Legg-Calvé-Perthes disease with delayed skeletal maturation suggests a systemic susceptibility to the problem. Some children have abnormalities of coagulation with decreases in the factors involved in thrombolyis, which may predispose them to avascular necrosis.

The clinical course is quite variable, making it difficult for the clinician to know for certain which patients need and will benefit from treatment. Current use of the lateral pillar radiographic classification has improved our ability to assess severity and prognosis in an individual case. Children younger than 6 years of age at onset usually have a benign course, and major treatment is not often necessary because they have a longer growing time to remodel abnormalities. Children between 6 and 9 years of age at onset have more symptoms and often benefit from surgical treatment. Children older than 9 years at age have a more severe course, and their response to treatment is less predictable. In the long run, 50% of patients have no disability as adults and the other half develop degenerative hip disease by the fifth or sixth decade of life.

Treatment has been based on the containment principle, which means positioning the femoral head within the acetabulum in such a way as to reduce lateralization and collapse of the softened head. In the past, this was done with braces, but at present, femoral or pelvic osteotomies are preferred.

COURSE OF DISEASE AND NATURAL HISTORY

The initial events in the course of Legg-Calvé-Perthes disease are well established. The femoral head becomes ischemic for reasons unknown and for an unknown period of time. Several studies suggest that at least two episodes of ischemia are necessary to produce the typical changes of Legg-Calvé-Perthes disease (7,27).

More recent studies have shown that a number of children have deficiencies of proteins S and C and hypofibrinolysis (8,9). The original studies suggested that the majority of children were deficient in these factors, but subsequent reports have found only a small proportion patients with Legg-Calvé with these coagulopathies (14).

Following the ischemic episode, the femoral head becomes radiodense, then appears fragmented radiographically as dead bone is resorbed, and finally reossifies with new bone formation. These sequential phases have been classified by Waldenström (30) as increased density, fragmentation, reossification, and residual stages. No treatment to date has been shown to either accelerate or delay the healing process, although it was initially thought that femoral osteotomy resulted in more rapid healing. This was disproved in studies by Clancy and Steel (6) and Kendig and Evans (15). During the fragmentation phase in more severe disease, the head loses height, enlarges, and may flatten. As the head enlarges, the anterior and lateral portions of the head extrude from the acetabulum. Over several years, the femoral head completely reossifies and may remain round in mild cases, become ovoid in moderate cases, and become flattened in severe cases. Stulberg and colleagues (29) classified these groups according to femoral head status as:

- **group I** normal head
- **group II** round head
- **group III** ovoid head and acetabulum
- **group IV** flattened head and acetabulum
- **group V** head collapsed and acetabulum failed to remodel

The prognosis for a child with Legg-Calvé-Perthes disease can be estimated to some degree. The most frequently reported prognostic factor is the age of the child at the onset of the disease. Most, but not all, children presenting at younger than 6 years of age have a good prognosis, whereas those between 6 and 9 years of age have a more variable course. Children older than 9 years of age presenting with Legg-Calvé-Perthes disease have a worse prognosis than those with an earlier onset. Within these general guidelines, the disease is quite variable, and individual prognostication is difficult.

There are several classifications of severity of Legg-Calvé-Perthes disease. The Catterall classification delineates four groups based on areas of femoral head involvement (2):

- **group I** anterior head involvement
- **group II** central head involvement
- **group III** lateral and central head involvement
- **group IV** total head involvement

In addition, the presence of two or more risk factors (extrusion, Gage’s sign, lateral calcification, and a horizontal growth plate) suggests a worse prognosis.

Because of problems with reproducibility of this classification, a newer system—the lateral pillar classification—has come into general use (Table 173.1 and Fig. 173.1, Fig. 173.2 and Fig. 173.3) (12). In this scheme, the lateral portion of the femoral head is evaluated on the anteroposterior (AP) radiograph in the early fragmentation stage of the disease.
Table 173.1. Lateral Pillar Classification

Figure 173.1. Lateral pillar group A classification. AP radiograph of the left hip showing well-demarcated lateral pillar. There is no loss of height in the lateral segment of the femoral head in spite of some changes in radiodensity.

Figure 173.2. Lateral pillar group B classification.

Figure 173.3. Lateral pillar group C classification. AP radiograph of the pelvis of a boy who has had a varus osteotomy for Legg-Calvé-Perthes disease. A: The lateral portion of the femoral head is lucent and collapsed relative to the central portion. B: AP radiograph 9 months later showing further collapse of the lateral pillar. C: AP radiograph several years later showing flattening of the femoral head.

The natural history of Legg-Calvé-Perthes disease has been well studied, and all reports state that the majority of individuals with the disorder do well through most of their adult lives (6,10,23). McAndrew and Weinstein (17) have shown that with follow-up studies of 48 years, about 50% of the patients will develop severe enough hip disability to require a total hip replacement by their fifth or sixth decade of life. In these studies, those with onset of disease after 9 years of age had the highest incidence of poor results. These studies demonstrate that long-term prognosis is closely related to the roundness of the femoral head and the congruity of the hip joint.

TREATMENT CONCEPTS

The earliest treatment efforts for Legg-Calvé-Perthes disease were directed at relief from weight bearing (16). This was a natural evolution, because in those early days, the disorder had just been distinguished from tuberculosis, and weight relief was the mainstay of treatment for tuberculous hips. With time, the concept of maintaining abduction along with bed rest became the basis for containment therapy (20). Subsequent studies showed good results with weight-bearing abduction devices, and ambulatory containment was born (11,19).

Salter (24) produced avascular necrosis in pigs and found that those animals whose hips were kept in abduction had femoral heads that remained round, whereas the femoral heads of the untreated animals flattened. Based on this work, surgical containment, either with femoral or pelvic osteotomy, has been commonly performed for Legg-Calvé-Perthes disease.

INDICATIONS FOR CONTAINMENT TREATMENT

Today there is considerable disagreement among different centers concerning indications for treatment of Legg-Calvé-Perthes disease. Our current approach is based on preliminary data from a long-term multicenter study that compared the treatment methods of range of motion, bracing, femoral osteotomy, and Salter osteotomy.

We recommend containment treatment for those children who meet the following criteria:

1. Age at onset of disease between 6 and 10 years
2. Lateral pillar group B involvement with bone age at onset of more than 6 years
3. Lateral pillar group C involvement
4. Hips with a reasonable range of motion

We recommend symptomatic treatment for the following:

1. All lateral pillar group A hips
2. Lateral pillar group B hips with a bone age at onset of 6 years or less
3. Any children younger than 6 years of age at the onset of the disease

Symptomatic treatment consists of reduction of activities when pain and limp worsen, and occasional periods of rest or traction when necessary for loss of range of motion. Anti-inflammatory medications are used when necessary. If persistent loss of motion occurs, a period of a few months of ambulatory abduction bracing may
The treatment of children older than 10 years of age at onset is difficult. Many surgeons perform containment surgery, with the caution that all may not go well. These children often lose range of motion after surgery and may even need abduction casting or bracing postoperatively. The combination of femoral and pelvic osteotomy may be appropriate in this age group.

RESTORATION OF MOTION

It is essential to regain range of motion before instituting containment treatment. In the child who has had recent onset of Legg-Calvé-Perthes disease and presents in the early radiographic stages, motion is usually relatively easily regained. Often a few days of bed rest are sufficient to regain enough abduction to “cover” the femoral head radiographically. If the hip is more resistant to loosening up, then a program of night traction in abduction may be helpful. After this, bracing or surgical containment may be instituted.

The child who has had symptoms for many months and who has reached the fragmentation stage may require more vigorous methods to regain motion. Try full-time traction and bed rest and, if these measures are insufficient, institute a period in Petrie plasters. The usual procedure is to evaluate the patient under anesthesia and perform an arthrogram to assess femoral head flattening. If the hip can be abducted sufficiently to cover the cartilaginous head, apply long-leg plasters with abduction bar. If the hip will not abduct, decide whether “hinge abduction” is occurring. This is a condition in which the head lever out of the acetabulum with abduction instead of moving within the socket. If there is hinge abduction, containment surgical procedures are contraindicated because severe hip stiffness may ensue. If the head abducts but motion is limited by tight adductor muscles, an adductor tenotomy may be helpful, followed by the Petrie casts.

SURGICAL CONTAINMENT TREATMENTS

FEMORAL OSTEOTOMY

Some surgeons attempt to obtain sufficient range of motion to cover the hip before femoral osteotomy, but others perform the procedure even when there is reduced motion (Fig. 173.4). Because there is the occasional very stiff hip after the operation, I recommend that the surgery be performed only in children with at least 30° of hip abduction. In those patients who lack this motion, I regain range of motion by using Petrie casts for 6 weeks before performing femoral osteotomy. If the patient has had Legg-Calvé-Perthes disease for many months, there may be flattening of the femoral head, and thus I perform an arthrogram before osteotomy. If the femoral head leaves out of the joint with abduction (hinge abduction), a varus osteotomy is contraindicated. Instead, a trial period of Petrie casts may be instituted with repeat arthrogram to determine if the hinge abduction has resolved, in which case the osteotomy may be performed. Otherwise, other procedures such as valgus osteotomy may be appropriate in these late cases.

The osteotomy is usually performed at the subtrochanteric level. There are a variety of opinions as to how much varus and derotation should be used. Some surgeons estimate the amount of varus based on the amount of abduction required to cover the lateral portion of the femoral head under the acetabulum. Most surgeons, however, seek a certain neck-shaft angle regardless of the estimated coverage. A commonly used angle is 115° to 120°. A greater amount of varus will result in an abductor limp that may persist. Some remodeling of the neck-shaft angle will occur in younger children with lesser involvement, but older children and those with severe disease may not have the growth capacity to remodel the neck-shaft angle. Rab (22) has published a review of preoperative radiographic evaluation for osteotomies about the hip, which is helpful in the planning stage.

Some surgeons also derotate the femur, based on the concept that this will improve anterior coverage of the femoral head. This may cause the patient to out-toe and probably should be done minimally, if at all. Other surgeons perform a proximal osteotomy, and extend or anteriorly angulate the osteotomy to improve anterior coverage.

Rigidly fix these osteotomies with one of the blade plates or screw plate devices specifically designed for children. Immobilize in a cast those patients requiring muscle releases and those who cannot cooperate with limited weight bearing. (Remember that these children tend to be extremely active.) See Chapter 158 for more details on the operative technique.

Complications often occur because of inadequate fixation with these active children. Malunion into varus is a serious problem, which will result in a poor gait. Nonunion, however, is uncommon. The more severely involved hips may become progressively stiffer following the osteotomy. When this occurs, the varus of the osteotomy results in adduction of the thigh. It may be necessary to return the patient to the operating room for adductor muscle releases and placement of Petrie casts for a period of time to restore hip range of motion. We have even had to return patients to brace wear for 6 to 8 weeks to maintain abduction postoperatively.

Remove the fixation plate a year after the osteotomy. At that time, if there is excessive varus (perhaps less than 110° neck-shaft angle), an arrest of the greater trochanter may be appropriate to keep the trochanter below the femoral head. Occasionally, when excessive varus has been introduced, it may be necessary to perform a valgus femoral osteotomy subsequently to restore a normal gait.

SALTER INNOMINATE OSTEOTOMY

The prerequisites for an innominate osteotomy are similar to those of the femoral osteotomy but are more rigorous (Fig. 173.5). Salter has recommended that a full range of motion be obtained and that an arthrogram show no flattening of the femoral head as a prerequisite to his operation (22,26). In practice, many surgeons perform the procedure when an adequate range of motion has been obtained and the flattening of the femoral head is mild.
The operation is usually performed as originally described. Salter has emphasized lengthening the ilioptos to reduce the pressure on the hip. Some surgeons prefer the Kalanchi modification of the procedure, which moves the distal fragment of the osteotomy into a notch in the posterior part of the pelvis (13). The purpose of this technique is to avoid lengthening the pelvis and increasing the pressure on the femoral head. Other surgeons add a shelf of cancellous bone over the femoral head to add to coverage. Most surgeons immobilize the hips in spica casts for 6 weeks, but some use screw fixation for the osteotomy and allow partial weight bearing until the osteotomy has healed. See Chapter 166 for details on operative technique.

An occasional complication of the procedure is hip stiffness, which at times can be severe. As with the femoral osteotomy, it may be necessary to perform muscle releases and use Petrie casts and braces postoperatively to regain range of motion. As with any osteotomy, it is important to position the osteotomy fragments properly and obtain secure internal fixation. If the fixation pins or screws are improperly placed, the osteotomy will displace posteriorly and be ineffective.

**VALGUS OSTEOTOMY**

A valgus osteotomy of the femur is occasionally indicated for the patient who presents late with well-established deformity and hinge abduction (3,21). The purpose of the osteotomy is to reduce the adduction of the thigh and allow better weight-bearing alignment. At times, the femoral head will remodel after this procedure. This should be considered a late, reconstructive operation and is not appropriate as primary treatment. See Chapter 29, Chapter 104, and Chapter 166 for details on the operation.

**COMBINED FEMORAL AND PELVIC OSTEOTOMY**

The use of combined femoral varus and pelvic osteotomy (either Salter type or Chiari) has been advocated for severely involved hips, especially in children older than 9 years of age at the onset of the disease. The current reports of this approach suggest that there is an improvement in outcome, but more evaluation is necessary before this procedure should be done commonly (3,18).

**REMOVAL OF LOOSE BODY**

Occasionally, a patient with Legg-Calvé-Perthes disease will develop an osteochondritic lesion, usually many years after the onset of the disorder. The symptoms of locking and popping suggest the diagnosis, which then may be confirmed with arthrography or computed tomography (CT) scanning. Arthroscopy may allow removal of either a loose body or, more commonly, a softened area in the center of the femoral head (1,28). Sometimes an anterior arthrotomy to locate the loose body is appropriate, but it may be necessary to dislocate the hip to find the loose body.

**AUTHOR'S PERSPECTIVE**

My current approach to the treatment of a patient with Legg-Calvé-Perthes disease who presents when the disease is in the phase of increased density or early fragmentation follows: For a child whose bone age is six years or less, I institute conservative treatment (rest, anti-inflammatory agents) until there is enough fragmentation to determine lateral pillar classification. If the patient's hip is determined to be class A, I perform no further treatment. If the hip is determined to be class B, I continue symptomatic treatment, and if it is Class C, I prefer containment surgery, usually a Salter osteotomy.

For a child whose bone age is greater than six years, if clinical signs are minimal, I observe the patient until I am certain of a significant degree of disease beyond class A. If significant clinical signs are present, I allow the patient to regain range of motion conservatively and consider containment surgery (I prefer Salter osteotomy).

In a child older than 10 years, decision making is difficult. I consider containment surgery if the disease is in the early phase. Usually a Salter osteotomy is performed, sometimes combined with a proximal femoral varus osteotomy. In children in this age group, one must recognize that the overall prognosis is poor.

CHAPTER 174

CONGENITAL LOWER LIMB DEFICIENCY

William L. Oppenheim, Hugh G. Watts, Robert M. Bernstein, and Yoshio Setoguchi

This chapter focuses on a group of diverse congenital anomalies affecting the lower extremities of children. Many involve a failure of formation of various tissues, as well as leg-length discrepancy. The general approach to these patients is to evaluate their limbs in terms of potential function, to estimate the projected leg-length discrepancy at maturity, and then to address the situation either by standard leg-length equalization techniques or through the use of a prosthesis that can be adjusted in length as the child grows. When amputation is indicated as part of the overall solution, one must identify a key joint for salvage and then convert the tissue distal to that joint into a usable weight-bearing organ. The key joint is the most distal joint with sufficient function to power a prosthesis. Complicating the technical problems are psychological feelings of helplessness, anxiety, and frustration among parents and physicians alike.

The concept of sacrificing a body part to facilitate prosthetic fitting is initially poorly accepted by most parents, particularly if the part proposed for sacrifice appears quite normal. The parents rightly question why modern technology cannot be called upon to salvage their child's limb. Physicians faced with this scenario must improvise based on their combined expertise in prosthesis and reconstructive surgery. Although some of the procedures may initially appear radical to parents, with education and counseling the child and parents can accept them as simply reconstructive. Experience has shown that it is frequently preferable to convert a limb to a logical prosthetic level rather than embark on a prolonged operative reconstruction that, even when modestly successful, frequently precludes participation in normal childhood activities (41). Treatment thus requires an understanding of the natural history of the specific defect as well as a thorough knowledge of any associated abnormalities.

Because of the complicated nature of these conditions, evaluation and treatment are best carried out at special clinics where appropriate psychological, social, and pediatric support is available. Surgical procedures are not easily undertaken and rely on the parents' informed judgment based on a balanced medical presentation and the experience gained through the consultation process. An opportunity to interface with other families in similar circumstances who have already gone through the process is a reassuring influence and should be part of the family's decision-making process.

ETIOLOGY

The period during which a developing embryo is most susceptible to malformations being perpetuated in subsequent cell lines is between the fourth and eighth weeks postfertilization, the so-called period of organogenesis. Both the axial and appendicular skeletons form at this time. A single cell gives rise to billions of descendants, so the surprising thing is not that congenital anomalies occur, but that they do not occur even more frequently. Some conditions have a familial origin and hence a preordained genetic derivation. For example, congenital dislocation of the knee may occur sporadically or in association with Larsen's syndrome, an autosomal dominant condition in which dislocations of other joints and anomalies of the cervical spine also occur. Whatever the cause, once a defect is present, with the limb bud developing in a proximal to distal progression, areas "downstream" from the initial insult may also be affected. For example, proximal femoral focal deficiency is frequently associated with a more distal fibula deficiency, and absence of the fibula in turn may be associated with absence of lateral foot rays.

Because other organ systems also differentiate during this gestational period, limb defects frequently are seen in the presence of anomalies exclusive of the musculoskeletal system. They, the VACTERLS syndrome refers to the association of vertebral, anal, cardiac, tracheoesophageal, renal or radial flaws, associated with limb defects and a single umbilical artery. In the amniotic band syndrome, the insult is thought to take place after limb bud development during the fetal period of gestation. Multiple bands may be present, predisposing to autoamputations. From this brief discussion, it is clear that limb reduction defects often present as part of a more general syndrome.

DIFFERENCES BETWEEN CHILD AND ADULT AMPUTEES

Amputation surgery in children differs from that in adults. In adults, amputation is frequently related to peripheral vascular disease or diabetes; healing is delayed and rehabilitation is difficult and prolonged. Adults are concerned about their body image, time lost from work, and their livelihood in general. Children, on the other hand, usually heal promptly and completely; conversion to an amputation at an early age is not ordinarily difficult or prolonged; and potential employability is not an immediate concern (see Chapter 175). Phantom pain and neuromas, which can significantly impact on the results in adults, do not appear as clinically significant in children and present only an occasional problem in adolescents. Gait training takes place spontaneously under the guidance of a prosthetist or physical therapist, and psychological acceptance of the limb is natural and not elaborate.

However, one problem peculiar to growing children is frequent overgrowth following transdiaphyseal amputations, particularly in the humerus, tibia, and fibula. This can result in a need for serial surgical revisions throughout growth (see section on Terminal Overgrowth at the end of this chapter). Where possible, perform amputation through an adjacent joint to avoid this problem, but this consideration must in turn be tempered by the concomitant goal of maintaining length. Through-joint amputations not only preserve length, but, by preservation of the adjacent growth plate, add to the length throughout childhood, preventing an initial adequate length...
TECHNIQUE OF SYME'S AMPUTATION

When assessing an infant with a limb deficiency, identify possible etiologic factors. Consider the influence of teratogenic agents such as thalidomide, maternal risk factors such as diabetes, and environmental factors such as radiation exposure. A genetics consultation is recommended to assess the risks for additional pregnancies and to offer counseling. Despite the gravity of the situation, the professional staff should maintain an optimistic demeanor. Nearly all children with lower extremity anomalies gain functional mobility, attend regular school, and lead quality lives, participating in sports such as swimming, skiing, tennis, and horseback riding. Schools may restrict participation in contact sports such as football and hockey because of the risk of injury to other children from prosthetic parts. The role of the parents and grandparents cannot be underestimated. Acceptance of the child as he is and the avoidance of overprotection, which can lead to an overly dependent and submissive personality, facilitates the child's development, sense of self worth, and eventual integration into the workplace.

CONGENITAL DEFICIENCY OF THE FIBULA

Congenital malformations of the fibula usually are not associated with classic modes of genetic transmission and thus likely result from embryonic insults occurring during the development of the limb bud. The severity ranges from simple hypoplasia to total absence of the fibula. Experimental evidence suggests that the earlier the insult occurs in embryonic development, the more likely is concurrent involvement of the proximal femur. Later insults involve the fibula and foot to a greater degree. Fibular deficiency thus may be accompanied by proximal femoral focal deficiency, shortening and/or bowing of the tibia, general limb growth retardation, delayed epiphyseal ossification, absence of rays, tarsal coalitions, residual fibrous bands, deficiencies of various muscles, genu valgum, and loss of ankle integrity.

The literature abounds with ankle stabilization procedures for the treatment of type II deformities, but the test of time has not supported this approach. Stabilization by arthrodesis is complicated by delayed ossification of the epiphyses, as well as by potential inadvertent injury to the distal tibial physis. Kruger and Talbott (11) have pointed out that whereas the goal of preserving the foot might be laudable, in fact many children who undergo repetitive operations eventually undergo amputation, and that upon honest review there is good evidence that conversion should have been offered as a primary treatment rather than a secondary salvage procedure. In type I deformities, the foot usually remains plantigrade but may be associated with a ball and socket ankle joint, and either equinovarus or equinovarus may be present. In type II, by contrast, the entire fibula is absent, tibial bowing is frequent, and ankle instability is the rule. A residual lateral fibrous band may contribute to the type II deformity.

Some surgeons have used the absence of rays to predict ankle stability (e.g., a four-toed foot can be salvaged, but a three-toed foot should be sacrificed), but we have found that stability can be directly assessed and that a three-toed foot can often be serviceable. The degree of tibial shortening increases with advanced stages, although associated femoral shortening is maximal in type I. Children with type I feet will not require conversion to an amputation, but conversion is usually performed for the majority of children with type II deformities.

The literature abounds with ankle stabilization procedures for the treatment of type II deformities, but the test of time has not supported this approach (11,15). Stabilization by arthrodesis is complicated by delayed ossification of the epiphyses, as well as by potential inadvertent injury to the distal tibial physis. Kruger and Talbott (11) have pointed out that whereas the goal of preserving the foot might be laudable, in fact many children who undergo repetitive operations eventually undergo amputation, and that upon honest review there is good evidence that conversion should have been offered as a primary treatment rather than a secondary salvage procedure. In addition, we have found a higher incidence of complications when Syme amputation was performed as a salvage procedure in multiply operated limbs rather than as a primary procedure (6). In areas where cultural concerns do not allow amputation, or in lesser developed areas where surgery is not available, it is feasible to fit a prosthesis around the foot.

In instances where the ankle is relatively stable and the overall length can be made acceptable, leg lengthening using Ilizarov techniques, in which the ankle is stabilized during lengthening, is an acceptable approach.

INDICATIONS FOR ANKLE DISARTICULATION IN CHILDREN

The indications for conversion to a below-knee amputation are (a) a deformity of the foot so severe that any surgery to make the foot plantigrade and functional is likely to fail (70) and (b) an estimated leg-length discrepancy at maturity of 7.5 cm or more (60). The value of 7.5 cm is arbitrary and tends to vary among physicians (46,59,60). We now base our decision more on the stability of the ankle than the leg-length discrepancy, per se, provided the overall limb-length discrepancy at maturity is not projected to exceed 12 cm.

TECHNIQUE OF SYME'S AMPUTATION

- Begin the procedure of Syme's ankle disarticulation (Fig. 174.2) by making a fish-mouth incision with anterior and posterior skin flaps. The apex begins 1 cm distal to the medial malleolus and parallels the anterior ankle joint to a point estimated to be the level where the fibular tip would ordinarily be palpable.

Figure 174.2. Syme's ankle disarticulation as performed in children. Make skin incisions from a point 1 cm distal to the medial malleolus to the tip of what would have been the fibula malleolus, as illustrated. A: Schematic of the anatomy posterior to the medial malleolus. B: Divide the collateral ligaments to facilitate hyper plantarflexion of the ankle. C: Location of the flexor hallucis longus posterior to the talus. D: Protect the neurovascular bundle by retraction of the flexor hallucis longus muscle tendon. E: Divide the Achilles tendon, taking care to include excision of the apophysis of the calcaneus. F: Preserve the neurovascular bundle to the end of the flap; avoid injury to the bundle at the level of the ankle joint. G: Close the wound over a drain, and stabilize the heel pad with a stout K-wire or smooth Steinmann pin inserted into the tibia from the plantar aspect of the heel.

- Carry the dissection down through the subcutaneous tissue to the level of the medial and lateral collateral ligaments of the ankle, ligating larger vessels and...
controlling smaller ones with electrocautery.

- Identify the nerves. Gently tension, sharply divide, and allow the nerves to retract away from potential subcutaneous positioning.
- Divide the collateral ligaments so that the talar dome can be pulled forward away from the distal tibia.
- In the interval between the talus and tibia, identify the flexor hallucis longus tendon. It is the key to locating and protecting the neurovascular bundle posteromedially. By protecting this tendon and drawing it medially with a retractor, the dissection can be continued with the neurovascular bundle shielded so that the actual division of the posterior tibial artery will be at the most distal portion of the posterior flap.
- Excise the calcaneus from the heel pad in a subperiosteal fashion so that the periosteum remains intact, maintaining the structural integrity of the fat pad, which has a hydraulic-like function during weight bearing. Be sure that the entire calcaneal apophysis is excised so that it will not form a persistent osseous later (Fig. 174.3). Two centimeters of the distal Achilles tendon can be resected to ensure there will be no tendency to retract and pull the heel pad posteriorly. Shave the distal tibia only in older children, because smoothing and remodeling occur spontaneously in younger children once the talus no longer occupies the mortise.

Figure 174.3. In performing Syme's amputation, be certain to excise the entire apophysis, otherwise it will persist and complicate later prosthetic fitting. This one required removal during adolescence.

- Finally, stabilize the heel pad under the tibia by inserting a stout Kirschner wire (K-wire) through the pad into the tibia, and close the skin over a Penrose drain with absorbable subcutaneous sutures and interrupted nylon sutures for the skin. In approximating the heel pad to the tibia, take care to avoid crimping the posterior tibial artery.

After skin repair, apply Xeroform (Sherwood Medical, Markham, Ontario) gauze, fluffs, sterile cast padding, and a spica cast for short stumps (as when the amputation is combined with a knee fusion for proximal femoral focal deficiency). A long-leg cast can be applied when the knee can be effectively flexed to prevent the cast from sliding off. Remove the drain at 2 days and allow 6 weeks for soft-tissue healing in the cast. An elastic wrap is occasionally necessary for several additional weeks to control any residual stump edema. The stump is ready for prosthetic fitting between the tenth and twelfth weeks.

Associated tibial bowing ordinarily corrects spontaneously after a Syme's amputation, but in those cases accompanied by bowing in excess of 30°, perform a tibial osteotomy simultaneously, and extend the K-wire to act as intramedullary fixation.

TECHNIQUE OF BOYD AMPUTATION

Some authors have reported problems with stabilization of the heel pad in the Syme's amputation and thus prefer the Boyd amputation, in which the calcaneus is displaced anteriorly in an effort to fuse it into the distal tibia or at least to stabilize it under the tibial plafond (6,10,70). Most additional length can be also be maintained by this approach. Alternatively, the distal tibial physis can be excised at the time of calcaneal tibial fusion, so that the bulbous self-suspending stump gradually “ascends” to the level of the opposite calf. In deformities with severely displaced equinus hind feet, repositioning of the calcaneus under the tibia may not be possible, and Syme's procedure is preferred. No shaping of the malleolus is necessary in young children in either the Boyd or the Syme ankle conversion. Without the talus occupying the mortise, the malleolus remodel to a satisfactory shape. Either procedure yields a pleasing stump because the prominent malleolus atrophy after talar excision.

Boyd amputation (B) utilizes an approach similar to the Syme procedure just described. However, excise only the talus and forefoot, leaving the calcaneus attached to the fat pad (Fig. 174.4).

Carefully shave the articular cartilage of the distal tibia with a knife until the ossific nucleus is encountered; take care to breach neither the distal tibial physis nor its surrounding perichondrium, unless shortening of the stump is desired.
- Osteotomize the anterior portion of the calcaneus, if necessary, just distal to the peroneal tubercle; shave the superior surface flat, allowing it to sit congruously under the prepared distal tibia.
- Divide the Achilles tendon through the space left by the excision of the talus. When performed properly, the heel pad can be positioned in its normal weight-bearing attitude but slightly displaced anteriorly.
- Use a smooth Steinmann pin to secure the final position, extending it through the calcaneus across the distal tibial physis into the medullary canal of the tibia.
- Close the skin over a drain.

The postoperative management is similar to that described for the Syme's amputation.

RESULTS OF ANKLE DISARTICULATION

With the exception of one patient who died of unrelated causes, in our series of 61 patients with Syme amputations (6), all were ambulatory, and patient satisfaction was excellent. Patients participated in sports activities, including bicycling, swimming, football, soccer, and roller skating. Although some did report occasional problems, such as calluses and rashes, on closer inspection these problems seemed to be related to prosthetic fit rather than to the stump per se, and they were easily addressed with minor prosthetic accommodations in the socket. Posterior heel pad migration was commonly encountered, although it rarely required surgical intervention. Hypertrophy of the skin over the distal tibia and prosthetic adjustment were usually enough to compensate for changes in heel pad position. Of these patients, 40% felt that they had no functional restriction at all, and all of the adults reviewed were employed.

In an alternate study evaluating the physical and psychological function in young patients after Syme's amputation, the results documented a surprisingly easy adjustment process (6). The age of amputation may be important, and it seemed preferable that the procedure be performed prior to the age of 18 months to 2 years, because at this time the infant has an incompletely developed body image and adapts to the new physical status quite quickly. It seems that a missing foot compensated by a functional prosthesis is more acceptable to a child or teenager than a significantly deformed foot that compromises activities and gait.

COMPLICATIONS OF ANKLE DISARTICULATION

Posterior heel pad migration, wound sloughs, and damage to the distal tibial physis are seen in both the Boyd and the Syme conversions. In addition, an occult retained calcaneal apophysis and later pencilling of the distal tibia may complicate Syme's amputation. Careful attention to the indications and surgical details will limit the
problems encountered. Displacement of the heel pad, although frequent, is rarely an indication for reoperation.

PROCEDURES TO STABILIZE THE ANKLE

In the past, many attempts have been made to create a lateral buttress to replace the fibula. The Bardenhauer procedure (7) involved inserting the talus into a sagittal split in the tibia, clearly breaching the growth plate. The Albee procedure (4) involved buttressing by autogenous bone grafted into the tibial metaphysis in an effort to replace the fibular malleolus. Lacking a growth plate, the buttress would quickly rise above the level of the ankle, mitigating its effectiveness.

More recent attempts at ankle stabilization have centered on the Gruca procedure (28,54). In a review of this technique by Thomas and Williams (60) at the Royal Children's Hospital in Melbourne, patients were considered for the procedure only if they exhibited minimal shortening of the tibia and had a foot that comfortably reached the ground with no gross deformity. Of seven attempts reported, three had been converted to an amputation, three were awaiting amputation, and the remaining patient had embarked on a program of leg-length equalization. Thus, this procedure is not definitive for most patients and can be regarded only as an interim procedure to be followed by an amputation because of the progressive leg-length inequality that develops. With rare exception, it appears that Syme's or Boyd's amputations are the preferred primary treatment for type II (complete) fibular deficiencies.

WILTSE OSTEOTOMY

While stabilization procedures in the absence of a fibula have not been very successful, for specific cases of partial absence resulting in a mild leg-length discrepancy and a valgus but stable ankle, Wiltse (69) proposed a supramalleolar osteotomy designed to minimize the prominence of the medial malleolus. The osteotomy is performed toward the end of growth through an anterior approach to the ankle (Fig. 174.5).

Figure 174.5. The Wiltse osteotomy reduces the medial prominence of the ankle following correction of a residual valgus ankle deformity, as might accompany lesser degrees of fibula deficiency. A: Plan of wedge resection. B: After closure and fixation of the osteotomy.

CONGENITAL DEFICIENCY OF THE TIBIA

Unlike most other longitudinal deficiencies, congenital deficiency of the tibia, the rarest form of lower extremity deficiency, may be sporadic or inherited. Both autosomal dominant and recessive patterns have been reported. The anomaly is frequently associated with other system deficits such as herniae, gonadal malformations, hypospadias, cleft palate, imperforate anus, and congenital heart disease. Associated vascular abnormalities may underlie the malformations (32). Always search for absent or duplicated rays, ipsilateral proximal femoral focal deficiency (PFFD), contralateral clubfoot, hemivertebra, hip dysplasia, coccyx agenesis, and lobster claw deformities (53). In contrast to fibular deficiencies, the foot is in a varus position, and the knee may be unstable due to an associated absence of collateral or cruciate ligaments.

There are two classification systems available in the literature. The Kalamchi classification is perhaps simpler and more straightforward (Fig. 174.6), but the classification of Jones et al. (55) is the most widely accepted. It separates the deficiencies radiographically into five types: 1a, 1b, 2, 3, and 4 (Table 174.1). Both classifications are helpful in formulating treatment.

Figure 174.6. The Kalamchi classification for congenital tibial deficiency. Type I, no tibial anlage. Type II, tibial anlage present. Type III, tibial fibula diastasis.

The distinction is whether a proximal portion of the tibia remains, and whether this portion is meaningfully powered by a quadriceps mechanism. Usually the fragment is palpable, and active knee extension is easily discerned. However, this is not always a simple distinction in a chubby uncooperative infant, so the cartilaginous remnant may need to be sought by orthography, ultrasonography, magnetic resonance imaging (MRI), or direct observation during surgery. Radiographically, a marked reduction in width and delayed ossification of the distal femur are also suggestive of an absent or nonfunctional proximal segment. When this tibial fragment is present and powered, surgery is warranted to fuse the fibula into the fragment and then to perform a Syme's amputation, which produces a functional below-knee amputation (Fig. 174.7).
The Brown procedure (12-13) (described in the following section), which centralizes the fibula under the femur, is an alternative that allows the child to function as a below-knee prosthetic user rather than as an above-knee amputee. Most authors report disappointing results, in part because of recurring knee flexion contractures, which result from an imbalance between the hamstrings and a weak, albeit present, quadriceps musculature (35-42,53). The Brown procedure (12) may nevertheless be offered if a functioning quadriceps mechanism of grade 3 strength or better is present, because some patients can achieve a functional below-knee stump that allows active knee flexion and extension, according to Simmons et al. (55). Residual ligamentous laxity following Brown centralization can be controlled by an appropriately designed prosthetic socket. Keep in mind that if the Brown procedure proves unsuccessful, the limb may be salvaged and a perfectly acceptable result obtained by performing a knee disarticulation, which would have been the alternative operation anyway. In some severe cases of concomitant femoral shortening, fusion of the fibula into the femur may be desirable to allow extension to an otherwise short above-knee stump. Unfortunately, 20% to 30% of tibial deficiencies occur bilaterally with an additional compromise of the final functional ability of the patient, regardless of the treatment approach.

When the proximal tibial anlage is present and powered (Jones types 1b and 2), surgery is warranted to fuse the fibula into the fragment when it is sufficiently ossified. Simultaneously, Syme's amputation is performed and the result is a functional below-knee amputee.

De Sanctis et al. (22) presented another strategy and reported three cases treated with Jones type 2 deformities (tibial anlage present) by correction of the foot deformity shortly after birth through a combination of casting and soft-tissue release followed by fibulotibial diaphyseal reconstruction, alignment of the axis of the leg with the foot (talofibular arthrodesis), and leg-length equalization by the Ilizarov method. In a preliminary report, two of the patients achieved satisfactory ambulation, whereas the other sustained recurrence of deformity during the lengthening process.

The Jones type 3 tibial deficiency, characterized by a deficiency of the proximal tibia with a distal, abnormally formed tibial remnant, is extremely rare. This has been adequately treated with a Syme's or Chopart's amputation. The Jones type 4 deformity, with diastasis of the distal tibia and fibula, may be treated by Syme's amputation, or an ankle reconstruction may be attempted (53).

**TOTAL ABSENCE OF THE TIBIA**

### Brown Fibula Centralization

- Create an anterior U-shaped incision that parallels the distal femoral condyles ([Fig. 174.8A](#)), and develop a skin flap proximally that allows access to the quadriceps expansion.

- Make a lateral parapatellar longitudinal incision through the expansion that, based on the radiograph, will allow exposure of the upper fibula, which is displaced proximally from its normal position. Now incise and excise the tissue between the upper fibula and the femoral epiphysis as necessary to allow transposition of the fibular head to a point under the midportion of the femoral epiphysis ([Fig. 174.8B](#)). Brown excised the upper 1/3 inch of the fibula to provide a flat surface to oppose to the distal femur.

- Fix the fibula in position with cross K-wires ([Fig. 174.8C](#)) and leave intact the insertion of the patella ligament; reattachment to the fibula itself is not necessary. If the fibula is too high to be brought distally, remove a segment of bone from the upper third of the fibula to facilitate positioning under the femur.

- Fix the reconstituted fibula with a smooth Steinmann pin placed intramedullary. A Syme's or Boyd's ankle disarticulation can be done simultaneously or at a later time.

- Close the skin over a hemovac drain, and immobilize the limb from toe to groin in a maximal, but comfortable, degree of extension.

Change the cast at monthly intervals up to the third or fourth month, at which time remove the K-wires and immediately apply a prosthesis. We prefer to attempt the operation at the age of walking, between 1 and 2 years of age, rather than keeping the patient in a cast until the time when a prosthesis can be applied.

Complications include ligamentous instability, dislocation or subluxation of the fibula from under the femur, stiffness, and recurrent knee flexion contracture. The latter can be treated by hamstring release, but after one or two attempts at making this procedure work, consider knee disarticulation or tibial fibula fusion.

### Knee Disarticulation

The mainstay of treatment for Kalamchi type I tibial deformity, in which there is no meaningful tibial remnant, is a knee disarticulation with prosthetic fitting as an above-knee amputee. The distal femoral growth plate is preserved by this technique and therefore considerable growth potential is salvaged. Take care during the procedure not to inadvertently breach the growth plate or the surrounding perichondrium. The following description assumes a nonfunctional tibial anlage, so the usual structures are described. In the actual situation, modifications may be necessary depending on what is actually encountered.

- With the patient in a supine position and under tourniquet control, make an anterior transverse skin incision commencing 1-2 cm distal to the tibial tubercle (or where it should be), sloping upward medially and laterally toward the joint line to a point slightly posterior to the mid-coronal plane ([Fig. 174.9](#)). Carry the incision posteriorly 2–3 cm distal to the popliteal crease. Any extraneous flap tissue can always be trimmed later, but too short a flap may necessitate shortening the femur, potentially injuring the physeis.
Meniscectomy, and posterior capsule reefing are rarely necessary.

Given the pathologic findings in CDK, direct surgery toward lengthening the contracted quadriceps mechanism by V-Y advancement or Z-plasty, and releasing the tight medial and lateral capsular structures; after that, reduction can be accomplished (Fig. 174.7).

Open reduction is necessary. A failure is defined by persistent subluxation of the tibia on the femur, as visualized on a lateral radiograph, or the inability to obtain 45° of flexion after a trial of closed reduction and serial casting. Obliteration of the suprapatellar pouch may be seen when arthrography is performed in nonresponsive patients. Accompanying congenital hip dislocation can be difficult to treat by conventional closed methods until the knee flexion is adequate to permit safe open reduction. Thus far unreported.

Children seen in the first few months of life can be treated with biweekly casting or traction until reduction is obtained or progress toward reduction is deemed to have failed. Parsch (48) found conservative treatment to be successful in two thirds of patients.

Should conservative treatment fail, open reduction is necessary. A failure is defined by persistent subluxation of the tibia on the femur, as visualized on a lateral radiograph, or the inability to obtain 45° of flexion after a trial of closed reduction and serial casting. Obliteration of the suprapatellar pouch may be seen when arthrography is performed in nonresponsive patients. Accompanying congenital hip dislocation can be difficult to treat by conventional closed methods until the knee deformity has been controlled. This is due to a tight quadriceps becoming even tighter with knee reduction and in turn precluding reduction of the hip. The Pavlik harness in such cases, aside from being difficult to apply, may actually be counterproductive unless knee flexion has been obtained prior to application. Some authors have reported its successful use in such instances (53,45).

Open reduction

Given the pathologic findings in CDK, direct surgery toward lengthening the contracted quadriceps mechanism by V-Y advancement or Z-plasty, and releasing the tight medial and lateral capsular structures after the knee flexion can be accomplished (Fig. 174.10). Anterior cruciate ligament augmentation or advancement, meniscectomy, and posterior capsule reefing are rarely necessary.
As mentioned, we routinely perform the Galleazzi semitendinosus transfer procedure to keep the patella relocated.

There are several techniques to correct a congenitally dislocated patella (individuals, the tibial tubercle itself may be translocated medially. The patellar ligament can be performed utilizing the Roux Goldthwait procedure (split patellar tendon transfer), or alternatively, the patellar ligament, in its entirety, can become clear. Most operative techniques have stressed a soft-tissue release of the quadriceps associated with a V-Y-plasty of the quadriceps tendon, with natural history of untreated patellar dislocation is early degenerative arthritis, pain, and disability. Conservative therapy is futile; surgery is indicated once the diagnosis becomes clear. Most operative techniques have stressed a soft-tissue release of the quadriceps associated with a V-Y-plasty of the quadriceps tendon, with realignment of the patellar ligament insertion. The operative technique must not breach the tibial physis in skeletally immature individuals, but realignment of the anterior position to one posterior to the femoral epicondyles. After quadriceps repair and closure, immobilize the knee in a long-leg cast flexed to 45° for 6–8 weeks.

Most children spontaneously move their knees following cast removal without the need for formal physical therapy. The goal is 90° of active flexion. Bilateral cases, however, do not seem to recover as much motion as unilateral cases (34).

CONGENITAL DISLOCATION OF THE PATELLA

Congenital dislocation of the patella (CDP) presents a challenge to the orthopedist. Not only is the patella small and misshapen, but the femoral groove is often shallow, and the entire quadriceps musculature is displaced laterally and contracted. In longstanding cases, the tibia may be laterally rotated, subluxated, and in mild valgus because of the abnormal pull of the quadriceps. The tibial tubercle appears lateral to its usual position, resulting in an increased Q angle. The diagnosis can be made by direct palpation and confirmed by radiography, ultrasonography, or MRI. Keep in mind that the patella does not normally ossify until 4–6 years of age. It is thus easy to miss the diagnosis if relying on radiography alone. The keys to diagnosis are a high level of suspicion in addition to the clinical findings of a knee flexion attenuated.

Use an anterior midline incision curving distally and laterally. Enter the joint through a parapatellar approach. If the iliotibial band is tight anteriorly to the lateral femoral condyle, release it with a diagonal incision that can later be reaproximated in a lengthened position.

The quadriceps tendon must be lengthened. Employ a V-Y technique (Fig. 174.10E). This release allows inspection of the joint prior to repair of the quadriceps, so that any remaining adhesions in the suprapatellar pouch area can be released, and reduction can then be obtained and secured by flexion of the knee.

The collateral ligaments of the knee may need to be carefully released to facilitate knee flexion. The hamstring tendons ordinarily spontaneously retreat from an anterior position to one posterior to the femoral epicondyles.

Figure 174.10. Open reduction of congenital dislocation of the knee. A: Visualize the pathology through a lateral approach. The iliotibial band and quadriceps tendon are usually contracted, the hamstring tendons may be subluxed anterior to the femoral epicondyles, and the anterior cruciate often is attenuated, stretched, or absent. B: A condensation of fibrous tissue may connect the distal quadriceps expansion to the distal femur and should be released. C: Perform a V-Y quadriceps plasty. D: With the quadriceps divided, flexion of the knee promotes spontaneous reduction and the anterior cruciate can be inspected. Do not repair the cruciate, even if attenuated. E: Repair the quadriceps with the knee located. F: Position of immobilization postoperatively. G–H: Result at 3-year follow-up. From Johnson EJ, Audell R, Oppenheim WL. Congenital Dislocation of the Knee. J Pediatr Orthop 1987;7:194, with permission.

CONGENITAL DISLOCATION OF THE PATELLA

The patellar ligament insertion is often lateral to that of the femoral groove, and the patella is often rotated around its longitudinal axis. The patient will have difficulty bending the knee, and the patella may be palpable just below the level of the tibia. Examination under anesthesia is important to determine the true range of motion.

The diagnosis can be made by direct palpation and confirmed by radiography, ultrasonography, or MRI. Keep in mind that the patella does not normally ossify until 4–6 years of age. The natural history of untreated patellar dislocation is early degenerative arthritis, pain, and disability. Conservative therapy is futile; surgery is indicated once the diagnosis becomes clear. Most operative techniques have stressed a soft-tissue release of the quadriceps associated with a V-Y-plasty of the quadriceps tendon, with realignment of the patellar ligament insertion. The operative technique must not breach the tibial physis in skeletally immature individuals, but realignment of the patellar ligament can be performed utilizing the Roux Goldthwait procedure (split patellar tendon transfer), or alternatively, the patellar ligament, in its entirety, can be medially transposed into the periosteum over the proximal tibia. We routinely perform a Galleazzi semitendinosus tenodesis of the patella. In skeletally mature individuals, the tibial tubercle itself may be translocated medially.

TECHNIQUE OF REDUCTION

There are several techniques to correct a congenitally dislocated patella (26,27,56). We prefer the following technique.

Begin with a straight lateral incision at the junction of the middle and upper thirds of the thigh and extend it distally lateral to the diseased patella across the femoral condyle, and then swing medially across but 2 cm distal to the tibial tubercle (Fig. 174.11).

Dissect down to the iliotibial band, and divide it obliquely so it may later be repaired in a lengthened position if necessary. Follow the band posteriorly to its insertion on the femur by separating it from the adherent fibers of the vastus lateralis; this portion of the band is known as the lateral intermuscular septum.

Elevate the quadriceps extraperiosteally off the femur and up the lateral aspect of the femur to the proximal one-quarter.

Lateral to the patella, make an incision through the capsule and connect it to the main release along the vastus lateralis.

On the medial side of the patella, incise the large flap of attenuated capsule for later plication, and separate the vastus medialis from the quadriceps expansion distally.

Relocate the patella in the femoral groove. If flexion cannot be accomplished to 90° with the patella in the groove, lengthen the quadriceps in a V-Y fashion and/or release any fibrotic bands.

Now sew the semicircular flap over the patella and anchor it to the tissue along its lateral aspect. Advance the vastus medialis insertion on the femur by separating it from the adherent fibers of the vastus lateralis; this portion of the band is known as the lateral intermuscular septum.

The patellar ligament almost always appears to be attached too laterally on the tibia, so split the patellar ligament longitudinally and detach the lateral portion just proximal to its insertion. Then transfer this detached free stump under the medial portion of the ligament and suture it into the periosteum along the medial aspect of the tibia near the insertion of the tibial collateral ligament. Take care not to make the attachment too tight that the patella becomes rotated around its longitudinal axis. A piece of tensor fascia lata may be used to close the lateral capsular defect, if desired, although we do not routinely do this.

GALLEAZZI PROCEDURE

As mentioned, we routinely perform the Galleazzi semitendinosus transfer procedure to keep the patella relocated.

First, identify the semitendinosus tendon at its insertion into the pes anserinus. Through the main incision or through a separate incision, release the tendon at its musculotendinous junction and free the tendon to its distal insertion into the pes anserina, which can be partially released to allow the insertion of the tendon to

Figure 174.11. Congenital dislocation of the patella. Plan of incision. A: Release the iliotibial tract. B: Raise the medial capsular flap. C: Develop the lateral half of the patellar ligament for transfer. D: Transfer the lateral patellar ligament to the medial aspect of the tibia. E: Repair the medial capsular flap over the patella and advance the vastus medialis insertion. The resulting lateral capsular defect may be patched with a piece of harvested fascia lata.
move more medially on the tibia.
- Make an oblique drill hole from intermedially to superolaterally through the lower medial patella, parallel to the articular surface.
- Then pass the semitendinosus stump through the drill hole and suture it to itself or to the dorsal peristemeum of the patella to complete the tenodesis.
- After wound closure, apply a long-leg cast for 4–6 weeks.

Commence active and passive exercises of the knee when the cast is removed if the child does not exhibit spontaneous motion and improvement. In older children, the hamstring may occasionally need to be lengthened to correct a residual fixed flexion deformity. We have not employed prolonged bracing following cast removal.

**CONGENITAL COXA VARA**

Congenital or developmental coxa vara occurs perinatally and is characterized by a decreased femoral neck shaft angle in association with a primary femoral neck defect. This defect involves both the inferior portion of the capital physis and the adjacent metaphysis. Histologically, it represents a defect in enchondral ossification (16,51). Some authors have commented on a hereditary tendency, but there is no predilection for sex or race (5,18,46,67). Radiographs confirm the decreased neck shaft angle as well as a shallow acetabulum and widened teardrop. Because of the varus, the center–edge angle may appear to be normal, which can cause the examiner to underestimate the true dysplasia of the acetabulum.

Although the etiology is unknown, studies of the natural history suggest the early onset of degenerative arthritis and increasing disability for those cases that progress (5). Because of this, the mainstay of treatment has been proximal valgus osteotomy. Most cases are diagnosed because of a limp or waddling gait in children 3–12 years of age. Only a few children present with leg or back pain. Coxa vara can also present in association with syndromes such as coxa vara with femoral shortening, coxa vara as part of PFFD, multiple epiphyseal dysplasia, cleftdcranial dysostosis, achondroplasia, or hypothyroidism. In addition, coxa vara can be acquired as a sequela of Legg-Perthes disease, infection, trauma, or as a complication of treatment for developmental hip dysplasia or other diseases. For the true developmental or congenital cases with only mild shortening or femoral bowing, Weinstein et al. (67) utilized Hilgenreiner's epiphyseal angle to help define treatment indications. This is the angle formed between Hilgenreiner's line and a line drawn on the anteroposterior (AP) radiographic projection parallel to the capital physis. In the study by Weinstein et al., when the angle was in excess of 60°, progression was the rule; if it was less than 45°, the deformities spontaneously corrected. In the 46° to 59° range, the natural history was not predictable so the patients were observed for signs of progression prior to undergoing surgery. The goal of surgical correction was to restore the Hilgenreiner epiphyseal angle to less than 45° (Fig. 174.12).

**Figure 174.12.** The Hilgenreiner epiphyseal angle. This measurement is helpful in predicting which cases of coxa vara should be observed and which should be operated on.

In our practice, we simply utilize the neck–shaft angle on standing AP radiographs with both knees in the same position and pointing as anteriorly as possible. Deformities associated with a neck–shaft angle of 110° or better are followed with the expectation of resolution. Those less than 100° are operated early to avoid continued shear stress on the physis. The group between 100° and 110° are observed for 6 months to 1 year to see whether they will spontaneously resolve.

The goal of surgery is to restore a normal neck–shaft angle while avoiding damage to the capital physis and greater trochanteric apophysis. However, Schmidt and Kalamchi (52) have noted premature closure of the capital physis in 90% of operated case, even when direct injury was avoided. In addition, they carefully studied the acetabular development, noted it to be deficient, and concluded that unless correction to 140° or better was achieved at surgery, the acetabular dysplasia did not improve. Thus the goal is correction of the neck–shaft angle to at least 140°.

**VALGUS OSTEOTOMY**

Determine the amount of correction to be obtained on the preoperative radiograph. Use an image intensifier prior to commencing the actual surgery to obtain a final check on the true neck–shaft angle. Rotate the hip until the femoral neck appears the longest, and then measure the neck–shaft angle on that particular projection. If necessary, perform a percutaneous adductor tenotomy to facilitate later closure of the bony osteotomy. Because of the incidence of premature physeal closure of the capital physis, and the possibility that this may be related to tight musculature, consider lengthening the iliopsoas as well.

- Approach the hip laterally through a longitudinal skin incision and split the iliotibial band. Elevate the vastus lateralis subperiosteally from the proximal femur. Use a pediatric osteotomy screw (or, alternatively, a pediatric blade plate and matching instrument set) (Fig. 174.13).

**Figure 174.13.** Valgus osteotomy for congenital coxa vara. A: Make a standard lateral exposure to the upper lateral femur through the iliotibial tract, dividing the posterior portion of vastus lateralis and reflecting it anteriorly. B: Guide wire placement and overreaming short of the capital physis. C: Insertion of cannulated pretapped screw and removal of lateral wedge of bone. D: Application of sideplate.

- Place a guide wire along the front of the femoral neck to locate its axis, and introduce a guide pin through the lateral cortex up to but not through the capital physis.
- Ream over this wire, then tap the hole under image intensifier control, and finally introduce a screw of appropriate length. Attach the spacer to the femoral neck screw to control the proximal portion while removing with an oscillating saw a wedge of bone based laterally at the level of the lesser trochanter.
- Now close the osteotomy and apply a two-hole side plate bent with the bending irons to accommodate the new shape of the lateral cortex.
- Check the position with the image intensifier or plain radiographs, and then secure the plate to the proximal femoral shaft using 4.5 mm screws.
- Then irrigate the wound and close it over a hemovac drain, which is removed at 48 hours.

Immobilize the child in a one-and-one-half hip spica cast for 6 weeks or until the osteotomy is radiographically united. Treat residual leg-length discrepancy by a lift and, if necessary, by an appropriately planned epiphysiodesis of the opposite femur.

Complications include continued acetabular dysplasia, premature closure of the capital physis, overgrowth of the greater trochanteric, leg-length discrepancy, recurrence of varus, malunion, nonunion, failure of fixation, avascular necrosis, and infection. These problems may be treated as necessary by techniques described in Chapter 29, Chapter 166, Chapter 170, Chapter 171, and Chapter 173. Repeat valgus osteotomy is sometimes required if the enchondral neck defect has not healed.
CONGENITAL DEFICIENCIES OF THE FEMUR

Congenital deficiencies of the femur form a continuum from simple hypoplasia to total absence. The deficiencies may be diffuse or limited to the upper or lower portions, and they are often associated with other limb deficits and other organ anomalies. Many classification schemes have been proposed to aid in selecting proper treatment. Most focus on PFFD. Some include congenital short femur as the least affected category in the spectrum. However, a child with a congenital short femur is most frequently amenable to lengthening, whereas few with PFFD are. Hence, we prefer to think of these deformities as separate entities.

Treatment may range from observation to amputation and fitting with a prosthesis, so a general treatment protocol is not easy to describe. Subtleties of hip, knee, or ankle strength and motion, along with the wishes of the family regarding cosmesis, may play pivotal roles in the final plan, and no one treatment will ever be correct for every child.

CONGENITAL SHORT FEMUR

For children with congenital shortness of the femur who have a stable hip and knee (including those instances in which a stable knee and hip have resulted through surgical intervention), limb lengthening may be indicated. Children whose limbs are predicted to have a discrepancy at maturity in the range of 5–15 cm can be considered for lengthening. We prefer to lengthen using Ilizarov’s biology (i.e., lengthening of a healing callus) while utilizing a unilateral half-pin fixator (such as the Wagner) (64) for its safety and convenience. For less than 5 cm of predicted leg-length discrepancy, we perform percutaneous epiphysiodysis.

Leg equalization of up to 5 cm can usually be gained by epiphysiodesis. For example, a child with a predicted discrepancy of 7.5 cm would be left with a 2.5 cm discrepancy after epiphysiodesis. The parents need to decide whether the potential complications associated with lengthening are worth it to correct the remaining discrepancy.

Keep in mind that the need to equalize the length of the extremities does not have to be accomplished by a single technique. A difference of 10 cm could, for example, be made up with an acceptance of a 2 cm difference, the addition of a 1 cm lift inside the shoe, and an epiphysiodesis of 7 cm, resulting in a final lengthening of 10 cm. A lengthening of 10 cm is within reason, whereas a lengthening of 20 cm would be beyond the margin of current practice. For discrepancies predicted to be in excess of 20 cm, seriously consider amputation and prosthetic fitting.

In general, the milder forms of femoral dysplasia are associated with coxa vara, whereas the more serious forms, normally classified under the banner of PFFD, are associated with subtrochanteric bowing. Subtrochanteric bowing may be corrected prior to consideration of limb-length equalization. However, coxa vara can help stabilize the hip joint during femoral lengthening and is better corrected after the lengthening is complete.

PROXIMAL FEMORAL FOCAL DEFICIENCY

The management of children with PFFD has been confused by an array of classification systems that have focused on the radiographic appearance of the hip. The major decisions in caring for a child with PFFD concern primarily the marked limb shortening and depend very little on the anatomy of the hip.

Classification

Clearly, children with PFFD are not all the same. Classification systems can be used to organize clinical material for presentation in the medical literature, or they can be used to help the orthopedic surgeon make clinical decisions for an individual child; sometimes they serve both functions. Aitken’s (3) classification of PFFD is an example of the first use. It focuses entirely on the radiographic appearance of the bones of the upper end of the femur and the pelvis (Fig. 174.14). This classification plays a moderately small role in the overall decision making. The classifications of Pappas (47). Fixen (24), and Amstutz (5) are similarly constrained. By contrast, the classification by Torode and Gillespie (62) is concise and practical: “short” (i.e., lengthenable) or “very short” (extend with a prosthesis). This useful classification scheme focuses on the real problem—the marked limb shortening.

Figure 174.14. The Aitken classification for proximal femoral focal deficiency. Types A and B generally have a well-developed acetabulum and by implication a femoral head anlage, even when not initially visualized. Types C and D are usually shorter and the acetabular landmarks are ill defined. Types B and C are characterized on early radiographs by a tufted appearance of the upper femur, which most likely is an ossified portion of femur above a nonossified area.

Clinical Decision Issues

Initially, help the family decide whether their child has a useful extremity that can be lengthened, or whether lengthening is unrealistic and the leg needs to be shortened and the difference to the ground made up with a prosthesis.

Amstutz (5) made a significant contribution by pointing out that the length of the short leg compared to the normal leg at infancy remains in the same proportion at maturity. This allows prediction, while the child is still an infant, of what the ultimate leg-length difference will be at the end of growth. The parents can become accustomed to the problems that need to be faced, which usually makes their decisions easier. Orthopedic surgeons have differed between stating leg-length differences as absolute numbers of centimeters versus percentages of the bone length. There is no agreement currently. An average male femur at maturity is approximately 46 cm, and an average female femur is 43 cm. A leg-length difference anticipated to be greater than 40% to 50% of the normal length at maturity will not likely leave a child with a good functioning extremity even if lengthened.

The options for making up for the marked leg-length difference are to (a) lengthen; (b) remove the foot and fit the child as a below-knee amputee, accepting the huge difference in knee heights; (c) remove the foot, fuse the knee, and shorten the limb so that the child can be fitted as an above-knee amputee; or (d) perform a Van Nes rotationplasty.

Lengthen the Short Bone If children with a congenitally short femur are excluded from the category of PFFD, relatively few children with a PFFD would have limbs that can be equalized by lengthening.

The hip needs to be stable before lengthening can proceed, although rarely the proximal arm of the lengthening device can be fixed to the pelvis.

Even though the diagnosis is described as a proximal femoral deficiency, most children have deformity in the distal femoral condyles and the ligaments about the knee, as well as deficiencies of the fibula and foot. Lengthening a femur that has a congenital deficiency is much more likely to result in anterior subluxation of the femur on the tibia, ultimately resulting in poor knee function. Lengthening should not be performed by surgeons who do not do it on a frequent basis.

Fit as a Below-Knee Amputee Remove the foot by Syme’s or Boyd’s amputation (discussed previously) and use an extra-long below-knee prosthesis. This is a simple solution, but it is cosmetically unappealing due to the great difference in knee heights, which is especially obvious when the child is sitting. This choice is less frequently
Shorten and Fit at the Above-Knee Level

If lengthening is not a realistically practical option, consider shortening the limb sufficiently that the child will be able to function well as an above-knee amputee. King (38) initially suggested the concept of a single skeletal lever, and he fused the knee joint in an effort to improve hip function and to facilitate prosthetic fitting. As a part of this procedure, the foot must be removed. This can be done either as Syme's or as Boyd's amputation. Many surgeons favor Syme's amputation because of its simplicity. However, Syme's amputation done in infancy has more of a tendency to "pencil-point thinning" of the distal tibia. The worries about heel-pad migration are probably overstated, because the skin of children will modify to the pressures applied, as witnessed in children with untreated clubfeet who are able to walk on the dorsum of their feet without skin breakdown. However, there is not good scientific evidence to enable an informed choice between these two procedures, so the choice tends to be one of personal preference of the surgeon.

Ultimately, the end of the stump on the deficient side should be sufficiently short to allow room for a standard mechanical knee joint in the prosthesis to be at the level of the opposite, normal knee. Although orthopedic surgeons have often focused on the end of the bony stump as seen on a scanogram, remember that there is soft tissue beyond that as well as room needed for the socket padding and the thickness of the socket itself—a total of almost 3 cm. An ideal to aim for is that the end of the bone of the stump be 10 cm proximal to the knee joint on the opposite side.

Most children with PFFD have a tibia on the short side that is approximately 90% or more of the normal length (i.e., boys about 37 cm and in girls about 35 cm, or about 10 cm shorter than the average normal femur). This means that if the tibia is left intact and there is any segment of femur remaining, the probability is overwhelming that the stump will be excessively long. There should therefore be plans to either excise one or both physes around the knee if considering a knee fusion or, alternatively, be a plan for epiphysiodesis at the appropriate time.

Knee Fusion

Most children with PFFD live with the anatomic knee held in flexion. They will often sit on the thigh section of their prosthesis. This gives decreased control and power over the prosthesis and aligns the vertical axis of the prosthesis lateral to the center of gravity, producing a lateral lurch in the stance phase of gait. Function can be greatly enhanced if the femur is fused to the tibia. When this is done, the fusion must be done with the knee in full extension. Initially, there may be enough of a hip flexion contracture that the residual extremity will not come to neutral at the hip, but this stretches out in short order (39). In the past, this procedure was not frequently performed, but it is now routine. Delay knee fusion until the proximal tibial center of ossification is easily visualized by plain radiography, usually between 18 months and 2 years of age.

- Use an anterolateral approach. Section the patellar ligament and remove the patella along with the menisci and cruciate ligaments. Perform the femoral resection just proximal to the distal physis; divide the gastrocnemius at the level of the insertions to the posterior femoral condyles. Protect the peroneal nerve and posterior neurovascular bundle throughout the resection.
- Use a micro- or air-saw to resect the articular cartilage of the tibia, carefully exposing the ossification nucleus to its widest diameter.
- Introduce a Rush rod retrograde through the intercondylar notch of the femur, exiting along the lateral aspect of the proximal femur. Then withdraw it and drive it antegrade across the knee to fix the fusion in good alignment. The Rush rod should be centralized in the proximal tibial physis as much as possible. We have not observed growth arrest, but cross K-wire fixation above the tibial physis is an alternative method of fixation.
- Use the resected distal femur for supplemental bone graft, if needed.
- Close the wound over suction drainage.

Syme's amputation may be performed at the same time, although some surgeons delay this stage for 6 weeks.

Van Nes Procedure

An alternative to the knee fusion just described and the fitting as an above-knee amputee is the Van Nes rotationplasty (63), in which the leg is rotated 180° so that the ankle functions as a substitute for the knee (25,29,38,40,63) (Fig. 174.15 A). A special prosthesis is used that uses the ankle as the knee and the foot as the leg, similar to a standard below-knee prosthesis. (The socket usually has an additional thigh support attached with outside hinges.) For this to be successful, there are three requirements:

- The length must be appropriate. Ultimately, the reversed ankle should be at approximately the level of the opposite knee joint. Plantar flexion and dorsiflexion of the foot is a composite of the motion at the ankle and the subtalar joints. The axis of rotation for the purposes of prosthetic fitting is at the tip of the lateral malleolus. The limb can be shortened an appropriate amount at the time of rotation and/or knee fusion. It is rare to have the extremely too short, because that would be due to a considerable deformity in the tibia and would probably be associated with an inadequately functioning ankle joint.
- The ankle must be sufficiently normal function to function as a substitute knee. It must have an appropriate range of motion and sufficient strength to power a prosthesis. A foot with all five rays usually has these requirements, but not invariably.
- The psychological acceptance of the procedure needs to be within the tolerable limits of the patient, the family, and the medical personnel looking after the child. Concerns may vary from age to age and culture to culture. In medical centers where the Van Nes procedure is frequently performed, there are usually other children and families who can act as models and counsel potential patients and their parents. The psychology of the medical staff cannot be ignored. If the medical personnel feel that such procedures are bizarre, it is clear that they will not be offered, or they will be presented in such a manner that no patient would accept the choice. As a consequence, some centers in the United States have moderately large numbers of children who have had the procedure and other centers have none.

Additionally, prosthetic facilities must be considered. The prosthesis that is required following a Van Nes procedure is difficult to fit. If good prosthetic facilities are not available, avoid this operation.

- Perform the knee fusion as previously described, but use the soft-tissue redundancy obtained from the femoral resection to derotate the limb.
- Secure the knee derotation with an oblique K-wire across the fusion site, supplementing the Rush rod fixation (61).
- Either extend the knee wound along the tibial crest or use an additional incision over the mid tibia. Incise the perioistium and resect and discard at least 1 inch of the tibia.
- Further rotate the limb laterally until the ankle is repositioned 180° with respect to the hip.
- Fix the tibia with a four-hole semilunar AO plate, or use a long enough intramedullary Rush rod to fix both the knee and the hip, and another oblique K-wire to secure rotation.
- Perform an anterior compartment release prior to closure, and use a spica cast until radiographic consolidation of the ostectomies, which usually requires 6–8 weeks.

Complications Late fractures at the end of the intramedullary fixation device occurred in two of our patients but healed uneventfully in a spica cast. Although Hall and Bochman (29) have stated that the procedure should not be performed until maturity because remodeling and derotation of the limb require further surgery, we perform the procedure at about 2 years of age. We are content with rototating the limb as necessary. In our experience, approximately half the patients required one repeat surgery to rotate the limb, but only one patient of 13 required a third surgery.
Other Issues

Length of the Stump As discussed, most children who have had conversion of their PFFD extremity to an above-knee amputation end up with a stump that is too long. At the time of knee fusion, consider excision of the distal femoral and/or the proximal tibial physis. Some orthopaedic surgeons are wary of doing this for fear that the extremity will be much too short; however, proper application of growth data using the Green-Anderson-Nesner charts (see Chapter 170) can alleviate that fear. Moseley's straight line graph (see Chapter 170) does not differentiate between the femur and the tibia and does not provide the answer for this calculation.

Before the Definitive Surgery Regardless of what the decision is for ultimate management, there is a period when the difference in leg lengths can be considerable, yet it is too early to do anything definitive surgically. Lifts greater than 5 cm in height tend to lead to ankle sprains, but ankle-foot prostheses can be used to decrease this likelihood. However, when the difference gets to 8 or 9 cm, an extension prosthesis (sometimes called an extension orthosis or even a prosthesis) can be made that has a hole in the front of the prosthesis distally through which the forefoot extends. If tried at too young an age, when the length difference is less than 5 cm, however, there is not room enough below the socket to fit a foot on the end of such a prosthesis.

Reconstruction of the Hip Joint In the past, there has been a great deal of focus on the radiograph of the upper end of the femur. What is seen by the radiograph, however, is only the bone. What is going on with the cartilage, let alone the muscles, is not seen. If there is absolutely no acetabulum, the decisions regarding the management of limb length given in this chapter apply. If, on the other hand, the acetabulum is satisfactorily formed and there is some element of a femoral head in the acetabulum and some segment of upper femur that are not joined, consider surgery. Wait until there is sufficient ossification of the two fragments that they can be fused together, bone to bone. There is certainly no rush to do this, and more complications occur from proceeding too soon, before there is adequate bone stock.

Fusion of the Distal Femur to the Pelvis The distal femur can be fused to the pelvis in order to use the knee joint as a replacement for the hip joint (Fig. 174.16). This has the theoretical advantage of providing a stable hip. However, the knee joint does not allow reasonable rotation. Once it is fused to the pelvis, the distal femur has some capacity to grow, and the hip joint will grow to a point that is mechanically disadvantageous, depending on the orientation of the distal femur at the time of fusion to the pelvis. Although there have been a small number of reports of such cases, most surgeons feel that this is not an advantageous procedure and avoid it.

MISCELLANEOUS ITEMS

TERMINAL OVERGROWTH

“Overgrowth” of amputation stumps in children has always been a problem and can occur even in congenital amputees. It is particularly a problem in the humerus, the fibula, and the tibia. Pellecore et al. (1,69) found that 15% of their juvenile patients who had amputations before 12 years of age required revision, whereas none did if the amputations were done at a later age. Yet, if children required stump revisions and they were older than 12 years, overgrowth could still occur.

This overgrowth is not a result of stimulation of the physeal by the growth of an ossific bone on the end of the stump (see Chapter 175). The easiest way to manage the problem is to avoid it by performing amputations through a joint, where possible, so that the end of the bone is covered by its normal cartilage. If this is not possible, a number of maneuvers have been used with varying success. Slastic end pieces (either as a stemmed plug that fits into the medullary cavity or as a cap that fits over the end of the diaphyseal bone) have been tried, but frequent breakage and dislodgement of the plug or cap have led to their abandonment. Surgical procedures that provide a smooth periosteal surface around the end of the bone appear to be successful in many cases. The Marquardt method (50) (Fig. 174.17) introduced the use of autogenous epiphyseal caps. Davids et al. (21) recently reviewed their patients. Apophyseal cartilage from the iliac crest can be used. Our preference is to use the proximal fibula and invert its diaphysis into the tibial or humeral medullary canal. This cartilage cap is not expected to grow but only to provide a smooth nonosseous surface to prevent osteoblastic reaction. This has been very effective. Keep this technique in mind for situations in which transosseous amputations are required. It may be possible to salvage an epiphyseal cap from part of the discarded specimen (e.g., the first metatarsal head, the talus head, or the os calcis), which could then be attached to the end of the cut bone.

CONSERVATION OF PARTS FOR TOE-TO-THUMB TRANSFER

Not infrequently in treating lower extremity defects, there are concurrent hand abnormalities. Toe-to-hand transfers are now well-established procedures, so before any lower extremity parts are discarded, search for possible uses for the reconstruction of the upper extremities. We have assisted the hand surgeon with harvesting the parts prior to Syme's or Boyd's amputation, with very gratifying results.
LENGTHENING OF SHORT AMPUTATION STUMPS

For children who have amputation stumps that are very short (acquired or congenital), the gain of even a small amount of length may provide an adequate lever to use a more functional prosthesis. The advantages are decreased energy consumption, improved prosthetic control, decreased heat retention, increased comfort from the lesser weight of the prosthesis, and fewer components requiring repairs, as well as decreased cost.

Children with loss of an upper extremity, especially if the loss is congenital, frequently choose not to wear prostheses. However, longer residual limbs may allow for grasping objects in the midline between the stumps for “bimanual” activity without a prosthesis. Additionally, a longer distal segment can permit objects to be grasped between a lengthened humeral stump and the chest, or between a lengthened forearm and the upper arm.

Watts et al. reported lengthening 32 short amputation stumps in 27 patients. All were lengthened by gradual distraction using Ilizarov techniques (see Chapter 32 and Chapter 171). The 16 children who completed lengthening of their femurs or tibias achieved sufficient length to be fitted with a prosthesis at one level more distal than previously possible (Fig. 174.18). Children who underwent lengthening of their upper extremities were more difficult to assess. Three patients were lengthened with the anticipation that a prosthesis would not be used after lengthening. All became “users,” in that they became able to grasp objects between the lengthened stump and trunk. Of the remaining patients—all with upper extremity lengthenings—all but one are “wearers” of their prostheses but not constantly.

A WORD ABOUT PROSTHESSES

Modern prosthetic methods help make the surgeon look good. Of less importance today than previously is the exact placement of the surgical scar, the nature of the skin, or even such complications as a displaced fat pad. Further enhancing the activities of these amputees are recent advances in prosthetic feet utilizing newer space-age energy-storing materials that have the ability to absorb and store energy at the beginning of stance, only to redeliver the energy at toe-off (14,43,65). This results in a livelier feel to the limb, and it may enhance certain activities such as running. Amputees now compete in athletic activities previously felt to be beyond their capabilities. A cottage industry has arisen that caters to amputees who are high-grade athletes in such sports as running, swimming, and skiing. Young children growing up with such conversions have a better chance than ever to enjoy an enhanced physical and psychological environment (6,21).

AUTHORS’ PERSPECTIVE

This is a very rewarding group of patients to treat surgically. Patients with these complex problems are frequently beyond the capabilities of most community orthopaedic surgeons and hospitals and are cared for at specialized centers. The long-term physician–patient relationship that develops is gratifying. The children are otherwise healthy and their zest for living and full participation in life is admirable. Early medical intervention is important for them to develop early independence and to reach their maximal potential. It is a privilege to care for them.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; 1, basic research article; and +, clinical results/outcome study.

Amputations in children, while following many of the same principles as in adults, require special considerations and techniques because of continuing growth (1). This chapter reviews the general disorders requiring amputation and specific techniques useful in the skeletally immature patient.

GENERAL PRINCIPLES

Skeletal growth and remodeling have an enormous effect on the ultimate success of a pediatric amputation, particularly in the younger child. For example, a 6-year-old child who has a successful above-knee amputation will have an extremely short stump at maturity because of loss of the distal femoral physis. In addition, stumps in children tend to become narrow and conical with growth, and this may subsequently lead to poor rotational control of a prosthesis.

A problem unique to pediatric amputations is terminal overgrowth. Overgrowth probably results from distal apposition of bone by the active periosteum, although the exact mechanism is not understood. Overgrowth is not dependent on the physis, and epiphysiodesis will not arrest it. Overgrowth never occurs after disarticulation. Terminal overgrowth is most severe before 6 years of age, and several revisions (three or more) may be required during the growing years. Overgrowth is not seen after about 12 years of age. The bones most likely to exhibit overgrowth are the humerus, fibula, and tibia. The exact incidence depends on the diagnostic categories of the reported series (congenital or traumatic). Many surgical remedies for overgrowth, such as capping, osteotomy, and surgical cross-union, have been attempted and discarded; the only effective treatment seems to be surgical revision of the pointed distal bone and its overlying bursa.

Emotional issues are generally far less troublesome for the pediatric amputee than for the adult amputee. The congenital amputee, born without the limb segment, accepts the condition as normal. Children who lose a limb traumatically generally rehabilitate quickly when a prosthesis is fitted. The main requirement of the child is function and durability, often with little concern for appearance or body image. However, parental acceptance of congenital or acquired amputations may be difficult. Feelings of guilt or inappropriate fears may require specialized counseling. Phantom limb and phantom pain, common in the adult amputee, are rare in children and generally absent in the congenital amputee.

The unique congenital disorders of children, special surgical techniques, and the special aspects of prosthetic fittings during growth have led to multidisciplinary child amputee clinics in centers throughout the country (6). The value and success of this approach has been documented, and the surgeon should consider referral to a regional center if one is available.

Standard surgical principles for amputation in the child include the following:

- Preserve the physis. Amputations through the metaphysis (such as above-knee or distal forearm level) or diaphysis are not recommended in children because of the progressive relative shortening of the residual limb. This is most critical in the femur, but it is applicable to other long bones as well.
- Disarticulate when possible. Disarticulation completely eliminates the problem of terminal overgrowth and subsequent revision surgery.
- Preserve stump shape. The pediatric amputation stump becomes conical with growth, so preservation of bony architecture such as a short segment of proximal fibula or the distal condyles of the humerus will assist in subsequent rotational control of the prosthesis.
- Be creative with soft-tissue coverage. Pediatric amputees rarely suffer from the wound-healing problems that commonly affect dysvascular adult amputees. Split-thickness skin can often be successfully used in the child to preserve an otherwise satisfactory stump without adequate skin coverage. The split-thickness skin graft can hypertrophy and become sufficiently strong to withstand the shear forces of prosthesis use.

DISORDERS REQUIRING AMPUTATION IN CHILDREN

CONGENITAL AMPUTATIONS

The child born with a single or multiple limb deficiency knows no other body image and has a remarkable ability to use a prosthesis to enhance function (5,8). Although the child automatically accepts the limb deficiency as normal, parents are often emotionally overwhelmed by depression and guilt. Early referral of the family to a regional child amputee clinic facilitates the counseling and acceptance by the family that is as necessary for a satisfactory outcome as orthopaedic or prosthetic management.

Many congenital amputees require no surgical conversion to a different level, but revision of stumps for terminal overgrowth is common, particularly for the humerus. Conversion of the upper extremity is rarely necessary. It is usually unnecessary to remove upper extremity nubbins, which the child may find useful for holding small objects or activating powered prostheses. Lower extremity conversion should be done to enhance prosthetic fitting if it facilitates ambulation, but durability and function, not cosmesis, are the goals. In general, useful deformities should be retained.

Prosthetic fitting of the upper extremity is done when the child is sitting independently, usually at about 6 months. Initial upper extremity terminal devices are passive, but they can be activated when grasping becomes important (1.5 to 2 years of age). Lower extremity prostheses are fitted when the child begins pulling to stand or cruising. A fixed knee with waistband suspension is used for above-knee amputees. Frequent length adjustments of the prosthesis will be required with growth. Children will discard upper-limb prostheses if they perceive them to be nonfunctional, and children with multiple limb deficiencies often reject prostheses because they interfere with the specialized movements required by daily living activities.

TRAUMATIC AMPUTATIONS

While traumatic injuries can occur to any child, there is considerable evidence that the typical child with a traumatic amputation comes from a socially dysfunctional background. Most are boys from single-parent homes who are rebellious or running away from home. The psychological ability of these patients to undergo extensive treatment, revision of level, and rehabilitation is often very limited. Be sensitive to these psychosocial issues and obtain consultation early from appropriate professionals.

Set surgical and rehabilitation goals early. Often it is necessary to consider amputation at a more proximal level rather than subject the child to an emotionally draining series of heroic procedures to preserve length. Traumatic amputees may not tolerate multiple procedures or extensive rehabilitation efforts if they do not have the emotional base of support of a functioning family system.
Most traumatic amputations involve the lower extremity, and terminal overgrowth, particularly of the tibia, is often a problem. Many of these patients will wait until they can no longer tolerate their prosthesis before presenting for a revision of the overgrown stump, making smooth coordination of surgery and prosthetic fitting difficult.

A special problem arises when the traumatic amputee has lost soft tissue from a degloving injury proximal to the bony amputation level. Occasionally, it is appropriate to sacrifice bone length if considerations warrant it. However, other options include extensive use of split skin graft (much better tolerated in children than in adults), tissue expanders, or microvascular free tissue transfer. Skin traction (Fig. 175.1) over a 1- to 2-week period can add several centimeters of full-thickness circumferential skin and allows inspection of the open wound for appropriate care in the interim.

Figure 175.1. Technique of application of skin traction after traumatic amputation.

If the wound allows it, a rigid plaster dressing permits rapid mobilization of the trauma patient, while minimizing pain and reducing the tendency to form contractures.

BURN AMPUTATIONS
Burn amputations present a dilemma: how to obtain skin coverage while salvaging the most distal amputation level possible. Extensive use of split-thickness skin is often successful in the child. Stump breakdown is less of a problem in the child than in the adult. Attempt to preserve length if at all possible. Proximal joint stiffness seems to be more of a problem in burn amputees than in other amputees, and it should be addressed early and aggressively in the rehabilitation effort.

AMPUTATIONS FOR MALIGNANT TUMORS
Limb salvage for malignant bone and soft-tissue tumors has become technically feasible in older children, but amputation is still often necessary for local control of tumors. Amputation also may be the treatment of choice for malignant tumors in children younger than 10 years because skeletal growth is disturbed by limb-sparing techniques. Amputation is usually indicated when a pathologic fracture occurs through a malignant lesion.

Amputation for a tumor requires the same technical care as any tumor procedure, with the goal being complete local control of the lesion for cure or palliation. Adjuvant chemotherapy or radiation therapy may be appropriate.

Because of the possibility of a short lifespan, and the added psychological stress to the family and child of adjuvant treatments in the addition to limb loss, these children should receive aggressive, early rehabilitation. Rigid dressings and immediate pylons can ease the immense emotional strain of the diagnosis and treatment. Use interim prostheses early, as chemotherapy and weight loss may postpone definitive fitting.

SPECIFIC AMPUTATION TECHNIQUES FOR CHILDREN
The surgical techniques (e.g., handling of soft tissues, division of bones, and treatment of sectioned nerves) for amputations in children are generally the same as the techniques in adults (see Chapter 120, Chapter 121, and Chapter 122). However, amputations in skeletally immature patients present special considerations.

UPPER EXTREMITY

Above-Elbow Amputation

Very short above-elbow amputations preserve the cosmetic contour of the shoulder girdle, but most children reject prosthetic fitting attempts. Mid-humerus and longer levels allow artificial limb function, but the stump will become thin and conical, so every attempt should be made to maintain its shape by preserving the distal humeral condyles if possible. Marquardt (?) has described a right-angle osteotomy 5 cm proximal to the end of the above-elbow stump to assist with prosthesis suspension and rotational control. Above-elbow amputees have a high incidence of terminal overgrowth, and parents should be warned of the likelihood of multiple revisions.

Elbow Disarticulation

Elbow disarticulation, while rarely performed, is an excellent amputation option for children. It eliminates the problem of overgrowth, and the preservation of the distal humeral condyles aids in prosthetic fitting. As puberty approaches, consider epiphysiodesis of the distal humeral epiphysis. This provides shortening of the amputated limb in comparison to the contralateral limb, allowing internal prosthetic elbow hinges.

Below-Elbow Amputation

Overgrowth is generally not a problem in the below-elbow stump. Preserve as much length as possible. Even short below-elbow stumps, distal to the biceps insertion on the radius, can aid with prosthetic stabilization and internal prosthetic control.

Wrist Disarticulation

Wrist disarticulation is an excellent amputation level in the child. It does not restrict pronation–supination, and overgrowth does not occur.

LOWER EXTREMITY

The same techniques described for adult amputation for hemipelvectomy and hip disarticulation are applicable to children. As in adults, the prosthetic rejection rate after hemipelvectomy or hip disarticulation is high (see Chapter 120 and Chapter 122).

Above-Knee Amputation

Except in adolescents, the above-knee amputation level is a poor option for children because of loss of the distal femoral physis. The relative shortening of the leg with growth is dramatic and is worsened by the problem of terminal overgrowth.

Knee Disarticulation

The long stump, preservation of growth, muscle control, and lack of terminal overgrowth make knee disarticulation an ideal amputation level in the child. The patella may be retained. Suture the hamstrings to the cruciate stump and oversew the quadriceps tendon to them. This tenodesis preserves the strength of the muscles for walking and prevents their slippage around the distal bone end.
As maturity (bone age 10–11 years in girls and 12–13 years in boys) approaches, do a distal femoral epiphysiodesis to allow slight shortening, which facilitates prosthetic design using an internal hinge. Consult a prosthetist to determine the optimal amount of shortening for prosthetic fitting.

**Below-Knee Amputation**

In adult amputees, preserving the knee joint enhances prosthetic ambulation potential, because above-knee amputees require more energy for prosthetic ambulation than do below-knee amputees. As most pediatric amputees will become geriatric amputees, it is desirable to salvage the knee joint in pediatric amputation surgery if possible. However, below-knee amputations have specific problems in children. Terminal overgrowth of the tibia and fibula are almost inevitable, and multiple revisions are the rule. Varus angulation in younger children occurs often and may be severe enough to require tibial osteotomy. The thin, conical stump makes rotational control difficult. Patellar-tendon-bearing prosthesis is a misnomer in the growing child, because the rapid change in length makes nearly all prostheses essentially end-bearing. For all of these reasons, ankle disarticulation is preferable to below-knee amputation if at all possible.

Surgical techniques for the below-knee amputations are the same for the child as for the adult, except that the skin flaps can be widely variable because the vascular supply in children is so rich. If possible, avoid scars directly over the end of the stump. Split-thickness skin is remarkably well tolerated in the child and may hypertrophy to give good results in maturity, even at this weight-bearing level. Preserve the fibula if at all possible, even if it is very short. The broad shape of the combined proximal tibia and fibula enhances rotational prosthetic control. Surgical cross-union and other techniques to prevent terminal overgrowth do not work and may lead to proximal migration of the fibula.

**Ankle Disarticulation (Pediatric Syme Amputation)**

Although the classic Syme amputation is not done in children, the similar procedure of ankle disarticulation carries the same name by popular usage (Fig. 175.2). The pediatric Syme amputation, while having the benefits of a disarticulation, can be difficult to perform well because of the late problem of posterior heel-pad migration. Modern prosthetic technique allows fitting of bulbous stumps, which often taper with maturation. The main use of the Syme amputation is in congenital anomalies, especially fibular hemimelia and proximal femoral focal deficiency. I prefer the Boyd amputation, described in the next section, over the Syme.

![Figure 175.2. Technique of pediatric Syme amputation. See text for details.](image)

- Perform surgery with a pneumatic tourniquet. Between points just distal to the medial and lateral malleoli, connect an anterior incision dorsally and a plantar incision directly inferiorly (Fig. 175.2). Carry the incisions, without extensive subcutaneous undermining, straight down to bone, ligating vascular structures and tagging the anterior tibial and toe extensor tendons.
- Grab the talus with a towel clip and plantar-flex it to its extreme. With a scalpel directed toward the bone, carefully dissect out first the talus and then the os calcis in a similar manner. Avoiding any injury to the subcutaneous tissue is critical to the success of the operation. Ensure that the excision includes the cartilaginous apophysis of the posterior os calcis.
- Sever the Achilles tendon and allow it to retract into the leg. Trim the cartilaginous malleoli transversely to the level of the tibial plafond with a scalpel. Suture the anterior tibial and toe extensor tendons to the anterior edge of the heel pad to prevent posterior migration. Avoid the temptation to trim the dog-ears over the malleoli. They will remodel. Trimming may jeopardize the vascular supply to the heel pad.
- Close the skin and subcutaneous tissue with fine absorbable suture over a suction drain, and apply an above-knee rigid plaster dressing with molding over the femoral condyles.

**Boyd Amputation**

The Boyd amputation, while similar to the pediatric Syme amputation, preserves the posterior os calcis and thus stabilizes the heel pad (Fig. 175.3) (3). Take care to place the heel in a plantigrade position and to divide the Achilles tendon, so that the heel does not drift into plantar flexion. If properly done, the Boyd produces an excellent end-bearing stump without the problem of terminal overgrowth. Boyd amputations produce a bulbous stump that may improve with growth.

![Figure 175.3. Technique of Boyd amputation. See text for details.](image)

- Make a skin incision in a fashion similar to that for the pediatric Syme amputation. Tagging the anterior tendons is unnecessary. Disarticulate the midfoot and forefoot from the talus and calcaneus. Grab the talus with a towel clip and carefully shell it out by plantar-flexing it and releasing soft-tissue attachments to the talus with a small scalpel. The subcutaneous tissue must not be damaged during this procedure.
- Shave the distal tibial articular surface transversely until the ossific nucleus of the distal tibial epiphysis is exposed, using a scalpel or fine osteotome (usually just held by hand; a mallet is unnecessary). Similarly, shave the superior surface of the os calcis down to cancellous bone, making it flat parallel to the weight-bearing surface of the heel. Shorten the anterior end of the os calcis. Sever the Achilles tendon and allow it to retract; this prevents late plantar flexion drift of the os calcis.
- Approximate the raw surfaces of the tibial epiphysis and os calcis while bringing the os calcis forward (anterior) slightly. Hold them together with one or more smooth Kirschner wires inserted through the heel pad. If the Boyd amputation is being combined with a knee fusion for proximal femoral focal deficiency, the heel can be fixed with a longitudinal Rush rod passed up the heel, tibial canal, and through the knee fusion site. Use bone graft from discarded bones if desired. Ensure that the weight-bearing surface of the heel is plantigrade; avoid even slight plantar flexion.
- Close the wound over a suction drain using fine absorbable stitches for all layers (I use 4-0 polyglycolic acid), and bend the pin(s) externally to avoid migration. Immobilize the limb in a spica cast or long-leg cast, depending on age.
- Remove the pins at 4–6 weeks and continue immobilization in a long-leg cast (molded over the femoral condyles) until radiographic union.
Foot Amputation

Midfoot amputations at the Lisfranc or Chopart level are usually traumatic; this is not a desirable level for an elective amputation. In managing these injuries, sever the Achilles tendon to help prevent equinus contracture, and anchor extensor tendons, if available, to the anterior bony structures. Conversion to a higher-level (Boyd or pediatric Syme) amputation is often required (2).

Distal partial foot amputations, usually at a metatarsal level, are very well tolerated by children and require only a space-filling prosthetic shoe insert.

PITFALLS AND COMPLICATIONS

The primary pitfalls and complications unique to the management of pediatric amputations come from the improper applications of adult amputation principles to the child. Adult principles fail to take into account the need to preserve epiphyses for normal growth, to preserve distal shape for prosthetic control, or to be creative with skin coverage so that length is not traded for simplicity of initial wound closure. The complication of terminal overgrowth following through-bone amputations in children is predictable and requires surgical revision at 2- to 4-year intervals until growth ceases. Painful neuromas and phantom pain are very rare and generally occur only when the amputation is acquired in adolescence. Management is the same as adults (see Chapter 120 and Chapter 121).

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Acute hematogenous osteomyelitis occurs in all age groups but is more common in children than in adults. The peak age for occurrence is 18 to 24 months, and the mean age about 6 years. Since the development of antibiotics, prognosis and results of treatment have dramatically improved so that acute hematogenous osteomyelitis should no longer be a life-threatening disease. Sequelae from the infection, if diagnosed early and treated appropriately, are minimal and chronic osteomyelitis is now rare. In older children, osteomyelitis is usually monostotic, but in the neonate, it is not uncommon to find multiple sites of infection.

PATHOLOGY

Acute hematogenous osteomyelitis is a blood-borne infection that begins in the metaphysis of long bones and in the metaphyseal equivalent areas of the remainder of the skeleton. In 1911, Koch (25) demonstrated that the intravenous injection of bacteria frequently caused infection that began in the metaphyses of long bones near the physis. The metaphyseal location of infection is related to the vascular anatomy in the region, where the terminal nutrient vessels enter large sinusoidal vessels. The blood flow velocity in these vessels is slow, which encourages the bacteria to settle. In addition, the host defense mechanism is compromised because of the paucity of monocytes in the sinusoidal spaces.

More recently, Morrissy and Haynes (29) demonstrated in the rabbit model that the inflammatory response and bone destruction are slightly more distal to the physis than the area where the bacteria are found. It is in the area of this inflammatory response that the destruction of the bone trabeculae occurs as a response to the inflammatory process. By injuring the metaphyseal area of the rabbit's extremity just before intravenous injection of a bolus of bacteria, Morrissy found that the development of osteomyelitis was much more predictable than when there was no preceding injury. This correlates with the clinical finding that there is frequently a history of injury before the onset of osteomyelitis. Trauma may cause thrombosis of the sinusoidal vessels, and the thrombus serves as a culture medium for the bacterial growth.

The inflammatory process begins with edema and a cellular influx that will evolve into an abscess if the response is not altered by appropriate treatment. The purulent exudate spreads through the thin porous cortex of the metaphysis and elevates the periosteum, which causes subperiosteal reactive bone formation.

If the infection is untreated, the periosteum eventually is destroyed. Loss of the periosteum severely interferes with the healing of a fracture should one occur in the course of the disease. Before the development of antibiotics, the exudate, if it was not surgically released, would eventually drain through the skin, as described by Smith in 1874 (39). The elevation of the periosteum interrupts the periosteal blood supply to the cortex. Loss of the periosteal blood supply, along with vascular thrombosis caused by the pus passing through the haversian system, renders the cortex ischemic. The ischemic bone becomes a cortical sequestrum.

In children younger than 2 years of age, it is rare that a cortical sequestrum is produced. The reason for this is not clear, but it may be that the increased porosity of the metaphyseal cortex in the young child allows the exudate to exit through the metaphyseal cortex and decompresses the bone before it is forced through the haversian system of the diaphysis. Where the metaphysis of the long bone is partially intracapsular, as in the proximal femur, humerus, and ankle, secondary septic arthritis can result from the spontaneous decompression of the metaphysis.

In newborns, Trueba (42) demonstrated that metaphyseal vessels transverse the proximal femoral physis. These vessels passing from the metaphysis to the epiphysis apparently allow bacteria and the inflammatory process to cross the physis into the epiphysis. In this age group, the physis and the epiphysis can be severely damaged from the infection (Fig. 176.1). The vessels that cross the physis in the neonate progressively disappear beginning at 8 months of age (42). By 18 months, the metaphyseal and metaphyseal circulations are completely separate. Once the physis becomes a barrier to the metaphyseal vessels, inflammatory destruction of the physis and epiphysis is rare.
CLINICAL PICTURE

The presenting symptoms of osteomyelitis depend on the severity of the infection, its location, and the age of the patient. Approximately 30% of the patients with osteomyelitis are not ill and have few systemic symptoms. In patients who are not ill, the initial diagnosis is frequently in error, with the most common misdiagnosis being some type of malignancy. Except for an elevated sedimentation rate, which is almost always present, the laboratory data may be normal in this subgroup of patients.

Regardless of the severity of the infection, the most constant symptom is localized pain that causes the child to limp or not use the extremity. Swelling is usually present, and its extent reflects the severity of the infection. Local tenderness is always present. The more superficial the bone, the more easily this can be demonstrated. Why 30% of patients have a mild presentation of osteomyelitis is not clear. In some instances, it reflects the use of antibiotics to treat fever of undetermined etiology or other infections in other areas of the body. It may also reflect the prevalence of the use of antibiotics in the production of meat for consumption.

In acutely unaltered hematogenous osteomyelitis, the signs and symptoms are an elevated temperature in an anorexic, irritable child with significant pain and limitation of function of an extremity. Swelling, tenderness, and sometimes redness are common and impressive. In the infant, swelling may extend throughout the entire segment of the extremity (Fig. 176.2). Motion in the adjacent joint is limited and causes protective muscle spasm. Infants may present with pseudoparalysis, and older children will limp or refuse to walk if the lower extremity is affected. Pain with localized tenderness and swelling in the metaphysis of a long bone is sufficient to make a presumptive diagnosis of osteomyelitis in an ill child.

The peripheral blood changes vary with the severity of the infection. The white blood cell count is usually elevated, with a shift to the left. If infection has been present for several days, the red blood cell count, hemoglobin, and hematocrit will be lower than normal. Sedimentation rate is almost always elevated. Blood cultures should always be taken when osteomyelitis is suspected; a positive culture is usually found in 60% to 65% of patients.

RADIOGRAPHS

Initial radiographic evidence of osteomyelitis is not in the bone but in the deep soft tissues, where swelling is the initial radiographic sign (Fig. 176.3). The swelling occurs within the first 2 days of symptoms and obliterates the lucent muscle planes progressively from the bone to the subcutaneous tissue. With this pattern of soft-tissue swelling, the diagnosis of osteomyelitis must be considered. When osteomyelitis is suspected, take radiographs with the appropriate exposure and anatomic position. It is important that both extremities have radiographs in the identical position for comparison. Ask the radiographic technician to use soft-tissue technique for the first radiograph and bone technique for a second. After 10 days of uncontrolled infection, radiolucent areas can be seen in the metaphysis. New periosteal bone is another late radiographic manifestation of osteomyelitis. This periosteal bone is a result of the elevation of the periosteum by the exudate that has passed through the cortex.

The current standard in evaluating a patient for possible early osteomyelitis includes the option of imaging with radionuclides. An increase in uptake may be present in the area of infection as early as 24 hours after onset, but an increase in uptake is not diagnostic of osteomyelitis; it only reflects increased blood flow and osteoblastic activity, which may also occur in the presence of tumors and trauma. The value of the radionuclide studies is in localization of the area of infection and in identifying multiple sites of infection. The greatest help from a bone scan is in a patient who has been partially treated: when the clinical signs are poorly defined, as in infection of the pelvis or spine, and in managing a patient with subacute osteomyelitis. False-negative bone scans and gallium scans do occur (1). This is particularly true in osteomyelitis of the pelvis and in the neonate. It is probably related to the decreased blood flow from thrombosis. In the neonate, the bone scan is accurate in only 30% to 40% of patients (2). However, if both technetium and gallium scans are positive, the diagnosis is almost always infection. This is particularly helpful in patients with suspected osteomyelitis in the pelvis and will facilitate an early diagnosis (12). Because gallium has more radioactivity than technetium, it should not be used except in
very difficult cases (5). Computed tomography (CT) scan and magnetic resonance imaging (MRI) can be of benefit when the clinical facts are not sufficient to make the diagnosis. Mazur et al. (27) reported a sensitivity of 97% and a specificity of 92% for MRI. However, these imaging modalities are seldom needed and should be used only in difficult cases. Their routine use is not justified. A particularly valuable area for the use of CT is in osteomyelitis of the pelvis, in which early swelling can be identified as well as very early bone changes that are seldom seen on routine radiographs made early in the course of the infection.

**DIAGNOSIS**

The diagnosis of acute hematogenous osteomyelitis is made from the history, physical examination, and laboratory studies, and is confirmed by radiographs, bone scan, MRI if needed, and aspiration of the bone. Although 30% of the patients are not acutely ill, the remainder are ill and give a history of the fairly rapid onset of pain accompanied by swelling, localized tenderness, and impaired function such as a limp, refusal to walk, or pseudoparalysis. In those who are ill, the temperature is elevated, and the young child is irritable and anorectic. An exception is in the neonate who may not show an elevated temperature and who may have minimal laboratory changes. Neonates frequently present with failure to thrive. The neonate may be moribund and respond poorly to physical stimulation. Because of these differences, the diagnosis is frequently delayed until destruction of the physis and epiphysis has occurred. In the neonate who shows failure to thrive, osteomyelitis should be considered as a possible cause. The most dramatic physical finding in the neonate usually is swelling of an entire extremity (Fig. 176.3). Radiographs should show the characteristic soft-tissue swelling.

With these findings, always aspirate metaphysis in the area of maximum tenderness with a large-bore needle. Use fluoroscopic control to make certain that the needle enters the metaphysis near but not in the physes. If pus is not obtained from beneath the periosteum, push the needle through the cortex. Culture any aspirate, pus, or blood obtained. In addition to culturing the aspirate, culture the blood, nose, throat, and any skin lesions. Perform peripheral blood studies, including a white blood cell count, hematocrit, and sedimentation rate.

**TREATMENT**

Early effective treatment is the most important factor that influences the results in osteomyelitis (43). Two significant sequelae arise with osteomyelitis. One is physeal and epiphyseal destruction in the neonate and infant; the other is chronic osteomyelitis with a cortical sequestrum in the older child. Prevention of these two problems depends on early diagnosis and effective treatment. When these two sequelae are prevented, the results from treatment of osteomyelitis is uniformly good.

Conservative treatment with systemic antibiotics plus rest and protection of the involved limb is successful in most patients. Surgical treatment is indicated if pus is obtained on bone aspiration or if the response to conservative treatment is not favorable within 48 hours. A favorable response is one in which the temperature elevation rapidly diminishes, and the pain and swelling is decreased. If no abscess is present and the correct antibiotic is delivered in an adequate dose, pain, fever, and even swelling should be significantly reduced by 48 hours.

Start antibiotics immediately after the aspiration. The choice of antibiotics is made from the statistics concerning the most likely pathogen as influenced by age, presence of chronic disease, and any organisms found on the Gram stain. After culture results and sensitivities are known, change the antibiotic to a more appropriate one, if necessary.

In the neonate, Staphylococcus aureus, group B Streptococcus, and gram-negative bacilli are frequent pathogens. Therefore, in the neonate a semisynthetic penicillin will be effective for the staphylococcal and streptococcal infections, but an aminoglycoside should be added because of the possible presence of a gram-negative organism.

After 3 years of age, Staphylococcus and Streptococcus organisms are the most common pathogens causing osteomyelitis. In this age group, a semisynthetic penicillin or a first-generation cephalosporin is the antibiotic of choice. Both give adequate bone levels and are effective. The advantage of the cephalosporins over semisynthetic penicillins is that if the treatment is changed from parenteral to oral antibiotics, the oral cephalosporins are more palatable than either cloxacillin or dicloxacillin. If the pathogen cultured is a methicillin-resistant S. aureus, vancomycin is the drug of choice.

Administer the initial antibiotics parenterally. After 2 or 3 days, if the response to treatment has been favorable with a decrease in the fever, pain, and swelling, oral antibiotics may be the preferred route of delivery in a selected group of patients. To use oral antibiotics, there should be a positive culture to ensure that the appropriate antibiotic is being administered. Compliance must be ensured by knowing the dependability of the patient and family. Tolerance of the oral antibiotic at the required dosage must be shown. The dose of antibiotic must be sufficient to give a bactericidal level as determined by measurement of the antibiotic level or by the dilution technique. In the dilution method, a 1 to 8 dilution at the peak and a 1 to 2 in the trough should be bactericidal. The required dose of a semisynthetic penicillin to obtain these bactericidal levels can be reduced by the addition of probenecid in children of 2 years and older (33).

Among the controversies that surround the treatment of osteomyelitis, the duration of the antibiotic treatment is the greatest. Dich et al. (10) reported data on a series of patients with staphylococcal osteomyelitis treated for less than 21 days compared with a group treated for more than 21 days. The rate of recurrence of development of chronic osteomyelitis was 19% in those treated for less than 21 days and only 2% in those treated for more than 21 days. I prefer to judge the need for extended treatment on the patient’s response and on the presence of bone changes on routine radiographs. In all patients, antibiotics for 21 days should be the rule, extending this to 6 weeks or more in selected cases. In the patient who presents early and responds rapidly and in whom no abscess is demonstrated by aspiration, the shorter period of antibiotic therapy may be adequate. When pus is present or radiographic evidence of bone destruction or a sequestrum is present, give antibiotics for longer periods of time. Before antibiotics are discontinued, the sedimentation rate should be declining and near normal.

**SURGICAL TREATMENT**

There are three indications for surgical drainage: if pus is obtained on the initial aspiration, if the clinical response is not significant after 48 hours of antibiotics, or if there is radiographic evidence of bone destruction requiring removal of a metaphyseal sequestrum or granulation tissue. This latter indication is controversial, and it should be considered as a possible cause. The most dramatic physical finding in the neonate usually is swelling of an entire extremity (Fig. 176.3). Radiographs should show the characteristic soft-tissue swelling.

With these findings, always aspirate metaphysis in the area of maximum tenderness with a large-bore needle. Use fluoroscopic control to make certain that the needle enters the metaphysis near but not in the physes. If pus is not obtained from beneath the periosteum, push the needle through the cortex. Culture any aspirate, pus, or blood obtained. In addition to culturing the aspirate, culture the blood, nose, throat, and any skin lesions. Perform peripheral blood studies, including a white blood cell count, hematocrit, and sedimentation rate.

The surgical opening in this proximal humerus is too distal to the epiphysis. The patient had a recurrence of symptoms 2 months later.

Figure 176.4. The surgical opening in this proximal humerus is too distal to the epiphysis. The patient had a recurrence of symptoms 2 months later.

Close the wound over drains. I prefer a suction drain. Controversy exists as to whether irrigation with saline is helpful. If it is done well, it should be of some benefit. Drains should be removed after 48 hours.
Protection of the extremity in a splint in a functional position is important to prevent a fracture. It usually increases the patient's comfort level as well. Unprotected weight bearing after surgical decompression or where there is extensive cortical destruction with or without a sequestrum may result in a fracture.

**SUBACUTE OSTEOMYELITIS**

The host defense against pathogen virulence frequently results in a standoff, with local bone destruction that is limited compared with that of acute osteomyelitis. This results in a subacute infection. In 1969, King and Mayo (24) reported data on a series of patients diagnosed as having subacute osteomyelitis. In all of these patients, radiographic changes were seen at the time the patients were first evaluated. They described eight types of subacute osteomyelitis based on the radiographic appearance. Others have added to this clinical description (14,15).

**CLINICAL PICTURE**

The onset of subacute osteomyelitis is insidious. The child is not ill, and little or no functional impairment is present. The most constant complaint is a localized pain that may have periods of exacerbation and remission. The pain frequently is exacerbated following a period of unusual activity. If the involvement is in a subcutaneous bone, local swelling is occasionally present. Like the pain, the swelling seems to increase and subside with activity. Symptoms may be present for weeks or months before the child is brought to a physician for evaluation. Laboratory studies may be normal, including the sedimentation rate, although it is elevated in some patients.

The diagnosis is made on the radiographic appearance of the lesion. The most common type of subacute osteomyelitis is a well-circumscribed lytic lesion with sclerotic borders, which is known as Brodie's abscess. Such lesions may be found in the metaphysis, epiphysis, and rarely, in the diaphysis. Metaphyseal lesions frequently extend across the physis and into the epiphysis (Fig. 176.5). Fortunately, this appears to be a response that does not injure the physis. A second type exhibits a lytic area in the cortex with little or no bone response. In others, the cortex becomes very sclerotic but without onion skin—like periosteal new bone. However, there is a subperiosteal new bone type that has an onion skin appearance. Rarely, the involvement in the metaphysis may be diffuse without a clear border.

![Figure 176.5](image)

Brodie's abscess extended from the metaphysis to the epiphysis. Normal growth continued after curettage of the lesion.

**DIAGNOSIS**

As many as 50% of patients with subacute osteomyelitis have an initial incorrect diagnosis. Subacute osteomyelitis should be the diagnosis until proven otherwise if there is local swelling, with local pain, and one of the classic radiographic appearances, along with an elevated sedimentation rate. Bone scans are almost always positive, although they are not diagnostic. MRI is frequently the most useful imaging and should be used in those with a destructive lesion or in any patient with radiographic changes suggestive of a malignancy.

**TREATMENT**

The initial step in treatment of the lytic type is surgery. If the diagnosis is established by the pathology, both gross and microscopic, curet and culture the granulation tissue present in the lesion. Start antibiotics immediately after surgery. In most of these lesions, *S. aureus* is the pathogen; therefore, a semisynthetic penicillin or a first-generation cephalosporin is the drug of choice. If the diagnosis is made without biopsy, some lesions will respond to antibiotics without surgery (35). If the lesion is in the epiphysis and a surgical approach is potentially harmful, the initial treatment should be antibiotics for several weeks (Fig. 176.6). However, most metaphyseal lesions can be drained without harm to the articular surface or to the physis if the surgical approach is appropriately planned (15). In the subperiosteal, cortical, sclerotic, and diffuse metaphyseal types, surgical treatment has less to offer. In these patients, the clinical picture is more likely to resemble a neoplasm, and a surgical biopsy will be necessary for diagnosis. These types usually respond to adequate antibiotic therapy.

![Figure 176.6](image)

Lesion in the proximal epiphysis of the tibia.

**CHRONIC OSTEOMYELITIS**

Chronic osteomyelitis is seen much less frequently today than before the antibiotic era. It usually results from a delay in diagnosis or inadequate treatment. It is seen more often today in North America in immigrants from underdeveloped countries. The delay in controlling the infection results in the formation of a cortical sequestrum, which is due to ischemia from the cortical, intramedullary, and subperiosteal spread of pus. The antibiotic cannot adequately reach the bacteria located within dead bone, so surgical removal of the infected tissue must be done.

**TREATMENT**

In chronic osteomyelitis, start antibiotics immediately after deep tissue cultures of the wound are made. Continue the antibiotics for an extended period of time until the sedimentation rate is normal and the wound is benign. The indication for surgical treatment in chronic osteomyelitis is the presence of local pain and swelling, with or without drainage, in a bone with an area of lysis or a sequestrum, or both. Removal of the sequestrum and granulation tissue is the goal of the surgical exploration. Care must be taken not to jeopardize the integrity of the diaphysis by excessive removal of bone. The sequestrum should be removed, preferably after the involucrum is mature. Wide sequestracectomy of the cortex should not be done because bone regeneration in chronic osteomyelitis may be severely limited. This is particularly true when there is no involucrum.

The removal of all dead tissue is the first step in surgical treatment. If possible, the wound should be closed and drains placed in the wound. Suction drainage and irrigation should be done for several days postoperatively. An antibiotic irrigation solution may be preferable to saline. The insertion of antibiotic-impregnated
methylmethacrylate beads in the defect after debridement should be considered in the patient who has had repeated surgical procedures. The absence of an involucrum indicates an inadequate periosteum. Periosteal healing is then unlikely. In such a patient, a cancellous bone graft should be placed in the defect after there is healing from the initial debridement and the infection is under control. If the bone cannot be covered by local skin, a local muscle should be transferred to cover the defect. In large uncovered areas, a mycetous flap may be required to cover the bone and fill the defect adequately (41). In some locations, a free microvascularized flap may be necessary. Good full-thickness and soft-tissue skin coverage will accelerate and improve the quality of healing (see Chapter 8 and Chapter 35). After surgical debridement, protect the extremity to extremity to pathologic fracture.

**SPECIAL CONDITIONS**

**SICKLE CELL DISEASE**

In the patient with sickle cell disease, differentiation between an infant and acute osteomyelitis can be difficult (23,26,31,32). Both produce fever, bone pain, tenderness, erythema, and swelling. An increase in the white cell count and an elevated sedimentation rate are also present. The presence of swelling and tenderness in the shaft of a long bone is more typical of osteomyelitis in a patient with sickle cell disease, whereas in a patient who does not have sickle cell disease, osteomyelitis has its onset in the metaphysis.

To distinguish an infant from infection requires an astute evaluation of the degree of clinical signs and symptoms. The bone should be aspirated and cultured, and blood cultures should made if there is a strong possibility of infection. The pathogen in sickle cell osteomyelitis may be S. aureus, salmonella, or any other organism. Staphylococcus and salmonella are the two most common organisms cultured in osteomyelitis in a patient with sickle cell disease. In 15 patients with sickle cell disease with osteomyelitis, Epps et al. (11) reported that S. aureus was culture in eight, salmonella in six, and Proteus mirabilis in one.

Treatment of osteomyelitis is surgical (11) with the addition of antibiotics for 6 weeks. Chronic osteomyelitis in the patient with sickle cell disease is more common than in those who do not have sickle cell disease. Repeat surgical debridement may be needed in those patients who are not free of symptoms by 6 weeks. As in all patients with sickle cell disease, good hydration and transfusion are preoperative requirements.

**CHRONIC RECURRENT MULTIFOCAL OSTEOMYELITIS**

This is a rare condition of unknown etiology. It is more common in Europe than in the United States. In some reports, many patients have pustulosis palmaris et plantaris as well as recurrent multiple osteomyelitis (3,6,22). However, Yu and associates (45) reported on seven patients, none of whom had pustulosis palmaris et plantaris. Benhamou and associates (1) found some patients who in addition to pustulosis palmaris et plantaris also had Crohn's disease and some others had polyarthritis. They suggested that this condition was linked with seronegative spondylarthritids.

The onset of chronic recurrent multifocal osteomyelitis is gradual and usually with significant bone involvement. Pain is commonly reported. Lesions most severe in the femur, tibia, and spine, but other bones may be involved. There may be swelling and erythema over the lesions. Pressure over the involved part is painful, and if the spine is affected, flexion and extension pressure and over the involved vertebra causes pain.

The diagnosis is one of exclusion. Radiographs may show sclerosis, hyperostosis, or lysis. The radiographic changes have the appearance of bacterial osteomyelitis or of a sarcoma. Peripheral blood changes are minimal. A technetium-99m scan may show increased uptake or may be normal. Changes of inflammation suggestive of osteomyelitis are seen on biopsy material. Cultures of the lesions are negative.

The symptoms usually last between 1 and 4 years. When the patient has pustulysis, symptoms generally last longer. Vertebral plana may result if a vertebra is involved. The height of the vertebra is not restored with time (45). Carr et al. (6) reported one patient with progressive kyphosis that required spinal fusion. Treatment is symptomatic with a nonsteroidal anti-inflammatory drug. Carr et al. (6) found that antibiotics may be helpful, and I have used cefalexin in one patient during recurrent episodes with possible benefits; however, antibiotics are not generally recommended.

**INFECTION IN THE SPINE**

The meaning of the “disclis” has been a source of confusion for many years. In 1964, Menelas (23) gave credit to Eric Price for coining the word discitis for an infection of the disc space with little or no bone involvement. For many years, this remained a common concept of spinal infection in children. However, with the use of tomography it became apparent that osteomyelitis of the adjacent vertebrae always was present when the disc was infection. Ring et al. (34) labeled this condition pyogenic infectious spondylitis. The nomenclature for discitis from a bacterial infection should no longer be confusing. Pyogenic infectious spondylitis is not common but must be considered as a possible cause of back pain in a child and particularly in the very young child. The most frequent etiologic agent cultured is staphylococcus; however, streptococcus and, to a lesser extent, salmonella may be cultured (43-37).

The gradual onset of back pain is the most consistent symptom. Small children refuse to sit or walk. Leg pain and weakness may cause the child to not walk or to limp. The classic picture is a child sitting with the spine in extension and hands resting on the bed behind the trunk for support. Percussion over the affected vertebra is painful even before changes on routine radiographs are present. When the clinical picture of bacterial spondylitis is present, blood cultures should be done. Hoffer et al. (13) recommended computer-guided biopsy if cultures were negative. I believe with the predominant bacteria known to cause this condition being staphylococcus and streptococcus it is reasonable to assume that one of these organisms is present and to treat the child with the appropriate antibiotic. A response should be noted within 3 days, and if not, an additional antibiotic added or biopsy done. Patients who are not treated with antibiotics do recover when the spine is immobilized; however, this approach may prolong the time to recovery and can increase the need for surgical drainage (38). I prefer to administer an antibiotic for the infection and to provide symptomatic treatment to relieve back pain.

**OSTEOMYELITIS OF THE PELVIS**

Infection of the pelvis is rare, and the diagnosis is difficult (18). The ilium is the most frequent pelvic bone affected, but the ischium and pubis may be involved. Pain about the hip and a limp or refusal to walk is commonly reported. Most patients have a fever. The white cell count is elevated, as is the sedimentation rate.

Symptoms may be localized to the hip, the abdomen, the buttocks or low back, with sciatica-like symptoms. The location of the infection determines the location of the pain. The hip is the most common area for pain, and when this is the presentation, an infection has to be considered. This pain occurs when the ilium is involved near the iliac crest bone, and osteomyelitis near the acetabulum can decompress in the hip joint and infect the joint. Buttock pain occurs if the ilium outer table is eroded, especially near the sacroiliac joint. Decompression through the inner wall may cause sciatica-like symptoms if the pus goes into the true pelvis and irritates the sciatic nerve or the pus may ascend and cause abdominal pain.

The diagnosis of osteomyelitis is made from the laboratory changes, the physical examination, and the use of the bone scan, CT, and MRI (30-39). Initial imaging with any of these modalities may be normal early in the course of the disease, but all tests will become positive eventually. The MRI will ordinarily be the first to show the swelling and bone involvement. It can distinguish soft-tissue swelling and show whether it is from bone or has a nonosseous origin. The MRI cannot differentiate infection from a tumor or infarction (49).

Physical evaluation includes observing the gait if the patient can walk. Perform range-of-motion examination of the hip gently. Passive motion of the infected hip is usually quite painful and limited whereas in infection of the pelvis more motion is present and less painful. Pressure on the pelvis is painful. Pressure over the buttock is painful if the ilium has decompressed through the outer table.

Administer appropriate antibiotics parenterally then orally. If treatment is started before an extracapsular abscess develops, antibiotic treatment is the only treatment required. When an abscess is present, surgical drainage is appropriate. Drain gluteal abscess posterior through the gluteus maximus, and a pelvic abscess through the abdomen but stay retroperitoneally. Chronic osteomyelitis of the pelvis is very rare, and most patients recover without residual problems (30).

**SEPTIC ARTHRITIS**

Septic arthritis occurs in all age groups but primarily affects the very young child. The peak incidence is between the age of 1 and 2 years of age (18). In neonates and other infants, the hip is the joint most commonly affected, but the knee is more commonly involved in older children. Infection in the hip joint is frequently secondary to osteomyelitis of the proximal femur, particularly in the infant. Septic arthritis of the shoulder and ankle may be secondary to spontaneous decompression of pus from the proximal humerus and distal fibula, respectively. Residual effects from septic arthritis are related to a delay in diagnosis and treatment, and to the presence of osteomyelitis.
BACTERIOLOGY

Over the last 20 years, the pathogens common in septic arthritis have changed. In the 1950s and 1960s, S. aureus was the organism most commonly cultured from septic joints. In a 1967 study of 116 infected joints in children with a mean age of 3 years, S. aureus was the most frequent organism cultured and 8% had H. influenzae (14). In the 1970s, the incidence of H. influenzae increased and was the most common organism cultured in children younger than 4 years of age (17). Jackson and Nelson (20) reported S. aureus in 30%, group B streptococcus in 21%, and gram-negative organisms in 28% in children aged 1 month to 5 years. However, in the infant younger than 3 months of age who acquires a joint infection while in the hospital, staphylococcus is the most common organism cultured. Approximately two thirds of hospital-acquired joint infections were found by Dan (6) to have S. aureus and one fifth Candida species as the pathogen. Since the development of the vaccine for H. influenzae, this organism is rarely the pathogen in septic arthritis.

PATHOPHYSIOLOGY

Septic arthritis in children is usually acquired by a hematogenous route. This may be either direct inoculation into the synovium or secondary to hematogenous osteomyelitis that decompresses into the joint. Osteomyelitis with secondary septic arthritis of the hip is common in the neonate but can occur in children of all ages. The ankle and shoulder, where the metaphysis may be partially intracapsular, occasionally is infected secondary to osteomyelitis. In the infant, in whom there are vessels that transverse the physis from the metaphysis to the epiphysis, the infection can spread from the metaphysis to the epiphysis and the adjacent joint. Bacteria are deposited in the synovium, and an inflammatory reaction develops. The inflamed synovium allows blood products and bacteria to enter the synovial fluid, including large numbers of leucocytes. The inflamed synovium, the white blood cells, and the bacteria contribute to the enzymatic destruction of the articular cartilage by the release of collagenase and proteases. Even the chondrocyte may contribute to cartilage destruction; Jasim (21) has shown that the chondrocyte may be stimulated to release chondroitinases by the action of either bacterial lipopolysaccharide or interferon I (IL-I). The depletion of glycosaminoglycans in the cartilage matrix begins rapidly. Within 24 hours there is a significant loss. The loss of collagen follows (28). It is because of the multiple sources of these enzymes (bacteria, white blood cells, and synovial cells) that antibiotics alone cannot prevent destruction of the cartilage. Thorough cleansing of the joint is essential to successful treatment.

CLINICAL SIGNS AND SYMPTOMS

The onset of septic arthritis is characterized by the rapid development of joint pain and a fever of 100° to 104°F (38° to 40°C). Although the rapid onset of pain is variable, it is usually severe within 24 to 48 hours so that the child refuses to use the extremity. Irritability and malaise may precede the onset of pain. Pseudoparalysis is common in the very young. The physical examination is dramatic in the severity of the limitation of motion of the affected joint. Even with the gentlest attempt to move the extremity passively, there is extreme pain and spasm, and little motion is obtained. The joint is swollen, hot, and globally tender. The affected joint assumes a resting position that maximizes the capsular volume to reduce the tension in the joint. The hip is held flexed abducted and externally rotated. The most comfortable position for most other joints is some degree of flexion. In the neonate, minimal spontaneous movement, swelling of the joints, slight fever, and irritability may be the only changes present.

DIAGNOSIS

The clinical features of acute septic arthritis are usually, but not always, dramatic enough to exclude other diagnoses. However, always aspirate a joint when infection is considered to be a possibility, even when the child does not have the classic severe pain of septic arthritis. Infected joint fluid is cloudy, and mucin is diminished. A drop of fluid rubbed between the thumb and a finger will feel watery and will not string as the opposed fingers are separated. The most important studies of the fluid are a culture, Gram stain, white blood cell count, and differential. If sufficient fluid is available, other valuable measurements that should be obtained are glucose and lactic acid levels. The white cell count is usually between 50,000 and 200,000. More important, the differential is greater than 90% polymorphonuclear leukocytes. A joint fluid sugar of 50 mg/dl less than the blood sugar is common. In nongonococcal arthritis, the lactic acid level is elevated. It is important that the specimen for cell count is anticoagulated; if this is not done, the fluid will quickly coagulate. This makes the cell count incorrect. Aspiration of the hip and shoulder should be done under fluoroscopic control. If no fluid is aspirated, injection of a radiopaque dye into the joint will confirm that the needle is intra-articular.

In addition to the joint aspiration, peripheral blood studies should be done to include a complete blood count and sedimentation rate. The white blood cell count is generally elevated with an increase in polymorphonuclear leukocytes, and the sedimentation rate is elevated. If the child is seriously ill and the infection present for several days, the erythrocyte count and hematocrit will be low.

Counterimmunoelectrophoresis of the synovial fluid can be helpful when the cultures are negative; it is particularly helpful when there has been partial treatment by antibiotics. This test can identify the presence of H. influenzae, Streptococcus pneumoniae, and meningococcus (9). A gallium scan has some use when the diagnosis is difficult. Bowman et al. (6) used gallium and reported accuracy in diagnosis of 91% in 34 patients with septic arthritis. The radiation dose from gallium is higher than from technetium, and it should be used only in difficult cases.

DIFFERENTIAL DIAGNOSIS

In the patient with the classic onset of fever, severe joint pain, and limited motion, there is little to confuse the diagnosis. However, conditions such as toxic synovitis, monarticular rheumatoid arthritis, and osteomyelitis can at times present a diagnostic problem. The child with toxic synovitis can usually be excluded by the clinical findings. The child is not ill, pain is not severe, and motion is only slightly limited. Acute-onset monarticular rheumatoid arthritis may have many of the features of septic arthritis in a non-weight bearing joint, e.g., chest, elbow, knee, or the wrist. Joint fluid analysis may be the only way to differentiate between these two diseases early in the course of the disease. In rheumatoid arthritis, pain can be severe, motion very limited, and the febrile and ill. The synovial fluid may have as many as 70,000 cells, but on the differential, there will be less than 80% polymorphonuclear cells, unlike the 90% to 100% found in septic arthritis. In rheumatoid arthritis, the joint sugar level is similar to that in the blood sugar. The mucin in rheumatoid synovial fluid is diminished, as it is in septic fluid. The leukocyte differential and the glucose levels may be the only differentiating feature between these two diseases.

Osteomyelitis can be difficult to differentiate from septic arthritis. In both conditions, the child may be febrile and have the peripheral blood changes of infection. In both conditions, the patient exhibits limited joint motion, but in osteomyelitis, the adjacent joint will generally have a moderate range of motion if the examiner is gentle and protects the extremity from sudden motion. By careful palpation, tenderness will be found over the infected metaphysis and not the joint. Swelling is also different. In osteomyelitis, the swelling begins over the metaphysis and spreads to include much of the extremity segment (Fig. 176.2). The adjacent joint may be swollen from a sympathetic effusion, but it is not particularly tender. The swelling in septic arthritis is confined to the intracapsular space. If there is swelling over the bone and also joint effusion, it is important to aspirate both the joint and the bone, with aspiration first at the most unlikely site for the infection, followed by aspiration of the suspected site. Radiographs will show the typical deep soft-tissue swelling if osteomyelitis is present. When soft-tissue swelling is present in the thigh and the hip joint space is wide on the radiograph, the patient has osteomyelitis plus a secondary septic arthritis until proven otherwise (Fig. 176.7).

Figure 176.7: A: Soft-tissue swelling in a neonate. Notice the hip joint space. B: Two years later, the metaphysis is subluxated, the acetabulum is dysplastic, and there is no ossified femoral head. C: This image demonstrates the shortening of the left femur.

TREATMENT

The objectives of treatment are to sterilize the joint, evacuate the debris associated with infection, relieve pain, and prevent deformity. Since the discovery of antibiotics,
controversy has arisen as to the most effective way to cleanse the joint of the products of infection. This has centered mainly on whether or not aspiration and irrigation are as effective as arthrothomy and irrigation. There are no adequate studies to evaluate the superiority of one method over the other, and because of the many variables, it is unlikely that a comparative study will ever be done.

What we do know is that early diagnosis and treatment with the appropriate antibiotic are the most important aspects of treatment (17). There is little proof that it affects the outcome. Intermittent or continuous irrigation for 48 to 72 hours through catheters has been in use for many years. There is little proof that it affects the outcome, but it is not to be condemned. Antibiotics reach the synovium and synovial fluid sufficiently to deliver the necessary bactericidal concentration of the antibiotic into the joint. If postarthrotomy intermittent irrigation is used, extreme care to maintain sterile technique is important to prevent a nosocomial infection through the irrigation system. I no longer use postarthrotomy irrigation.

The first step in treatment of septic arthritis is aspiration of the joint to confirm the diagnosis. If pus is obtained, the joint should be irrigated with saline until the fluid returns clear. The hip and shoulder should be immediately opened and irrigated after aspiration and joint fluid analysis confirms the diagnosis. In other joints, if infection has been present for 4 or 5 days, the large amount of fibrin and debris that has accumulated may be difficult to remove by needle. In these patients, arthrothomy or irrigation by arthroscope is the preferred method of joint debridement. I do not recommend arthroscopic irrigation because I believe the motions of the assistance to remove the debris adequately irritates the inflamed synovium. I have seen several failures when this technique is used in a joint that by all rights should have had a successful outcome.

Decompression/Debridement of the Hip

I prefer the anterior approach to the hip to the posterior approach. In the anterior approach the posterior superior epiphyses vessels are less likely to be damaged, and the anterior arthrothomy does not leave a posterior defect in the capsule where the hip can dislocate.

- Make an anterior approach (see Chapter 3).
- Then make a 1 cm capsulotomy through which the joint is irrigated.
- Then make a spinal needle and inject the hip joint. When the neck within the capsule is osseous, so drilling is likely to injure the physis. If the septic hip is secondary to osteomyelitis, the femoral neck has already decompressed itself.
- Although I no longer use irrigation postoperatively, I do leave a drain near the opening in the capsule and allow it to drain 48 hours later.
- Take a synovial biopsy for culture and close the skin. Synovial tissue cultures may be positive when the aspiration is negative.

Immediately after the aspiration, the appropriate systemic parenteral antibiotic should be started. It should be one that is effective for the most likely pathogen. Age, environment, and the Gram stain determine the initial choice of antibiotic. In the neonate, multiple organisms may be uncommon. A semisynthetic penicillin for the staphylococci and streptococci plus an aminoglycoside for the gram-negative organisms should be used in the neonate. Between the age of 1 month and 5 years, H. Influenzae is as common as staphylococcus and streptococci infection if the child has not been vaccinated for H. influenzae. In this age group, cefuroxime or ceftriaxone may be the drug of choice because they are effective against both the gram-positive cocci and H. influenzae. After age 5 years, a semisynthetic penicillin or a first-generation cephalosporin is the drug of choice. Both are effective against streptococci and staphylococcus organisms. The oral cephalosporins taste better than the oral synthetic penicillin, and for that reason, a cephalosporin may be preferable.

The use of oral antibiotics after 2 to 3 days of intravenous antibiotics can be effective in selected patients. The prerequisite for the use of oral treatment is a rapid clinical response to the treatment, a positive culture, a clear knee, and no fever with the patient able to drive. The duration of oral treatment is 2 weeks. The duration of oral treatment is 3 weeks. The duration of oral treatment is 4 weeks. The duration of oral treatment is 5 weeks. The duration of oral treatment is 6 weeks.

The residual effects from septic arthritis diagnosed and treated within 2 days and in some cases even longer are minimal. In the infant, a delay in diagnosis and treatment is more likely than in older children. The hip is more commonly affected in the infant, and osteomyelitis with secondary septic arthritis is more common in the proximal femur. Until the physis becomes a barrier to the metaphyseal vessels crossing into the epiphysis, the physis and epiphysis are in jeopardy. This anatomic fact and the frequent delay in diagnosis in the infant are the reasons that the poorest results from septic arthritis are in infants and in the hip. The physis and the epiphysis may both be completely destroyed by osteomyelitis with associated septic arthritis. Spontaneous decompression of the pus into the hip joint may cause damage to the epiphysis and synovium, but the epiphyseal death is due to the intracapsular pressure and not the extracapsular pressure. Gross destruction of the hip. In my report in 1967, 15% of infected hips had a poor result and 75% of poor results were patients with septic arthritis of the hip secondary to osteomyelitis (18).

Significant sequelae to septic arthritis are rare except in the hip, where delay in treatment of the infant has allowed the partial or complete destruction of the physis and epiphyseal blood supply by tamponade, and the intracapsular pressure may cause a dislocation of the hip. In my report in 1967, 15% of infected hips had a poor result and 75% of poor results were patients with septic arthritis of the hip secondary to osteomyelitis (18).

TUBERCULOUS ARTHRITIS

Tuberculosis of the bones and joints is uncommon in the countries of the developed world, particularly in North America. But it remains a common scourge in underdeveloped countries. Over the past decade, there has been a substantial increase in migration to developed countries from underdeveloped areas, such that tuberculosis is no longer treated as a problem common and must always be suspected in children who present with chronic infections, particularly if their families have recently immigrated from underdeveloped countries. Tuberculosis is a chronic granulomatous infection caused by Mycobacterium tuberculosis. In countries where raw milk is consumed, bovine transmission can cause infection by Mycobacterium bovis. Tuberculosis is a localized destructive disease that spreads by the hematogenous route from a primary focus, most commonly located in the lungs and infected mediastinal lymph nodes.

As with pyogenic infections, tuberculosis infections of joints can occur by direct hematogenous infection of the synovium or by invasion of the joint from an adjacent osteomyelitis involving the epiphysis or metaphysis. A tuberculosis focus in bone spreads by centrifugal destruction of bone, producing increasing amounts of exudate and pus. The exudate and pus form a purulent mass that can be aspirated. This mass forms a “cold abscess” so named because of the absence of acute inflammation. The infection spreads along tissue planes and may present as a subcutaneous abscess or fistula. In my report in 1967, 15% of infected hips had a poor result and 75% of poor results were patients with septic arthritis of the hip secondary to osteomyelitis (18).

Primary joint tuberculosis or secondary spread from adjacent bone involvement results in the proliferation of tuberculous granulation tissue in the joint, which produces a pannus that rapidly covers articular cartilage, destroying the cartilage and underlying subchondral bone. Destruction is most extensive around the periphery of the joint at the attachments of the synovial membrane.

The clinical presentation of a chronically ill child with a history of easy fatigability and weight loss. The evolution of the disease is insidious, and involvement is usually multicentric or in a single site. It is important to seek a family history of tuberculosis. With lower extremity involvement, the patients limp and the affected joint is stiff. Clinically, the knee is the most common site, because the pain is less likely to cause the patient to walk. Infection is frequent in the spine, followed in order of frequency by the hip, knee, ankle, sacroiliac joint, shoulder, and wrist. Tuberculosis spondylitis in the child is characterized by a painful, stiff back and a protective gait with which the child keeps the back hyperextended. Infection in the thoracic spine and the thoracolumbar junction is common. Kyphosis develops as bone destruction progresses. In the extremities, muscular atrophy is usually marked.

Characteristic laboratory findings are a hypochromic anemia, normal or only a slight increase in the peripheral white blood cell count, a modestly elevated erythrocyte
sedimentation rate, and positive tubercular skin test. Synovial fluid analysis shows a white blood cell count averaging 20,000 cells/mm³ (range 3,000 to 100,000 cells), with 40% lymphocytes and monocytes, which is much more than that seen in pyogenic infections. Cultures are usually positive, but diagnosis can be quickly confirmed by histologic examination of tissue obtained by biopsy of the synovium of infected joints or sites of bone involvement.

Plane film radiography is usually adequate to demonstrate the changes from tuberculous arthritis, although it is often indistinguishable from monoarticular rheumatoid arthritis. Characteristic findings are the triad of Phehister, which consists of periarticular osteoporosis, gradual narrowing of the joint space, and erosions of the bone peripherally at the synovial attachments. In the late stage of tuberculosis, there may be complete destruction of joints, with dense sclerotic changes in adjacent bone. The disease is typically monoarticular, as opposed to juvenile arthritis, which is usually polyarticular. In the spine, the initial presentation shows disk space narrowing and destruction of the adjacent endplates of the vertebrae. With progression of the disease, a paraspinal mass is common. Subsequent collapse of involved vertebra and extension of the infection to adjacent levels leads to kyphosis and formation of a gibbous. Infection often extends along the psoas muscle sheaths and can present as abscesses in the flanks or groin. Paraplegia can occur due to tuberculous involvement of the meninges or due to mechanical pressure from the infection and collapse of the vertebral elements. This is known as Pott's disease.

Treatment is primarily with multiple antituberculous drugs. General medicine measures to treat other focuses of the disease and to ensure good health habits and adequate nutrition are important. Orthopaedic care consists of conservative measures to preserve motion and strength, and to prevent deformity. Surgery is performed when necessary to debride necrotic bone and soft tissue, and to eliminate abscess. Today, surgery is most commonly required to correct spinal deformity and treat paraplegia. For treatment, three drugs are preferred, and because of the large percentage of drug-resistant infections in certain areas, four drugs may be advisable. Drugs include isoniazid, rifampin, streptomycin, ethambutol, and pyrazinamide, as well as others. Pyridoxine supplementation may be necessary when treating with isoniazid. Monitor patients for hepatotoxicity, impaired renal infection, eighth cranial nerve toxicity, serum sickness–like syndromes, and thrombocytopenia.

CHAPTER REFERENCES

Each reference is categorized according to the following scheme: *, classic article; #, review article; !, basic research article; and +, clinical results/outcome study.

Cerebral palsy (CP) is a disorder of movement or posture caused by a nonprogressive lesion of the brain acquired at or around the time of birth (3). Although musculoskeletal deformities and imbalances are usual, and certain clinical patterns are relatively common, the condition is extremely heterogeneous. The brain lesions tend not to be highly localized and therefore usually produce more than an isolated deficit. At least five basic movement disorders—spasticity, athetosis, ataxia, rigidity, and tremor—are described, and various possibilities for distribution include monoplegia, hemiplegia, diplegia, and total body involvement.

Although spasticity is most common, many patients have more than one movement disorder. It is important to identify the primary movement disorder because, in general, operations are designed for patients with spasticity. Because the brain lesion is often diffuse, deficits in proprioception, stereognosis, and perceptual integration can result. Keeping cognizant of these other deficits will remind the orthopaedic surgeon to set reasonably modest goals for treatment.

Specific deformities and functional losses are seen repetitively in patients with CP, depending on the pattern of neurologic involvement. For example, the combination of windblown hips and scoliosis is typically seen in the total-body-involved spastic quadriplegia patient. Valgus feet and mild crouch gait are typically seen in spastic diplegia. By applying basic principles of surgical correction, the orthopaedist may improve positioning, function, and appearance of the extremities in selected patients.

GOALS OF TREATMENT

Many CP patients will need and benefit from lower extremity surgery. The goals vary depending on the overall functional ability of the patient (i.e., nonambulator, “therapy” or nonfunctional ambulator, household ambulator, community ambulator with assistive devices, or independent community ambulator). Goals for lower extremity surgery in nonambulators are often limited to improving comfort and easing nursing care, or decreasing contractures sufficiently to allow deformed feet to be fitted with shoes. Assisted transfers of a nonambulator in and out of a wheelchair can be facilitated if the patient can be stood on plantigrade feet with fairly straight hips and knees. For household or community walkers, the goal should be to improve the efficiency of gait (i.e., decrease the energy cost) by minimizing contractures and balancing spasticity. However, the basic ability to walk is dictated by the patient's brain and is not affected by the orthopaedic surgeon. Because the prognosis for independent walking can be established by 2 or 3 years of age (depending on the equilibrium and primitive reflexes), the surgeon should have realistic goals in mind by the time surgery is undertaken (3).

A far smaller percentage of CP patients will need or truly benefit from upper extremity surgery. The goals of upper extremity reconstructive surgery usually relate to improvement in function, occasionally for ease of hygiene or personal care (such as pulling a long sleeve shirt over a wrist and hand that is locked in flexion), and rarely for improvement in cosmesis. Coexistent deficits in stereognosis and motor planning limit the goals that should be expected when trying to reestablish motor control about the wrist and hand. Additionally, any cognitive problems further minimize the ability of the CP patient to cooperate in a postoperative therapy program. In general, this will mean that most upper extremity surgery for functional improvement will be performed on children who are spastic hemiplegics with only mild or no cognitive deficits.

For the sake of clarity, it is important to discuss only one anatomic deformity at a time. However, it is vital always to think of the joints and muscles above and below the target deformity. Make repeated examinations before deciding on surgical intervention. Consideration must be given not only to the effects of other deformities on the index deformity, but also to the effects that any proposed surgery will have on the neighboring joints. A classic example of this is the increased lordosis that occurs after an apparently appropriate hamstring lengthening because of a lack of attention to preexisting increased hip flexor spasticity. Similarly, a mild tendency toward crouch gait will often worsen following a heel cord lengthening done in isolation.

I have found the gait analysis laboratory to be helpful in planning surgical procedures in CP, especially when several procedures must be performed simultaneously. By using combinations of dynamic gait electromyographic (EMG) analysis and video monitoring of joint range during gait, I have found that in more than half the cases the preoperative gait analysis affects my decision as to which operative procedures are necessary.

Most surgery designed for gait improvement should probably be delayed until the pattern of gait is fairly well established (usually between 4 and 8 years of age) with a goal of finishing surgical intervention (if possible) by the first or second grade of school. Similarly, surgery for upper extremity functional improvement usually is most appropriate at about the same age. It often takes a series of examinations on a young child to accurately assess the motor, sensory, and cognitive resources of a not-always-cooperative child.

The procedures described here represent my preferences for treating the most common lower-extremity deformities in spastic CP. Keep in mind that even with well-planned and carefully executed surgery, deformities occasionally recur or progress in children with CP, and salvage or reconstructive procedures may later become necessary.

FOOT AND ANKLE DEFORMITIES

EQUINUS DEFORMITY

Indications for Surgery

Equinus deformity is very common and is one of the few deformities that may actually exist in isolation in spastic CP, especially in hemiplegics. The indications for surgical correction are simple: fixed equinus such that the ankle cannot be dorsiflexed to neutral, with the hindfoot locked in varus in a walking or potentially ambulatory patient. In diplegics, equinus helps in transferring the weight-bearing line anteriorly, which assists in extending the knee. Thus, when crouching is present in diplegia, the surgeon should not lengthen the triceps surae in isolation; usually, hamstring or hip flexor surgery must be combined with it. Not all tightening CP patients have fixed equinus. For a dynamic deformity, it is best to try an extended period of bracing with a rigid plastic ankle–foot orthosis or a series of short-leg walking casts for 2–3 weeks at a time.

An additional alternative for the patient with dynamic equinus is an injection of botulinum-A toxin (1–2 mm/kg body weight per calf), which will fairly reliably temporarily...
Tendo-Achilles Lengthening through the Posteromedial Approach

In an older patient with a severe, longstanding equinus contracture (e.g., a 10-year-old hemiplegic who has always walked on his toes), heel cord lengthening through a standard posteromedial longitudinal incision with a Z-type tendon lengthening is recommended, because there is likely to be a fixed capsular contracture of the ankle requiring capsulotomy as well. The amount of lengthening should be approximately enough that with the foot in neutral, half the available excursion of the tendo-Achilles is set. An additional check for the amount of lengthening is the so-called geometric method, in which the amount of lengthening is half the perpendicular distance that the first metatarsal head protrudes inferiorly to the heel during maximal passive dorsiflexion (10). Once the amount of lengthening is determined, perform the suture repair with the foot in equinus so as to minimize tension during the repair. After the repair, check the foot in the neutral position to make sure that there is still some residual tension on the muscle-tenon unit.

Hoke Procedure

- In most patients, a Hoke procedure is preferred for heel cord lengthening (Fig. 177.1). This can be accomplished in a number of ways. The method involves three opposing cuts, each one halfway through the tendon. Make two medial cuts proximally and distally, with one lateral cut halfway between the two, or vice versa. Then dorsiflex the foot just to neutral, thus causing a sliding lengthening. No sutures are necessary.

- The best visualization of the procedure is accomplished through a medial longitudinal incision 4–6 cm in length. It is rare to need a posterior capsulotomy of the ankle in CP. By placing the incision slightly further anteriorly, the posterior tibial tendon or toe flexors may also be approached, if desired. However, occasionally the longitudinal scar may be prominent. Alternatively, use two small transverse incisions, with two of the tendon cuts through one incision and one tendon cut through a second incision. With a subcuticular closure, the scar is essentially invisible.

- Finally, the entire procedure can be performed percutaneously. This is now my preferred technique if a heel cord lengthening is the only procedure needing to be done. Make the same three cuts in the tendon using a #15-C scalpel blade through three tiny percutaneous incisions. The proximal cut should be at about the level of the musculotendinous junction. It is essential to dorsiflex the foot to only 10° or 15° above neutral, with the knee slightly flexed.

Gastrocnemius Recession

In the occasional ambulatory, tilttoeing child with a dramatic and consistently positive Stiffversköld test (in which the amount of dorsiflexion is much improved with the knee flexed as compared to the degree in full knee extension), I perform a simple gastrocnemius recession (24).

- Make a longitudinal incision in the lower middle calf slightly medially over the palpable lower border of the gastrocnemius muscle belly. Separate the gastrocnemius aponeurosis from the underlying soleus; this plane is easier to find proximally.

- Divide transversely only the gastrocnemius aponeurosis and dorsiflex the foot to 5° to 10° above neutral. I will usually tack down the aponeurosis with a few absorbable stitches. Occasionally, it is also necessary to divide a few fibers of the underlying soleus aponeurosis to obtain adequate dorsiflexion. No muscle fibers, however, are divided. This has the theoretical advantage that overcorrection is very unlikely, although recurrence of equinus may be slightly more likely.

Postoperative Care

The postoperative care is the same whatever type of equinus correction is chosen. Apply an above-knee cast with the knee in 5° or 10° of flexion. At 2–3 weeks, cut the cast down to a below-knee walking cast. Allow ambulation immediately after surgery if no other contraindications are present. If no other simultaneous surgery was performed requiring immobilization above the knee (e.g., hamstrings or iliopsoas release), a below-knee walking cast can be used following any type of heel cord lengthening. The child will tend to flex the knees with only a below-knee cast, but within 24 hours she can be coaxed into extending her knees to near neutral. Using a below-knee cast facilitates the rehabilitation. Remove all casts at 6–8 weeks. A plastic, right angle, or articulated ankle–foot orthosis (AFO) is frequently used part-time for at least 3–6 months. Patients who have no selective control of dorsiflexion will often require the orthosis on a more or less permanent basis. Use nighttime splinting in neutral in those patients who tend to drift back into equinus.

Complications

If fixed equinus recurs, lengthen the tendon by the Z technique a second time. Forewarn parents that recurrence of some equinus does occur in perhaps 10% of children who undergo tendo-Achilles lengthening (TAL); however, many children who do not make heel contact at foot strike do so more because of flexed knees than because of fixed equinus. Overlengthening is far worse than a recurrence of the original equinus. There is no universally successful management for postoperative calcaneus deformity. The first rule is to avoid overlengthening. Some tension should always remain on the tendon until after lengthening. If calcaneus deformity does occur, tendon reconstructions have not always been satisfactory. Reshortening of the tendo-Achilles may be tried, or tenodesis of the Achilles to the posterior tibia or fibula, but these are unlikely to restore true muscle function.

A dynamic gait analysis may demonstrate which muscles are active in stance. The anterior tibial tendon can be transferred posteriorly to the heel, and theoretically the peroneus brevis and half the posterior tibial tendon can also be transferred to the os calcis. However, restoration of fully satisfactory plantar flexor strength is unlikely. Should postoperative calcaneus deformity occur, a rigid AFO with a wide proximal anterior tibial restraint (“floor reaction” AFO) will have to be used in addition to attempts at reinforcing plantar flexor strength.

VARUS DEFORMITY

Indications for Surgery

Varus deformity may be either dynamic or fixed. It appears most often in hemiplegics, compared with the more typical valgus deformity seen in diplegics. Dynamic gait EMG analysis is most helpful in determining the phasic nature of the tibialis anterior and posterior muscles and the peroneals. Generally, patients under 4 years of age have not fully established a gait pattern and can be managed with orthotics. The indications for surgery then depend on the age of the patient, whether the varus is mild or severe, and which muscles are most “at fault” on the EMG.

For the milder, flexible varus deformities, a posterior tibial myotendinous lengthening (25) is the simplest approach, but it is rarely appropriate to perform it as an isolated procedure. This is often combined with a TAL. For more significant, but still flexible, varus deformities, a split anterior tibial tendon (SPLATT) procedure (13) can be combined with the posterior tibial myotendinous lengthening, or the posterior tibial tendon can be split and transferred laterally to the peroneus brevis (15-23).

If any of these procedures are being considered, preoperative gait EMG, if available, should demonstrate excessive or even continuous phasic firing of the anterior and posterior tibial muscles throughout the gait cycle. One should not expect postoperative changes in the phasic pattern of muscle firing after transfer (11). Currently, I favor the split posterior tibial tendon transfer (usually along with TAL) in patients with dynamic varus and equinus deformity, because plantar flexor strength is not sacrificed quite as much, and only the muscle direction is changed. It is important to realize that spastic muscles, although overactive, are still weakened. In fact, I frequently split both the anterior and the posterior tibial tendons with lateral transfer of both in cases of dynamic varus. Others perform just the SPLATT transfer with TAL for the same dynamic varus deformity. The postoperative regimen in either case is the same as described for TAL.
I would caution against ever transferring the entire posterior tibial tendon anteriorly through the interosseous membrane in a patient with spastic CP. I have abandoned that technique because of the occurrence of late calcaneovalgus deformity. I would also caution against complete tenotomy of the posterior tibial tendon in the spastic foot, because late valgus is likely.

If a fixed varus deformity is present in the hindfoot, as determined by the block test, add a bony reconstruction to the soft-tissue releases or transfer. Perform the block test by having the patient stand with a 1–2 cm block under the heel and lateral border of the foot. If the heel varus resolves, then it is compensatory and results from hoof pronation of the first ray. If heel varus persists on the block, it is fixed (see the section on cavus in Chapter 167). In the case of a younger patient, the choices are either a sliding lateral displacement osteotomy or a Dwyer-type of laterally based closing wedge of the calcaneus. In a patient older than 12 years with significant fixed varus deformity, perform a triple arthrodesis.

**Posterior Tibial Tendon Lengthening**

- Through a longitudinal supramalleolar posteromedial incision, approach the posterior tibial muscle. At least 2–4 cm proximal to the most distal muscle fibers, divide the tendinous portion of the posterior tibial muscle obliquely. Passively evert the foot under direct visualization to observe the tendon slide. This produces an aponeurotic lengthening that leaves the muscle fibers in continuity. No sutures are needed.
- Alternatively, a supramalleolar Z-lengthening of the posterior tibial tendon can be performed, but this is a more complex procedure and requires suture repair.

I prefer the first method, usually in combination with a TAL and SPLATT. Use a postoperative short-leg walking cast for 6 weeks.

**SPLATT Procedure**

- Isolate the anterior tibial tendon at its insertion as far distally as possible through a 1-inch (2.5 cm) incision over the first cuneiform bone. Split the tendon in half longitudinally and free the lateral half (see Chapter 167).
- Make a second incision over the anterior compartment of the leg 3–4 inches (7.5–10.0 cm) above the ankle. Pass the lateral half of the tendon proximally into the second incision. It is helpful to have a Bunnell-type suture through the free end of the tendon.
- Then make a third incision laterally over the cuboid bone. Pass the lateral half of the anterior tibial tendon subcutaneously, deep to the extensor retinaculum to the third incision. Suture the tendon either to the periosteum of the cuboid or, better, route it through a small bony vertical tunnel in the cuboid. I prefer using an absorbable pullout stitch over a pedled plantar button or splint. On subsequent removal of the cast, the pullout suture can simply be cut flush with the skin.
- Prior to closure, tension on the tendon proximally should tend to dorsiflex the foot in a neutral position. That is, a yoke has been created and the tension in each limb both medially and laterally should be fairly similar. Use a short-leg cast for 6 weeks.

**Split Posterior Tibial Tendon Transfer**

Usually four small 1- to 1.5-inch (2.5 to 3.4 cm) incisions are used, although the entire procedure can readily be performed through the Cincinnati horizontal transverse incision commonly used for clubfoot (33) (see Chapter 167).

- Begin with a 1-inch (2.5 cm) medial longitudinal incision over the navicular tuberosity. Isolate the posterior tibial tendon at its insertion and split it distally, detaching the plantar half. Tag this with a heavy nonabsorbable suture. **(Fig. 177.2)**

**Figure 177.2. Split posterior tibial tendon transfer.**

- Make the second incision medial and longitudinal, 1 cm posterior to the medial border of the tibia. Using a curved tendon passer, pass the tagged suture with the plantar half of the posterior tibial tendon through the sheath directly posterior to the tibia. Tease this backward to propagate the split. Deliver the tendon into the medcial proximal incision.
- Place a third incision just posterior to the distal fibula. Then pass the tagged tendon laterally just posterior to the tibia and fibula to the peroneal tendon sheath. Pass the split tendon within the sheath to the area of the fifth metatarsal–cuboid articulation, where the fourth short incision is made. Then suture the split tendon to the peroneus brevis under moderate tension with the foot in neutral. Apply a short-leg cast.

**Calcaneal Osteotomy (Lateral Displacement, or Dwyer)**

- Expose the lateral calcaneus subperiosteally through an oblique lateral incision immediately behind the peroneal tendons. Use an oscillating saw to cut through the calcaneus more or less parallel to the posterior calcaneal facet. Temporarily open the osteotomy laterally to use a curved Freer or small elevator to medially strip subperiosteally. Unless this step is done, it will be impossible to displace the tuberosity fragment. I caution against hammering an osteotome to complete the osteotomy medially because of the danger to the neurovascular bundle and flexor tendons, which are directly apposed medially **(Fig. 177.3)**.

**Figure 177.3. Calcaneal osteotomy for fixed hindfoot varus.**

- When the tuberosity has been sufficiently mobilized, displace it laterally enough (0.5–1.2 cm) to put the heel in neutral or slight valgus. Make sure that the tuberosity fragment does not slide proximally. Insert a single smooth pin from the plantar surface of the calcaneus across the osteotomy to hold the reduction. Leave it in place for 3 or 4 weeks.
- The Dwyer technique is perhaps simpler because no medial dissection is necessary; however, it mildly decreases the heel height and theoretically also decreases plantar flexor strength. Make the first bony cut as described previously, but then remove an oblique laterally based wedge **(Fig. 177.3)** sufficient to correct the hindfoot varus, bringing the heel directly in line with the long axis of the tibia. Close the bony surfaces and stabilize with either a smooth Steinmann pin (which is removed in 3 weeks) or a staple. I prefer pins. Allow weight bearing after 3 weeks.

**Triple Arthrodesis**

The technique for triple arthrodesis is fairly standard (see Chapter 115).
Make an oblique incision over the sinus tarsi and expose the sinus by maintaining a distally based flap of the extensor brevis muscle and overlying fat pad. Instead of continuing distally in the subperiosteal plane toward the calcaneal–cuboid joint, i use a 2 cm osteotome to cut across the joint dorsally in the longitudinal plane. This creates a small myo-osseous flap, but more important, it nicely exposes the calcaneal–cuboid articulation.

Depending on the degree of varus, take laterally based wedges from the subtalar and calcaneocuboid joints. I use a micro-oscillating or sagittal saw. In general, the wedges should probably be taken smaller than you initially think is necessary, so that an excessive amount of bone is not removed.

I usually use two pins, both placed axially: one to hold the calcaneocuboid joint and the other the talonavicular joint. A third pin, vertically placed across the talocalcaneal articulation, is optional. Apply a heavily padded, above-knee cast.

Allow no weight bearing until the pins are removed at 6 weeks. Then apply a short-leg walking cast and maintain it until the fusion is solid, which usually takes an additional 6–8 weeks.

VALGUS DEFORMITY

Valgus feet are common in CP and are especially frequent in spastic diplegia and quadriplegia. Although, at first glance, predominant spasticity of the peroneal muscles would seem to be the primary cause, the etiology usually is multifactorial and includes excessive external tibial torsion, knee flexion deformity, and calcaneal equinus. The deformity usually remains flexible until adolescence. Secondary callosities develop over the talar head and the first metatarsal head, and hallux valgus develops. Initially, manage the deformity with an AFO; however, if the deformity becomes severe, brace fitting is increasingly difficult.

Indications for Surgery

Subtalar stabilization is indicated before the valgus deformity becomes fixed, usually by 6–10 years of age. Traditionally, some modification of the Grice extra-articular arthrodesis procedure was most commonly performed, using internal fixation (3,7). Depending on calcaneal position, a TAL is often necessary as well. The deformity must be passively correctable (at least with the foot in equinus) for the Grice procedure to work. More recently, one of several types of calcaneal osteotomies has become preferred because it maintains subtalar mobility while correcting the valgus (18, 23-27). Although correction can be obtained by a simple opening lateral wedge osteotomy in the tuberosity using a cortical graft (bank or autogenous), I prefer either a medial calcaneal slide, or, occasionally, a lateral column lengthening. This latter technique of Evans, popularized by Mosca (18), has the advantage that it can partially correct the lateral subluxation at the midfoot. All of these also require reasonably supple feet that are passively correctable to neutral, or that can be made so with a simple heel cord lengthening.

The Grice procedure should not be performed in children less than 4 years of age because the bones are too small and cartilaginous. After age 12, a triple arthrodesis procedure was most commonly performed, using internal fixation (18, 23-27). Although correction can be obtained by a simple opening lateral wedge osteotomy in the tuberosity using a cortical graft (bank or autogenous), I prefer either a medial calcaneal slide, or, occasionally, a lateral column lengthening. This latter technique of Evans, popularized by Mosca (18), has the advantage that it can partially correct the lateral subluxation at the midfoot. All of these also require reasonably supple feet that are passively correctable to neutral, or that can be made so with a simple heel cord lengthening.

Calcaneal Osteotomy (Medial Displacement or Lengthening)

Use the same lateral oblique incision (posterior and parallel to the peroneal tendons) as for a Dwyer osteotomy. Use an oscillating saw to cut the tuberosity parallel to and below the posterior facet. If only the hindfoot is in valgus, then there is a choice of either using a laterally based opening wedge (held with an allograft cortical wedge), or sliding the distal fragment medially (Fig. 177.4).

To successfully displace medially, it is necessary to carefully subperiosteally dissect medially from the lateral approach to mobilize the distal fragment. After medial displacement sufficient to place the heel in neutral alignment, accomplish fixation with a smooth Steinmann pin placed vertically from the plantar surface.

I do not have long-term experience with distal calcaneal lengthening, but I have used it in cases of mild to moderate, very flexible valgus, and early results have been excellent. In this technique, make a transverse vertical osteotomy in the calcaneal neck, parallel to the calcaneal–cuboid joint. After mobilizing the distal fragment, use a laminar spreader to open the osteotomy, and simultaneously reduce the lateral talonavicular subluxation. Insert a trapezoidal cortical cancellous graft (I prefer allograft). It may be wise to provisionally fix the calcaneocuboid joint with a smooth Kirschner wire before lengthening; this prevents subluxation. A longitudinally placed K-wire, from distally across the calcaneal–cuboid joint, is optional if needed to maintain stability, and once it is passed through the calcaneocuboid joint, the original wire is removed. If a TAL has not been performed prior to the osteotomy, recheck after completion of the osteotomy to make sure that there is not a fixed ankle equinus deformity.

Grice Procedure

Through an oblique incision extending from the lateral talonavicular joint to the peroneal tendons, sharply elevate the contents of the sinus tarsi from proximal to distal. Clean the lateral body and neck of the talus and the calcaneal floor of the sinus tarsi of all soft tissue. Ideally, expose no articular surfaces.

Pack the sinus tarsi with corticocancellous graft taken from the iliac crest. Iliac graft rather than tibial or fibular is preferred because it is incorporated readily, it is abundantly available, there is enough graft from one crest to fuse both feet simultaneously, and the iliac crest graft does not carry the risks of donor site fatigue fracture after surgery (as do tibial grafts) or later valgus deformity (as with fibular grafts). Unlike “structural” grafts of tibial or fibular cortex, iliac graft is not used to correct deformity, only to obtain fusion. Because the iliac graft itself does not provide fixation, supplemental internal fixation is mandatory.

Some surgeons insert a screw through the neck of the talus into the calcaneus, and this has the advantage of earlier weight bearing. However, I prefer to use a percutaneous Steinmann pin, inserted under direct vision from the lateral plantar aspect of the calcaneus proximally across the sinus tarsi into the talus, because there is no retained hardware that can either back out or impinge against the anterior ankle structures (Fig. 177.4).

Apply a long-leg cast for 4 weeks postoperatively, and then remove the pin. Weight bearing may be allowed in a short-leg cast for the next 4–6 weeks.

Figure 177.4. Calcaneal osteotomy for fixed hindfoot valgus.

Figure 177.5. A: Subtalar arthrodesis with screw fixation. B: Temporary fixation using a Steinmann pin for subtalar arthrodesis.
Distal Hamstring Lengthening

Failure to deal with fixed equinus of the hindfoot will make reduction of the calcaneus under the talus difficult or impossible. The heel will remain in valgus despite positioning the graft. Another potential complication is that the graft may “melt away.” This is especially likely when excessive external tibial torsion is present. Occasionally, sufficient fibrous stability may remain even with graft resorption so that further treatment is not necessary. If significant valgus recurs, triple arthrodesis may be considered as a salvage procedure.

Overcorrection into varus may appear to develop gradually, but it is usually the direct result of intraoperative overcorrection. If the extra-articular arthrodesis is solid, correction of a postoperative varus can be obtained with a closing lateral wedge osteotomy of the heel.

Triple Arthrodesis

The basic technique for triple arthrodesis is described in Chapter 115; however, for spastic valgus feet, additional principles are important. It is critical to ascertain before surgery that the ankle itself is in relatively normal alignment. If there is excessive external tibial torsion, correct this before performing the triple arthrodesis. Although flexible valgus feet can be corrected by the simple removal of joint surfaces, possibly with an ilary graft, most spastic valgus feet in older patients are rigid and require extensive bony wedge resection to obtain correction. Additionally, poor correction can be caused by inadequate exposure of the talonavicular joint.

- Use an additional 1-inch (2.5 cm) medial longitudinal incision over the talonavicular joint if the medial aspect is not well visualized from the main incision. This will allow excellent visualization when a Chandler retractor is passed from the main lateral incision out through the medial incision to protect the dorsal soft-tissue structures.
- If the foot is passively correctable to neutral before surgery, only the cartilaginous joint surfaces must be removed. However, in more severe valgus feet, remove medially based wedges of bone. Pack the sinus tarsi with cancellous bone from either the wedges or the iliac crest.
- I recommend using at least two smooth Steinmann pins for fixation. Pass one distally through the center of the exposed navicular and pass a second distally through the center of the cuboid. Then drive them retrograde into the talus and calcaneus, respectively. A third vertical pin through the talocalcaneal joint is optional. Take intraoperative radiographs; it is surprising how misplaced the pins can be. I usually place a small suction drain.
- Use an above-knee (or patellar tendon bearing) non-weight-bearing cast for 6 weeks postoperatively, and then remove the pins and apply a short-leg walking cast.

EXCESSIVE TIBIAL TORSION

Indications for Surgery

Excessive external tibial torsion is commonly seen in diplegia and quadriplegia, apparently as a compensation for excessive medial femoral torsion. This malalignment will contribute to valgus foot deformities, bunions, and other problems. Tibial osteotomy is indicated when it is necessary to keep the foot pointed correctly forward, especially following femoral derotation (external) osteotomy, or as part of correction for severe valgus feet.

Tibial Osteotomy

- Make a 5–10 cm longitudinal incision proximally over the lateral anterior compartment. Always perform a fasciotomy of both the anterior and the peroneal compartments.
- By following the intermuscular septum, make a limited subperiosteal exposure of the fibula somewhat more distal than the tibial site to avoid the peroneal nerve.
- Osteotomize the fibula with a micro power saw.
- Expose the tibia circumferentially subperiosteally just distal to the tibial tubercle. To avoid anterior growth arrest, the osteotomy site must be distal to the anterior extension of the physis. The operation can also be performed in the supramalleolar metaphysis, where the risk of compartment syndrome and peroneal palsy is less. I recommend operating distally if correction of an valgus ankle is also desired.
- Insert half-pins from medial to lateral through separate incisions prior to the osteotomy. Place one pin proximal to the incision and one distal, with both pins going through two cortices but only through the medial skin. Perform the osteotomy with an oscillating power saw, and control rotation with the pins. It is helpful to insert the pins so that the angle between them is the same as the angle of rotation you want. Then, when rotation is complete, the pins will be exactly parallel to each other.
- Immobilize the limb in a long-leg cast, incorporating the pins in plaster. If no additional tendon work has been done, an external fixator could be used, but this does not seem worth the expense. Clinical union occurs within 2 months in children. Weight bearing is usually allowed after 4 weeks, at which time the pins are pulled out through the cast.

See Chapter 168 for the alternative technique of supramalleolar tibial rotational osteotomy.

KNEE DEFORMITIES

FLEXION DEFORMITY

Indications for Surgery

Although the most common knee deformity in spastic CP is flexion contracture, the knees may be neutral or even hyperextended during the midstance phase of gait (3,8,21,23). The knees (like every other joint in CP) cannot be evaluated in isolation. The cause of severe knee flexion—whether dynamic or fixed—is rarely as simple as excessive hamstring spasticity. Overlengthened or weak plantar flexors, fixed hip flexion contracture, and poor equilibrium all contribute to crouch. We can do little about faulty equilibrium, and we certainly recognize that a small knee flexion deformity is usually preferable to recurvatum. Therefore, not all knee flexion deformities (even fixed ones) require surgical release.

I divide spastic knee flexion deformity into two types. In the more common and familiar “crouched” type, the knee flexion is associated with feet that are flat on the floor or the heels are only slightly elevated (often in valgus). There is usually a fixed hip flexion deformity with increased iliopsoas spasticity, which must be released. The worst thing to do in these cases is a TAL, because it will increase the crouch.

In the “jumped” type of knee flexion deformity, the ankles are in marked fixed equinus. This type of patient needs a modest TAL, in addition to lengthening of the hamstrings and probably the iliopsoas.

In ambulators or potential ambulators, perform distal hamstring lengthening when the knees cannot be straightened during ambulation to less that 15° of flexion, and when other causes of crouch gait (at the hips or ankles) are absent or can be dealt with simultaneously. Knee flexor release is also indicated in older patients who are crouched and have knee pain during transfers or limited ambulation. If the degree of fixed contracture of the knee is greater than 20°, posterior knee capsulotomy is occasionally needed, but usually this is not needed in a walking CP patient with crouch.

In nonambulators, distal hamstring release is occasionally performed to decrease extreme flexor spasticity at the knee; this facilitates sitting and dressing. The hamstrings may also be released proximally through the same medial incision used for adductor and psoas release. However, the only time I use a proximal release of the hamstrings is in the patient who has not only tight hamstrings but also severe hip extension deformity. Such a patient stands with an absent or reversed lumbar lordosis. She tends to slide out of a wheelchair because the hamstring spasticity extends the hips. When proximal release is performed, the sciatic nerve must be avoided; it can be confused with the tendinous origin—a potential catastrophe.

Distal Hamstring Lengthening

- Place the patient supine and make a short, midaxial, longitudinal incision on the back of the knee. This allows repeated intraoperative assessments of the degree of improvement of straight-leg raising. In a typical patient with either no fixed-knee flexion contracture or only a mild one (10° to 20°), the contracture can be stretched out by wedging casts after hamstring release.
- Perform a Z-lengthening or simple tenotomy of the semitendinosus. The gracilis may also be tenotomized at your discretion. Perform an aponeurotic lengthening of the semimembranosus and biceps tendon by oblique division of the tendon within the muscle belly. The lengthening should be sufficient to allow 70° of straight-leg raising. This is easily determined in the supine position.
- I always lengthen the biceps last because it is often not as tight as the medial hamstrings. In such cases, if adequate straight-leg raising is present after
lengthening only medially, leave the biceps intact.

After surgery, apply a cylinder or long-leg cast. Mobilize the patient immediately with a walker or crutches if equilibrium is satisfactory. Mobilize more severely equilibrium-impaired patients in a standing frame chosen by the physical therapist.

Recently, if no additional surgery has been performed simultaneously at the ankles, I have used only a knee immobilizer postoperatively, again allowing immediate mobilization. If a joint capsule contracture was present preoperatively, do not apply the cast fully straight, but only at the limits of the maximal preoperative degree of extension. Begin wedging in 2 days.

In the rare, walking CP patient who actually needs a posterior capsulotomy, a better exposure is obtained by operating with the patient prone. In such cases, I prefer short posterior medial and posterior lateral incisions to better visualize the capsule. After a simple hamstring release, 3 weeks of immobilization is usually sufficient, although a little extra time may be needed if the casts have to be progressively wedged into extension following a capsulotomy.

**Proximal Hamstring Lengthening**

If you elect to release the hamstrings proximally (21), perform the operation through an oblique adductor approach or through a short medial transverse incision just below the buttocks.

- Make certain that this operation is performed without the use of anesthetic paralyzing agents, so that stimulation of the sciatic nerve with the cautery can warn you if the sciatic nerve is in close proximity to the hamstring origins.
- After choosing which skin incision to use, make a longitudinal incision in the fascia. Use blunt finger dissection in the plane posterior to the adductor magnus or brevis.
  - Do not divide the proximal hamstrings until you are certain that the nerve is safe from harm; use the cautery. Gently retest the length of knee extension with the hip flexed; after satisfactory release, knee extension should markedly increase. Never forcefully extend the knee maximally while the hip is flexed.
- Base postoperative immobilization on whatever other releases are carried out. If only hamstrings are released, then knee immobilizers for 2–3 weeks is sufficient, and mobilization can begin immediately.

**Complications**

Failure to fully assess the cause of the knee flexion deformity before surgery may lead to a poor result. The crouch gait will persist if a hip flexion deformity is ignored or if hyperdorsiflexed ankles are not braced. If preoperative quadriceps spasticity is severe, recurvatum may occur following overly generous hamstring weakening. Myotendinous (aponeurotic) lengthening, when performed too far distal (close to the junction of the tendon with the most distal muscle fibers), may result in complete transverse separation. The key here is simply to get enough proximal exposure so that there are plenty of muscle fibers distally to allow the slide after the intramuscular release of the tendon.

The popliteal artery and sciatic nerve are limiting structures about the knee. When applying the cast, do not try to forcibly straighten the knee if the patient is under anesthesia. A sciatic stretch palsy is difficult to detect acutely in a CP patient with severe involvement but is still a very undesirable complication. If the preexisting fixed contracture is significant (i.e., more than 20°), plan to correct it gradually after surgery using wedged casts with the patient awake.

**EXTENSION DEFORMITY**

**Indications for Surgery**

Knee hyperextension is not a fixed deformity in CP. It usually occurs dynamically at midstance and is secondary to fixed ankle equinus or excessive quadriceps spasticity, especially of the rectus femoris. The heel cord contracture, if present, must be corrected, but weakening of the quadriceps remains a problem. There is a natural reluctance to weaken the quadriceps, because it is necessary to maintain upright posture. However, many CP patients, even with mild degrees of crouch, will have excessive capacisticity of the rectus femoris. The simultaneous, excessive rectus femoris and hamstring spasm leads to a stiff-kneed, short-stide gait (8). However, I do not believe that every ambulatory patient who undergoes a hamstring lengthening needs a simultaneous rectus femoris procedure.

If knee hyperextension is associated with a hip flexion deformity, it is simple to release and sew a small section of the origin of the rectus femoris tendon at the time of the iliopsoas recession or lengthening. This produces minimal quadriceps weakening, but it is safe. Unfortunately, a tenotomized rectus may spontaneously reattach to the anterior inferior iliac spine.

Do not release the rectus origin routinely at the time of hip flexor release in CP. Release it only if there is a hyperextended knee gait, or occasionally in nonwalkers if the fixed flexion contracture is very severe.

For the patient with a rigid stiff-knee gait without much of a hip flexion deformity, the usual indication for rectus surgery is inadequate knee flexion late in the swing phase. Such extensor spasticity interferes with foot clearance. In such cases, it is reasonable to selectively transfer the rectus femoris either medially to the semitendinosus or laterally to the iliotibial band. If a laboratory analysis of the gait is available, the rectus will usually be found to fire excessively or throughout swing phase on dynamic gait EMG. The rectus femoris transfer can be performed simultaneously with hamstring lengthening without fear of increasing crouch, or it can be performed some time later if the knee tends toward recurvatum.

**Distal Rectus Femoris Transfer**

- Make an anterior incision transversely or longitudinally about 6 cm proximal to the patella (8). Undermining proximally allows identification and separation of the interval between the vasti and the rectus. Proximally, this can easily be done bluntly, but distally the rectus tendon blends with the common quadriceps tendon.
  - Further separation must be done sharply, while avoiding entry into the knee joint, to a level near the superior pole of the patella.
  - If a slight correction of gait into external rotation is desired (i.e., in cases in which there is excessive inturning at the knee), isolate the rectus tendon and bluntly separate proximally. Then transfer the distal stump through a subcutaneous tunnel to the semitendinosus medially. If the hamstrings have been lengthened sometime previously, and the distal stump of the semitendinosus is not available, the transfer can be into the sartorius. If there is preexisting excessive external rotation at the knee, then transfer the distal stump of the rectus through a subcutaneous tunnel to the iliotibial band or the biceps femoris. There should be no tendency toward increased crouch as long as the vastus medialis, lateralis, and intermedius remain intact, because they provide the bulk of quadriceps strength.
  - Postoperatively, use removable extension knee immobilizers part time for 3–4 weeks.

**HIP DEFORMITIES**

Hip deformities in CP span a spectrum from mild hip dynamic flexion deformity to complete painful dislocation. The three most common components are adduction, flexion, and internal rotation. Although these components will be considered separately, usually all three coexist to some degree.

**ADDUCTION DEFORMITY**

Some degree of excessive adductor spasticity is seen in most patients with CP. Primary abduction deformity is rare and usually the result of overzealous adductor release and necrectomy of both the anterior and the posterior branches of the obturator nerve.

**Indications for Surgery**

Adductor release is indicated in ambulators when scissoring occurs or when passive abduction (in extension) is less than 20°. It is also indicated in limited walkers or sitters as part of the surgery for early hip subluxation. Occasionally, in the patient with severe total body involvement, the adductor release is necessary to facilitate perineal care. Adductor release is nearly always a part of the treatment for more severe degrees of hip subluxation, which require sufficient release to obtain a satisfactory range of abduction (1). Patients must be assessed individually because the extent of release required and the need for adductor transfer or necrectomy varies. In general, there is a trend away from anterior branch necrectomy except in the severely involved, nonwalking patient.

As an alternative procedure, the longus and gracilis may be recessed (sutured more distally to the underlying adductor magnus or brevis) or transferred posteriorly to...
dislocated hips in otherwise normal children. The brevis may also be transferred; however, its entire origin is a fleshy muscle belly that does not hold sutures well. In all but two of the adductor transfers I have performed, the transferred origins pulled off the bony ischium. Postoperative radiographs proved this, as I placed radiopaque markers in the origin of the longus. Others have also noted the tendency for posteriorly transferred adductors to migrate postoperatively back to their origins (17). The extra dissection necessary for adductor transfer hardly seems worthwhile in most patients, and I have abandoned it. I simply perform a release without anterior neurotomy in the majority of cases. The extent of the release depends on the degree of deformity.

Bilateral adductor release should be performed in most diplegic and quadriplegic patients when both hips are adducted or have limited passive abduction. This is the most common situation. Even when one is less adducted than the other, both hips should usually be released in these patients, because when only a unilateral soft-tissue release is performed, there is a tendency for the nonoperated hip to subsequently become unstable (4).

However, an occasional severe quadriplegic CP patient will have true windblown hips. This is especially common with severe neurogenic scoliosis and pelvic obliquity (the pelvis is “down” on the abducted side). The abducted hip will be well covered and should not have an adductor release if the abduction is fixed. Of course, the hemiplegic patient with adductor limitation will also need only a unilateral release. The posterior branch of the obturator nerve should very rarely be divided. Only following failure of a prior extensive adductor release and anterior branch obturator neurotomy with recurrence or persistence of adduction deformity would one consider a posterior branch or intrapelvic obturator neurotomy.

Adductor Release

Under most circumstances, other surgery will be performed simultaneously on the hip (e.g., iliopsoas recession, open reduction). Therefore, my preferred technique is to simply extend the anterior bikini incision slightly medially. (The bikini incision is oblique, just distal and parallel to the inguinal ligament.) The skin incision also may be made longitudinally or obliquely over the adductor longus origin. Through the Ludloff-type approach (Chapter 3), the psoas tendon can be tenotomized, but it cannot easily be resected or divided above the pelvic brim.

- Whichever skin incision is chosen, define the adductor tendons, including the longus and gracilis, by blunt dissection after longitudinally opening the fascia. Completely release the longus and gracilis at their origins as proximally as possible. Next, assess the range of passive abduction. If this is not at least 40°, further release is necessary, including the brevis and pectineus. If it still is tight, the medial hip capsule may need to be divided transversely.
- Because the anterior branches of the obturator nerve lie on the anterior surface of the adductor brevis, always identify the nerve before releasing much of the brevis. Only in the nonwalking patient with severe involvement is a segment of the nerve (usually two or three branches) removed. I often use a small suction drain for the rather considerable dead space.
- Maintain postoperative abduction for 2–3 weeks, using two long-leg casts with a bar between them. Recently, I have used just two knee immobilizers with an abduction pillow, allowing immediate weight bearing and mobilization if there was no simultaneous bony surgery requiring a cast.

Complications

The most common problem with adductor release is expecting too much and doing too little. If there is a pelvic obliquity from scoliosis and the “higher” femoral head is luxating, adductor release alone will not maintain hip reduction unless the structural scoliosis and obliquity are controlled. If there is any evidence of early hip subluxation (even with a level pelvis), the iliopsoas must be lengthened.

FLEXTION DEFORMITY

A mild degree of fixed hip flexion deformity is normal in neonates. In the spastic CP patient, this flexion deformity may persist or gradually worsen, especially if the patient is a nonwalker. Spasticity of the iliopsoas is the main cause of the deformity, although every muscle that passes anterior to the transverse axis of the hip contributes to hip flexion. Clinical measurement of hip flexion deformity is best performed by the prone-lying Staheli test (29). The better-known Thomas test is affected more by spasticity of the contralateral side, which tends to roll the pelvis as the opposite limb is flexed. This makes it difficult to ascertain the neutral position of the pelvis.

Radiographic assessment of hip flexion deformity is made by measuring the lateral sacrofemoral angle on films taken with the patient prone or supine and the hips lengthened or recessed. In nonwalkers, a simple complete distal tenotomy (usually performed with an adductor release) can be made through either a Ludloff incision or an anterior bikini incision. In patients with bilateral flexion deformities but fixed, windblown hips, adductor release is performed only on the adducted (high) side. The iliopsoas is released bilaterally. In the rare case when there is truly limited adduction on the abducted side of the pelvis (the down hemipelvis), the origins of the tensor and the gluteus medius and minimus are also released on the abducted side.

In most cases of ambulatory CP patients, I prefer a simple oblique tenotomy of the psoas tendon as far proximally as possible, where there are still abundant investing iliacus muscle fibers. This has the net effect of markedly weakening the psoas while only moderately weakening the iliacus portion. No sutures are required, making it a very short, simple, and relatively bloodless procedure. The iliopsoas is released bilaterally. In the rare case when there is truly limited adduction on the abducted side of the pelvis (the down hemipelvis), the origins of the tensor and the gluteus medius and minimus are also released on the abducted side.

Indications for Surgery

Iliopsoas weakening is indicated in walkers with radiographically normal hips if fixed hip flexion is greater than 15°. Release or lengthening of the psoas is also a part of correction of any degree of hip subluxation in CP. Usually, whenever a derotation osteotomy is performed for excessive anteverision, the iliopsoas should be lengthened or released. In nonwalkers, a simple complete distal tenotomy (usually performed with an adductor release) can be made through either a Ludloff incision or an anterior bikini incision. In patients with bilateral flexion deformities but fixed, windblown hips, adductor release is performed only on the adducted (high) side. The iliopsoas is released bilaterally. In the rare case when there is truly limited adduction on the abducted side of the pelvis (the down hemipelvis), the origins of the tensor and the gluteus medius and minimus are also released on the abducted side.

In most cases of ambulatory CP patients, I prefer a simple oblique tenotomy of the psoas tendon as far proximally as possible, where there are still abundant investing iliacus muscle fibers. This has the net effect of markedly weakening the psoas while only moderately weakening the iliacus portion. No sutures are required, making it simpler than the formal recession, as no suture repair is necessary. This is similar to what most surgeons usually do in performing open reduction of congenitally dislocated hips in otherwise normal children.

Iliopsoas Recession or Lengthening

- I perform an iliopsoas recession or lengthening through the usual bikini anterior incision by identifying the interval between the sartorius and the iliacus, assuming no acatabular procedure or open reduction is necessary (Fig. 177.6). Visualize and protect the lateral femoral cutaneous nerve deep to the enveloping fascia exiting the pelvis on the anterior surface of the sartorius just medial to the anterosuperior iliac spine. Do not detach the sartorius. On the other hand, if the psoas lengthening is a part of an open reduction or acatabular procedure, use the more extensile standard Smith-Peterson anterior interval between the sartorius and the tensor fascia muscle.

![Figure 177.6. Iliopsoas lengthening at the pelvic brim.](image)

- Locate the femoral nerve on the anterior surface of the iliacus but deep to the iliacus fascia, and retract it gently medially with a blunt retractor. The psoas tendon is deep in the iliacus muscle fibers and tighly applied to the anterior medial hip capsule. Isolate the tendon proximally, separating it from the muscle fibers of the iliacus, and divide it at the pelvic brim (32).
- In performing a formal recession, flex and externally rotate the hip so that the tendon can be followed distally to the lesser trochanter where the entire tendon is detached. Free the conjointed muscle–tendon unit from the anterior hip capsule and realatch it with two heavy sutures more proximally on the anterior capsule (2). The net effect is to decrease the mechanical advantage of the iliopsoas muscle by placing the insertion closer to the axis of hip flexion.
Postoperative Care
Postoperatively, avoid prolonged hip flexion for 3 weeks. This is most easily accomplished by applying two long-leg casts. If bilateral adductor release has also been done, place a broomstick bar between the casts to maintain abduction. The patient is cared for in the prone, the supine, or even a standing position as long as hip flexion is avoided, except briefly for meals, transport, and so forth. If the patient underwent an open reduction, some type of spica cast will be necessary for at least 6 weeks. If the hips were windblown before surgery, two long-leg casts with a spreader bar can be used, but instruct the parents to maintain the hips windblown to the opposite direction. If the pelvis is level and only soft-tissue procedures have been done, I now prefer to mobilize the patient immediately postoperatively, so I use just knee immobilizers and an abduction pillow at night.

Complications
There should not be any confusion between the femoral nerve and the psoas tendon. Distal tenotomy of the entire psoas tendon severely weakens hip flexion and should not be done in a child who can or potentially might be an independent, crutch-free walker. One should expect that in most patients younger than 7 years without severe scoliosis or pelvic obliquity, a psoas and adductor release performed in the presence of no more than mild hip dysplasia will prevent subsequent dislocation. There is not universal agreement as to whether postoperative nighttime abduction bracing is necessary. However, I recommend at least 3-6 months of abduction bracing using a foam wedge or abduction brace if there is any radiographic evidence of dysplasia (14).

When there is severe preexisting pelvic obliquity, severe acetabular dysplasia, or another type of secondary bony change (typically in patients older than 8–10 years), correction of the scoliosis or acetabular reconstruction must be performed to maintain hip reduction; muscle release alone will be insufficient in such cases. Most commonly, for patients 6 years or older, with mild to moderate degrees of acetabular dysplasia, I will add a Dega-type pelvic osteotomy (19) or Staheli acetabular augmentation (shelf)-type procedure (32).

INTERNAL ROTATION DEFORMITY
Indications for Surgery
Excessive medial femoral torsion (increased femoral anteverision) is very common in spastic CP. It manifests as internal rotation deformity, mainly in walkers. In spastic patients who are only sitters, the excess anteverision contributes to hip dysplasia and dislocation, but the internal rotation is not so apparent with the patient in the sitting position. The cause of the increased anteverision is probably muscle imbalance of more than just the psoas; the iliopsoas is nearly always contracted in patients with excessive hip antversion and internal rotation gait. In normal patients, the anterior fibers of the gluteus medius and minimus and the tensor are the main hip internal rotators. This is described by Steindler (23) to perform anterior transfer of the trochanteric insertion of the gluteus medius and minimus for internal rotation gait, converting abductors to external retractors. In general, I do not favor this operation because it carries the risk of weakening the abductor mechanism, thus possibly trading an internal rotation deformity for a Trendelenburg limp. Furthermore, the operation is indicated only in patients with no flexion contracture (i.e., a normal iliopsoas) and spastic abductors—a situation seldom encountered.

My preferences for correction of internal rotation gait are based on patient age and ambulator status. In patients 4–8 years of age, I usually perform adductor release and iliopsoas intramuscular lengthening or recession, and I follow the patient for a number of years. In most patients, the excessive internal rotation will gradually improve as the hip flexion contracture and adduction tendency improve and the anteverision decreases. After 8-10 years of age, if the patient is still ambulating with an excessive internal rotation gait, I usually prefer subtrochanteric derotation osteotomy using the AO-ASIF (Association for the Study of Internal Fixation) technique. In many cases, a little varusization is needed because the “coxa valga” seen on radiographs is more apparent than real, and it will disappear with derotation alone.

Subtrochanteric Derotation Osteotomy
- Perform the operation on the image intensifier table with the patient supine and the leg draped free. Place a small folded blanket or towel under the buttocks so that the prep and exposure will be sufficiently proximal and posterior.
- Make a standard lateral approach to the proximal femur and insert three guide pins: one for the chisel alignment, one more proximal in the greater trochanter to be used as a joy stick to control the proximal fragment, and one distal to the end of the plate to control rotation. Typically, the distalmost pin will be inserted at an angle of 30° to 45°, internally rotated in relation to the proximalmost pin (Fig. 177.7).

![Figure 177.7. Use of pins to control rotation.](image)

- Make sure that the femur is circumferentially exposed subperiosteally in the area of the planned osteotomy. Insert the appropriate child or adolescent blade chisel into the greater trochanter along the course of the first pin so that the osteotomy can be cut through the middle of the lesser trochanter. Always use the chisel guide; otherwise, there is a tendency to angle the blade so that the shaft of the plate is placed in flexion.
- Confirm the chisel position with the image intensifier; remove the chisel halfway through, and complete the osteotomy with an oscillating saw. Rotate the distal fragment externally using the preplaced pins as a guide. If increased varus is desired, remove a small wedge medially, which is one half of the shaft diameter after derotating. Insert the blade plate using the bone-holding forceps to maintain reduction. I use the dynamic compression feature of the plate to close the osteotomy further. At least 20° to 30° of residual internal rotation should be left after the derotation (i.e., the distal fragment should not be excessively externally rotated). Varus should be added to the osteotomy only when there is a true valgus deformity of the femoral neck, and when there is an abundant range of abduction. Each added degree of varus is equivalent to adding 1° of abduction and subtracting 1° of abduction.

If hamstring lengthening is contemplated, the femur may easily be derotated through the lateral hamstring exposure incision. Use a six-hole plate, as described in Chapter 168.

If preoperatively there was no subluxation, and neither acetabular reconstruction nor capsulorrhaphy has been performed, then no cast is needed. Manage the patient in a wheelchair for 4–6 weeks, allowing gentle motion. Then allow partial weight bearing with crutches or a walker until healing of the bone is secure, usually at about 3 months. Most commonly in CP, some other acetabular work will have been done, so a spica cast will be necessary. The spica cast should usually be placed in nearly full hip extension and moderate abduction. Iliopsoas recession or release is usually performed prior to or simultaneously with the subtrochanteric osteotomy.

One potential pitfall is failure to consider concomitant excessive external tibial torsion. In such a case, following femoral derotation, the foot will point excessively laterally unless a simultaneous internal derotation is performed on the tibia (2).

SUBLUXATION AND DISLOCATION OF THE HIP
Hip dislocation generally occurs in nonwalkers with total body involvement, whereas in those patients who walk with crutches, the deformity more often progresses only to subluxation. However, even patients who are independent ambulators may develop complete dislocations. The etiology of the dislocation is a combination of excessive femoral anteverision with persistent spastic adduction and flexion, often associated with pelvic obliquity secondary to structural scoliosis. Dislocation has been alleged to cause scoliosis, seating problems, decubiti, fractures, and difficulties with perineal care (6,12,14,19,20,26). Although hip dislocation is associated with all these problems, they are in fact caused not by the dislocation but by the muscle imbalance and the rigidity of the hip contracture. Furthermore, for CP adults, the status of hip location per se is not as important a determinant of walking ability as having reasonable cognitive function, balance, and a level pelvis with mobile hips.
Indications for Surgery

Not all severely subluxated or dislocated spastic hips will cause pain, although probably at least half will be symptomatic. The ability for a severely involved patient to sit comfortably probably has as much to do with the enthusiasm and motivation of the people caring for him as it does with whether his hip is radiographically reduced. Thus, it is not always necessary to treat older patients with spastic dislocated hips (20).

On the other hand, it is always desirable to maintain range of motion and prevent subluxation by appropriate early soft-tissue release and bracing in younger patients. The following guidelines and prerequisites are suggested for decision making for surgical correction of spastically dislocated hips:

1. Prevention of hip dislocation by early soft-tissue release is easier and more effective than late reconstructions (14).
2. The degree of reconstruction is determined by the degree of dysplasia. That is, to relocate a completely dislocated hip in an 8-year-old CP patient will usually require at least a femoral osteotomy, possibly a pelvic osteotomy, as well as soft-tissue release.
3. Soft-tissue release is always necessary whenever bony reconstruction is planned.
4. Femoral varus osteotomy, although still useful in maintaining reduction, cannot be counted on to induce acetabular development in patients older than 8 years. The femoral neck–shaft angle should not be placed in excessive varus (i.e., leave at least 110°).
5. Femoral shortening is a useful adjunct to relocating a high-riding dislocation without tension. This is far preferable to any type of traction, which is generally poorly tolerated by CP patients.
6. For patients older than 8 years with hip dysplasia and dislocation, acetabular reconstruction usually will be necessary (3,9,19,32). Although nearly all types of pelvic osteotomies have been performed in the past, including Salter and Pemberton procedures, the most useful include the Dega and Chiari osteotomies and the shelf procedure (acetabular augmentation). The shelf procedure can be added to any other pelvic osteotomy should additional femoral head coverage be necessary.
7. A severely deformed femoral head with absent cartilage should not be relocated. A painful located hip is probably no better than a painful dislocated hip. This is common in patients older than 10 years with a chronically subluxated hip.
8. Always try to keep spica cast immobilization to a minimum.
9. Finally, do not attempt relocation of a unilateral hip dislocation using hip surgery alone if a severe scoliosis with fixed pelvic obliquity is present. The pelvis should probably belevated first.

In those patients 8 years or older with a fully dislocated spastic hip, my typical correction would consist of, in one stage, a femoral shortening and Chiari osteotomy with a supplemental shelf. Very little varus would be added to the femur, and appropriate soft-tissue release (e.g., adductors, psoas) and anterior branch obturator neurectomy would also be performed (Fig. 177.8). In the more common 6- to 10-year-old spastic patient with moderate dysplasia but without frank dislocation, I do extensive soft-tissue release and a Dega osteotomy, or possibly an acetabular augmentation. I find the advantages to be no retained hardware, technical simplicity, the possibility of doing both hips simultaneously, and consistently satisfactory results (Fig. 177.9). In a patient under 6 years with a unilateral dislocation, a soft-tissue release with femoral derotation and shortening is performed, with the occasional addition of a pelvic osteotomy or shelf procedure (Fig. 177.10).

The Dega procedure is similar to a Pemberton osteotomy in that both are periacetabular incomplete innominate osteotomies that bend down the superior portion of the acetabular roof. The main difference is that the hinge for acetabular roof redirection is medial with the Dega (so that the added coverage is more superolateral), whereas with Pemberton’s osteotomy the hinge is more posteriomedial (so that the coverage is more anterolateral). I prefer the Dega procedure in cases of CP because it more adequately deals with the usual elongated acetabulum with superolateral deficiency (Fig. 177.11).
Dega Osteotomy

Usually, a medial adductor and psosas release is performed first, often with a femoral shortening and/or varus osteotomy if necessary for reduction (19). Use an image intensifier with the leg draped free.

- Perform the Dega osteotomy through the standard anterior bikini incision with the iliac apophysis split and the iliac wing exposed both medially and laterally. I usually do not separately detach the sartorius but leave it attached to the medial half of the apophysis and abdominal muscles. Release the origin of the direct head of the rectus tendon and peel off the reflected head from the superior capsule. Place blunt retractors superior and inferior to the capsule for a wide exposure.
- If there is dysplasia but no significant subluxation, the capsule does not have to be opened. However, subluxated or dislocated hips require a standard acetabular debridement and capsulorrhaphy.
- The Dega osteotomy itself is performed from directly lateral, on a line from the middle of the anterior inferior iliac spine to the sciatic notch. Use a series of curved osteotomes, starting with a saw or high-speed cutting tool. Aim the osteotomes medially and inferiorly, extending to but not through the medial cortex near the tiradrate cartilage, as monitored on the image intensifier. Both anterior and posterior corners of the osteotomy need to be completed to the medial wall. Anteriorly, this is easy to do, as it is under direct visualization. Posteriorly, place a blunt Hoffman retractor in the notch, and use a 45° Kerrison rongeur to complete the posterior corner of the osteotomy from lateral.
- Next, insert a wide, curved osteotome into the osteotomy and lever the superior portion of the acetabulum in a caudal direction until the relatively vertical lateral acetabulum has been brought to a more horizontal position. There will now be a lateral gap at the osteotomy site of 1–1.5 cm. To hold the osteotomy open, use two or three bicortical triangular grafts from the anterior crest (or occasionally from the femoral varus triangle osteotomy, if done). No internal fixation is necessary. When performed correctly, the osteotomy will be remarkably stable because of the intact medial column.
- After routine closure, apply a hip spica cast and leave it in place for 6 weeks.

**Figure 177.11. Dega osteotomy.**

### Shelf Procedure

The technique for a shelf procedure is as follows (32):

- Make a standard anterior approach to the hip using a slightly extended bikini incision. Expose subperiosteally the entire outer wing of the ilium. Isolate the direct head of the rectus tendon but leave it intact; detach and tag the reflected head where it veers off the direct head just below the anterior inferior spine.
- Perform a proximal psosas lengthening or tenotomy simultaneously with any other necessary adductor release. Expose the hip capsule extensively, as for an open reduction. Leave the reflected head of the rectus femoris tendon as far posteriorly as possible, at least to a position of approximately 1 or 2 o'clock. This can be done easily more anteriorly, but it will require sharp dissection from where the origin of the reflected head blends with the capsule posteriorly.
- Thin the superior capsule near the bone of the lateral wall of the ilium using a scalpel and curet. Make a series of drill holes or use a high-speed burr to create a gently curved slot over the superior dome of the acetabulum. Either plain film radiographic control or image intensification is mandatory to confirm that the slot is created far enough inferiorly. Ideally, the slot should be just proximal to the acetabular cartilage; there is always a tendency to create the slot several millimeters too far superiorly. (Hint: Continue thinning the superior capsule against the lateral iliac cortex until a fine line of cartilage is just visible.) The hip joint itself is usually not entered despite the ease with which the femoral head may be palpated thorough the capsule.
- After creating the slot, harvest abundant corticocancellous strips with a gouge from the outer wall of the ilium. It is perfectly acceptable to take a full-thickness graft from the crest in the area just behind and including the anterior superior spine. This will facilitate closure, although it will diminish the normal pelvic contours. It is important, however, that the bone graft be no thicker than unicortical when placed, so that it will mold to the convexity of the femoral head.
- Pack the grafts into the slot, first in a radial direction and then perpendicularly. Bring the previously tagged reflected head of the rectus back over the entire mass of bone graft, helping to seat it, and anchor it on the superior capsule. Tie the reflected head of the rectus back to the original straight head of the rectus. The purpose of retying the reflected head is simply to hold the graft in place.
- Closure is routine. A single spica cast may be used if the patient is hemiplegic or if the opposite hip has a fixed abduction contracture. However, it is usually preferable in patients with CP to use a one-and-a-half spica or a double spica cast if both hips are done simultaneously.

### Pitfalls

The graft for a shelf must be placed at least part way posterior as well as superior. It is easier to pack grafts superiorly and anteriorly, but it is probably more important in a sitting patient to cover the posterosuperior femoral head. It is possible to pack too much graft over the femoral head. In this situation, abduction will be limited, although one would expect remodeling to eventually occur. An acetabular augmentation is usually not needed in a very young patient, 4 years or younger. If it is placed, one cannot expect the augmented portion of the acetabulum to enlarge because there is no growth cartilage in the shelf itself. Therefore, the femoral head as it grows may gradually “outgrow” its socket.

### Salvage Procedures

If the femoral head is severely deformed and the patient is skeletally mature with a high-riding dislocation, the alternatives are arthrodesis, resection arthroplasty, or total hip arthroplasty. None of these procedures are highly desirable for the majority of patients (12). All are salvage procedures, and all have considerable complications. Femoral head and neck resection usually improves pelvic pain in the adult patient with a severe high-riding dislocation and severe contracture. However, subsequent heterotopic ossification is common, and some of the patients still have pain despite femoral head and neck resection. In such cases, it is desirable to interpose some type of soft tissue, such as by closing the hip capsule or by sewing the psosas tendon to the lump of the proximal femur. There is no agreement as to how much of the femur to resect, but it should certainly be enough to allow a full range of motion. This usually means that the resection must be done to the level above, at, or just below the lesser trochanter. This is certainly much more bone resection than would be done in any other Girdlestone-type resection. The patient should not be immobilized in a spica cast but may be placed in skeletal traction for 2 weeks. If the patient will tolerate it, an articulated external fixator is a reasonable alternative. As femoral head and neck resection is a salvage procedure, perform it only in total-care, severely involved patients to improve nursing care and comfort.

---

Recent advances in molecular genetics have greatly enhanced our knowledge of the gene abnormalities causing neuromuscular diseases (Genetic Analysis). Elevated levels of creatine phosphokinase (CPK) and other muscle enzymes are often seen in muscle disorders. CPK is released from muscle cells during necrosis and is a sensitive and valuable screening test for muscular dystrophy. Other enzymes such as aldolase and serum glutamic-oxaloacetic transaminase may be elevated in muscle disease but are not as sensitive as the CPK level.

Common muscle disorders include congenital myopathies, metabolic myopathies, and muscular dystrophies. The hallmark of a muscle disorder is weakness, but signs such as delayed motor development, fatigability, muscle cramps during activity, muscle wasting, and orthopaedic conditions such as cavus feet, claw hands or toes, and caput ulnae syndrome are often seen. Most muscle and nerve disorders can be diagnosed by a careful history and physical examination, and by specific laboratory tests, electromyography, nerve conduction studies, muscle and nerve biopsies, and genetic evaluation.

**DIAGNOSIS OF MUSCLE AND NERVE DISORDERS**

**HISTORY AND PHYSICAL EXAMINATION, LABORATORY TESTS**

Each symptom in the patient's history must be pursued to determine its onset, duration, exacerbating or relieving factors, and response to any treatment. The history can provide important clues to help in the diagnosis. Was the weakness present at birth or of recent onset and is it progressive? Weakness present at birth but not progressive may describe a child with a congenital myopathy, whereas onset of weakness in a young boy with gradual worsening is typical of muscular dystrophy. Detecting muscle weakness, usually by observation or muscle testing, is a major component of the clinical examination. Generalized muscle weakness results in hypotonia (floppiness), ptosis, a tent shaped mouth (bouche de tapir) and delayed motor development. Localized muscle atrophy is often observed at the shoulder girdle and the quadriceps muscle.

Strength can be evaluated by observing activities such as walking, dressing or undressing, and by testing individual muscles. Grading of activity-related muscle strength is a good screening method, especially in young, uncooperative patients. The activities are considered by regions: the hips, legs, shoulders, arms, and bulbar area (ie, respiratory function). Weakness can result in delayed development of the motor milestones (eg, head control, sitting, crawling, standing, walking, running). Meryon's sign (ie., reduced muscle resistance of the shoulder against the examiner's hand when lifted under the arms), Gowers' sign (ie., use of the hands to "climb up the legs" to a standing position when rising from a sitting position on the floor), and difficulty in climbing steps or rising from a chair (117,137,229). A 5-year-old boy with Duchenne muscular dystrophy may have a normal walk but when asked to run, the pelvic girdle and quadriceps weakness is quickly unmasked.

Evaluation of muscle strength is an excellent means of localizing the distribution of weakness, but it requires patient cooperation and can be difficult if there are associated fixed deformities. Agonist muscles (ie, prime movers) and antagonist muscles (ie, stabilizers) are graded for strength through the range of joint mobility. For example, the muscles controlling the foot may be tested for strength in dorsiflexion, plantar flexion, inversion, and eversion.

Although individual muscle testing is time consuming, tedious, and almost impossible in young, uncooperative children, it is essential as a baseline study for patients with suspected muscle or nerve disease. Muscle testing often is better performed in a special therapy session in which adequate time can be allotted. The Medical Research Council scale is generally accepted and grades muscle power as follows: 0, no contraction; 1, flicker or trace of contraction; 2, active motion with gravity eliminated; 3, active motion against gravity; 4, active motion against gravity and resistance; and 5, normal power (226). Myometric (dynamometric) methods are also useful in quantitating muscle strength, especially in evaluating therapeutic techniques (27).

Deep tendon reflexes of the biceps, triceps, knee, and ankle should be tested, along with the superficial reflexes of the abdomen and the great toe plantar response. The quality of reflex is judged by the briskness of muscle contraction and is best graded as absent, hypoactive, normal, or hyperactive. Children with spinal muscular atrophy and peripheral neuropathies typically have absent reflexes, whereas myopathic disorders such as muscular dystrophy have reflexes with latency in the course of the disease.

The sensory examination includes the evaluation of pain, light touch, deep touch, two-point tactile, vibration, and temperature. Self-mutilation and Charcot joint changes are almost always manifestations of sensory loss. In neuropathies, multiple modalities may be affected, producing a “glove” or “stocking” distribution of loss. Parasthesia, “pins and needles” sensation, and dysesthesia. Bulbar involvement is evaluated by cranial nerve testing. Cerebellar testing, particularly the Romberg sign for ataxia, is important when the differential diagnosis includes Friedreich's ataxia.

Muscle fasciculation, best seen by looking at the tongue or hands, is common in neuropathic disorders such as spinal muscular atrophy.

**INVESTIGATION**

**Serum Enzymes**

The serum enzymes elevated in muscle disorders include the aminotransferases (transaminases), aldolase, lactate dehydrogenase, and creatine phosphokinase (CPK). The serum CPK level is a sensitive and valuable screening test to demonstrate disease of striated muscle (343). Skeletal muscle, heart muscle, and brain tissue contain CPK, which catalyzes the release of phosphate from creatine phosphate. The high CPK level seen in Duchenne's muscular dystrophy (50 to 100 times normal) and other muscle disorders represents leakage from the muscle cell during necrosis. Aldolase and serum glutamic-oxaloacetic transaminase levels also may be elevated in muscle disease but are not as sensitive as the CPK level (352) and are also elevated by hepatic dysfunction.

**GENETIC ANALYSIS**

Recent advances in molecular genetics have greatly enhanced our knowledge of the gene abnormalities causing neuromuscular diseases (Table 178.1).
Molecular genetic techniques have been used to define other rare neuromuscular disorders in children. Metabolic myopathies, which are caused by abnormalities of glycogen, glucose, or lipid metabolism, have been well characterized. Mitochondrial DNA defects or mutations cause a broad spectrum of mitochondrial encephalomyopathies, which feature variable weakness with encephalopathy, cardiac, and visceral manifestations.

Cardiac and Pulmonary Evaluation

Cardiac and pulmonary abnormalities are very common in children with neuromuscular disease. Careful evaluation allows optimal daily management and an assessment of preoperative risks.

Electrocardiography and echocardiography are used to evaluate cardiac function (65). Patients with muscular dystrophy may develop cardiomyopathy or mitral valve prolapse. Cardiac tumors can secondarily cause papillary muscle weakness. Children with Friedreich’s ataxia, Emery-Dreifuss dystrophy, and infantile myasthenia gravis may have arrhythmias (96,113,166,288,295,378).

Pulmonary compromise so commonly seen in these patients can be assessed by questions about shortness of breath, frequency of pulmonary infections, and more objectively, by pulmonary function or sleep studies.

ELECTROMYOGRAPHY

Electromyographic (EMG) studies can differentiate a neuropathy from a myopathy but are seldom specific. A normal muscle is silent at rest and produces an interference pattern at maximal activity. In neuropathies, fibrillations and fasciculations occur at rest and the interference pattern is reduced at maximal activity. In myopathies, the muscle is silent at rest and has polyphasic individual potentials of low amplitude and short duration during activity. Myotonia frequently presents as a classic pattern of spontaneous bursts of potentials that wax and wane and give an acoustic pattern resembling a dive bomber. Muscle evaluation should include the areas of the body involved in the weakness, and examination of four muscles is usually sufficient. The deltoid and vastus lateralis are good muscles to study in children, because they are frequently involved in neuromuscular diseases of childhood. In myopathies, there may be no correlation between the severity of the muscle weakness and the electromyography.

NERVE CONDUCTION STUDIES

Nerve conduction velocities depend on the degree of myelination and the diameter of the neuron. The median, ulnar, peroneal, and posterior tibial nerves most commonly are studied, and normal adult values are 45 to 65 m/s. In infants, the velocity is about half that of the adult level, which is reached by 3 to 5 years of age (236). Motor conduction velocity typically is delayed in demyelinating neuropathies but is normal in anterior horn cell disease, root disease, or myopathies. Repetitive stimulation of the motor nerve can reveal pathologic fatigability, as in myasthenia gravis (34). Sensory conduction velocities are delayed and occasionally are helpful in diagnosing the mixed neuropathies, such as peroneal muscle atrophy or Friedreich’s ataxia.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia is characterized by muscle rigidity and necrosis associated with a rapid rise in body temperature (62,219,274). One in about 15,000 people in the general population develops malignant hyperthermia during general anesthesia. Although it has been reported to be associated with many disorders including the congenital myopathies, muscular dystrophy, osteogenesis imperfecta, myelomeningocele, and King’s syndrome (ie, short stature, scoliosis, cryptorchidism, pectus carinatum, characteristic facial features) (62,174,175,189,229,328,336,360), it is mainly associated with central core myopathy, with which it is closely linked. There is an abnormality of the ryanodine receptor gene at the 19q13.1 locus (121).

These reactions of malignant hyperthermia can be triggered by the administration of depolarizing muscle relaxants (e.g., succinylcholine chloride) or inhalational anaesthetics (e.g., halothane). If possible, these medications should be avoided in patients at known risk. Patients with previous episodes or a positive family history are at high risk for malignant hyperthermia, and the recommended local anesthesia is lidocaine (239).

Prompt treatment of malignant hyperthermia is imperative at the earliest signs of tachycardia, tachypnea, or a rigid masseter muscle, because survival is unlikely after significant hyperthermia. Treatment consists of termination of all anesthetic agents, ventilation with 100% oxygen, cooling (e.g., ice packs, iced intravenous fluids, gastric irrigation, cooling blankets), intravenous sodium bicarbonate for metabolic acidosis, and administration of sodium dantrolene (1 mg/kg/min, up to 10 mg/kg total dose) (187,193). Treatment is continued for as long as 6 hours after an attack. In patients at high risk for malignant hyperthermia, the recommended local anesthesia is procaine, and for general anesthesia, narcotics, barbiturates, or neuroleptic drugs, and prophylactic dantrolene sodium are used (239).

MUSCLE BIOPSY

A muscle biopsy is often valuable for a definitive diagnosis of muscle disorder (149). Three issues are important: selection of the muscle, technique of the biopsy, and specimen care. Muscles with mild involvement should be selected in chronic disease, but severely involved muscle should be chosen in acute disease. The histology of severely involved muscle in chronic disease may show only secondary changes and not be diagnostic. Commonly selected muscles are the vastus lateralis, rectus femoris, deltoid, gastrocnemius, and biopsia brachii. Obtain an adequate specimen from the belly of the muscle. Avoid areas of musculotendinous junction, scar from previous surgery, immunization sites, and electrode insertion sites for EMG (103).

Obtain an adequate specimen, and either give it directly to the technologist or have it transported quickly to the laboratory. Traditional techniques of maintaining muscle length are not needed for routine muscle biopsy. A moderate volume (250 mg) is needed to assay for enzyme systems to characterize metabolic myopathies. Part of the specimen is sent for genetic and protein analysis, and part of the specimen is frozen rapidly in liquid nitrogen to preserve the enzymes and prevent. Histochonometric evaluation includes staining with hematoxylin and eosin, Verhoeff–van Gieson, periodic acid–Schiff (PAS) stain for glycogen, Gomori trichrome, oil red O for lipids, and muscle green–pyronine for RNA. Staining for adenosine triphosphatase (ATPase) at selected pH determines fiber types. In skeletal muscle, the ratio of muscle fiber types I and II is 1 to 2. Type I fibers have low ATPase activity and glycogen and high oxidative activity, and type II fibers have the opposite relative amounts. At present, fibers are subtyped based on ATPase activity (68).

Open biopsy technique offers the advantages of a large sample and proper orientation and length of the specimen fibers, but it has the disadvantage of unsightly scars. Needle biopsy is cosmetically better but has the disadvantage of producing a small sample with disoriented fibers (63,96). Coordinate the method of specimen handling and biopsy technique with the pathologist to ensure adequate results.
Open Muscle Biopsy Technique

Open muscle biopsy is usually performed with local anesthesia (1% Xylocaine without epinephrine) and sedation. The muscle must not be infiltrated with Xylocaine. Make a 1.5 cm incision, preferably following the skin lines, over the belly of the selected muscle. Expose a 2 × 0.5 cm cylinder of muscle (the long axis parallel to the muscle fibers), and excise the specimen with a scalpel. Electrocautery should not be used before removing the specimen. Sutures at either end of the specimen tied over a tongue blade or muscle biopsy forceps can be used to maintain specimen length. The procedure is usually performed on an outpatient basis, and complications are uncommon.

Needle Muscle Biopsy Technique

The vastus lateralis muscle is commonly used as the site of needle biopsy. The Bergstrom needle, consisting of a cannula and sliding trocar with cutting blade, typically obtains a specimen of about 200 fibers. After administration of local anesthesia (1% Xylocaine without epinephrine), make a stab incision over the belly of the muscle. Insert the needle into the muscle, and activate the cutting blade to obtain the specimen. Suction can be applied to the needle hub to improve the biopsy size (239).

Several repeat specimens may be obtained through the same skin incision by changing the direction of the needle. Close the skin by a single stitch or adhesive strip and apply pressure over the muscle for several minutes to reduce the risk of hematoma formation.

NERVE BIOPSY

A nerve biopsy may aid in the diagnosis of a peripheral neuropathy but is rarely required. The sural nerve, which is entirely sensory, usually is selected because it innervates only a small area of the skin over the dorsolateral aspect of the foot, and the sensory loss is not usually a functional problem. Light and electron microscopy, the latter of which requires glutaraldehyde fixation are used for specimen evaluation. Preparation of the specimen needs to be coordinated with the pathologist before the biopsy (327).

To biopsy the sural nerve, make a 3-cm longitudinal incision over the posterolateral aspect of the leg parallel to the interval between the tendon Achilles and the peroneus brevis muscle. The nerve courses beside the ischial saphenous vein. Isolate 2.5 cm of the nerve in the interval and cut it sharply (not with scissors). If less than 1 cm of the nerve is taken, the ends can be reaproximated with microvascular sutures, but this repair is very time consuming for such a mild sensory loss and not usually done. If the nerve is not resutured, secure the proximal end in the deep layer of the subcutaneous fat, which helps to protect against painful neuroma formation.

COMMON MUSCLE DISORDERS WITH ORTHOPAEDIC DEFORMITIES

Muscle diseases (myopathies) are inherited or acquired and constitute a diverse group of conditions that include structural congenital myopathies, diseases that typically present as a floppy infant, with muscle biopsy demonstrating structural abnormalities within the muscle cell; dystrophies, conditions in which the muscle initially develops and functions normally but then progressively degenerates and atrophies; myotonias, syndromes characterized by the delayed relaxation of muscle; and metabolic conditions, including to consider diseases with specific metabolic abnormalities and acquired myopathies, such as those secondary to infections, autoimmune disorders, and conditions related to toxins (66).

BENIGN CONGENITAL MYOPATHIES OF CHILDHOOD

Congenital myopathies are a group of clinically similar illnesses that present with hypotonia and weakness from birth; muscle biopsy demonstrates structural abnormalities within the muscle cell. Most myopathies have an autosomal dominant transmission, are nonprogressive, and are characterized by symmetric proximal muscle weakness. Serum enzyme levels are normal or mildly elevated, and an EMG may show myopathic changes. The types of myopathies are differentiated by genetic studies, histochemical, or electron microscopic evaluation of the muscle biopsy specimen and include nemaline myopathy (rod body), central core disease, myotubular myopathy (central nuclear), congenital fiber-type disproportion, minicore disease, and nonspecific congenital myopathies (4,15-36.35.70.76.88.91.161.192.194.199.241.303.321). Myotubular myopathy has a gene abnormality at the xq28 locus, central core disease at 19q13.1, and nemaline myopathy at 1q21 (2-topomysin gene).

Contractions and Foot Deformities

The contractures and foot deformities in patients with congenital myopathies are caused by hypotonia with abnormal posturing and are usually controlled with stretching therapy, periodic serial stretching casts, supportive orthoses, or occasionally, tendon lengthenings.

Hip Dislocation

Dislocated hips can occur at birth or develop later in children with congenital myopathies. They are usually easily reducible in early infancy but require prolonged treatment to achieve stability. Any lax-jointed, low-toned infant or any older child who presents before walking with an easily reducible dislocated hip without hip contracture should be suspected of having hip dysplasia. The hips of infants with typical congenitally dislocated hips, except that the total time of treatment is often prolonged and stability of the hip is difficult to achieve.

The Pavlik harness is excellent for maintaining reduction in newborns and young infants. The hips reduce initially in flexion of about 110° and mild abduction of 45°. Instruct caregivers not to dislocate a hip inadvertently by positioning it in adduction. These hips tend to redisclose easily, requiring frequent (initially, almost daily) adjustment of the Pavlik harness. Prone positioning in the Pavlik harness is helpful. It is important not to allow the hip to remain persistently posteriorly dislocated in the Pavlik harness, because this creates a severe treatment complication. After the hip is stable, maintain the harness in about 90° of flexion and 45° of abduction until adequate bony and cartilaginous support develops. There is no time-honored rule for the length of treatment, but the total course should be long enough to allow joint stability and formation of a normal cartilaginous acetabulum.

Treat an older child who has developed contracture of the hip or whose hip does not easily reduce initially in skin traction until the femoral head approaches the area of the acetabulum. With the patient under general anesthesia, gently reduce the hip and apply a cast to maintain stability. Cast treatment may be necessary for as long as 6 months. Hip dysplasia after treatment for dislocation from hypotonia and joint laxity may improve with abduction bracing. Use an abduction brace and a standing frame with the legs in abduction for these children, in whom the development of walking skills is usually delayed. After ambulation is achieved, an abduction brace is helpful, but most children have difficulty walking in the brace. If dysplasia persists despite brace therapy in an ambulating child, perform a varus derotation proximal femoral osteotomy and, if needed, an acetabular redirection osteotomy.

Scoliosis

Scoliosis that presents at a young age tends to be progressive, often has a long C-shaped or double-curve pattern, and is most difficult to treat in a hypotonic patient with respiratory compromise. The orthopaedic dilemmas include poor tolerance from respiratory compromise in a thoracolumbosacral orthosis or spinal fusion with subsequent inhibition of spinal growth in a young child, resulting in a short trunk. As soon as scoliosis is recognized, institute treatment by linearly posturing the spine on a back and spine supports and, if respiratory capacity permits, by a thoracolumbosacral orthosis with abdominal relief. Pulmonary function studies of the patient in and out of life-threatening complication of treatment in patients with central core myopathy is malignant hyperthermia (52.101.174.175.189.238).

Indications for Spinal Fusion

If the scoliosis progresses despite orthodox treatment, posterior spinal fusion is necessary, unless cardiopulmonary incapacity is life threatening, even though this fusion inhibits longitudinal growth of the spine if performed before skeletal maturity. Internal fixation is essential, preferably with segmental instrumentation. The fusion extends from the 5th thoracic area to the sacrum. The Luque technique has been performed without fusion to allow spinal growth in the young child, but this remains an unproven technique because of certain obvious risks, such as wire breakage, rod breakage, and growth over the upper ends of the rods, with subsequent kyphoscoliosis. We recommend a posterior spinal fusion with the unit rod, a modification of the Luque technique, from the first or second thoracic vertebra to the sacrum, and we discourage the use of anterior spinal procedures in patients with respiratory compromise. The unit rod is preferred because it prevents cephalad-caudal movement of the rods, spinal rotation, and pelvic obliquity without the use of rod connecting devices. In nonambulatory patients with progressive scoliosis, we recommend stabilization to the sacrum.
Segmental Posterior Spinal Fusion with Unit Rod or Luque Rod Instrumentation

- Place the patient in the prone position on a four-poster scoliosis operative frame so that the abdomen is free of pressure (6,25,37,77,110,213,214,218,231,247).

- Make a dorsal longitudinal skin incision over the spinous processes of the vertebrae to be fused, and forcibly retract the skin margins with Weitlander retractors to reduce the bleeding.

- Incise the subcutaneous tissue to the dorsolumbar fascia, exposing the tips of the spinous processes from T1 to the sacrum.

- Sit the cartilaginous caps of the spinous processes longitudinally, and interconnect them by splitting the supraspinous ligament.

- With a Cobb elevator, retract the cartilaginous caps laterally, perform a subperiosteal dissection down each side of the lamina, and pack gauze between the bone and paraspinal muscle to maintain hemostasis.

- Then expose each vertebra subperiosteally laterally from inferiorly to superiorly to the tips of the transverse processes in the thoracic area and to the base of the transverse processes in the lumbar area.

- Place the self-retaining Weitlander retractors progressively deeper in the wound, and spread them widely against the paraspinal muscles to minimize bleeding.

- Promptly electrocauterize soft-tissue bleeding and control bone bleeding with small quantities of bone wax.

- Expose the posterior superior iliac spines and adjacent iliac crest by elevating the erector spinae off the sacrum.

- Expose the outer table of the ilium subperiosteally down to the greater sciatic notch. With the drill guide developed for the unit rod, drill holes in the ilium from the bottom of the posterior superior spines to pass 1 to 2 cm above the sciatic notch (Fig. 178.1). Be very careful to stay within the intrasosseous area, and probe the hole to confirm this.

**Figure 178.1.** The holes in the ilium are drilled by using a drill guide that hooks into the sciatic notch. The hole enters at the posterior superior iliac spine and is drilled 2 cm past the sciatic notch. (From Dias RC, Miller F, Dabney K, et al. Surgical Correction of Spinal Deformity Using a Unit Rod in Children with Cerebral Palsy. J Pediatr Orthop 1996;16:734, with permission.)

- Carefully remove the ligamentum flavum from the midline for sublaminar wire passage.

- Pass dual stainless steel wire strands under each lamina, except at the top of the fusion and at L5, where two dual strands are used for strength. Be extremely cautious not to cause neural damage while passing the wires.

- With a rongeur, osteotome or power burr, decorticate and perform facetectomies of the vertebrae in the area to be fused. Corticocancellous allograft is typically used in these children (150 to 250 g).

- If instrumentation with the unit rod is required, select the appropriate length of rod.

- Place a flexible measuring rod along the lamina on the concave side of the scoliosis. The unit rods are present to the contour of the normal spine, which corresponds to the desired postoperative spinal posture. The unit rod is available in 1/4- and 3/8-inch sizes, the smaller being used in children weighing less than 30 pounds or in very osteopenic children.

- Secure the unit rod to the pelvis in a manner similar to the Galveston technique for Luque segmental spinal fusion (6,72).

- Cross the pelvic legs of the rod, and insert them into the pelvis, being careful to be in line with the drilled holes. Rod holders can be used to guide the legs during gradual alternate side impaction (Fig. 178.2).

**Figure 178.2.** The rod is inserted into the pelvis by crossing the pelvic legs, keeping them aligned with the orientation of the drilled holes. (From Dias RC, Miller F, Dabney K, et al. Surgical Correction of Spinal Deformity Using a Unit rod in Children with Cerebral Palsy. J Pediatr Orthop 1996;16:734, with permission.)

- Then tighten the sublaminar wires by twisting at each level starting at L5 and moving proximally. Push the rod to the spine at each level, resulting in gradual correction of the deformity.

- Close the fascia with interrupted and overlying continuous suture with no drains. Perform subcutaneous and skin closure.

If Luque rod instrumentation is desired, contour two Luque rods, one for the concave side of the scoliosis and one for the convex side. The Luque rods are available in the same sizes as the unit rods, and the suggestions for use are outlined above. Before the operative procedure, obtain lateral bending radiographs to determine the flexibility of the scoliosis, and bend the Luque rods to achieve no more than 10° additional correction beyond the preoperative bending radiographs. Bend the superior end of the convex rod and the inferior end of the concave rod into the shape of an L. Apply the rod on the concave side of the scoliosis first, and place the L portion between spinous processes or through a drill hole in the spinous process to prevent migration of the rod. If stabilization to the pelvis is required, bend the inferior end of the Luque rods as described for the Galveston technique (6). As described for the unit rod instrumentation, secure the rod to the lamina using the sublaminar wires. Apply the convex wires in similar manner, and cut and carefully tighten all wires. The two rods are connected inferiorly and superiorly to provide additional stability. We prefer to interconnect the rods securely to prevent cephalad-caudal shifting, spinal rotation and loss of pelvic obliquity correction. Rod connectors can prevent shifting of the rods. The fusion technique, bone grafting, and wound closure are identical to that described earlier for the unit rod.

**MUSCULAR DYSTROPHY**

The muscular dystrophies constitute a group of inherited muscle disorders characterized by progressive muscle weakness due to primary degeneration of muscle fibers. It has become apparent that these disorders are caused by specific gene abnormalities (301,349).

The muscular dystrophies are classified by age at onset, groups of muscles first affected, genetic transmission, and areas of body with progressive weakness (301).

**Duchenne Muscular Dystrophy**

Duchenne muscular dystrophy occurs in about 3 of 100,000 boys and usually has an early childhood onset, leading to loss of ability to walk and eventual death (128-229). It is transmitted genetically as a sex-linked recessive trait and is due to a mutation or deletion of DNA at a locus (Xp21) on the short arm of the X chromosome (106,120,163,164,200,312). About two thirds of the boys inherit the gene abnormality from the mother, and one third are thought to be due to new mutations. The onset is initially insidious, often with delayed motor milestones, with weakness clinically apparent by 3 years age (385). The weakness first involves the pelvic-girdle musculature, followed by the shoulder girdle musculature, and then distal musculature of the upper and lower extremities (2-387).

By 4 years of age, the boy stumbles, falls frequently, and has difficulty climbing steps and running. Pseudohypertrophy of the gastrocnemius (Fig. 178.3), deltoid, and serratus anterior muscles is secondary to the dystrophic process and accumulation of fat within the muscles and fibrous tissue. The weakness results in a wide-based waddling gait associated with increased lumbar lordosis (Fig. 178.4). Gowers’s sign (Fig. 178.5) is a characteristic way for a child with this type muscular dystrophy to rise from the floor to a standing position (137). This maneuver may be demonstrated by placing the boy prone on the floor. First, he crawls into the knee-elbow position;
then, with hands and feet on the floor, he raises his hands consecutively to the knees and pushes to an upright posture. The knee reflexes are diminished and sensation is normal. Progressive weakness is unremitting, and ambulation becomes more difficult, until between ages 9 and 12 years, the boy loses the ability to walk. Scoliosis and increasing contractures of the lower extremities develop. The weakness progresses until total care is required and severe cardiopulmonary compromise occurs between ages 17 and 22 years (5, 14, 44, 49, 173, 201, 314, 319, 387).

Figure 178.3. Pseudohypertrophy of the calf muscles in a boy with Duchenne muscular dystrophy.

Figure 178.4. A boy with Duchenne muscular dystrophy who stands with lordotic spinal posture and has pseudohypertrophy of the calf muscles.

Figure 178.5. Gowers’ sign is a characteristic way for a child with Duchenne muscular dystrophy to rise from the floor (A to C) by first using the hands to crawl into the knee-elbow position (D to E) and then to push on the knees to achieve an upright position. Gowers’ maneuver demonstrates weakness in the shoulder and pelvic muscles.

The diagnosis can often be made on the basis of family history, clinical presentation, and an elevation of serum creatinine phosphokinase (often 100 times normal in young children). Traditionally, muscle biopsy has been used to confirm the diagnosis but modern techniques of DNA analysis using peripheral blood can provide a definitive diagnosis, help to identify carriers, and allow prenatal diagnosis for 70% to 80% of the children (298). The molecular basis of Duchenne and Becker’s muscular dystrophy is the absence or abnormality of dystrophin (a subsarcolemmal protein) and dystrophin-associated glycoproteins (found in the sarcolemma or muscle cell membrane) (106, 120, 163, 184, 200, 312). These proteins are found in skeletal, smooth and cardiac muscle, and brain. In the 20% of children who do not have a diagnosis by DNA analysis, muscle biopsy can be diagnostic. The biopsy typically from the vastus lateralis shows muscle fiber degeneration, regeneration, fibrosis, fatty infiltration, central nuclear migration and hypertrophic muscle cells (86). Absence of dystrophin is diagnostic. EMG, rarely required, shows myopathic changes with muscle action potentials of reduced amplitude and brief duration. The nerve conduction velocities are normal.

Orthopaedic treatment is aimed at maintenance of strength and walking ability for as long as practical and prevention of deformities (144, 179, 309, 353, 367, 361, 382). The single most important factor in maintaining strength is prevention of prolonged immobilization. If a boy with Duchenne muscular dystrophy is immobilized by any method, functional losses tend to be permanent. Therefore, make every reasonable effort to maintain strength by resistive muscle exercises. The patient should perform stretching exercises, especially of the muscles most subject to contractures (e.g., tensor fasciae latae, hip and knee flexors, and ankle plantar flexors) several times each day.

Prednisone and other steroids have been used successfully in these children from about 5 years of age to improve muscle strength (142). Complications from this treatment include weight gain, hypertension, behavior disturbances, increased appetite, cushingoid features, and osteopenia. Take into account chronic steroid useage when administering general anesthesia.

Myoblast transfer therapy to induce dystrophin production has not been successful (206). Attempts are being made to use viral vectors to transfer functional parts of the dystrophin gene to affected individuals.

Fractures

Muscle weakness predisposes the patient with Duchenne muscular dystrophy to falls, and relative inactivity results in osteopenic bone (162). Fractures of long bones occur in 20% of children with Duchenne muscular dystrophy, typically occurring with falls during daily activity or physical therapy (26, 162, 305, 320). These fractures often herald the end of the ambulatory stage. Treat nondisplaced fractures of the femur and tibia in lightweight long-leg casts or splints. Encourage weight bearing on the noninvolved leg immediately and within days on the fractured leg. Bed rest and traction are contraindicated. Displaced fractures of the lower limbs require prompt surgical stabilization. Apply a lightweight orthosis to the leg over the area of internal fixation and begin ambulation. The family should be aware that fracture complications are higher with early mobilization but that the added risk is necessary to avoid even more serious problems.

Contractures

Contractures are inevitable in these patients, but controlling the severity greatly enhances the quality of life. Toe walking, caused by contractures of the tendo Achilles, can sometimes be detected in patients as young as 3 years of age, and it responds to stretching therapy or serial plaster casts. Tendon lengthening in young ambulatory patients is discouraged because of resulting weakness. For the ambulatory patient, a nighttime ankle-foot orthosis helps eliminate the typical equinus posture of the foot during sleep, and muscle stretching therapy delays progression of contractures (320). Despite aggressive therapy, the ability to walk becomes threatened between 8 and 12 years of age from quadriceps muscle weakness (331); contractures of the hip flexors (Thomas test), hamstring muscles, and iliotibial tract...
Open Lengthening of the Tendo Achilles

As these children lose the ability to walk independently, surgical releases of lower extremity contractures and long-leg bracing can prolong standing and ambulation for several years (19,26,29,64,73,156,265,272,279,310,316,320,354,355,387). When surgical releases are delayed until the children have almost stopped walking, the severity of weakness usually means that standing or walking is possible only with knee-ankle-foot orthoses. Earlier surgery followed by physical therapy and limited bracing (ankle-foot orthoses) can be just as effective (15,198,179,266).

Procedures used to treat contractures in Duchenne muscular dystrophy include Yount fasciotomy of the iliotibial tract, Ober release of the iliotibial band, distal hamstring lengthening, transfer of the posterior tibialis tendon to the dorsum of the foot, percutaneous lengthening of the tendo Achilles, and open lengthening of the tendo Achilles.

The iliotibial tract is released by a combination of the Yount (380) fasciotomy distally and the Ober (245) release proximally. The hamstrings are released distally, and the tendo Achilles is lengthened by a percutaneous method (Figs. 178.6, 178.7). The late weakness lengthened by a posterior tibialis muscle often causes a varus deformity of the foot, which is sometimes treated by a posterior tibialis tendon transfer through the interosseous membrane of the tibia and fibula to the dorsum of the foot, which maintains a plantigrade foot. If, however, the varus is not severe and the posterior tibialis muscle is weak, a tenotomy can be performed easily just posterior to the medial malleolus (308). The tenotomy is often the treatment of choice, because the child must wear an orthosis in any case.

![Figure 178.6](image.png)

A boy with Duchenne muscular dystrophy who has undergone operative release of the iliotibial tract, distal hamstring muscle release, and percutaneous tendo Achilles lengthening. He now ambulates with long-leg braces.

Yount Fasciotomy of the Iliotibial Tract

- Expose the iliotibial tract through a 2 cm lateral longitudinal incision, located proximal to the lateral femoral condyle.
- Incise the iliotibial tract, fascia lata, and intramuscular septum transversely at a level 2.5 cm proximal to the patella. Protect the biceps tendon and the common peroneal nerve posteriorly.
- A segment of the iliotibial tract and septum may be removed in patients with severe contractures to prevent recurrence.

Ober Release of the Iliotibial Band

- With the patient in a lateral decubitus position, make an incision from 3 cm posterosuperior to the greater trochanter of the femur obliquely to 2 cm inferior to the anterosuperior iliac spine.
- Incise the fascia lata from the anterior portion of the gluteus maximus muscle anteriorly to the anterosuperior spine.
- Incise the fascia surrounding the tensor fasciae latae transversely.

Transfer of the Posterior Tibialis Tendon to the Dorsum of the Foot

- Through a 2 cm medial longitudinal incision centered over the talonavicular joint, free the posterior tibialis tendon from its distal insertions.
- Make a second 2 cm incision midlateral at the muscular tendon and tendon junction of the posterior tibialis tendon just postero medial to the tibia, and isolate the posterior tibialis tendon.
- Place a blunt, smooth elevator beneath the tendon and lift it medially, drawing the tendon into the proximal wound. E elevate the muscle origin from the fibula and interosseous membrane for several centimeters proximally.
- Make a third incision of 1 cm anterolaterally between the tibia and the fibula, 2.5 cm above the ankle joint.
- Direct a long, curved tendon passer from the second incision posterior to the tibia, through the interosseous membrane, to the third incision.
- Open the jaws of the tendon passer to create an opening in the interosseous membrane. Some surgeons fashion a long window in the membrane using a scalpel; this reduces the chance of adhesions between the tendon and membrane (although this is not a major consideration in patients with Duchenne muscular dystrophy).
- Place a heavy, nonabsorbable suture in the distal end of the tibialis posterior tendon. Using a suture, draw the posterior tibialis tendon forward through the interosseous membrane to the third incision.
- Make a fourth 2 cm incision over the dorsal surface of the third cuneiform or the third metatarsal.
- Retract the extensor tendons and incise the peroneus in a cruciate fashion.
- Drill a 0.6 cm hole plantarly through the bone.
- Direct the tendon passer subcutaneously from the fourth incision to the third incision, and deliver the tendon subcutaneously to the fourth incision. During passing, be careful to allow no twisting or kinking of the tendon. Some surgeons prefer to pass the tendon beneath the extensor retinaculum, but in our experience, this procedure is unnecessary, and it may become the site of tendon adhesion that restricts motion.
- Pass the sutures attached to the tendon end through the plantar surface of the foot with long, straight needles. The needles and sutures should exit the plantar surface of the foot in a non-weight-bearing area.
- Direct the tendon into the drill hole, hold the foot in a neutral position, and anchor the sutures snugly over a heavily padded button. The tendon can also be fixed to the midfoot using one of the available anchor systems.
- Further secure the tendon to the drill hole site by interrupted sutures to the peroneus.
- Close the incision and apply a well-padded long-leg cast with the foot in a slightly dorsiflexed position. Particular attention should be directed toward padding the proximal fibula, where the peroneal nerve is most cutaneous.

Postoperatively, remove the long-leg cast after 2 weeks, and apply a short-leg walking cast for an additional 4 weeks. After cast removal, remove the button, place the extremity in a brace, and begin active exercises.

Percutaneous Lengthening of the Tendo Achilles

- Perform a percutaneous tenotomy with the patient in a prone position.
- Dorsiflex the foot to maintain the tendo Achilles in a taut position.
- Palpate the posterior tibial artery in the neurovascular bundle, protect it during the procedure. The tendo Achilles rotates 90° on the longitudinal axis between its origin and insertion, and the medial fibers proximally are posterior at the insertion.
- Make a longitudinal 3 mm stab wound medial to the tendo Achilles and 1 cm superior to the calcaneus, and divide the anterior two thirds of the tendon fibers.
- Make a second stab wound incision dorsally 2 cm below the palpable musculotendinous junction and divide the medial two thirds of the tendon fibers.
- Dorsiflex the foot and the tendo Achilles lengthens.
- Close the stab wounds, and apply a well-padded cast at 5° dorsiflexion for 4 weeks.

Open Lengthening of the Tendo Achilles

- With the patient in a prone position, make a 5 cm longitudinal incision from the superomedial aspect of the calcaneus proximally along the medial border of the tendo Achilles. Divide the subcutaneous tissue and tendon sheath, and evacuate the rotation of the tendo Achilles.
- Incise the midposterior area of the tendon longitudinally by a stab wound. Place a clamp in the stab wound incision, and open it so that the tendon splits in the longitudinal direction of the fibers.
Postoperative Care Most surgery is performed bilaterally in one operative procedure, and lightweight long-leg casts are applied with the knees in extension and the feet neutral.

Standing is begun the day after surgery, and a rapid return to walking is encouraged. We incorporate a strip of polyurethane foam (7.5 × 1.5 cm) for padding dorsally under the standard long-leg cast. Ten days later, the casts are removed, and long-leg orthoses are measured, and casts are reapplied until the orthoses are fabricated. The knee-ankle-foot orthosis prescription should include lightweight materials (usually plastics), contouring proximally to allow the buttocks to rest on the brace, drop-lock hinges at the knee, solid ankles in the neutral position, talar straps, and extension beyond the metatarsal heads (377).

Equinovalvar Deformity

Later in the disease process, the child becomes confined to a wheelchair. At this stage, contractures of the knees and hips are inevitable. Surgical releases usually are not required; instead, a program to maintain motion is indicated to prevent the progression of contracture that would hinder a good sitting position in the wheelchair. Occasionally, a patient, especially one who earlier refused surgery to prolong walking or refused orthotics, develops a severe, rigid equinovalvar deformity of the foot that causes pain on the anterolateral aspect of the foot or the inability to wear shoes. Multiple tenotomies (tendo Achilles, tibialis posterior, and flexor digitorum longus) and postoperative casting can achieve a satisfactory foot position. Severe, stiff longstanding deformity can be corrected operatively with a tarsal medullostomy, but postoperative foot edema may persist for at least 6 months.

Tarsal Medullostomy

- Place the patient in the supine position, and control hemostasis during the procedure with a pneumatic tourniquet.
- Make a 3 mm stab wound skin incision obliquely over the sinus tarsi.
- Introduce a 3 mm oval curette into the sinus tarsi. Curette the talonavicular, calcaneocuboid, and subtalar joints, leaving the outer cortical margins intact.
- Carefully avoid injuring the neurovascular structures.
- Close the stab wound incision with a single stitch, and place the leg in a well-padded long-leg cast with the knee flexed and the foot in neutral position.

After surgery, elevate the foot to control edema. Use a long-leg cast for 1 month, and a short-leg cast for an additional 2 months (Fig. 178.7).

**Figure 178.7.** A: A boy with Duchenne muscular dystrophy and a severe equinovalvar foot deformity. B: The deformity was corrected by a tarsal medullostomy. C: After surgery, the foot has maintained a neutral position.

**Figure 178.8.** A: After becoming nonambulatory from Duchenne muscular dystrophy, this boy developed a severe scoliosis, which led to pelvic obliquity and difficulty sitting. B: The radiograph demonstrates a long C-shaped pattern of scoliosis. AP (C) and lateral radiographs obtained after a posterior spinal fusion with Unit rod instrumentation (D).
Becker’s Muscular Dystrophy

Becker’s muscular dystrophy is an X-linked disorder with a clinical pattern similar to that of the Duchenne type, but it is milder and with slower progression (22,23,31). It results from a deletion in the same gene that causes the Duchenne type. Dystrophin is present but in reduced amounts, typically above 20% (164,189). Proximal girdle muscle weakness and pseudohypertrophy are apparent by 7 years of age, with maintenance of walking ability until age 16 and death occurring in middle adult life after cardiopulmonary failure (105). Clinically, the patient with Becker’s muscular dystrophy resembles a "strong" patient with Duchenne muscular dystrophy in the juvenile years. The CPK level is markedly elevated, with levels similar to those seen in Duchenne muscular dystrophy, and the results of muscle biopsy resemble those in Duchenne muscular dystrophy. Orthopaedic problems include equinus, cavus, and scoliosis (186). The early major orthopaedic problem is progressive contracture of the tendos Achilles, which may be controlled by muscle-stretching therapy and by a nighttime ankle-foot orthosis to prevent the typical equinus postureing of the foot during sleep. Periodic serial stretching casts usually control the mild contractures, and tendo Achilles lengthening has occasionally been necessary.

Progressive proximal muscle weakness causes a wide-based gait and exaggerated spinal lordosis. In the teenage years, ambulation can be facilitated by canes for balance and a knee-ankle-foot orthosis. Scoliosis can occur and is managed as for the Duchenne type (186).

Limb Girdle Muscular Dystrophy

The term limb girdle muscular dystrophy represents a group of patients with muscle weakness in a girdle distribution and autosomal inheritance. Leyden (209) described a type with predominantly pelvic girdle weakness, and Erb (105) described a shoulder girdle type. Typical findings include elevation of the CPK level, myopathic changes on EMG, and dystrophic changes on muscle biopsy. Recent advances in molecular genetics have established several syndromes with different gene abnormalities that had been classified as limb girdle dystrophies (87). There is a wide range of clinical severity. For example, severe autosomal recessive muscular dystrophy of childhood is characterized by absence of a sarcoglycan called adhalin (87) and can present with a clinical course similar to that of Duchenne's muscular dystrophy or with a later onset, milder type.

Orthopaedic problems are similar to those seen in other types of muscular dystrophies, and the principles of management are the same.

Facioscapulohumeral Dystrophy

Facioscapulohumeral dystrophy (Landouzy-Déjerine dystrophy) is transmitted by an autosomal dominant gene, has an onset usually in adolescence, involves the facial and then the shoulder girdle muscles, and has a slow progression, with an expected average to long life span (87,148,204,349). The disease is uncommon, with a prevalence of about 1 in 20,000 (259,250). The early weakness results in a lack of facial mobility, sloping of the shoulders, and difficulty in raising the arms above the head. The upper arm and scapular muscles are involved earlier than the deltoid and forearm muscles. In longstanding, severe cases, the wrist extensor muscles are more involved than the flexors, producing a wrist drop called the praying mantis posture. The CPK level is normal to slightly elevated, and muscle biopsy shows only slight changes, such as isolated atrophic fibers and variation in fiber size. The gene abnormality has been localized to 4Q35, but no gene product has been identified (114,365).

Facioscapulohumeral dystrophy presents as four clinical variations: typical, as described; late exacerbation type, which may consist of only mild facial weakness for years and then rapid deterioration in midlife; infantile type, which has an onset before age 1 year and is severely crippling, requiring a wheelchair by age 9 years (38); and scapuloperoneal syndrome, in which the peroneal and tibialis anterior muscles are involved early in the illness (16,109).

The facioscapular pattern of weakness occurs in several diseases that must be differentiated, including myotubular myopathy, nemaline central cord disease, and mitochondrial myopathy (34).

Orthopaedic problems include a dropped wrist and foot, scapular instability, and back pain. The dropped wrist is treated by a splint and the dropped foot by an ankle-foor orthosis with a rigid ankle in neutral position. Lordosis (Fig. 178.9A, Fig. 178.9B), which is initially flexible, usually develops in the lumbar spine but may become so severe and rigid that the sacrum becomes horizontal. The lordosis produces severe back pain that may be treated by a lumbarosacratal orthosis. In ambulatory patients, the orthosis should support the back but not necessarily correct the lordosis, which may be necessary for walking. Surgery for back pain is almost never indicated.

Figure 178.9. Photograph (A) and radiograph of a boy with facioscapulohumeral dystrophy and severe spinal lordosis (B). The lordosis frequently results in disabling back pain.

Weakness of the serratus anterior, rhomboid, trapezius, and latissimus dorsi muscles limits elevation of the shoulder by allowing scapular winging and rotation (Fig. 178.10A, Fig. 178.10B). If the deltoid muscle is strong and scapular winging inhibits function so that the arm cannot be raised above the horizontal level, a scapulothoracic arthrodesis may be effective in improving shoulder flexion and abduction (42,43,61,177,188,207,321) (Fig. 178.10C). The operation initially should be performed on one side; if helpful, it can be considered for the contralateral side.

Figure 178.10. Facioscapulohumeral dystrophy in a young woman with shoulders in neutral (A) and abduction (B). Note the improved abduction and appearance of left shoulder after scapulothoracic arthrodesis. Radiograph (C) demonstrates the wiring technique and preoperative position of the right scapula.

Scapulothoracic Arthrodesis

- Place the patient prone on bolsters. Free drape the shoulder and arm to allow shoulder motion and access to the brachial and radial pulses.
A few patients develop severely rigid equinovarus feet that cannot be corrected with serial casting and thus require surgical correction. We recommend that surgical maintenance a difficult orthopaedic problem. Bivalved casts are most useful, although they have a tendency to slip distally on the foot, and orthoses require frequent maintained until ambulation begins. Frequently, these patients are severely hypotonic, and walking may be delayed until they are 3 to 4 years old, making prolonged directed toward molding the cast at the longitudinal arch of the foot, so that a breach of the arch will not occur. After the foot is casted to a neutral position, it must be casted to a neutral position. Careful attention should be given to the toe plate on the cast to maintain a neutral position; otherwise, the toes curl around the end of the other toes. There is usually a wide space between the first and second toes. In the newborn, the clubfoot is best treated by serial casting, gradually bringing the foot to equinus is the most dramatic component of the deformity. The forefoot is usually plantarflexed on the hind foot, and the first toe is usually more plantarflexed than the other toes.

Congenital Muscular Dystrophy
The term "congenital muscular dystrophy" is used to describe an autosomal recessive group of disorders that present with muscle weakness at birth or shortly thereafter and a dystrophic pattern on muscle biopsy. Neonatal hypotonia is typical, but some children present with joint contractures (which may be an arthrogrypotic picture). The condition tends to remain static, but there may be slow progression or, alternatively, functional improvement and achievement of walking ability. Respiratory and swallowing problems depend on the severity of the weakness. The CPK may be slightly elevated, EMG reveals a myopathic pattern, and the muscle biopsy indicates severe dystrophic changes (87.224.384).

A number of syndromes of congenital muscular dystrophy in association with central nervous system involvement have been described: Fukuyama-type congenital muscular dystrophy, muscle-eye-brain disease, and the Walker-Warburg syndrome (87.124.125.199). Children with congenital muscular dystrophy have severe mental retardation and guarded prognoses. A subgroup of children with classical congenital muscular dystrophy with white matter changes in the brain lack laminin M (merosin), an extracellular protein (97.45).

Orthopaedic care includes obtaining a muscle biopsy, treating contractures, and correcting deformities (182.251.370). Mild contractures respond to therapy and splinting but tend to recur. Rigid and recurrent deformities are difficult and are treated as described in the section on arthrogryposis.

MYOTONIC SYNDROMES
Pathology
Myotonia is characterized by a sustained or relaxed relaxation of skeletal muscle after cessation of voluntary contraction or mechanical stimulation. It does not occur spontaneously but is initiated by voluntary contraction or stimulation and is usually accentuated by cold or periods of rest (74). Myotonia is seen in a number of illnesses, such as myotonic dystrophy, myotonia congenital, parahyponia congenital, Schwartz-Jampel syndrome, drug-induced myotonia, and muscle contracture induced by exercise (80.227.344.372). Significant orthopaedic deformities occur in myotonic dystrophy and in Schwartz-Jampel syndrome, which is rare.

Myotonia is best demonstrated clinically by muscle contractions after a blow to the muscle belly by a reflex hammer or by a hand-grasp test, in which the patient grasps the observer's hand, tries to release, but immediate relaxation fails and an unwinding motion of the fingers must occur to unclasp the hand (34). In infants, myotonia may be manifested by delayed opening of the eyes after closure with crying. EMG demonstrates a characteristic pattern and confirms the clinical myotonia. The frequency of discharge is initially increased, followed by a gradual decrease and cessation, which produces an acoustic pattern that sounds like a dive bomber.

Myotonic Dystrophy
Myotonic dystrophy (Steinert's disease) is an autosomal dominant disorder characterized by myotonia, a progressive dystrophic process of muscle leading to weakness and atrophy and various endocrine and systemic abnormalities (48.60.75.374). The molecular abnormality is an unstable expansion of DNA with a variable number of trinucleotide repeats in the myotonia protein gene on chromosome 19 (12.35.45.123.151.152.157.216.291.298).

This disorder is classified into congenital and adult forms, which are very distinct.

Congenital Myotonic Dystrophy
Congenital myotonic dystrophy occurs almost entirely in children born to mothers with myotonic dystrophy (Fig. 178.114). Myotonic mothers usually have premature onset of labor, postpartum hemorrhage, and poor uterine tone, which predisposes the infant to cerebral damage and static encephalopathy (ie, cerebral palsy). The pregnancy is frequently complicated by poor fetal movements and hydramnios. In children with severe encephalopathy, an underlying myotonia can be overlooked. The child appears to have only a complex form of cerebral palsy, but evaluation of the mother demonstrates the characteristics of myotonia, and the diagnosis in the child can be suspected. In the neonatal period, the main characteristic features are hypotonia with difficulty in sucking and respiratory distress (27). The neonate frequently has facial paresis and a triangular, fish-shaped mouth, with the upper lip forming an inverted V. Mental retardation is common, and the mean IQ is approximately 66 (51). There is marked wasting of the sternocleidomastoid and trapezium muscles, and in most patients, muscle function improves in the first decade of life. Most of these children walk by age 4 or 5 years. Cataracts usually do not occur until about 14 years of age. Conduction abnormalities and myocardial dysfunction are common, and these children routinely require electrocardiograms and echocardiograms routinely (118).

Almost all children with congenital myotonic dystrophy have orthopaedic problems, including talipes equinovarus, congenital dislocation of the hip, severe truncal weakness, and contractures of the extremities (167). Children with congenital myotonic dystrophy should be treated aggressively orthopaedically because their conditions improve for several years after birth (24.51.153.154.246.351.358).

About half of the children with congenital myotonic dystrophy have talipes equinovarus (262) (Fig. 178.11). The talipes equinovarus is not a typical clubfoot. The equinus is the most dramatic component of the deformity. The forefoot is usually plantarflexed on the hindfoot, and the first toe is usually more plantarflexed than the other toes. There is usually a wide space between the first and second toes. In the newborn, the clubfoot is best treated by serial casting, gradually bringing the foot to the neutral position. There is considerable variation in the stiffness of the foot, from a rigid foot to a hypotonic positional deformity. In most patients, the foot can be casted to a neutral position. Careful attention should be given to the toe plate on the cast to maintain a neutral position; otherwise, the toes curl around the end of the cast, resulting in an increasingly severe toe deformity. The most resistant component of the clubfoot is usually the equinus deformity; therefore, attention should be directed toward molding the cast at the longitudinal arch of the foot, so that a breach of the arch will not occur. After the foot is casted to a neutral position, it must be maintained until ambulation begins. Frequently, these patients are severely hypotonic, and walking may be delayed until they are 3 to 4 years old, making prolonged maintenance a difficult orthopaedic problem. Bivalved casts are most useful, although they have a tendency to slip distally on the foot, and orthoses require frequent modifications to accommodate growth.

A few patients develop severely rigid equinovarus feet that cannot be corrected with serial casting and thus require surgical correction. We recommend that surgical
procedures not be performed before the child is 1 year of age, because the children are exceedingly hypotonic, and the risks of anesthesia and subsequent surgical complications are high. A premedication dose of midazolam usually prevents the child from crying in the procedure room, and sedation allows a comfortable performance of the surgery. The postoperative care is similar to that for Charcot-Marie-Tooth disease (type I).

Structural hypophosphatemia develops slowly over the childhood years in some children (67). An orthosis typically prevents progression in the childhood years until the pubertal growth spurt, when progression occurs. Spinal fusion and instrumentation is effective, but mesenteric artery syndrome has been reported and experienced by the authors (67).

Adult Myotonic Dystrophy

In the adult form of myotonic dystrophy, symptoms become noticeable in late adolescence or early adult life, although myotonia may be present in childhood. Muscle cramps, naris voice character, and progressive weakness are observed first. The facial muscle atrophy of the temple, jaw, and neck muscles produces a lower lip droop called an inverted smile and a characteristic “hatchet-face” or “swan-neck” facies. The muscle weakness is more prominent distally, especially in the calf muscles and forearms, but the intrinsic muscles of the hands and feet frequently are spared until later in the disease. Smooth muscle may be involved, resulting in dysphagia, recurrent pulmonary infections, and lower gastrointestinal tract dysfunction (135). Cataracts, frontal baldness, mild mental retardation, and cardiac abnormalities are also seen. The endocrine abnormalities result in abnormal glucose tolerance and insulin release, with frank diabetes mellitus, hypothyroidism, and gonadal dysfunction (171). Deep tendon reflexes are usually absent or diminished in the distal muscles, and the disease is progressive until death in the fifth to sixth decade of life from cardiorespiratory compromise.

Laboratory tests frequently show a slightly elevated CPK level, hypogammaglobulinemia with low IgA, and a glucose tolerance test of the diabetic type (143). The EMG demonstrates typical myotonia. The muscle biopsy shows changes that include internal nuclei and type I fiber atrophy.

Orthopaedic problems are associated with weakness of the neck muscles, pain, or mild subluxation that usually responds symptomatically to a soft cervical collar. Equinus deformity of the foot may be controlled by an ankle-foot orthosis. Occasionally, a pes cavusus or pes planus deformity develops, and orthotic devices typically resolve painful callouses. If a rigid foot deformity causes pain and instability, a triple arthrodesis to realign the hind foot and midfoot is helpful. Toe deformities consist of a flexion and a valgus deformity of the hallux, which may curl under the second toe. The second to fifth toes develop flexion contractures of the distal interphalangeal joints with dorsal callus formation. If these deformities are severe, the hallux is treated by an osteotomy of the middle phalanx with realignment and Steinmann pin fixation, and the second through fifth toes are treated by partial phalangeotomy of the distal aspect of the proximal phalanx and internal fixation with Kirschner wires. These surgical techniques are described later in the section on peripheral neuropathies.

Anesthetic complications are common, and careful preoperative evaluation is important (220).

COMMON NERVE DISORDERS WITH ORTHOPAEDIC DEFORMITIES

PERIPHERAL NEUROPATHIES

A neuropathy is a condition of a peripheral nerve that may have motor signs manifested as weakness or decreased deep tendon reflexes; sensory abnormalities, which are usually more severe distally than proximally; or autonomic changes, resulting in impaired sweating, atrophy of the skin, or loss of hair.

The neuropathies are categorized as mononeuropathy, which is limited to a nerve, nerve root, or plexus (e.g., entrapment syndrome, brachial plexus injury, Bell's palsy); mononeuropathy multiplex, which involves multiple peripheral nerves (e.g., polyarteritis nodosa); and acquired polyneuropathies (e.g., diabetes, vitamin deficiencies, alcoholic neuropathy, drug-induced neuropathy, collagen vascular disease, genetic polyneuropathies such as Charcot-Marie-Tooth disease). Peripheral neuropathy, demyelinating polyneuropathy, myasthenia, encephalopathy, and recurrent infection are associated with acquired immune deficiency syndrome (AIDS) (171, 208). The incidence of neuromuscular disease in AIDS patients is unknown, but the diagnosis must be considered in inflammatory polyneuropathy or myopathy. Complex orthopaedic problems occur in many of the neuropathies.

The hereditary neuropathies are a group of genetically determined diseases with nerve fiber degeneration or segmental demyelination. The pathology of nerve fiber degeneration involves a “dying-back” phenomenon that usually begins peripherally in the longest nerve fibers. Segmental demyelinating diseases involve inadequate peripheral myelination by the Schwann cells and result in slowed nerve conduction velocities.

The hereditary neuropathies are classified as hereditary motor and sensory neuropathies (e.g., Charcot-Marie-Tooth disease), hereditary sensory neuropathy (e.g., congenital absence of pain), spinocerebellar degeneration (e.g., Friedreich's ataxia), and metabolic defects with neuropathy. The hereditary metabolic neuropathies are rare and include metachromatic leukodystrophy (ie, sulfatide lipidosis), Bassen-Kornzweig syndrome (ie, beta-lipoproteinemia), infantile and juvenile amaurotic idiocy, globoid cell leukodystrophy (ie, Krabbe’s disease), angleroketoma corporis diffusum (ie, Fabry’s disease), Chediak-Steinbrinck-Higashi syndrome, Tangier disease (ie, alpha-lipoproteinemia), and Cockayne's syndrome.

Hereditary Motor and Sensory Neuropathy

The hereditary motor and sensory neuropathies are an inherited group of diseases of peripheral nerves with sensory and motor involvement. The general characteristics include distal symmetric muscle weakness, manifested by equinus feet, steppage gait, cavus feet, and loss of fine motor function in the hands; there is a mild sensory abnormality, usually causing poor balance and clumsiness and decreased deep tendon reflexes. Evaluate any patient with distal muscle weakness and sensory abnormalities for the possibility of hereditary motor and sensory neuropathy. The disorders have been classified according to clinical manifestations, pathology, heredity, and electrophysiologic changes (72, 92, 94, 95, 130, 141, 149, 185-186, 264, 277, 278, 324) (Table 178.2).

Table 178.2. Classification of Hereditary Sensory-Motor Neuropathies

Hereditary sensory and motor neuropathy types I and II are most common and constitute the classic forms of Charcot-Marie-Tooth disease, which is also called peroneal muscular atrophy (64, 134). The hypotrophic form of Charcot-Marie-Tooth disease (type I) is associated with segmental demyelination, reduced nerve conduction velocity, and an enlarged palpable sural nerve with an insidious onset in the first or second decade of life. There is a broad range of clinical severity. The progression is slow, although a wheelchair is often required in middle to late adult life. Type IIA is usually caused by a duplication of a gene on chromosome 17 for conduction velocity, and an enlarged palpable superficial nerve with an insidious onset in the first or second decade of life. There is a broad range of clinical severity.

The neuropathies are categorized as mononeuropathy, which is limited to a nerve, nerve root, or plexus (e.g., entrapment syndrome, brachial plexus injury, Bell's palsy); mononeuropathy multiplex, which involves multiple peripheral nerves (e.g., polyarteritis nodosa); and acquired polyneuropathies (e.g., diabetes, vitamin deficiencies, alcoholic neuropathy, drug-induced neuropathy, collagen vascular disease, genetic polyneuropathies such as Charcot-Marie-Tooth disease). Peripheral neuropathy, demyelinating polyneuropathy, myasthenia, encephalopathy, and recurrent infection are associated with acquired immune deficiency syndrome (AIDS) (171, 208). The incidence of neuromuscular disease in AIDS patients is unknown, but the diagnosis must be considered in inflammatory polyneuropathy or myopathy. Complex orthopaedic problems occur in many of the neuropathies.

The hereditary neuropathies are a group of genetically determined diseases with nerve fiber degeneration or segmental demyelination. The pathology of nerve fiber degeneration involves a “dying-back” phenomenon that usually begins peripherally in the longest nerve fibers. Segmental demyelinating diseases involve inadequate peripheral myelination by the Schwann cells and result in slowed nerve conduction velocities.

The hereditary neuropathies are classified as hereditary motor and sensory neuropathies (e.g., Charcot-Marie-Tooth disease), hereditary sensory neuropathy (e.g., congenital absence of pain), spinocerebellar degeneration (e.g., Friedreich's ataxia), and metabolic defects with neuropathy. The hereditary metabolic neuropathies are rare and include metachromatic leukodystrophy (ie, sulfatide lipidosis), Bassen-Kornzweig syndrome (ie, beta-lipoproteinemia), infantile and juvenile amaurotic idiocy, globoid cell leukodystrophy (ie, Krabbe’s disease), angleroketoma corporis diffusum (ie, Fabry’s disease), Chediak-Steinbrinck-Higashi syndrome, Tangier disease (ie, alpha-lipoproteinemia), and Cockayne's syndrome.

Hereditary Motor and Sensory Neuropathy

The hereditary motor and sensory neuropathies are an inherited group of diseases of peripheral nerves with sensory and motor involvement. The general characteristics include distal symmetric muscle weakness, manifested by equinus feet, steppage gait, cavus feet, and loss of fine motor function in the hands; there is a mild sensory abnormality, usually causing poor balance and clumsiness and decreased deep tendon reflexes. Evaluate any patient with distal muscle weakness and sensory abnormalities for the possibility of hereditary motor and sensory neuropathy. The disorders have been classified according to clinical manifestations, pathology, heredity, and electrophysiologic changes (72, 92, 94, 95, 130, 141, 149, 185-186, 264, 277, 278, 324) (Table 178.2).

Table 178.2. Classification of Hereditary Sensory-Motor Neuropathies

Hereditary sensory and motor neuropathy types I and II are most common and constitute the classic forms of Charcot-Marie-Tooth disease, which is also called peroneal muscular atrophy (64, 134). The hypotrophic form of Charcot-Marie-Tooth disease (type I) is associated with segmental demyelination, reduced nerve conduction velocity, and an enlarged palpable sural nerve with an insidious onset in the first or second decade of life. There is a broad range of clinical severity. The progression is slow, although a wheelchair is often required in middle to late adult life. Type IIA is usually caused by a duplication of a gene on chromosome 17 for conduction velocity, and an enlarged palpable superficial nerve with an insidious onset in the first or second decade of life. There is a broad range of clinical severity.
Cavus Feet

Cavus feet (Fig. 178.12A) are commonly seen in peripheral neuropathies, spina bifida, polymyelitis, Friedrich's ataxia, spinal cord lesions, and several less common neurologic illnesses. The pathogenesis involves muscle imbalance, but the specific mechanism is unknown (32,33,252,283,287). A cavus foot has a pathologic elevation of the longitudinal arch of less than 150° on the lateral radiograph at the intersection of the axis of the first metatarsal and the calcaneus (169). There are three forms of pes cavus, as determined by the orientation of the os calcis during stance: pes cavovarus if the os calcis is inverted; pes calcaneocavus if the os calcis pitch (long axis of the os calcis to the floor) is greater than 30° or the long axis of the tibia to the long axis of the os calcis is greater than 130°, and pes equinocavus if the os calcis pitch is less than 20° (287).

Figure 178.12. A: A cavus foot in a patient with Charcot-Marie-Tooth disease. B: A cavus foot, demonstrating heel varus during stance. The depression of the first metatarsal forces the foot into varus. C: The Coleman block test, demonstrating the flexibility of the hindfoot. When the depressed first metatarsal is allowed to hang off the block, the heel is no longer forced into varus during stance.

In Charcot-Marie-Tooth disease, a pes cavovarus deformity combined with decreased proprioception results in difficulty in walking, lack of balance, and painful callouses. The peripheral neuropathy initially causes weakness of the intrinsic muscles of the foot and peroneal muscles, resulting in a footdrop drop, relative shortening of the long toe extensors because of the footdrop drop, and hyperextension at the metatarsalphalangeal joints. Hyperextension leads to a secondary tightening of the long toe flexor tendons and to flexion of interphalangeal joint and a claw toe deformity. The posterior tibialis muscle initially remains strong, and the first metatarsal drops more than the remainder of the foot. During stance, the plantarflexed first metatarsal forces the foot into supination, and contracture of the relatively strong posterior tibialis tendon holds the heel in varus (Fig. 178.12B). Initially, the foot is flexible, but the plantar fascia also shortens, contributing to the depression of the first metatarsal and a fixed varus deformity of the heel. The rigidity of the heel varus is determined by the Coleman lateral block test (Fig. 178.12C), in which a plantarflexed first metatarsal is allowed to hang over a 2.5 cm block, eliminating the forced forefoot pronation (negating the tripod effect); if the heel returns to a neutral position with this maneuver, the hindfoot deformity is not fixed (36,58,252). Therefore, attention may be directed toward the midfoot and forefoot.

The patient progressively becomes more clumsy, and as the cavovarus deformity becomes more rigid, painful calluses develop over the heel, the base of the fifth metatarsal, and the head of the first metatarsal (tripod foot). Subsequent bony adaptations result in a rigid equinocavovarus foot deformity (Fig. 178.13).

Figure 178.13. A: A rigid cavus foot caused by Charcot-Marie-Tooth disease in a skeletally mature patient. B: Radiograph of a rigid cavus foot, demonstrates the elevated longitudinal arch, heel varus, hypertrophy of the fifth metatarsal, and claw toes.

Treatment of the cavus foot depends on the patient's age, flexibility of the foot, bony deformity, and muscle imbalance. In the early stages, the whole foot may be slightly supinated, the arch moderately elevated, and the great toe slightly cocked upward. As soon as the diagnosis is confirmed, begin daily manipulation of the foot to resist the depression of the first metatarsal, stretching of the plantar fascia and tendo Achilles, and extension of the toes. A nighttime ankle-foot orthosis in a neutral ankle position is recommended to prevent the foot from dangling into the equinus posture during sleep and to delay the onset of a fixed deformity. A supply foot can be treated nonoperatively by manipulation followed by serial stretching in a short walking cast, followed by an ankle-foot orthosis with a rigid ankle in neutral position and a lateral heel extension to resist varus.

If fixed soft-tissue or bony deformity develops, surgery becomes necessary to maintain a plantigrade foot. The goals of surgery are to correct deformity, restore muscle balance, and stabilize the foot. Rigid deformities, usually consisting of a heel varus and a plantarflexed first metatarsal, must be corrected before tendon lengthening. In children younger than 12 years of age, triple arthrodesis is contraindicated (364). Other procedures that can be performed include a plantar medial release to reduce the midfoot contracture; extension osteotomy of the first metatarsal to correct a rigid plantarflexed first metatarsal; transfer of the extensor hallucis longus tendon to the neck of the first metatarsal and interphalangeal fusion (Jones procedure); transfer of the extensor digitorum longus tendons to the third cuneiform (Hibbs procedure); transfer of the posterior tibialis tendon through the tubifibular intersosseous membrane to the dorsum of the foot to remove a deforming force and achieve dorsiflexion of the ankle; Dwyer or medial translation calcaneal osteotomy to correct heel varus if the heel does not correct with the Coleman block test; and a metatarsal osteotomy to correct the forefoot (30,91,161,181,273,297,302,333,358,361). In children younger than 8 to 10 years of age, the heel and first ray are usually flexible and will correct with soft-tissue releases and serial casting. Hindfoot equinus and tendo Achilles contracture are often present. Tendo Achilles lengthening should not be performed simultaneously with the plantar medial release because it is important to have a stable hindfoot to allow correction of the longitudinal arch with serial casting. In the older child with greater weakness, a rigid hindfoot, and fixed plantar flexion of the first metatarsal, the plantar medial release is combined with an extension osteotomy of the first metatarsal (and adjacent metatarsals if required), calcaneal osteotomy, and a posterior tibialis tendon transfer to the dorsum of the foot (Fig. 178.14A, Fig. 178.14B). In the skeletally immature, avoid damage to the first metatarsal physis when performing proximal osteotomies.
Plantar Medial Release (Modified Steindler Procedure)
Postoperatively, allow weight bearing after 2 weeks, and remove the cast and Kirschner wire 6 weeks after surgery.

Jones Procedure
Calcaneal Osteotomy for Pes Cavovarus Deformity (Dwyer Procedure)
Transfer of the Common Extensor Tendon to the Third Cuneiform for Claw Toe Deformities (Hibbs Procedure)

Long-term review of patients with triple arthrodesis indicates satisfactory results, but there is a high incidence of radiologic ankle and midfoot arthritis (289,364). A study of triple arthrodesis using force plate analysis demonstrates increased midfoot load bearing and load concentration under the metatarsal heads (126). The incidence of pseudarthrosis, typically in the talonavicular joint, is reported to occur up to 25% of the time. This can be symptomatic and require revision surgery (289).

Transfer of the Common Extensor Tendon to the Third Cuneiform for Claw Toe Deformities (Hibbs Procedure)

| Make a slightly curved, longitudinal incision on the dorsum of the common extensor tendons, centered over the third cuneiform (126). |
| Incise the subcutaneous tissue by sharp dissection, and protect any neurovascular structures. |
| Divide the common extensor tendons as far distally as possible. |
| Drill a 6.3 mm diameter hole in the third cuneiform from dorsal to plantar. |
| With a pullout suture, draw the proximal ends of the common extensor tendons into the drill hole, and secure the pullout suture on the plantar surface over a padded button. |
| Close the wound, and apply a well-padded short-leg cast for 6 weeks. |

Midtarsal Tarsal Wedge Osteotomy for Cavus Deformity (Cole Procedure)

| Make a dorsolongitudinal skin incision over the extensor tendons to the third and fourth toes, beginning just proximal to the midtarsal joints and extending distally through the middle of the metatarsals (67). |
| Separate the extensor tendons to the third and fourth toes, and excise the periosteum overlying the tarsal bones. |
| Identify the tarsal bones radiographically. |
| Perform a dorsally based wedge osteotomy centered over the navicular medially and the cuboid laterally to include the navicular cuneiform joints. The width of the wedge is determined by the severity of the deformity to be corrected. |
| Remove the dorsal wedge, and elevate the forefoot to close the wedge osteotomy. Be sure to correct for rotation deformities (e.g., pronation, supination) of the forefoot at this time. |
| Close the periosteum with interrupted sutures, and approximate the skin. Apply a short-leg plaster cast from the toes to the knee. Adequate healing is usually obtained within 4 weeks. |

Calcaneal Osteotomy for Pes Cavovarus Deformity (Dwyer Procedure)

| Expose the lateral area of the calcaneus through an incision parallel, posterior, and inferior to the peroneus longus tendon (69). |
| Strip the periosteum of the lateral area of the calcaneus superiorly and inferiorly. |
| Remove a laterally based wedge of bone from the calcaneus just posterior, inferior, and parallel to the peroneus longus tendon. The medial edge of the wedge should not penetrate the medial cortex of the calcaneus. |
| Correct the varus deformity of the calcaneus by closing the osteotomy and fracturing its medial cortex. dorsiflex the forefoot against the pull of the tendon Achilles to stabilize the osteotomy. The varus deformity should be corrected with the heel in neutral or slight valgus position. |
| Close the wound and immobilize the foot in a short-foam cast until the osteotomy is healed in about 6 weeks. |

Jones Procedure

| A Jones procedure is transfer of the extensor hallucis longus tendon to the neck of the first metatarsal and fusion of the interphalangeal joint. |
| Make a dorsolongitudinal 1.5 cm incision over the interphalangeal joint of the halluc (18). |
| Expose the extensor hallucis longus tendon, and cut it transversely 1 cm proximal to the interphalangeal joint. |
| Cut the dorsal capsule of the interphalangeal joint transversely, and excise the cartilaginous surfaces of the interphalangeal joint. |
| Insert a Kirschner wire from distal to proximal across the interphalangeal joint; cut the wire approximately 3 mm from the cutaneous margin, and bend it to prevent migration. |
| Close the skin by interrupted sutures. |
| Postoperatively, allow weight bearing after 2 weeks, and remove the cast and Kirschner wire 6 weeks after surgery. |

Plantar Medial Release (Modified Steindler Procedure)

| Make a longitudinal 4 cm incision along the medial side of the foot from the calcaneal tuberosity distally (325). Separate the plantar aponeurosis from the plantar foot muscles, and incise the plantar fascia transversely at the plantar surface of the calcaneus. |
| With a blunt periosteal elevator, lift the origins of the abductor hallucis muscle, the flexor digitorum brevis muscle, and the abductor digiti minimi muscle from the periosteum of the calcaneus. Avoid removal of cortical bone or periosteum with the fascia and muscle attachments. |
| Carry the dissection to the calcaneocuboid joint, releasing the quadratus plantae and the long plantar ligament. The entire dissection should be carried out near the periosteum of the calcaneus, avoiding neurovascular structures. |
| Postoperatively, allow weight bearing after 2 weeks, and remove the cast and Kirschner wire 6 weeks after surgery. |

Figure 178.14. Preoperative (A) and postoperative radiographs of a cavovarus foot (B). Surgery included a plantar medial release; extension osteotomy of the first metatarsal, Dwyer calcaneal osteotomy, and anterior transfer of the tibialis posterior tendon (note method of fixation of tendon at arrow).
the skin.

Postoperatively, maintain the cast for 6 weeks. Apply serial stretching casts on a weekly basis to obtain adequate correction, if desired, beginning about 1 week after surgery.

**Triple Arthrodesis**

- Make a straight 5 cm incision obliquely over the sinus tarsi, extending from the peroneus brevis tendon to the extensor tendons.
- Incise the capsule of the calcaneocuboid joint, and remove the articular surfaces with an osteotome.
- Then incise the lateral capsule of the talonavicular joint, and remove the articular surfaces of this joint with an osteotome. A small incision over the medial aspect of the talonavicular joint allows better visualization for cartilage removal.
- Incise the capsule of the subtalar joint. With an osteotome, excise the surfaces of the anterior, medial, and posterior articular facets of the subtalar joint. Carefully remove the medial borders of the subtalar joint so that the neurovascular bundle and tendons are not damaged.
- Remove wedges of bone as necessary to correct any deformity, and position the foot in the neutral position. Maintain the foot in the neutral position, and suture the reflected flap of the extensor digitorum brevis in the sinus tarsi. Fixation can be achieved with staples, Steinman pins, or cannulated screws.
- Close the wound and overlay it with a gauze dressing. Apply a well-padded long-leg cast as the foot is maintained in neutral position.

Postoperatively, triple arthrodesis typically requires 12 weeks to heal. In patients in whom continued ambulation and standing are necessary for maintenance of function, walking may begin as soon as tolerable, but periodic radiographs are necessary to verify proper foot position.

**Claw Toes**

The claw toe deformity (Fig. 178.16) is caused by intrinsic muscle weakness that allows the long toe flexor muscles to continue to flex the interphalangeal joint and the long toe extensor muscles to extend the metatarsophalangeal joint without stability provided by the weak intrinsic muscles. Callosities develop over the heads of the proximal phalanges from contact in the shoes and under the metatarsal heads. Initially, clawing is flexible and should receive daily manipulative therapy. Fixed clawing requires operative treatment, which is usually performed simultaneously with other procedures for the cavus foot. Our choice of treatment of the second to fifth toes includes a tenotomy of the long extensor tendons, dorsal capsulotomy of the metatarsophalangeal joint, and arthrodesis of the interphalangeal joint if the toes cannot come down into 20° of passive flexion.

**Figure 178.16.** A: Preoperative photograph of flexible claw toes in a patient with Charcot-Marie-Tooth disease. B: The toes corrected. C: Preoperative photograph of rigid claw toes in a patient with Charcot-Marie-tooth disease. D: Postoperative radiograph demonstrates straightening of the toes by an interphalangeal fusion with Kirschner wires.

- Stabilize the interphalangeal arthrodesis with intramedullary Kirschner wire fixation.
- Transfer the extensor tendons to the middorsal area of the foot to assist in active dorsiflexion of the foot, if desired (Hibbs procedure).
- For clawing of the hallux, transplant the long extensor tendon to the neck of the first metatarsal (Jones procedure), and perform interphalangeal joint fusion. Take care not to damage the extensor brevis tendon, or the hallux will drop.

**Extensor Tendon Tenotomy, Dorsal Capsulotomy of the Proximal Interphalangeal Joint, and Interphalangeal Fusion**

- Make a 1 cm dorsolongitudinal incision over the proximal interphalangeal joint of the toe.
- By sharp dissection, identify the common extensor tendon, and incise it transversely.
- Then incise the dorsal capsule of the proximal interphalangeal joint transversely, and expose the articular surface by flexing the toe.
- With an osteotome, excise the articular surfaces of the interphalangeal joint, and then close the incision.
- Extend the toe to a neutral position, and place a smooth Kirschner wire from the tip of the distal phalanx through the distal phalangeal joint and proximal interphalangeal joint to the proximal phalanx.
- Cut the Kirschner wire 0.5 cm from the tip of the phalanx and bend it at least 45° to prevent proximal migration.

After surgery, the toes are protected by a well-padded short-leg cast with the plantar surface extending well past the phalanges, or have the patient wear a hard-soled wooden shoe until interphalangeal arthrodesis has occurred in about 4 weeks.

**Scoliosis**

There is a 10% incidence of scoliosis in hereditary motor and sensory neuropathy types I and II (157). The other types of hereditary sensory-motor neuropathy also have associated scoliosis, but the incidence is unknown. Progressive curves between 20° and 40° in immature patients are treated by a thoracolumbosacral orthosis until maturity. The amount of progression after treatment is unknown. Progressive curves greater than 40° to 50° in immature patients are treated by a posterior spinal fusion and instrumentation. The patterns are similar to those seen in idiopathic scoliosis. The fusion should include the measured curve (i.e., Cobb method) and additional vertebrae as necessary to achieve adequate truncal balance because of the associated truncal weakness. No patients in our series have required fusion to the sacrum or to the cervical area. Because there is a high incidence of failure of somatosensory-evoked potential monitoring, preparation must be made for a wake-up test (195).

**Claw Hands**

Intrinsic muscle weakness (Fig. 178.17) interferes with fine motor coordination, as in writing, and wrist weakness makes sports and carrying heavy objects difficult. Most patients tolerate the weakness by adjusting their lifestyle or by using simple adaptive equipment. In some patients with type I hereditary sensory-motor neuropathy and moderate weakness, opponensplasty with intrinsic muscle reconstruction is helpful (234,375). Kling and Drennan (192) reported on a small group of patients with type II hereditary sensory-motor neuropathy who developed severe upper extremity atrophy, which leads to a functionless hand. An orthosis may help to maintain a neutral posture.
therapy is to teach the patient protective techniques and to use protective orthoses. Trauma, causing ulceration, osteomyelitis, and autoamputation of the phalanges. In childhood, ulcerations of the feet are most common (Neuropathic Ulcers) protection of the extremity, and excision of infected or necrotic bone may contain the infection, but uncontrolled infection may require amputation (eliminate repetitive trauma and should be treated aggressively with local care to obtain healing. After a joint is infected, the prognosis is poor. Antibiotic therapy, to prevent neurologic damage. Osteomyelitis by hematogenous or contiguous spread occurs frequently in Charcot joints. Cutaneous ulcers should be protected to become deformed. Periodic radiographic spinal evaluation should be performed to detect early Charcot changes of vertebrae and to allow treatment by a spinal fusion to prevent neurologic damage. Osteomyelitis by hematogenous or contiguous spread occurs frequently in Charcot joints. Cutaneous ulcers should be protected to eliminate repetitive trauma and should be treated aggressively with local care to obtain healing. After a joint is infected, the prognosis is poor. Antibiotic therapy, protection of the extremity, and excision of infected or necrotic bone may contain the infection, but uncontrolled infection may require amputation (Neuropathic Ulcers) Neurpathic ulcers are caused by repetitive trauma to an anesthetized area. In children, the hands may be mutilated by repetitive biting or other trauma, causing ulceration, osteomyelitis, and autoamputation of the phalanges. In childhood, ulcerations of the feet are most common (Fig. 178.19). The only effective therapy is to teach the patient protective techniques and to use protective orthoses.

**Hip Dysplasia**

Severe bilateral hip dysplasia has been reported in patients with onset of neuropathy in the first decade of life (198,357). The dysplasia can be asymptomatic or minimally symptomatic and may remain undetected until early adolescence. Children with Charcot-Marie-Tooth disease need to be evaluated radiographically to detect early dysplasia. Typically, the femur has mild coxa valga and anteverision, and the superolateral corner of the acetabulum is deficient, which allows lateral subluxation during ambulation (Fig. 178.17). The acetabular dysplasia is treated by redirection of the acetabulum by single, double, or triple innominate osteotomies or shelf arthroplasty, depending on the severity of the deformity (286,323). The Chiari procedure may be necessary if severe changes in the acetabulum prevent the femoral head from being fully reduced into the true acetabulum.

**Hereditary Sensory Neuropathies**

Hereditary sensory neuropathies are characterized by decreased specific sensory perceptions, painless ulcerations, and Charcot joints. There are four major hereditary sensory neuropathies: autosomal dominant hereditary sensory neuropathy, autosomal recessive hereditary sensory neuropathy, familial dysautonomia (Riley-Day syndrome), and familial sensory neuropathy with anhidrosis (248,259).

Patients with autosomal dominant hereditary sensory neuropathy have marked loss of sensation to pin prick and temperature in the lower extremities that can result in severe trophic changes. The upper extremities are less involved. A nerve biopsy shows a decreased number of myelinated sensory fibers. In autosomal recessive hereditary sensory neuropathy, the sensation of touch is more severely affected than those of pain and temperature, but the upper and lower extremities are severely affected, and nerve biopsy shows a total absence of myelinated sensory nerve fibers.

Familial dysautonomia, a disease of the peripheral nervous system secondary to a gene defect at the 9q31-33 locus, is characterized by a reduction in small and large myelinated nerve fibers. Clinical manifestations include a labile blood pressure, insensitivity to pain, abnormal gastrointestinal mobility, lack of fungiform papillae on the tongue, ataxia, areflexia and kyphoscoliosis. It occurs in Ashkenazi Jews with a prevalence of 1/3600. The children develop a progressive kyphoscoliosis, and death usually occurs in infancy or childhood from chronic pulmonary insufficiency and aspiration (287,268,379). Familial sensory neuropathy with anhidrosis is characterized by decreased temperature perception, intact touch sensation, absent axon reflex to histamine, below-normal intelligence, and anhidrosis. Orthopaedic problems in patients with hereditary sensory neuropathy include Charcot joints, joint dislocations, fractures, chronic osteomyelitis, and severe kyphoscoliosis (215,256). Treatment of spinal deformity is difficult because of the typical high rigid kyphosis, osteopenia, labile autonomic nervous system, and insensitivity to pain. Spinal fusion and instrumentation have a high incidence of complications but is beneficial (280). Charcot Joints A Charcot joint is characterized by a painless arthropathy in which the synovium is hypertrophic, ligamentous laxity causing joint instability, and eventual joint surface destruction. The lack of protective sensation allows unrestricted repetitive trauma, and large weight-bearing joints are most frequently and severely involved. Recurrent microtrauma causes synovial inflammation, hemarthrosis, periosteal elevation with subsequent cortical bone thickening, physseal widening, osteonecrosis, and osteochondritis dissecans. Minor trauma can lead to undetected dislocations and fractures (1,180,194).

Treatment initially involves protecting the joint from trauma by patient training, adaptive tools to reduce traumatic exposure, and protective orthoses. Joint instability usually can be treated by an orthosis, or if it is severe, a fusion can be attempted. Fusions are difficult to achieve and require prolonged immobilization; because delayed union and pseudarthrosis are common, augmentation with a bone graft is often required. A fusion also tends to transfer stress to adjacent joints, which can become deformed. Periodic radiographic spinal evaluation should be performed to detect early Charcot changes of vertebrae and to allow treatment by a spinal fusion to prevent neurologic damage. Osteomyelitis by hematogenous or contiguous spread occurs frequently in Charcot joints. Cutaneous ulcers should be protected to eliminate repetitive trauma and should be treated aggressively with local care to obtain healing. After a joint is infected, the prognosis is poor. Antibiotic therapy, protection of the extremity, and excision of infected or necrotic bone may contain the infection, but uncontrolled infection may require amputation (136). Neuropathic Ulcers Neuropathic ulcers are caused by repetitive trauma to an anesthetized area. In children, the hands may be mutilated by repetitive biting or other trauma, causing ulceration, osteomyelitis, and autoamputation of the phalanges. In childhood, ulcerations of the feet are most common (Fig. 178.19). The only effective therapy is to teach the patient protective techniques and to use protective orthoses.
Friedreich’s Ataxia

Friedreich’s ataxia (i.e., hereditary spino-cerebellar ataxia) is the most common spinocerebellar degenerative disease. It usually is autosomal recessive, although it may be autosomal dominant or sex linked (60). The gene abnormality is on chromosome 9 (56). The onset is at the end of the first decade and is characterized by progressive ataxia of the limbs and of gait, the presence of Romberg’s sign, absent knee and ankle reflexes, extensor plantar responses, dysarthria, scoliosis, pes cavus, weakness, loss of position and vibration sense in the legs, cardiomyopathy, and diabetes (88,131-292).

By the age of 15 years, most patients are severely ataxic; by 20 years of age (average, 15.8 years), most are confined to a wheelchair; and by 40 years of age (average, 36 years), death occurs from cardiopulmonary failure (47,160,339). Sural nerve biopsies show axonal degeneration; the central nervous system exhibits changes in the posterolateral columns of the spinal cord and cell loss in the deep cerebellar nuclei. Muscle biopsy reveals fiber group atrophy characteristic of denervation (68).

Although there is no known cure for Friedreich’s ataxia, treatment of the orthopaedic deformities of pes cavus and scoliosis substantially enhances the quality of life, especially in the less severely involved patient.

Foot Deformities
The foot deformities of Friedreich’s ataxia are an equinus foot, pes cavovarus, tripod stance, and claw toes. As in Charcot-Marie-Tooth disease, the intrinsic muscles are weak, with the foot everters and dorsiflexors being weaker than the foot inverters and plantar flexors, unlike the usual Charcot-Marie-Tooth disease, the severe ataxia causes a markedly unstable foot.

The goals of treatment are achieving a stable plantigrade foot, balancing muscle function, and correcting deformity. In the immature foot, which is almost always flexible, an ankle-foot orthosis and stretching exercises are usually sufficient. More rigid foot deformities occur during the adolescent years. Our preference for treatment of the cavus foot and instability is a triple arthrodesis; for the muscle imbalance, a transfer of the posterior tibialis tendon through the interosseous membrane to the dorsum of the foot is indicated; and for claw toes, an interphalangeal joint arthrodesis is preferred (217). These surgical techniques were previously described under peripheral neuropathies.

Scoliosis
Scoliosis occurs in more than 80% of patients presenting between ages 9 and 21 years and is relentlessly progressive, even after skeletal maturity (47,66,112,157,160,203). Scoliosis in this disorder is not a collapsing spine disorder, such as that seen in poliomyelitis. It is very similar to idiopathic scoliosis in its behavior. A thoracolumbar orthosis may be prescribed for a curve between 20° and 40°, but there is insufficient evidence to support the efficacy of this treatment, and at best, it only slows progression (47,66). The orthosis is poorly tolerated in ataxic, unstable ambulatory patients, because it eliminates trunk motion used to correct imbalance during gait. Nighttime bracing often is an acceptable compromise. For progressive scoliosis greater than 45° to 60°, extension of the fusion to the sacrum is at best, it only slows progression (47,66).

SPINAL MUSCULAR ATROPHY

Spinal muscular atrophy is a group of hereditary illnesses with proximal muscle weakness caused by degeneration of the anterior horn cells of the spinal cord and bulbar motor nuclei (337). The hypotonia is symmetric, the lower extremities are weaker than the upper extremities, there is no sensory loss or upper motor neuron signs, and fasciculations of the tongue and tremors of the hands are common (48,350). Cardiac function is not impaired. The prognosis for life expectancy depends on respiratory capacity. The spinal muscular atrophies are divided into several syndromes according to the severity of weakness, age at onset of symptoms, distribution of muscle weakness, and pattern of heredity (334) (Table 178.3). The clinical presentations of the syndromes vary and may overlap in the spectrum of syndromes (133). The most common forms are types I, II, and III (184,253-254).

Type I spinal muscular atrophy (i.e., Werdnig-Hoffmann disease) is the most severe illness. The onset occurs within the first 3 months of life, and the patient presents with progressive weakness and hypotonia with spontaneous movement confined to the toes, fingers, and hands. Infants with this disease are never able to develop head control or roll over, bulbar weakness results in difficulty in sucking, tendon reflexes are absent, and death usually occurs within the first year of life, before significant orthopaedic problems develop (40,155,353). Types I, II, and III are caused by abnormalities of the survival motor neuron gene (SMN) on chromosome 5.

In Type II spinal muscular atrophy (i.e., intermediate to severe spinal muscular atrophy) the infant develops normally for the first 6 months of life and learns to sit, but symmetric proximal muscle weakness ensues (155). The children never stand or walk. Fasciculations of the tongue and a fine motor tremor of the hand are helpful diagnostic signs. The weakness is moderate, with survival until late adolescence or early adult life. The patients must use a wheelchair, and they develop postural contractures of hip flexion, knee flexion, and foot equinus. Scoliosis is common, progressing rapidly and markedly reducing respiratory ability. Prognosis is related to the progressive muscle weakness and spinal deformity, which eventually lead to respiratory failure.

Type III spinal muscular atrophy (i.e., Kugelberg-Welander disease, mild spinal muscular atrophy) has an insidious onset in children from 2 to 12 years of age with episodes of weakness. Patients have a waddling gait, with difficulty in climbing steps and getting up from the floor. The prognosis is good, and there is only a minimal respiratory deficit. Patients tend to have flat feet (eversion of the foot), pelvic girdle weakness, a mild hand tremor, and scoliosis (129,195).

Evans and Drennan (157) group patients with spinal muscular atrophy according to function. Group I children are unable to sit independently and usually die in infancy of pulmonary failure. Group II patients develop head control, can sit independently, and usually survive until young adult life. Group III patients walk to stand and walk, and may live into the fourth decade. Group IV patients can walk, run and climb steps, but usually require wheelchairs by the third decade and have a long life expectancy (197,383). The major orthopaedic problems are spinal deformities, contractures, and hip instability.

Spinal Deformities

Spinal deformities develop in virtually all patients who are poor ambulators and in about half of those who initially learn to walk and run. The most common deformity is a long C-shaped scoliosis, and severe pelvic obliquity develops as the curve progresses. A kyphosis is usually associated with the scoliosis, and a progressive spinal deformity decreases pulmonary capacity and jeopardizes sitting posture (66,81,150,157,228,284). In a series of patients followed at the Alfred I. du Pont Hospital for Children (Wilmington, DE), the average age at onset of scoliosis was 7.6 years (range, infancy to 13 years) (8). In a mild deformity, a soft thoracolumbar-sacral orthosis with a large abdominal relief provides trunk support and may delay progression of the curve, but the orthosis must not compress the chest and further compromise respiratory function (229). Pulmonary function evaluations before and after application of the orthosis are used to determine safe parameters, because often an orthosis decreases the tidal volume by as much as 20% (8). In severely compromised patients, the posterior half of an orthosis may be used alone, but this is less effective. Typically, scoliosis is progressive, and when the curve reaches 40° to 45°, a posterior spinal fusion from the high thoracic area to the sacrum with internal fixation is...
recommended. In a child younger than 10 years old with a progressive scoliosis greater than 60°, surgery is indicated.

Before any anticipated surgical procedure, pulmonary evaluation must be performed. Severe postoperative respiratory problems are seen with a vital capacity less than 25% normal (226). An intense respiratory rehabilitation program, emphasizing inhalation strength, coughing, and maintenance of good pulmonary hygiene, can improve respiratory ability by about 15% to help during the postoperative period. After surgery, the pulmonary function usually returns to the preoperative level and gradually declines, but one study suggests an improvement (271).

We prefer segmental fixation with the Luque rods and Galveston pelvic fixation or the unit rod in this group of patients because they allow rapid postoperative mobilization, which helps in the general care and especially in pulmonary care (39,258). Patients with spinal muscular atrophy typically have severely osteopenic bone, and supplemental bone grafts are necessary to achieve an adequate fusion mass. Loss of pelvic fixation due to the rods cutting out of the ilium anteriorly requires revision because of pelvic perforation can occur (228). In young children with a large deformity and osteopenic bone, do not attempt an extensive correction, and use the smaller 1/4 or 3/8 inch rods. Rod connectors when using Luque rods prevent rod shift and increasing deformity. For 3 to 4 months postoperatively, a thoracolumbosacral orthosis can be used when the patient is sitting or standing to give additional support and to prevent the wires of the Luque rod or unit rod from pulling loose from the osteopenic bone. In patients with severe respiratory compromise with a large curve, the usual methods of internal fixation may be impossible, and halo-dependent traction followed by spinal fusion and limited instrumentation may be the only reasonable alternative. Anterior spinal fusions generally are not recommended in patients with spinal muscular atrophy because postoperative respiratory compromise is severe (6,228). Postoperative ventilation for 24 to 48 hours in an intensive care unit is often required. For all patients, the period of immobilization should be only a few days, and sitting or ambulation should be started as soon as tolerable, except for the rare problem requiring the halo-dependent technique. Even in this situation, the patient can be up in a wheelchair in overhead traction during the day.

Contractures

Contractures develop in the upper and lower extremities and are more frequently seen in the severely weak children. Flexion contractures of the elbow and adduction contractures of the shoulder are common but rarely a functional problem. Bedridden infants assume a frog-leg position, and lower extremity contractures occur with the hip in flexion abduction, the knee flexed, and the foot in equinus. Wheelchair-dependent patients develop flexion contractures of the hip and knee and equinovarus deformity of the foot (107). Ambulatory patients have only mild contractures, which seldom interfere with walking. A maintenance motion-therapy program with intermittent splinting can control most contractures, and surgery is seldom required. Soft-tissue procedures are effective in reducing contractures but are indicated only if a contracture inhibits some functional ability or becomes painful. Surgical releases are used to get these children into long-leg braces or a standing frame. Hip flexion contractures require release of the iliacus, sartorius, rectus femoris, and iliacposas. Knee flexion contractures require tenotomy of the medial and lateral hamstrings and iliotibial band. Foot deformities seldom require surgery, but a severe equinovarus contracture occasionally causes a skin ulceration on the foot. Tenotomy of the tendo Achilles and posterior tibialis tendon with manipulation and casting for 6 weeks with lightweight plastic material are usually adequate to correct the foot posture.

Hip instability is a common problem in the more severe types of spinal muscular atrophy (107,294,341). Hip dislocation was seen in 50% of the functional group I children (39,258). In group III, but up to 37% of group IV, according to an unpublished series. The highest incidence of hip pain occurred in the group II children. In children who are limited ambulators or confined to a wheelchair and have a mobile painless dislocated hip, nonoperative management is recommended.

POLIOMYELITIS

Poliomyelitis is an acute enteral illness that selectively involves the anterior horn cells of the spinal cord and the brain stem motor nuclei. New cases have been rare since prophylactic vaccines became available in the 1960s (282,283). The virus is transmitted by the oropharyngeal-fecal route, and humans are the reservoir. The incubation period is 6 to 20 days, and an estimated 1% to 2% of infected people develop neural symptoms. Coccoxavieiras and echoviruses produce a similar illness and should be considered in sporadic cases.

The illness is divided into three stages: acute, convalescent, and chronic. The acute stage begins with gastrointestinal symptoms (e.g., nausea, vomiting, sore throat), a febrile illness (usually less than 103°F), followed by meningeal symptoms (e.g., headache, nuchal rigidity, back pain, pain on straight-leg raising), and severe muscle pain. An asymptomatic paralysis occurs within 2 days of the meningeal symptoms and usually reaches its maximum within 48 hours. The legs are usually weaker than the arms, but weakness may occur in any muscle group, including the bulbar muscles. The most commonly involved muscles are the gluteal muscles, hip flexors, quadriceps, tibialis anterior, medial hamstrings, deltoid, triceps, and pectoralis major (299). There is no sensory loss, and the cerebrospinal fluid has a high protein level in the active stage. The EMG and muscle biopsy results show denervation. During the acute phase, patients should minimize activities (usually by bed rest), apply hot packs to painful muscles, position extremities in the anatomic position to prevent contractures, and perform general passive range of motion on all joints to the limits of tolerance (299). The acute stage ends when the temperature is normal for 48 hours and there is absence of progressive muscle involvement.

The convalescent stage begins 48 hours after the temperature has returned to normal and continues for as long as 2 years, during which time muscle strength improves spontaneously. The major recovery occurs in the first month, with the exception of the triceps surae and deltoid muscles, which improve much more slowly. Sharrard (300) reports recovery of muscle strength to average two grades above the level at 1 month and one grade above the level at 6 months. Orthopaedic treatment consists of restoring a full range of motion of joints, correcting contractures, and maximizing muscle strength. Overactivity of muscles in the early convalescent stage can inhibit functional return, and contractures of antagonistic muscles must be stretched before weaker muscles are exercised. Braces and orthoses may be used at night to prevent deformities and during therapy sessions to assist function. Equinus deformity of the foot requires a short-leg brace, and quadrieps weakness of grade IV or less requires a long-leg brace with knee-hinge locks.

The chronic stage begins 2 years after the onset of weakness, and no further muscle strength recovery is anticipated. Orthopaedic treatment consists of managing the chronic consequences of paralysis, muscle imbalance, and growth. Joint imbalance is classified into two types: flaccid joints (i.e., negative, static) and active joints with overactivity of muscles in the early stage. The EMG and muscle biopsy results show denervation. During the acute phase, patients should minimize activities (usually by bed rest), apply hot packs to painful muscles, position extremities in the anatomic position to prevent contractures, and perform general passive range of motion on all joints to the limits of tolerance (299). The acute stage ends when the temperature is normal for 48 hours and there is absence of progressive muscle involvement.

Orthopaedic treatment consists of prescribing orthoses, performing muscle-balancing procedures, and performing bony procedures (Table 178.4, Table 178.5, Table 178.6, Table 178.7 and Table 178.8). Orthoses can permanently stabilize a flaccid joint or augment function in a dynamically imbalanced joint. Spring-loaded orthoses are useful to counterbalance unopposed muscle tensions. Muscle-balancing procedures consist of tendon transfers, which produce joint stability and active motor power and eliminate deformity forces (292). The principles of tendon transfer demand that muscle of normal or good strength must be used because typically one grade of strength is lost after a transfer, and loss of function of the transferred muscle must be balanced or an iatrogenic deformity will occur (158,221,236,244). The joint to be moved by the transferred tendon must be free of deformity and have an acceptable range of motion, or the transferred tendon cannot overcome the deformity. The excursion and strength of the transferred muscle must be similar to those of the muscle being replaced, and good surgical technique is essential. The tendon must be routed straight from its origin to its insertion, have a smooth gliding channel, and be placed under tension. Postoperative management of a transferred tendon usually includes immobilization for 4 weeks with the joint in a slightly overcorrected position, followed by guarded motion for an additional 3 to 4 weeks. Postoperative muscle training is important to obtain optimal function of transferred tendons.

Note: Table 178.4 is a summary of the procedures used for the treatment of the involved hip in poliomyelitis. The procedures are selected based on the specific needs of the patient and the stage of the disease. The table includes tendon transfers, soft-tissue procedures, orthoses, muscle-balancing procedures, and bony procedures. The procedures are designed to restore joint stability, balance muscle function, and improve mobility and function. The table also includes a list of references for further reading.

Table 178.8. Selected Procedures for the Treatment of the Involved Foot and Ankle in Poliomyelitis

Bony procedures are directed toward correcting fixed deformities and stabilizing joints (66.205.242.243). Residual growth and loss of joint function must be considered before performing a bony procedure. Ideally, bony procedures are not performed until the patient reaches about 12 years of age, when adequate growth has been achieved.

ARTHROGYPYSIS

Arthrogryposis multiplex congenita is a nonprogressive disorder associated with neurogenic and myopathic disease. It is characterized by rigid or dislocated joints, muscle atrophy or aplasia, fusiform or cylindrical extremities with thin subcutaneous tissue and lack of skin creases, and normal sensation and intelligence (3,19,79,119,255,275,276,326). The pathogenesis involves severe weakness during early intrauterine life that restricts fetal mobility, with subsequent loss of muscle mass and contractures of joints. All extremities are involved in 46% of patients with arthrogryposis, only lower extremities in 43%, and only upper extremities in 11% (335). Serum CPK, chromosomal analysis, EMG, and nerve conduction studies are rarely helpful in diagnosis, but a muscle biopsy may show neuropathic or myopathic changes. More than 90% of these patients have neurogenic illnesses, and 7% have myogenic disorders (18,342).

Although more than 150 conditions have been associated with congenital contractures, amyoplasia congenita or arthrogryposis multiplex congenita accounts for the classic form of arthrogryposis that is characterized by symmetric contractures; internally rotated shoulders, extended elbows, markedly flexed hands and wrists, flexed or extended knees, severe talipes equinovarus, frequently dislocated hips, and a port-wine stain over the forehead area (122,146). Even though these patients are severely disabled, many develop ambulatory potentials; 46.6% have independent ambulation, 33.3% walk with braces, and 20% use wheelchairs (323). Another infrequent form of arthrogryposis is distal arthrogryposis, which has autosomal dominant transmission with variable penetrance. The hands and feet are primarily involved, but knees and hips occasionally are affected (147).

The combination of weakness and stiffness of joints in arthrogrypotic patients produces severe disabilities, and the goals of orthopaedic treatment are to obtain the maximum range of motion of joints and maintain the extremities in a functional position. Twenty-five percent of infants with multiple congenital contractures sustain birth fractures (usually of the femoral shaft) or epiphyseal separation, which are attributed to difficult deliveries. If they are not displaced, these fractures heal rapidly with splint immobilization (76).

Contracts

Initial therapy for all contractures consists of passive stretching and serial splinting to improve joint motion (132,251). Passive stretching exercises are performed at least four times daily and are guided by the patient's parents, who are trained and supervised by physical therapists. Avoid rigid cast fixation for most patients. Many
parents tend to exercise the extremity as a unit, and this should be discouraged; specific attention should be directed to passive stretching of independent joints. After each joint is passively stretched, apply thermoplastic splints between sessions to maintain position. The thermoplastic splints require frequent modifications as the patient grows and the joint mobility increases. In the knee and elbow, the contractures may be so severe that radiographs are occasionally necessary to determine the proper plane for passive flexion and extension exercises.

### Upper Extremity Deformities

The goals of treatment of the upper extremity in children with arthrogryposis are to provide an extremity that can be brought to the mouth and stabilized for feeding and to provide for toilet care or pulling up from sitting (370).

Passive stretching exercises have been the most successful to obtain motion, but the wrist, shoulder, and fingers are the most resistant. The elbow achieves the most significant benefit from the stretching therapy, and mild changes substantially improve the ability to dress, self-feed, and care for personal hygiene. Defer most surgery until the patient is old enough to demonstrate functional achievements (211).

A derotation osteotomy of the humerus is occasionally useful if the hand is in a nonfunctional position from shoulder rotation. Perform the derotation osteotomy at the proximal third of the humerus, and immobilize the site in a shoulder spica cast until healing occurs. Tricepsplasty (i.e., lengthening of the triceps tendon and posterior capsulotomy of the elbow joint) is recommended by Williams (369) to restore motion to the extended elbow (235). Unfortunately, some motion is lost with growth. Flexor muscle power can be facilitated by triceps tendon transfer, but this is done at the expense of active extension. In our experience, the posterior transfer by fascia lata extension through to the ulna has been most desirable. The maintenance of the triceps function is very helpful for the mobility of the patient. Transfer of function can be successful only if an adequate range of motion has been obtained by conservative or, if necessary, surgical methods.

The wrist flexion deformity can be managed by a proximal row carpectomy or wrist fusion toward the end of growth. Surgery of small joints of the hand has not been successful in achieving motion or improving function (21).

### Tricepsplasty and Posterior Capsulotomy of the Elbow (Williams Procedure)

- Make a posterolongitudinal incision from the distal third of the triceps tendon to 2 cm inferior to the olecranon.
- Expose the triceps tendon, and incise it as an inverted V just below the musculotendinous junction.
- Reflect the insertion of the triceps tendon distally, and incise the capsule between the humerus and olecranon. Gently flex the elbow. Tight collateral ligaments and occasionally the radioulnar capsule may require division to obtain adequate flexion.
- Protect the ulnar nerve by removing it from its sheath and allowing it to prolapse forward if any tension develops. The elbow should flex to at least 90°.
- Repair the triceps tendon in the lengthened position by the V-Y technique, and close the wound.
- Postoperative immobilization is necessary for 10 days, after which physical therapy is instituted to maintain the increased range of motion.

### Steindler Flexorplasty of the Elbow

A Steindler flexorplasty of the elbow to restore active elbow flexion is indicated if there are active, strong forearm pronator and flexor muscles (e.g., pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum sublimis, flexor carpi ulnaris), the elbow has adequate motion, the triceps muscle extends the elbow, and the elbow flexor muscles are paralyzed.

- Make an approximately 9 cm curved longitudinal incision over the medial side of the elbow, beginning about 7 cm proximal to the medial epicondyly, extending over the posterior aspect of the medial epicondyly, and ending distally on the volar surface of the forearm along the pronator teres muscle. Identify the ulnar nerve.
- Remove the common attachment of the flexors to the medial epicondyly with an osteotome.
- Free the muscles distally for about 4 cm.
- Flex the elbow, and reattach the excised medial epicondyly with its muscles to the humerus with a screw or strong sutures 5 cm proximally at the intermuscular septum between the brachialis and triceps.
- Close the wound, and apply a cast with the elbow flexed and the forearm supinated.

Postoperatively, the cast is worn for about 6 weeks, after which begin active training.

### Transfer of the Pectoralis Major Muscle to the Ulna with Fascial Graft

- Place the patient in a supine position, with the arm held in mild abduction and the elbow extended.
- Use two incisions. Make the first incision from the inferior half of the axillary crease distally to the level of the middle third of the humerus. Expose the insertion of the pectoralis major muscle, and free it from the humerus.
- Make a transverse incision at the anterior aspect of the elbow. Carry dissection down bluntly to the anterior surface of the ulna.
- Using the tip of the olecranon as a guide, expose the ulna anteriorly about 2 cm distal to this point.
- Incise the periosteum and drill a hole in the ulna from anterior to posterior. Leave the drill in place.
- Make an incision along the lateral aspect of the thigh from the greater trochanter to just above the knee.
- Dissect free a strip of fascia lata as long and wide as possible, and remove it.
- Close the wound in a routine manner, with no attempt to close the defect in the fascia lata.
- Sew the fascia lata into a tube with interrupted stitches. Then pass the rolled-up fascia lata subcutaneously between the wounds on the forearm.
- Crisscross a strong absorbable suture along the lower end of the fascia lata, and thread it onto two straight needles that are placed through the hole in the ulna after the drill point has been removed. Pull the end of the fascia lata down in to the ulna, and tie the free ends of the suture over a sponge and button.
- Flex the elbow 70° to 90°, and drape the other end of the fascia lata around and suture it under slight tension to the pectoralis major.
- Close the wounds, and apply a splint to hold the elbow at 90°.

At 2 to 3 weeks postoperatively, replace the cast by a dial lock brace to allow flexion and block extension just below a right angle. Gradually increase the extension over the next month, and have the patient exercise the elbow into flexion several times daily.

### Anterior Transfer of the Triceps Muscle for Restoration of Elbow Flexion (Bunnell-Williams Procedure)

- Make a posterolongitudinal incision over the distal fourth of the triceps tendon, extending distally midway between the radius and ulna, over the proximal third of the forearm.
- Dissect the triceps tendon off the olecranon with a strip of periosteum from the upper shaft of the ulna.
- Mobilize the triceps off the humerus to the midhumeral level.
- Flex the elbow 90°, and separate the interval between the brachioradialis and pronator teres muscles.
- Roll the periosteal elongation of the triceps and tendon into a tube, pass it around the lateral side of the arm superficial to the radial nerve, and attach it to the bicipital tubercle of the radius through drill holes.
- Secure the tendon under tension with the elbow almost fully flexed.
- Close the wound.

Postoperatively, hold the arm in the flexed position for 1 month, after which general physical therapy can begin.

### Carpectomy for Severe Flexion Deformity of the Wrist (White and Stubbins Procedure)

- Expose the carpal bones through a transverse posterior incision.
- Retract the extensor tendons medially and laterally to expose the dorsal area of the proximal row of carpal bones.
- Excise the proximal row of carpal bone, and dorsiflex the wrist to test the position. If inadequate dorsiflexion is achieved, all carpal bones except the pisiform may be excised to obtain adequate dorsiflexion. Dorsiflex the wrist to about 20°, and hold the forearm in a neutral position.

After surgery, use a long-arm cast for 3 weeks, followed by a short-arm cast for an additional 2 to 3 weeks. After removal of the cast, have the patient wear a wrist splint part time, usually at night, to prevent recurrence of the flexion deformity.

### Wrist Arthrodesis
The reported incidence of scoliosis varies from 0% to 42%, but a figure of about 20% seems acceptable (Scoliosis). Postoperatively, change the long-leg cast at 2 weeks to a short-leg cast for an additional 10 weeks. Allow weight bearing about 1 month after surgery. After the cast is removed, place a corticocancellous iliac bone graft in the slot, and close the wound. A Steinman pin placed down the third metacarpal into the radius provides some fixation. After surgery, place the wrist in neutral, and apply a long-arm cast. This cast is worn until the arthrodesis is firm, usually 10 to 12 weeks.

Knee Deformities

The knee deserves excessive attention, because most patients with arthrogryposis can walk or stand if the knee is in a suitable position (15). Motion at least 15° to 45° of flexion is desirable but may not be obtained in rigid extremities. Rigid knees that have 35° to 40° of flexion are stable for standing and sitting; full extension makes sitting awkward, and excessive flexion makes standing impossible. Knee flexion contractures (6%) are common more than extension contractures (6%). Daily passive stretching with thermoplastic maintenance splinting is the most effective treatment to increase motion in infants and young children. Forty percent of patients can be managed by nonoperative treatment programs (38).

Recurrence of a knee deformity is common, and in juvenile and adolescent patients, recalcitrant contractures, often with posterior subluxation of the tibia, respond to two-pin traction. Place the proximal pin in the proximal metaphysis of the tibia, so that longitudinal traction can reduce the flexion contracture of the knee. The two-pin traction method requires prolonged hospitalization and may be combined with hamstring lengthening and posterior capsulotomy. Recurrence of the flexion deformities may occur in growing children because the joint capsule and rigid periarthritic soft tissues do not stretch adequately during growth. A few patients develop marked bony and cartilaginous joint deformities, making joint motion impossible. An osteotomy, usually of the distal femur, is used to reposition the knee to 35° of flexion, which allows adequate sitting and standing. The anulization of the distal femur causes a mild iatrogenic cosmetic deformity.

In the extended knee, the joint is often rigid and resistant to therapy. The patella may be dislocated laterally, and the tibia may be dislocated anteriorly. A radiograph of the knee is often necessary for orientation before initiating to stretching therapy. For the dislocated knee in the infant, apply longitudinal skin traction to the tibial area of the legs, initially at 1 lb (0.45 kg) and progressing to a maximum of 5 lb (2.25 kg). Continue traction until the tibial plateau is beneath the femoral condyle, and then initiate stretching therapy (see the knee section). As soon as the knee can be flexed to about 30° in the reduced position, discontinue traction and apply splints to maintain reduction. If reduction cannot be achieved by traction, open reduction, consisting of a quadriceps release, release of the lateral patellar retinaculum, and occasionally, knee ligament lengthening is necessary (65). After flexion is acquired, prolonged orthotic management is necessary to maintain motion.

Hip Deformities

In patients with arthrogryposis, the hip joint is frequently contracted (82%) and dislocated (58%) (289). The absolute treatment goal for hip contractures is to obtain a functional position of abduction and rotation of the femoral head, which is a major benefit. At birth, the hips are frequently in a nonfunctional position of abduction, flexion, and external rotation (i.e., Buddha-like position) and should be passively stretched and sprinted. In the newborn, a cloth band can be wrapped around the proximal part of the leg to reduce the abduction contracture. In patients between 1 and 3 years of age, casts are applied to the legs, with a bar incorporated between the casts to control abduction and rotation, and the hips are passively stretched, placing the patient in a prone position. A hip flexion contracture of 30° is acceptable, because the lumbar spine can provide adequate compensatory motion. If adequate correction has not been obtained in the patient by 2 years of age, a soft-tissue release is helpful, or a varus extension intertrochanteric osteotomy may allow the desired position without producing additional muscle weakness. If a rigid contracture prevents ambulation, intertrochanteric osteotomies can reposition the extremity at about 35° of hip flexion and bring the hip out of the abducted position to allow adequate sitting and standing (290).

Hip dislocation is typically teratogenic and can be bilateral or unilateral. Occasionally, there is a reasonably mobile, nonteratogenic dislocated hip that can be treated in a manner similar to a typical congenitally dislocated hip if treatment is initiated before 3 months of age. Bilateral hip dislocations are best left untreated and attention directed toward obtaining adequate motion (172). A teratogenic unilateral hip dislocation was formerly thought to cause severe contractures, pelvic obliquity, and secondary scoliosis, but this is not always the case in arthrogryposis (84). An iliopsoas knee flexion contracture should be corrected before reduction is attempted, because knee therapy can redissociate the hip. Skin traction (i.e., a home traction program) and passive stretching therapy are used to obtain as much hip motion as possible (183). Occasionally, the femoral head reduces to the level of the acetabulum, and a closed reduction can be performed similar to that done for a typical congenitally dislocated hip, but posterior osteotomy should not allow the hip to contract in a nonfunctional position. By the time a child is 1 year old, most teratogenic unilateral dislocations of the hip require open reduction through an anterior approach, extensive soft-tissue release, and possibly femoral shortening to obtain an adequate reduction. After surgery, a maximum of 5 weeks of casting from the thorax to the toes, followed by prolonged orthotic casting, is necessary for adequate joint remodeling. Inadequate reduction or subluxation does occur, if the hip cannot be reduced adequately, the pelvic obliquity is treated by an intertrochanteric femoral osteotomy to position the leg functionally, and a shoe lift is used to accommodate the limb length discrepancy until a properly timed iliopsoas epiphysiosis is performed (28,287). If there is any question about obtaining good motion, it is better to leave the unilateral hip dislocation unreduced. A stiff hip produces more disability than the other possible related conditions.

Foot Deformities

The most common (84%) foot deformity in arthrogryposis is talipes equinovarus. Convex pes valgus, calcaneovalgus, and cavovarus deformities are seen occasionally. These severely deformed feet are often extremely stiff, and the goal of treatment is to obtain a pain-free plantigrade foot at maturity.

At birth, the talipes equinovarus is treated by serial taping and passive stretching therapy. The passive stretching is performed four times each day, and the taping is continued until the foot is semiflexed (339). In patients with nonplantigrade feet but reasonable motion, a posteromediolateral release was satisfactory in 15 of 20 feet. At a posterioromedialateral release, prolonged orthotic casting and extensive passive stretching are necessary.

Recurrence in patients older than 10 years of age is best treated by a triple arthrodesis. In the rigid foot, a taelectomy performed when the child is between 1 and 3 years of age gives the most satisfactory plantigrade foot (84,138,145,570,151). Recurrence after the age of 10 years is best treated by a triple arthrodesis.

Taelectomy

Make a skin incision from just distal to the head of the talus, extending obliquely inferoposteriorly to 1 inch (2.5 cm) inferior to the lateral malleolus (Ollier approach).

Retract the peroneus longus and brevis tendons inferiorly, and incise the talocalcaneal portion of the bifurcate ligament.

Turn the foot medially to expose the talar neck. The talus may be excised as one piece or in fragments.

Strip the ligaments from both the medial and lateral aspects of the malleolus, and displace the foot posteriorly on the tibia so that the medial malleolus is in contact with the naviculare and the lateral malleolus is at the calcaneocuboid joint.

Align the foot along the long axis of the foot (i.e., midline of the anterior tibia), and eshape the malleoli to fit the calcaneeus in the new position. Any tight tendons or ligaments may be lengthened to allow proper orientation of the foot. The foot should align without tension.

Close the wound, and apply a long-leg cast with the knee flexed and the foot in the corrected position. If the knee motion is inadequate to achieve cast support, place a Steinmann pin through the tibia and incorporate it into a short leg cast.

Postoperatively, change the long-leg cast at 2 weeks to a short-leg cast for an additional 10 weeks. Allow weight bearing about 1 month after surgery. After the cast is removed, use a solid ankle-foot orthosis to maintain position.

Scoliosis

The reported incidence of scoliosis varies from 0% to 42%, but a figure of about 20% seems acceptable (159,260). Noncongenital scoliosis may be present at birth or...
may develop in early childhood; it is progressive, becomes rigid, and is associated with pelvic obliquity (83,115,304). Congenital scoliosis is far less common. A thoracolumbar-sacral orthosis is preferred in curves between 20° and 40°, and a posterior spinal fusion and instrumentation is preferred in progressive curves of more than about 40°. Because the scoliosis tends to be rigid, the fusion should not be delayed in progressive curves, or a severe deformity will develop. Arthrodesis is difficult to achieve, and a high incidence of pseudoarthrosis is reported.

In severe curves with pelvic obliquity, an anterior release followed by a posterior spinal fusion to the sacrum with instrumentation enhances correction of the curve and pelvic obliquity (233).

CHAPTER 179

THE ORTHOPAEDIC MANAGEMENT OF MYELODYSPLASIA AND SPINA BIFIDA

Nigel S. Broughton and Malcolm B. Menelaus

Myelodysplasia and spina bifida are congenital anomalies characterized by abnormality of the closure of the neural tube. They constitute a group of disturbances including failure of full development of structures derived from the neural tube and the meninges. These disturbances result in abnormal neural control of organs innervated by the affected part of the spinal cord. This abnormal innervation gives rise to multiple organ involvement, including effects on bladder and bowel, as well as denervation of muscles resulting in paralysis.

The orthopaedic management of spina bifida is aimed at allowing children to fulfill their maximum physical and social potential within the limitations imposed by the congenital anomaly.

ASSESSMENT OF NEUROSEGMENTAL LEVEL

Assessment of the neurosegmental level is important because it allows us to predict the functional status of the child. Assessment should be performed as early as possible and repeated annually, using the grading indicated in Table 179.1 with accurate recording of muscle power. Neurosegmental level can be confirmed and any significant deterioration in neurologic status requiring investigation for a tethered cord or cord syrinx is easily detected (Fig. 179.1). Assessment of the level becomes more accurate after the age of 5 years, when the child is more cooperative.

Table 179.1. Coding of Muscle Strength

Figure 179.1. In hemimyelodysplasia, there is gross asymmetry of the neurosegmental level, often resulting in leg-length discrepancy. The difference in leg lengths can usually be managed by epiphysodesis in the long limb, but when there is gross discrepancy, leg lengthening may be more appropriate. (Reproduced with permission from Menelaus MB. Orthopaedic Management of Spina Bifida Cystica, 2nd ed. Edinburgh: Churchill Livingstone, 1980.)
We use a classification based on Sharrard's original description of nerve root innervation to define a precise level and code the power in the muscle as shown in Table 179.2. Assessment of quadriceps and hip abductor power provide a reasonable estimate of walking ability. Community ambulation is unlikely if the quadriceps and hip abductors have no power; community ambulation with splints and aids is likely if quadriceps are innervated but hip abductors are not; and community ambulation is probable if both quadriceps and hip abductors have power. The prediction of walking ability is important in determining the type and extent of surgical treatment required to correct deformity in childhood.

Recent work has suggested that the hip abductors are innervated at the same or higher level than the tibialis anterior and has confirmed that the medial hamstrings are innervated at a higher level than was originally described (15). However, further work is necessary to determine the significance of these findings.

CAUSES OF DEFORMITY

MUSCLE IMBALANCE DUE TO LOWER MOTOR NEURON LESIONS

In large part, the lowest innervated segment is determined by the developmental defect. However, further lower motor neuron lesions may be caused by postnatal drying and infection of the neural plate. If the child is expected to survive, this should be avoided by closure of the defect within 24 hours. Shurtleff has also demonstrated that trauma to the exposed neural plate at vaginal delivery can produce further lower motor neuron lesions; this problem can be prevented by electing to deliver known spina bifida fetuses by cesarean section at 36 weeks’ gestation (20). Lower motor neuron lesions can also be produced in childhood when growth produces traction on a tethered cord, damaging nerve roots.

Various patterns of paralysis are seen according to the lowest innervated myotome. The resulting muscle imbalance can, in some cases, predict the likely deformity. For example, in a limb where there is innervation down to and including L-5, indicated by activity in the tibialis anterior, peroneus tertius, and the extensor digitorum longus with no activity in soleus or gastrocnemius, a calcaneus or calcaneovalgus deformity of the foot commonly occurs.

Sharrard stated that hip flexion contracture was greatest where the muscle imbalance was greatest, that is, with innervation to L-2, L-3, and L-4 (19). However, our findings have been that hip flexion contracture is most common in children with a thoracic lesion where there is no muscle activity at the hip. There is no evidence of spasticity in patients with the most severe flexion contracture at the hip (2, 21). Fixed hip deformity is not predictable from the state of muscle activity around the hip.

Dislocation of the hip in spina bifida has been considered to be due to muscle imbalance (19), but our studies have shown that about 30% of hips with no muscle imbalance dislocate, whereas 70% of hips with innervation to L-4 and presumed to have the greatest muscle imbalance neither dislocate nor require any operation. Dislocation of the hip in spina bifida is not inevitable when there is muscle imbalance across the hip (2).

Studies on the natural history of deformity at the knee also raise doubts about the role of muscle imbalance in producing fixed deformity (24).

MUSCLE IMBALANCE DUE TO UPPER MOTOR NEURON LESIONS

Upper motor lesions resulting in spasticity of muscles are present in two thirds of children with myelomeningocele (Figs. 179.2A, 179.2B, 179.2C).

Figure 179.2. Spasticity has resulted in deformity in the upper and lower limbs of this child. A: An abduction contracture has developed at the hip. This was corrected by a lateral release. B: Spasticity of flexor hallucis longus. C: Spasticity of wrist flexors and the intrinsics in the hand. (B and C reproduced with permission from Menelaus MB. Orthopaedic Management of Spina Bifida Cystica, 2nd ed. Edinburgh: Churchill Livingstone, 1980.)

Three patterns can be recognized. In the first pattern, flaccid paraplegia is present, but in levels more distal, there is a spastic paralysis with exaggerated reflex activity. In the second pattern, there is only a narrow segment of flaccid paralysis (resembling spinal cord transection) and purely reflex activity below the level. In the third pattern, there is incomplete transection and hence myotomes can show spasticity with increased reflexes, but there is also a degree of voluntary movement.

Because muscles across a joint may be flaccid, normally innervated, or spastic, various degrees of imbalance may be produced. Although muscle imbalance between flaccid and spastic muscles can give rise to severe deformity of the foot, the argument for this is less convincing at the hip or knee, and other explanations for severe deformity should be sought.

INTRAUTERINE POSTURE

The average hip flexion contracture, in all children with myelomeningocele at birth, is about 20°, and this angle decreases with lesions at all levels up to the age of 1 year. In children with a lesion at the thoracic level, this decrease is less than in other levels. Intrauterine pressure causes various patterns of foot deformity at birth in paralyzed feet.

HABITUALLY ASSUMED POSTURE

Children with thoracic level lesions often develop external rotation and abduction deformities of the hips if they are allowed to lie for long periods in this position. Prolonged sitting may be a factor in the development of flexion deformity at the hips and knees in high-level lesions.
ARHTROGRYPOSIS-LIKE DEFORMITIES

Some children with significant deformity at birth resemble patients with arthrogryposis multiplex congenita, with rigidity of joints and absence of normal creases. These deformities may be present at one or more joints, are resistant to standard management, and require radical surgery for their correction.

UNKNOWN FACTORS

We simply do not know why most patients with thoracic level lesions develop deformity, including all possible foot deformities.

GOAL OF ORTHOPAEDIC MANAGEMENT

The goal of orthopaedic management is to produce a stable posture for sitting or walking. Hip flexion contractures and knee flexion contractures give rise to difficulties in standing and walking, as well as increased energy expenditure. Successful treatment of these deformities ensures a stable posture.

Conservative treatment of deformity in the child with spina bifida is ineffective and gives rise to cast sores and pathologic fractures; therefore, in general, surgical intervention is preferable.

The goals of surgical management are to avoid unnecessary operations that confer no benefit on the patient, to perform multiple operations at the same time, and to use the minimum period of postoperative immobilization possible. We plan surgery with an awareness of what the child is likely to achieve in walking in the long term so that the surgical goals are realistic (11,12 and 13).

Children with thoracic neurosegmental levels are unlikely to continue effective walking into adolescence. Until then, we encourage them to walk and they enjoy standing. As their condition progresses, we use reciprocating gait orthoses or hip-knee-foot orthoses (HKFOs). They will require increasing use of a wheelchair with time. Surgery aims at a trouble-free wheelchair existence. We correct foot deformity of a degree that precludes normal footwear, generally by soft-tissue release. Extensive hip surgery is not indicated, but we aim to correct excessive flexion contracture by soft-tissue release to prevent excessive lumbar lordosis.

Children with L-1 and L-2 neurosegmental levels are rarely community ambulators as adolescents, but the time spent walking in braces may be longer than in children with thoracic level lesions, so surgery to improve brace fitting should be considered.

Children with L-3, L-4, and L-5 neurosegmental levels with strong quadriceps are usually good walkers. They usually require an ankle-foot orthosis to stabilize the ankle. The need for crutches or walking aids depends on the strength of the abductors at the hip. The surgeon should assume that the child will achieve worthwhile walking, and therefore, extensive surgery to correct deformities at the hip, knee, and foot may be justified. Furthermore, soft-tissue surgery is justified for these patients during childhood, recognizing that bony surgery, such as triple arthrodesis, may be necessary at maturity.

The child may start walking with extensive bracing, including hip control orthoses, but as confidence builds up, the extent of the bracing can be reduced to below the knees.

Most children with sacral lesions are effective community ambulators until adulthood, when some deteriorate and cease walking. Hip deformity is uncommon, but surgery is often necessary for foot and toe deformities.

SURGICAL CORRECTION OF DEFORMITIES OF THE HIP

Hip flexion contracture and hip dislocation were previously thought to be due entirely to muscle imbalance across the hip (19). We have now shown that the hip flexion contracture is most common and most severe in children with thoracic neurosegmental level (2). Dislocation of the hip is also common in thoracic neurosegmental level, whereas in children with innervation to L-4, who presumably have maximum muscle imbalance, only a third develop hip dislocation or require hip surgery (2). Therefore, muscle imbalance is one of a number of factors implicated in the development of hip flexion contracture and hip dislocation. Prophylactic surgery to correct muscle imbalance is no longer undertaken because many children with muscle imbalance develop no deformity or dislocation at the hip.

RELEASE OF HIP FLEXION CONTRACTURE

Hip flexion contracture is commonly seen in normal neonates and in neonates with spina bifida with all neurosegmental levels. The deformity decreases during the first year of life but improves least in thoracic neurosegmental levels (2,21), and in these patients, it has a strong tendency to increase again with advancing years.

If hip flexion deformity is interfering with the child’s ability to walk (generally this occurs when the deformity is greater than 20°), we perform a soft-tissue release.

- Drape the patient so that Thomas’ test can be performed throughout the procedure.
- The procedure is best performed through the incision described by Salter for innominate osteotomy (see Chapter 166).
- Sweep the muscles off both the inner and the outer surfaces of the ilium, divide the psoas tendon, release the sartorius and rectus femoris, and if necessary, divide the anterior capsule of the hip joint transversely.
- At the conclusion of this procedure, the anterior superior iliac spine and adjacent portions of the iliac crest will protrude forward and should be removed.

Our results of long-term follow-up are satisfactory (3). If the hip is also dislocated, consider reducing the hip along the lines described in the next section. In a thoracic-level non-walker, correction of the hip flexion contracture is commonly attempted without reduction of a dislocated hip (Fig. 179.3A, Fig. 179.3B, Fig. 179.3C).

Figure 179.3. A: Undesirable flexion posture in a boy with L-4 lesion. He has strong psoas and quadriceps muscles but gluteal weakness and has developed fixed flexion deformity of both hips. Note the gross lumbar lordosis and that his center of gravity is in front of rather than directly over his feet. B: We are usually able to correct the deformity with an extensive soft-tissue anterior hip release. However, on this occasion, because of the severity of the deformity, extension femoral osteotomies have been performed. No attempt was made to reduce the left hip; he remains a community ambulator. C: Postoperatively he has a much better extension posture, although some of his lumbar lordosis is fixed. The operation was performed 25 years ago and the patient is still walking. (Reproduced with permission from Meneaust MB. Orthopaedic Management of Spina Bifida Cystica, 1st ed. Edinburgh: Churchill Livingstone, 1971.)

Postoperatively, the child should be nursed alternately prone and supine, with the hips extended for 6 weeks. We also use low trolleys on casters so the child can lie prone on these and move around the house using the arms.

CORRECTION OF HIP DISLOCATION

The presence of hip dislocation is not an indication to attempt reduction. Reduction should be attempted only when the child will derive considerable benefit from this
procedure (6,7,9). Attempts at operative reduction are not always successful, may result in stiff painful hips, are sometimes associated with heterotopic calcification, and generally reduce the child's ability to walk. An untreated dislocated hip is rarely painful, but if the dislocation is unilateral, it may give rise to limb-length discrepancy, which is troublesome for walkers and can cause seating difficulties for wheelchair users. Most specialists would agree that there is little difference in walking ability of children with high neurosegmental levels who have located or dislocated hips (Fig. 179.4).

Figure 179.4. A: This child was born with severe arthrogrypotic deformities of the lower limbs. He was treated by soft-tissue releases on one occasion, but his bilateral hip dislocations were not reduced. B: Same child at the age of 17 years demonstrating a satisfactory extension posture in KAFOs. He is now 32 years old and remains a household ambulator. (Reproduced with permission from Menelaus MB. Orthopaedic Management of Spina Bifida Cystica, 2nd ed. Edinburgh: Churchill Livingstone, 1980.)

Children with hip dislocation who would benefit from surgery to reduce the hip are those with low-level lesions at L-3 and below. They usually have strong quadriceps, do not require bracing above the knee, and will probably be good walkers. In this group, unilateral hip dislocations should generally be reduced (Fig. 179.5A, Fig. 179.5C, Fig. 179.5D, and Fig. 179.6A, Fig. 179.6B). In general, bilateral hip dislocations in this group do not benefit from attempts at reduction, but reduction is occasionally performed if the dislocated hips are not high and surgery is necessary in any case for hip flexion contracture. In children with high-level lesions (thoracic, L-1, and L-2) and therefore weak quadriceps, bilateral hip dislocations should not be reduced. Children with unilateral hip dislocations may benefit from reduction if the dislocation is not gross, the other leg has a low lesion, and surgery is necessary anyway to correct hip flexion deformity. We have seen few problems from leaving a unilateral hip dislocation untreated in a child with a high-level lesion (Table 179.3).

Figure 179.5. A: This child had normal muscle power in her right leg but an L-5 lesion on the left. B: A radiograph demonstrates dislocation of the left hip. C: Same child treated by open reduction, psoas lengthening, and a Pemberton osteotomy. The follow-up radiograph shows a concentric reduction. D: At the age of 15 years there is little leg-length discrepancy, but note the left calf is slightly smaller. (A and B reproduced with permission from Williams PF, Cole WG. Orthopaedic Management in Childhood. London: Chapman and Hall, 1991)

Figure 179.6. A: Unilateral hip dislocation in a low-level lesion. B: This dislocation has been treated by open reduction, Pemberton osteotomy, and a femoral osteotomy.

Table 179.3. Indications for Reduction of Hip Dislocation in Spina Bifida

If the hip dislocation is present at birth and is irreducible, attempts at reduction should not be made because it will lead to stiffness. If the hip is unstable but can be easily reduced by Ortolani's test and the lesion is low, it is worthwhile using abduction bracing to encourage acetabular development. However, the brace should not interfere with closure of the spinal defect and its postoperative management.

Operative reduction should aim for correction with the minimum of postoperative immobilization. The principles of the operation are

- to achieve a concentric reduction of the femoral head with capsulorrhaphy and excision of intra-articular structures (see Chapter 166),
- correction of muscle imbalance by flexor and adductor releases.
• improvement in acetabular coverage, generally by a Pemberton osteotomy. This is performed through an approach similar to that described for a soft-tissue release of the hip (see the previous section).

Plaster immobilization is necessary for only 6 weeks postoperatively.

**PROVISION OF ABDUCTOR AND EXTENSOR POWER AT THE HIP**

Muscle transfers about the hip were popular for spina bifida (4) when it was thought that muscle imbalance caused hip dislocation and contractures. Because we now know that the relationship between muscle imbalance and hip deformity is less clear, we believe that there is no place for the use of prophylactic muscle transfers, because prediction of development of deformity is not possible from muscle strengths.

Some surgeons believe that muscle transfers are appropriate in selected circumstances, but there is general agreement now against the use of posterior iliopsoas transfer (19) because gait analysis has established that the energy cost following this procedure is unacceptably high.

If the surgeon believes that there is a specific patient with a low lumbar lesion who might have a better gait following muscle transfer (gait analysis may facilitate the decision-making process), then the triple transfer, described by Yngve and Lindseth (25), or external oblique transfer alone would seem to be the most logical, considering our present state of knowledge. The triple transfer consists of external oblique transfer to the greater trochanter, transfer of the adductor origin posteriorly, and posterior transfer of the origin of tensor fascia lata, often in combination with a varus derotation femoral osteotomy to improve gait and reduce the risk of dislocation. Transfer of the iliofemoral to the anterior greater trochanter, as described by Mustard (15), frequently leads to fixed flexion deformity. The indications for muscle transfers at the hip are now few.

**CORRECTION OF DEFORMITIES OF THE KNEE**

**KNEE FLEXION CONTRACTURE**

Flexion deformity of the knee and limitation of flexion of the knee are most common in children with thoracic neurosegmental lesions and not in children in whom there is muscle imbalance at the knee (28).

Flexion of up to 20° is common at birth and generally improves spontaneously. If there is a fixed flexion deformity of greater than 20° in the neonate, then serial casting may be necessary. If a fixed flexion deformity is found in a child older than 3 years of age who has the potential for walking, we perform a soft-tissue release. Knee flexion correction often occurs with hip flexion contracture, and both should be corrected at the same time. Knee flexion is corrected by releasing all of the hamstring tendons at the knee. Posterior capsulotomy of the knee is usually necessary to achieve full correction (14) (Fig. 179.7A, Fig. 179.7B, Fig. 179.7C). It is important that a full correction of the flexion deformity is obtained at operation because recurrence follows incomplete correction and further correction with serial plaster casts is usually incomplete. Transfers of the hamstrings into the patella or lower femur have generally been disappointing and are not advised. An extension supracondylar osteotomy is infrequently used for flexion deformity in the child approaching skeletal maturity.

**EXTENSION DEFORMITY**

Some neonates present with a recurrent extension deformity of the knee, but this usually responds to serial casting. The knee may be held rigidly in extension and have the featureless appearance of arthrogryposis multiplex congenita. Tenotomy of the ligamentum patella (18) is best performed at about 6 years of age, when the muscle imbalance is more likely to be due to an imbalance of quadriceps to hamstrings. Plaster immobilization is necessary for only 6 weeks postoperatively.

**VALGUS DEFORMITY**

Valgus deformity is uncommon. It can generally be managed by medial growth plate stapling, and it seldom requires lower femoral or upper tibial osteotomy.

**CORRECTION OF TORSIONAL DEFORMITIES OF THE TIBIA**

**EXTERNAL ROTATION OF THE TIBIA**

External rotation of the tibia is commonly associated with a valgus ankle. It should be treated after the age of 8 years by supramalleolar rotational osteotomy of the tibia, which can be combined with correction of the valgus ankle at the supramalleolar level (see later).

**INTERNAL ROTATION OF THE TIBIA**

Although minor degrees of internal rotation of the tibia can be corrected by transfer of the semitendinosus to the biceps femoris, we have now largely abandoned the procedure because such an indication is seldom present. Gross degrees of the deformity are corrected in the first 3 years of life by osteoclasis of the tibia and fibula (Fig. 179.8) or at a later age by supramalleolar external rotation osteotomy.
CORRECTION OF DEFORMITIES OF THE FOOT

Deformities of the foot in spina bifida are common at all levels of neurosegmental defect. In patients with high-level lesions, 89% of feet are deformed despite the absence of muscle imbalance (1). Of those with low-level lesions, 76% are deformed, and the incidence of various deformities is similar to those encountered in high-level lesions (2). Those with calcaneus deformity have a higher incidence of activity of the tibialis anterior with calf weakness but calcaneus is common in the absence of this muscle imbalance. Spasticity is present in a high percentage of patients with high-level lesions but in none of those with undeformed feet. Spasticity is much less common (ratio of 1:2) in patients with low-level lesions.

TRIPLE ARTHRODESIS

The goal of the management of foot deformity is to achieve a plantigrade and mobile foot. However, there are occasions when triple arthrodesis is the most appropriate method to correct a complex deformity. The lateral inlay technique (23) has proved particularly valuable in patients with spina bifida (Fig. 179.9A, Fig. 179.9B, Fig. 179.9C). Long-term follow-up has confirmed this impression (17). Triple arthrodesis must be used with caution in the older ambulatory patient because of the risk of plantar pressure sores in a rigid foot that is devoid of sensation.

EQUINOVARUS DEFORMITY

The rigidity of the equinovarus deformity varies from that seen in the usual form of talipes equinovarus to the more commonly seen rigid, “arthrogrypotic” deformity, which has a high rate of recurrence despite apparent adequate correction initially. In general, a varus deformity requires operative correction to establish a plantigrade foot; otherwise, pressure sores due to weight bearing on a small area of the sole are inevitable.

Initially, the treatment consists of serial correction in well-padded plaster casts that are changed frequently while the baby is still hospitalized after birth, and later at 2- to 4-week intervals as circumstances demand. Although it may not be apparent at birth, the tendo Achillis is usually short, and a closed tenotomy should be performed when convenient, between 3 and 6 months of age.

If a child older than 3 months of age is thriving and does not require surgery for concomitant conditions in other systems, we perform a posteromedial release. The Cincinnati surgical approach for this technique is described in Chapter 167. Because recurrence is likely, excision of portions of the tendo Achillis, tibialis anterior, tibialis posterior, and the long toe flexors is necessary rather than lengthening. If the deformity recurs, we perform a repeat soft-tissue release.

If some patients for whom demands on the foot are high, trophic ulceration is likely, so in cases in which repeat soft-tissue release is not controlling the deformity, further procedures are necessary. Although we have used takedown for this situation in the past, we now prefer variations of the Verebelyi-Ogston procedure with decancellation of the talus and cuboid to allow collapse of these bones and correction of deformity (22). Tendon transfers have no part in the management of this deformity (see Chapter 167).

If deformity recurs between the ages of 7 and 14 years, it is wise to accept the deformity, provide appropriate footwear, and aim to correct the deformity by triple arthrodesis at skeletal maturity.

Pure Equinus Deformity

A pure equinus deformity can be present in patients with any neurosegmental level. It responds well to open or closed tenotomy, depending on the severity of the deformity and the age of the child.

CALCANEUS DEFORMITY

Calcaneus deformity is common in spina bifida patients, most commonly seen in children with an L-5 neurosegmental lesion but also commonly seen in the absence of muscle imbalance. The major problem with calcaneus deformity is the development of pressure sores because large forces are transmitted through a small area of insensitive heel. This deformity is usually left untreated until muscle power can be properly assessed at the age of about 3 years.

If the deformity is progressing and the tibialis anterior is of normal strength, a transfer of the tibialis anterior through the interosseous membrane to the heel is appropriate, although some surgeons simply lengthen it. If extensor hallucis longus, extensor digitorum longus, or peroneus tertius are active, they should be divided at the same time. If the calcaneus deformity is fixed, we combine this procedure with a full anterior ankle capsulotomy to allow correction of the deformity (1).

If the anterior muscles are weak or spastic, we perform a tenodesis of the tendo Achillis to the lower fibular metaphysis. This procedure may stimulate growth at the lower end of the fibula and correct any tendency to develop ankle valgus.

In a late-presenting severe fixed calcaneus deformity with a “pistol-grip” heel, an osteotomy of the calcaneus removing a wedge based posteriorly improves the weight-bearing area. Concomitant valgus of the heel may be corrected by adding varus to the osteotomy. This can be performed in combination with tendon transfers and tenodesis as appropriate. A plantar release may be required as well in the treatment of concomitant cavus deformity.

VALGUS DEFORMITY

In general, valgus feet create less trouble than varus feet and can usually be controlled by orthoses until adolescence. The precise site of bony deformity should be

Figure 179.8. Internal tibial torsion of the left leg. This problem was treated by tibial osteoclasis.

Figure 179.9. Surgical technique for triple arthrodesis as originally described by Eric Price of Melbourne; the “inlay triple arthrodesis.” (Redrawn with permission from Romness MJ, Menelaus MB. Inlay Triple Arthrodesis: A Technique for the Undeformed or Valgus Foot. Orthop Traumatol 1995;4:114.)

- Make a straight incision centered over the junction of the four bones to be fused (Fig. 179.9A).
- Lift the extensor digitorum brevis distally and resect the extensors medially to allow exposure of the talonavicular, calcaneocuboid, and subtalar joints. Excise the capsules and expose the sinuses.
- Hold the foot in the desired position and insert 4.5 mm wires through the talonavicular, the calcaneocuboid, and the subtalar joints (Fig. 179.9C). Cut a trough as shown and decorticate the sinus tarsi. Take an oblong-shaped graft from the upper third of the ipsilateral tibia and push it into the trough to give a tight fit. Insert chips of bone graft into the subtalar joint.
**Ankle Valgus**

Ankle valgus can be recognized clinically because the distal end of the fibula can be palpated proximal to the tip of the medial malleolus. On the radiograph, the distal fibular growth plate lies proximal to the dome of the talus, as opposed to the normal relationship for that age. This appearance is associated with a wedge-shaped distal tibial epiphysis.

The relative shortening of the fibula can be reduced by tenodesis to the filula if this procedure is indicated for coexisting calcaneus deformity. The valgus effect of the wedge-shaped distal tibia epiphysis can be corrected by a medial arrest of the distal tibial growth plate either by the insertion of a screw from the tip of the medial malleous across the growth plate or by the Phemister technique. To be effective, this procedure must be performed before the child is 7 to 8 years of age. After this age, a supramalleolar osteotomy is indicated if the deformity is sufficiently severe to be producing undue pressure on the skin over the medial malleous, where its excessive prominence rubs on ankle-foot orthoses or footwear. This is done 1 cm above the growth plate with excision of a medially based wedge, together with an oblique distal fibular osteotomy. The fibial osteotomy is fixed with two crossed K-wires. Any rotational deformity can be corrected at the same time. We have experienced a 5% incidence of wound breakdown and delayed union following this procedure.

**Subtalar Valgus**

Subtalar valgus can usually be controlled by orthoses in children younger than the age of 10 years, but division of spastic peroneal muscles may be necessary. If an orthosis fails to control this problem, we would now avoid subtalar fusion and perform a calcaneal osteotomy by excising a medially based wedge and also shifting the distal calcaneus medially. The position is held by a Steinmann pin. If the presentation is close to skeletal maturity, it is commonly associated with a planoabductus deformity, which is best treated by a lateral inlay triple fusion (23).

**Ankle Plus Subtalar Valgus**

Each deformity should be addressed separately and corrected as described in the previous section. If the patient is nearly mature, this may well necessitate a supramalleolar osteotomy with a lateral inlay triple fusion.

**Cavus Deformity**

Management of a cavus deformity depends on the degree and rigidity of the deformity and the age of the child. Minor deformity can be observed and any pressure effects minimized with an appropriate insole. Treat progressive deformity for children up to the age of 5 years by a plantar release procedure. For children older than 5 years, soft-tissue release may have to be combined with osteotomies at the bases of all metatarsals. If there is an element of supination in the forefoot deformity and the hindfoot is mobile, the osteotomies may be limited to the first or first and second metatarsal bases to improve the weight-bearing area of the foot. Osteotomy of the calcaneus is indicated if there is an associated varus deformity of the heel. Triple arthrodesis is indicated if there is a significant varus and cavus deformity in the child close to skeletal maturity.

**Paralytic Convex Pes Valgus (Vertical Talus)**

Paralytic convex pes valgus (vertical talus) occurs in less than 2% of children with spina bifida. It can present at birth and is then similar to the congenital vertical talus that is not associated with spina bifida. It can also occur in a less rigid form, which develops slowly over the first years of life (6).

Surgical correction is necessary and involves reduction of the talonavicular (and sometimes the calcaneocuboid) joint and correction of the ankle equinus and heel valgus. These objectives can be achieved through a Cincinnati surgical approach (see Chapter 167). The operation is best performed in the first year of life.

- Section the tibialis anterior, extensor digitorum longus, and the peroneal muscles, and lengthen the tendo Achillis.
- Perform a lateral release of the subtalar joint and, if the valgus deformity is gross, insert a lateral bone block into the subtalar joint.
- Maintain correction with longitudinal and vertical K-wires for 4 to 6 weeks, as well as immobilization in a cast for 3 months postoperatively.
- Use a carefully molded ankle-foot orthosis to control planus, heel valgus, and the flail ankle.

**Flail Ankle**

We treat the flail ankle with an ankle-foot orthosis until maturity. Ankle fusion in children has a high failure rate, as does pantalar fusion.

**Claw Toes**

Claw toes are common in patients with L-5 and sacral lesions. In the second to fifth toes, open flexor tenotomy and closed extensor tenotomy generally corrects the mobile deformity sufficiently to prevent pressure effects on the tip or dorsum of the affected toe. Rigid deformity requires interphalangeal arthrodesis and extensor tenotomy, as well as dorsal release at the metatarsophalangeal joint.

Clawing of the hallux can give rise to pressure sores over the first metatarsal head and over the dorsum of the interphalangeal joint. If the deformity is correctable in the younger child, tenodesis of flexor hallucis longus to the proximal phalanx corrects the deformity but may have to be combined with a dorsal capsulotomy of the first metatarsophalangeal joint. In the older child, when the interphalangeal joint deformity is fixed, we perform a Robert Jones procedure with fusion of the interphalangeal joint and transfer of the extensor hallucis longus to the neck of the first metatarsal (Fig. 179.10).

![Figure 179.10](image-url) Interphalangeal valgus and pronation of the hallux. This problem was treated by interphalangeal arthrodesis. (Reproduced with permission from Menelaus MB. Orthopaedic Management of Spina Bifida Cystica, 2nd ed. Edinburgh: Churchill Livingstone, 1980.)

SKELETAL DYSPLASIAS

The skeletal dysplasias are a diverse group of disorders in which the structure of the bone is inherently abnormal, thus altering the growth of affected individuals. The trunk and extremities are abnormally sized, leading to disproportionate short stature, defined as a height less than the third percentile for the individual’s chronologic age. Some of the dysplasias are genetically transmitted, whereas others occur sporadically.

The diagnosis in skeletal dysplasias can most often be made clinically. Short stature should be noted when present, and body proportion and trunk and limb shortening may be helpful. The various definitions of skeletal dysplasias are shown in Table 180.1. If limb shortening is most notable in the proximal segments (i.e., humerus or femur), the term rhizomelic can be applied. Shortening of the midportion of the limb is termed mesomelic, and acromelic describes distal shortening. The area of the bone most disturbed by the dysplasia can help establish the diagnosis. For example, multiple epiphyseal dysplasia (MED) affects the epiphyses, whereas the metaphysis is most involved in the various forms of metaphyseal chondrodysplasia. The presence or absence of spinal involvement also is helpful in reaching a diagnosis.

Table 180.1. Definitions

| Rhizomelic | Shortening in the proximal segments of the extremity |
| Mesomelic | Affecting the midportion of the limb |
| Acromelic | Distal shortening |

Associated medical findings, such as precocious puberty in fibrous dysplasia, may aid in the diagnosis. In addition, identifying a specific dysplasia may lead to the identification and, therefore, treatment of associated medical conditions. For example, patients with nail-patella syndrome are at increased risk for renal failure, the onset of which is insidious and would go unnoticed if not for the proper surveillance due to the known association with the syndrome (84).

Collaboration with a geneticist can facilitate making the diagnosis in difficult cases. Genetic counseling may be of interest to the patient and family. Some dysplasias are unclassifiable and should be treated on an individual basis.

Advances in molecular genetics have furthered understanding of the mechanisms of bony abnormalities in these conditions. Although gene replacement treatment is not yet possible, research is progressing rapidly in this direction. See Dietz and Mathews (65) for an excellent review of the genetic basis of the inherited skeletal dysplasias.

ACHONDROPLASIA

Achondroplasia is the most common form of dwarfism, with a prevalence of 1.3 per 100,000 live births (3). It is inherited in an autosomal dominant pattern, although most cases are the result of spontaneous mutations. Molecular genetic research has found that there is a point mutation in the gene that encodes fibroblast growth factor receptor 3 (19, 32, 229), located on the short arm of chromosome 4 (183). Achondroplasia is characterized by a rhizomelic pattern of involvement, with the humerus and femur affected more than the distal extremities. Prenatal diagnosis is possible by monitoring the growth of the femur during the second trimester (165).

Histology reveals disturbed endochondral ossification. Intramembranous bone formation is not affected. Pathologic study of the growth plate shows marked abnormalities in the zone of hypertrophy, with loss of normal columnation of chondrocytes and accumulation of excess matrix (171). Periosteal bone formation is histologically normal. Additionally, the epiphysis itself is not affected by the dysplasia; therefore, there is no predisposition toward early degenerative arthritis.

The clinical appearance of achondroplasia is recognizable at birth. The baby is short limbed and has a disproportionately large head. Trunk length is normal. Facial features include a flattened nasal bridge, prominent mandible, and enlarged forehead. The hands characteristically have a space between the long and ring fingers,
referred to as the "trident hand." Elbow flexion contractures and radial head dislocation may be present. The lower limbs may be bowed, and the musculature appears enlarged. Thoracolumbar kyphosis may be present in infants (Fig. 180.1).

**Figure 180.1.** Four-year-old boy with achondroplasia. Note the prominent forehead, flexion contractures of the elbow, trident hand, and thoracolumbar kyphosis.

Radiographic findings in achondroplasia include an inverted V-shaped growth plate, best seen in the distal femur (Fig. 180.2). The metaphysis is widened, and the epiphysis is relatively normal. The long bones of the leg may be bowed. The pelvis is wide but short, with small sciatic notches. The shape of the inner pelvis has been described as a "champagne glass" appearance. The radiographic hallmark of the achondroplastic spine is progressive narrowing of the transverse interpedicular distance as one measures from cephalad to caudad in the lumbar spine (Fig. 180.3). The pedicles are thickened, and there may be posterior scalloping of the vertebral bodies.

**Figure 180.2.** One-year-old girl with achondroplasia. The physis of the distal femur appears as an inverted V.

**Figure 180.3.** Progressive interpedicular narrowing in the lumbar spine of a 5-year-old girl with achondroplasia.

Orthopaedic concerns most frequently focus on the spine (25,237). In infancy, compression of the brain stem and cervical cord secondary to stenosis of the foramen magnum has been described (127,167,265). Symptoms include sleep apnea (more specifically, central hypoapnea), and neurologic examination may reveal hypotonia (which is common in all infants with achondroplasia) or clonus. When compression is noted, posterior surgical decompression of the foramen magnum is recommended to prevent sudden death (265,289). Other neurosurgical concerns include Chiari malformations at the craniocervical junction and hydrocephalus, which occasionally requires shunting (76). Sleep apnea can also occur because of upper airway obstruction, and sleep studies may be able to identify those children whose respiratory compromise is due to craniocervical abnormalities and those due to obstructive airway problems (254,255,272). Because the orthopaedist often is involved in the care of the infant with achondroplasia, awareness of these conditions is imperative if appropriate neurosurgical referral is to be made.

Thoracolumbar kyphosis occurs in the slightly older infant with achondroplasia (Fig. 180.4). Kyphosis occurs nearly universally in the young baby. Possible causes include ligamentous laxity, hypotonia, enlarged head size, and hip flexion contractures. In most cases, the kyphosis resolves as the child begins to walk. A recent theory, popularized by Hall (110) and Pauli et al. (168), proposes that unsupported sitting by the hypotonic infant leads to the development of thoracolumbar kyphosis. The authors advocate prohibiting unsupported sitting to prevent the kyphosis from occurring, and early brace treatment with a thoracolumbosacral orthosis (TLSO) for those babies who do develop kyphosis. Other authors have recommended using a brace if kyphosis persists beyond 2 years of age. For refractory cases, surgical treatment consisting of anterior and posterior fusion without instrumentation may be necessary. Progressive kyphosis and kyphosis measuring greater than 40° at 5 years of age are indications for surgery (237). Fusion is generally obtained without instrumentation, because the narrowed canal and kyphotic deformity predispose the patient to neurologic injury and paraplegia if hardware is introduced (see Chapter 158 and Chapter 161).

**Figure 180.4.** Persistent thoracolumbar kyphosis in a 4-year-old boy with achondroplasia.

Spinal stenosis is the most common orthopaedic problem in achondroplasia (237) and may become symptomatic in patients in their early teen years (119). Symptoms
include leg and back pain (neurogenic claudication), lower extremity weakness, and loss of endurance during ambulation. The patient attempts to relieve pain during walking by hunching over to reduce the lumbar lordosis, which produces more space within the spinal canal. The decreased space within the spinal canal is due to narrowing and thickening of the pedicles, hypertrophy of the facets, and enlargement of the laminae (132). Magnetic resonance imaging (MRI) is useful in visualizing the extent of the stenosis. The condition is treated by posterior decompression, with wide laminectomy. The surgeon should attempt to preserve the facets, but this may not be possible if the stenosis is severe. Primary fusion usually is not necessary.

Angular deformity may occur in the lower limbs in childhood (18), and may be due in part to overgrowth of the fibula in relation to the tibia (171) (Fig. 180.5). Tibial osteotomy remains the treatment of choice for patients with symptomatic or cosmetically objectionable varus. Epiphysiodesis of the fibula has had mixed results (see Chapter 169).

![Figure 180.5](image)

**Figure 180.5.** Relative fibular overgrowth in a 13-year-old girl with achondroplasia.

Treatment of the patient's short stature remains controversial. There has been enthusiasm, particularly in Europe, for the application of the Ilizarov technique for lengthening the limbs in children with achondroplasia (98,267) (see Chapter 171). Treatment with recombinant growth hormone has been investigated and found to increase growth in some individuals with achondroplasia (111,156,257).

**DIASTROPHIC DYSPLASIA**

Diastrophic dysplasia is a severe form of short-limbed dwarfism, which is inherited in an autosomal recessive pattern. Its gene, located on chromosome 5, is responsible for the sulfation of proteoglycans, a crucial component of cartilage (230). Prenatal DNA testing can establish the diagnosis. Histologic study of the growth plate shows abnormalities in collagen (221) and decreased numbers of chondrocytes.

Clinical features are striking at birth. The child has very short limbs. There is flattening of the nasal bridge and a puffy-cheeked appearance. Cleft palate is frequently present. Severe clubfoot deformities are always present, and joint contractures are common. The thumb, which is radially deviated and short, has been described as a “hitchhiker thumb.” Within the first months of the child's life, the pinnae of the ears become swollen and ossify. The crumpled and enlarged pinnae have been termed “cauliflower ear” (249). In some affected children, tracheomalacia may be life-threatening during the neonatal period. The child's intelligence is normal.

Radiographic findings include the delayed appearance of the epiphyses. When the epiphyses do ossify, they are irregular and may be flattened (especially at the proximal femur) (244). Coxa vara is common and may result in hip dislocation. The long bones are short but appear thickened. Scoliosis is seen in older children (Fig. 180.6). The first metacarpal is short in relation to the rest of the hand and is triangular in shape, leading to the development of the hitchhiker deformity.

![Figure 180.6](image)

**Figure 180.6.** Scoliosis in an 8-year-old girl with diastrophic dysplasia. Note the bilateral hip dislocations.

Orthopaedic concerns include the severe clubfeet, which are resistant to casting and are prone to early recurrence after surgical intervention. Postoperative bracing is used in these children. Repeated surgical releases of the feet are difficult but should be aggressive (see Chapter 167). Other foot deformities are also seen in patients with diastrophic dysplasia (180). Joint contractures of the hip and knee may not be treatable with soft-tissue release. Osteotomy is required for fixed deformity. Hip dislocation is common and is difficult to treat. Because of the epiphyseal abnormalities, premature degenerative arthritis does occur.

Scoliosis is common and frequently severe in children with diastrophic dysplasia (109,173,237). Surgical fusion is indicated for large curves. Cervical kyphosis may be severe and lead to neurologic compromise (80,173) (Fig. 180.7). Atlantoaxial instability has also been described with diastrophic dysplasia (180). Careful assessment of the child's neck before general anesthesia can prevent death due to neurological causes (23). Surgical atlantoaxial fusion is indicated in progressive cases.

![Figure 180.7](image)

**Figure 180.7.** Cervical kyphosis in a 2-year-old girl with diastrophic dysplasia.

**METAPHYSEAL CHONDRODYSPLASIA**

Metaphyseal chondrodysplasia is a group of diseases of autosomal dominant and recessive inheritances. The two most common forms are the Schmid and McKusick types. The McKusick form is also known as cartilage hair hypoplasia. The primary defect is an abnormality in the physis of the zone of primary calcification, with
clusters of chondrocytes protruding into the metaphysis. The gene coding for type X collagen, which is present in hypertrophic chondrocytes located at the growth plate, is abnormal in Schmid metaphyseal chondrodysplasia (250,253).

Clinically, short stature is always present but varies in severity (182). Genu varum is common. Radiographs reveal widened physes and cupping of the epiphysis (Fig. 180.8), which may be mistaken for rickets. Serum chemistry, however, is normal in metaphyseal chondrodysplasia (77) (except for Jansen type, in which hypercalcemia may be present [197]). Coxa vara can be seen in the Schmid form, and cervical instability may be seen in the McKusick form. The long bones may be bowed, leading to angular deformities. The epiphyses are normal.

**Figure 180.8.** Radiograph of the lower extremities of a 4-year-old girl with metaphyseal chondrodysplasia. Genu varum and widened physes are seen.

Orthopedic treatment consists of osteotomies for symptomatic or progressive angular deformities. Patients with the McKusick form, which has been linked with immunodeficiency, have recently been treated by bone marrow transplantation (23,245).

**MULTIPLE EPiphySEAL DYSPLASIA**

Multiple epiphyseal dysplasia (MED) is one of the most common of the bone dysplasias. It is inherited by autosomal dominant transmission and has been found to be genetically variable among families (60).

The disorder is characterized by symmetric involvement of the epiphyses with a delay in their ossification. Radiographically, they appear mottled and irregular. The hips, knees, and ankles are most frequently involved; in the upper extremity, the shoulder is most commonly affected (113). The spine is essentially normal. In the differential diagnosis of bilateral Legg-Calvé-Perthes disease, always include MED (2) and perform radiographs of the knees and ankles. An abnormal epiphyseal height-to-metaphyseal width ratio for the distal femur has been found in most children with MED and has been proposed as helpful in early diagnosis (246). Another characteristic finding is the double-layered appearance of the patella on lateral radiographs (205). Avascular necrosis of the femoral head frequently occurs in patients with MED (153).

Adult height usually is at the lower range of normal. Joint pain may appear in the first decade or remain quiescent until early adult life. Treatment is the same as that for osteoarthritis, consisting of joint replacement for advanced cases (238).

**OSTEOGENESIS IMPERFECTA**

Osteogenesis imperfecta (OI) is a group of genetically transmitted dysplasias in which the bones are extremely fragile, predisposing the patient to multiple fractures. Several classifications of the disease exist (123). In 1906, Looser divided OI into congenita and tarda forms, with the specific type determined by whether the patient developed fractures at birth or later. The most commonly applied classification is that by Sillence (208), who categorized patients based on how the condition was inherited (i.e., autosomal dominant or recessive) and on the presence of specific clinical features (Table 180.2).

The prevalence of OI is 21.8 per 100,000 live births, with Silence type I being the most common form (3). Prenatal diagnosis of the congenital form of OI is possible with ultrasound (22), but milder forms of OI (e.g., Silence types I and IV) do not have abnormal ultrasound findings (235). In families with known mutations, chorionic villous sampling may help establish the prenatal diagnosis (235).

The underlying genetic defect in OI is an abnormality in the gene that encodes for the alpha chain of type I collagen (45). Mutations are almost always present, involving either the COL1A1 or COL1A2 genes, which encode the procollagen. In affected individuals, the organization of type I collagen is in disarray. In type I OI, there is a quantitative abnormality in the amount of type I collagen; in the other forms of OI, there are both quantitative and qualitative anomalies in type I collagen (44). Abnormalities can be seen in dental fibroblasts obtained from skin biopsies, in which the ratio of type I to type III collagen (which is uninvolved in patients with OI) is compared with age-matched normal specimens. Routine use of skin biopsy for diagnosis is discouraged, however, because the history and physical examination usually are sufficient to establish the diagnosis (224).

Morphologic changes are seen in growth plate cartilage (193). Histologically, there is a relative increase in woven bone that does not mature to lamellar bone. The osteocyte number is increased. Trabeculae are thin and poorly arranged, and the haversian canal system does not develop. Bone mineral density is decreased on dual energy x-ray absorptiometry (DEXA) scans, even in milder forms of the disease (271).

Clinical manifestations vary, with the spectrum ranging from that of stillborn babies with numerous fractures and intracranial bleeds to active adolescents with a history of several fractures occurring at various times during their childhood. Musculoskeletal findings include short stature, bowing of the extremities, and scoliosis. Blue sclerae are seen in Sillence type I and II patients, and in some type III patients, with the color most intense and long-lasting in type I patients (209). Dentition may be poor due to defective dentin, a condition known as dentinogenesis imperfecta. Hearing loss may occur secondary to middle ear involvement. The face is trefoil shaped. Clinical findings in patients with type IV OI may be quite subtle, and the differential diagnosis between OI and child abuse can be vexing.

Radiographic findings vary with disease severity as well. Fractures may be seen throughout the skeletal system. Coxa vara is a common sequela of femoral neck fracture. Prolonged acetabulum can develop. Wornian bones are seen on skull radiographs. The vertebrae may be biconcave, and compression fractures may be present (Fig. 180.9). The long bones are thin and osteopenic. The femur may have a “concertina” appearance, that is, a crumpled shape due to multiple fractures. There is widening of the metaphyses, and growth arrests may occur. Irregular calcifications may extend into the metaphysis, a condition referred to as “popcorn epiphysis” (Fig. 180.10).
The motor development of children with severe OI is delayed. Physical therapy has been useful in helping the patient develop head and trunk control, and when therapy is used in combination with surgery and bracing, sitting and ambulation may be improved (27). The ability of the child to sit independently by age 10 months has been correlated with achieving walking as a primary means of mobility (55).

Orthopaedic management is required to treat fractures as well as to attempt to prevent fractures. Fractures usually heal within a normal time interval, but the tendency to refracture persists. Disuse osteopenia further weakens the bones, so immobilization should be kept to the minimum time necessary to ensure fracture healing. Orthoses may be needed on a long-term basis to assist in weight bearing and to reduce the incidence of fractures (89). Nonunions may occur (867).

Surgical intervention can help prevent fractures and maintain limb alignment. Intramedullary fixation for load sharing, in combination with multiple osteotomies, was popularized by Sofield and Miller (215). Telescoping rods are technically more challenging to insert, but because they grow with the child, the chances of refracture with growth are lessened (13,14) (Fig. 180.11). Gamble et al. (87) showed that although the Bailey-Dubow rod was difficult to insert properly, it was beneficial in providing internal support to growing bones. Other authors also have published favorable results using the Bailey-Dubow device but state that the hardware does require periodic revision during patient growth (154,270).

MULTIPLE FEMORAL OSTEOTOMIES AND INSERTION OF BAILEY-DUBOW RODS

The insertion of a Bailey-Dubow rod in the femur proceeds as follows (Fig. 180.12):

- Preoperatively, check available lengths of rods.
- Type and crossmatch blood.
- Position the patient in the lateral decubitus position on a radiolucent table and drape the lower extremity free.
- Perform a gentle subperiosteal exposure of the femur.
- Perform multiple osteotomies where needed to pass a straight rod.
- Ream the medullary canal to allow rod passage.
Drill the female end of the rod into proximal fragment in a retrograde direction through the fracture or osteotomy, exiting just medial to the greater trochanter.

Exchange the drill bit for a T-piece through the proximal skin incision.

Crimp the T-piece onto the female end of the rod using pliers.

Perform a perapatellar exposure of the femoral intercondylar notch at the knee.

Insert the male solid rod up through the femoral notch.

Engage the male rod into the female rod.

Tap each rod in fully.

Twist the male rod 90° within the femoral epiphysis to deter distal migration into the knee.

Close and dress the incisions and apply a spica cast.

Rush and Sheffield rods also have been used to treat OI-related fractures (228). Intramedullary fixation has been recommended in the treatment of severely involved young children with type III OI (43). Motor development has been augmented in children with type III OI by performing surgery before 3.5 years of age (74).

Vertebral involvement leads to scoliosis and kyphosis in the severely affected groups of patients. Biconcave deformity of the vertebral bodies has been linked with the early onset of scoliosis (114). Chest cage deformity may result from bracing because of rib fragility (21), and curve progression is not halted by brace wear (102,268). Treatment is surgical but is fraught with technical problems. Fixation of the spine with conventional spinal hardware is difficult to achieve because of osteopenia. Methylmethacrylate augmentation and the use of mersilene tapes have been proposed as means to assist in fixation (21). Fusion in situ is the norm, because correction is very difficult to achieve.

Brain stem compression from basilar invagination has received recent attention (43). The condition has been found in as many as 25% of patients (210) and is often associated with macrocephaly and hydrocephalus. Clinical signs of basilar invagination include nystagmus, cranial nerve palsies, papilloedema, and facial spasm. Surgical treatment is difficult (194). In severely involved patients, basilar invagination may lead to early death due to respiratory arrest (143).

Anesthetic management of the child with OI can be complicated. There is a predisposition to hyperthermia that is biochemically different from the classic malignant hyperthermia (172). Blood loss during surgery may also be massive (219).

Medical treatment of OI is still experimental. Fluoride, vitamin therapy, and calcitonin have been tried in the past. Current research is aimed at treating OI at the molecular level (90,139).

MORQUIO’S SYNDROME

Morquio’s syndrome, one of the mucopolysaccharidoses, is characterized by the lack of N-Ac-Gal-6 sulfate sulfatase, a lysosomal enzyme. Deficiency of this enzyme causes an increase in urinary keratan sulfate (112). The syndrome is inherited in an autosomal recessive pattern.

Clinically, affected patients appear normal when they are babies. The clinical features appear later, as glycosaminoglycans accumulate (Fig. 180.13). Signs of Morquio’s syndrome include short-trunk dwarfism, ligamentous laxity, and genu valgum. Facial features are not striking. Kyphosis of the thoracic spine and pectus carinatum may be present. The patient’s intelligence is normal. Hepatosplenomegaly is not associated with Morquio’s syndrome.

Radiographs reveal tongue-shaped projections originating from the anterior vertebral body (Fig. 180.14). Platypondylsy is present. Odontoid hypoplasia, resulting in atlantoaxial instability, is common and the surgeon should look for it (152). The epiphyses are irregular and flattened, and may fragment in the weight-bearing joints. The bases of the metacarpals are pointed, and the bones of the hand are short and thick (196). The radiographic appearance is very similar to that seen in spondyloepiphyseal dysplasia.

Orthopaedic management of atlantoaxial instability often is necessary, with atlantoaxial fusion the recommended treatment (152,228) (Fig. 180.15) (see Chapter 158). Difficulty in walking is easily attributed to the genu valgum (Fig. 180.16), but the surgeon must be cautious and confirm that the cervical spine is not the cause of the changes in ambulation. Anesthesiology concerns are related to possible cervical instability. Life expectancy usually is normal.
MULTIPLE HEREDITARY OSTEOCHONDROMATOSIS

Multiple hereditary osteochondromatosis is one of the more common forms of dysplasia, occurring in 9 per million people. It is genetically transmitted as an autosomal dominant trait. Severity of involvement varies among family members, but penetrance is 100% (260). Masses develop in those bones that are formed by endochondral ossification, with a predisposition for the long bones, scapula, ribs, and pelvis.

Histologic examination reveals normal bone that is in continuity with the metaphysis of the parent bone. The exostosis is covered by a cap of hyaline cartilage, usually less than 3 mm in thickness. The deep surface of the cartilaginous cap is involved in endochondral ossification, leading to growth of the lesion.

The diagnosis normally is made during the patient's first decade of life. Multiple bumps, which are usually nontender, may be palpable throughout the skeleton. The spine is rarely affected (1,9,157). Limb-length discrepancy and angular deformity are common because of disturbance of normal longitudinal growth. Scapular lesions can lead to “winging” (56).

On radiographs, lesions can be seen around the metaphysis of the long bones, along the borders of the scapula, on the ribs, or originating from the iliac apophysis. The exostoses may be sessile, with a broad base or origin, or they may be pedunculated, arising from the bone on a bony stalk. The medullary canal of the mass is in continuity with the canal of the long bone. There is a predilection for the masses to appear at the end of the bone that grows fastest (e.g., the distal rather than the proximal radius) and for greater involvement of the smaller bone of two-bone limbs (e.g., the ulna more so than the radius) (Fig. 180.17). Pedunculated lesions typically point away from the epiphysis.

Orthopaedic management consists of excision of painful exostoses and observation of those that remain asymptomatic (40,264). Excision may be postponed until adolescence, when multiple symptomatic lesions can be excised under one anesthetic. Angular deformities may require correction, especially at the knee, where valgus is common (163). Genu valgum may lead to patellofemoral instability (151). Compression of surrounding structures may occur owing to the size of the osteochondromas. The peroneal nerve is particularly prone to compression from masses and is susceptible to injury during surgical excision of proximal fibular lesions (38,264). Proximal tibial lesions may irritate the pes anserinus (61). Large exostoses of the distal tibia can compress the adjacent fibula, leading to erosion and deformity (57,214).

Wrist involvement in hereditary osteochondromatosis is quite common, consisting of distal ulnar and radial osteochondromas, shortening of the ulna, tilt of the distal radial epiphysis, and ulnar translation of the carpus (Fig. 180.18). Dislocation of the radial head may occur because of the ulnar shortening (117). At present, treatment of osteochondromatosis of the forearm is controversial. Some authors advocate early excision of osteochondromas around the wrist, believing that such treatment prevents subsequent deformity and radial head dislocation (189,170). However, a recent study comprising 78 patients with forearm osteochondromas found that function was not compromised and that cosmetic concerns were rare in those patients who did not have early, aggressive treatment of their exostoses (19). Outcome studies agree that deformities of the upper extremity in patients who have hereditary multiple exostoses are well tolerated and cause little loss of function as measured both objectively and subjectively (222). When osteochondromas result in progressive discrepancy in length between the radius and the ulna, and forearm rotation becomes painful, osteotomy of the bowed radius can be performed with satisfactory but not perfect results. Acute lengthening and gradual lengthening of the ulna (via the Ilizarov technique) have both been described (54,256). Radial head excision is reserved for pain relief in skeletally mature patients.

Malignant transformation of benign osteochondromas into chondrosarcoma occurs in less than 1% of affected individuals. The physician should become clinically suspicious when a lesion increases in size or becomes painful after skeletal maturity. The cartilage cap of a benign osteochondroma is quite thin; a cap greater than 1
cm in thickness suggests malignant transformation. Accurate measurements of cartilage cap thickness can be made using MRI or ultrasound scans (135). Even if a chondrosarcoma occurs, such malignancies are rare to metastasize; usually respond well to wide resection; and have a good prognosis, particularly in long bone lesions (see Chapter 127 and Chapter 128).

**ENCHONDROMATOSIS**

Enchondromatosis is a noninherited bone dysplasia in which masses of cartilage form within the metaphyses of tubular bones and the pelvis. Lesions may be single or multiple and involve only a single extremity, or they may affect multiple extremities. Asymmetry is a hallmark of the disease, with one side of the body markedly more involved than the other side. Multiple enchondromatosis is known as Ollier's disease; enchondromatosis with multiple hemangiomas is known as Maffucci's syndrome.

Pathology reveals clusters of chondrocytes within the lesions. Mitotic figures may be present but should be few in number. Grossly, the lesions appear as gray-white masses amid the bone and may feel gritty due to calcification.

Radiographic findings show lucent, streaky lesions within the metaphyses (134, 194). Calcification can be seen within the lesion. The cortex of the bone may expand with the lesion, especially in the phalanges of the hand. The metaphysis becomes widened and trumpet shaped. Anular deformity and shortening are seen (179) (Fig. 180.19).

**FIBROUS DYSPLASIA**

Fibrous dysplasia is a noninherited dysplasia in which bone is replaced by abnormal fibrous tissue. One bone (monostotic fibrous dysplasia) or multiple bones (polyostotic fibrous dysplasia) may be affected. In the polyostotic form, usually one side of the patient's body is involved to a greater degree than the other side. The disease can be associated with endocrine abnormalities and hyperpigmented skin lesions, known as McCune-Albright syndrome (41, 126, 129). Precocious puberty is the hallmark of the McCune-Albright variant.

Pathology reveals a fibrous stroma full of fibroblasts. Multiple immature fragments of woven bone are seen within the stroma, an appearance similar to that of alphabet soup. The bone has widened osteoid seams and does not mature into lamellar bone.

The clinical diagnosis usually becomes apparent within the patient's first two decades of life. Presenting signs include pain, limp, deformity, or pathologic fractures. Involvement of the skull and facial bones can occur in varying degrees. Leg-length discrepancy is common.

Radiographs reveal ill-defined, lucent lesions that have a ground-glass appearance because of the calcification of immature bone. The cortex is thinned, and the shaft of the involved bone may expand. Lesions are metaphyseal or diaphyseal in location. Coxa vara with "shepherd's crook" deformity of the proximal femur is a classic radiographic finding (Fig. 180.20). Isolated lesions may be mistaken for simple bone cysts, particularly in the humerus. Spinal involvement, usually associated with neurologic compromise, has been described (73, 86, 150, 174). Because the diagnosis can usually be made from radiographs, biopsy is rarely necessary.

**Figure 180.20.** Extensive fibrous dysplasia of the femur and pelvis in a 13-year-old boy. Note the "shepherd's crook" deformity of the proximal femur.

Orthopaedic treatment depends on the site of the lesions and on the biomechanical implications of the weakened bone. Pain, progressive deformity, and impending pathologic fracture are indications for surgery. Closed treatment of fractures due to fibrous dysplasia usually is sufficient for the upper extremities but is rarely successful for the lower extremities, for which the demands of weight bearing require strong bony support (229). Excision and curettage rarely work because bone graft is quickly replaced by the abnormal fibrous tissue (287). When bone grafting is necessary, cortical strut grafts (e.g., the fibula) take longer to resorb and thus provide more structural support (35, 75).

Femoral neck lesions are particularly problematic. Osteotomy to correct coxa vara, combined with curettage and grafting of the femoral neck (usually with cortical bone), is performed when the calcar becomes progressively thin, leading to coxa vara and a painful limp. Internal fixation should be used, but extension of the lesion up into the femoral neck makes standard fixation tenous (57). Osteotomies to correct deformity and intramedullary fixation, particularly using reconstruction nails, which provide fixation into the femoral head and neck, can help restore alignment and support in the femur and tibia (62). Because the medullary canal in fibrous dysplasia is less distinct and very vascular, the surgeon should anticipate difficulties when using closed techniques as well as increased blood loss during intramedullary fixation. Osteotomies tend to heal reasonably well, and nonunions are uncommon.

Leg-length discrepancy may be significant enough to require surgical equalization. For moderate discrepancies, contralateral epiphysiodesis is far simpler than lengthening procedures.

The activity of the disease usually regresses in adulthood (106). Malignant tumors have been described as having originated from both the monostotic and the polyostotic forms of fibrous dysplasia (105, 189, 196). A 3% rate of malignant transformation has recently been reported by the Mayo Clinic, with the majority of tumors...
NEUROFIBROMATOSIS

Neurofibromatosis (von Recklinghausen’s disease) is the most prevalent skeletal dysplasia transmitted by a single gene. It is inherited in an autosomal dominant pattern with variable expression, although the disease is believed to occur due to a new mutation in half of the affected individuals (248). The estimated prevalence is 1 per 1000 live births.

The disorder has two forms. Neurofibromatosis type I (NF-I) is the more common form and is characterized by peripheral neurofibromas, skeletal involvement, and “café au lait spots.” The genetic locus for NF-I has been localized to chromosome 17q11.2, an area that encodes for the protein neurofibromin (98,206). This protein is present in several organ systems and is believed to be a tumor suppressor (249). Neurofibromatosis type II (NF-II) manifests as central neurofibromas with bilateral acoustic neuromas and usually presents in the third or fourth decade of life (142). The gene for NF-II has been localized to chromosome 22 and encodes for the protein schwannomin (131). Histologic examination of neurofibromas has shown a palisading arrangement of densely packed fibrous bundles and spindle cells. Grossly, the masses are firm and pale.

There are numerous clinical features of neurofibromatosis. The National Institutes of Health has developed specific criteria for the diagnosis of neurofibromatosis (Table 180.3). The most common skin lesion is the café au lait spot, a hyperpigmented irregular area with a smooth border that varies in size and shape (Fig. 180.21). These spots usually are not present immediately after birth but appear and increase in number throughout childhood. More subtle skin findings in patients with neurofibromatosis include axillary or inguinal freckling. Fibroma molluscum are superficial, raised nodules that represent dermal neurofibromas. They are not seen in infants or neonates, but are common in children and adults (131). Freckles are common in patients with neurofibromatosis and are considered characteristic. Freckles are not seen in infants, but appear and increase in number throughout childhood. More subtle skin findings in patients with neurofibromatosis include axillary or inguinal freckling. Fibroma molluscum are superficial, raised nodules that represent dermal neurofibromas. They are not seen in infants or neonates, but are common in children and adults (131). Freckles are common in patients with neurofibromatosis and are considered characteristic. Freckles are not seen in infants, but appear and increase in number throughout childhood.

Figure 180.21. Multiple café au lait spots in a 3-year-old boy with neurofibromatosis and scoliosis.

Skeletal lesions vary as well. Scoliosis is most common, occurring in up to 64% of patients with neurofibromatosis (50). Three types of scoliosis exist. The first is an idiopathic-appearing curve without significant bony changes or kyphosis. A second form is the dysplastic type, a short, sharp curve in which six or fewer vertebrae are involved. The dysplastic curve occurs in up to 72% of patients with neurofibromatosis and scoliosis (212). The vertebrae may assume a wedge shape, rotation usually is severe, and penciling of the apical ribs is characteristic. The neural foramen may be expanded owing to pressure from dumbbell neurofibromas. A third form of scoliosis is a dysplastic curve with associated hyperkyphosis (Fig. 180.22A, Fig. 160.228).

Figure 180.22. PA (A) and lateral (B) radiographs of a dysplastic kyphotic curve in a 3-year-old boy with neurofibromatosis.

Hypertrophy or hemiatrophy due to neurofibromatosis can be seen, and the physician should rule out the disease whenever evaluating a child with hemihyper trophy. Congenital pseudarthrosis of the tibia and forearm may be present. Protrusio acetabuli is also seen in patients with neurofibromatosis.

Orthopaedic treatment of the skeletal involvement of neurofibromatosis most often involves the spine. Treatment of the idiopathic-type curve is similar to the treatment of adolescent idiopathic scoliosis (see Chapter 155, Chapter 156, and Chapter 158). Bracing is used for progressive curves in growing patients, with spinal fusion reserved for larger curves. Dysplastic curves have a more ominous prognosis, with rapid progression commonly seen. Those curves that are most prone to progression occur in younger patients, are greater in magnitude at presentation, are associated with kyphosis, and have vertebral and rib erosive changes (54). Spinal fusion was often complicated by pseudarthrosis (50,212), leading to the current recommendation of combined anterior and posterior spinal fusions to treat these curves (263). Surgery should not be delayed in young children with dystrophic curves (37). Even with anterior and posterior fusion, some dystrophic curves continue to progress, requiring difficult subsequent revision procedures (50,199,118,261).

Spinal surgery in patients with neurofibromatosis is technically challenging for several reasons. First, the bone itself is often soft due to erosion from neurofibromas. This compromises the purchase of hooks or screws used during instrumentation. Second, the surgical approach can be difficult owing to thoracic neurofibromas surrounding the spine (199). Last, intradural lesions and outpouchings of dura (known as dural/cysts) are seen in patients with neurofibromatosis, increasing the risk...
of neurologic complications during surgical correction (72, 108). Preoperative MRI studies of the spinal cord are imperative in patients with neurofibromatosis (60).

Cervical spine involvement in patients with neurofibromatosis has also been described (60, 99). Severe cervical kyphosis has been seen in patients with plexiform neurofibromas (252) (Fig. 180.23). Neurologic compromise has been described in these patients (47, 130).

Figure 180.23. Cervical kyphosis in a 3-year-old girl with neurofibromatosis.

Leg-length discrepancy may occur due to neurofibromatosis. The treatment of hemihypertrophy is individualized and ranges from epiphysiodesis for mild cases to ablative amputation for severely affected persons.

Congenital pseudarthrosis of the tibia is one of the most challenging disorders treated by pediatric orthopaedists. The condition usually, but not always, is associated with neurofibromatosis. Boyd (33) described four types of congenital pseudarthrosis of the tibia (Fig. 180.24; Table 180.4).

A recently described variant of congenital anterolateral bowing of the tibia has been described in which the fibula is stout, and the bowing remodels without treatment and does not progress to pseudarthrosis. This benign form does not occur in patients with neurofibromatosis (241).

Treatment of congenital pseudarthrosis of the tibia is controversial (169). Myriad methods have been employed to obtain union, but all have led to failures in some patients (15). The prepseudarthrosis should be treated with total contact clamshell orthoses. Once the tibia has fractured, closed treatment will not be successful (49).

The traditional treatment for congenital pseudarthrosis of the tibia is intramedullary fixation of the tibia and fibula, with excision of the pseudarthrosis and bone grafting. The Williams rod can be inserted through the calcaneus into the tibia and usually is left protruding across the ankle joint. With growth, the rod migrates proximally into the tibia (4) (Fig. 180.25A, Fig. 180.25B).

Figure 180.25. A: Intramedullary fixation in congenital pseudarthrosis of the tibia. B: Note the proximal migration of the distal end of the rod.

Newer methods of treating congenital pseudarthrosis of the tibia have been recommended in response to the high rate of nonunion using intramedullary fixation. Advocates for Ilizarov fixation and bone transport as well as for vascularized fibula transfer find that union can be achieved in some, but not all, patients with congenital pseudarthrosis of the tibia (31, 46, 62, 66, 78, 91, 93, 211, 242, 258) (see Chapter 36, Chapter 169, and Chapter 171). The long-term ability to maintain union in these patients remains unknown. Amputation continues to be a feasible option for the patient who has undergone several operations and still fails to achieve union (115). A long-term study by Crossett et al. (52) found that approximately half of their patients with congenital pseudarthrosis of the tibia eventually were treated by amputation. Regardless of the method used to achieve union, precaution must be taken to prevent recurrent fractures. Protection of the tibia with ankle-foot orthoses is usually
prescribed. Even when union is achieved, muscle weakness and gait disturbances are almost always present (122).

Leg-length discrepancy is nearly universal following congenital pseudarthrosis of the tibia, with the affected leg being shorter than the normal limb. Equalization surgery is often indicated.

Pseudarthrosis of the forearm is also associated with neurofibromatosis and likewise is difficult to treat (48,141). Protrusio acetabuli may also result from neurofibromatosis (118) and usually is associated with contiguous neurofibromas (136).

Patients with neurofibromatosis are prone to developing malignancies of tissues of neural crest origin as well as others (49,204).

METABOLIC BONE DISEASES

Metabolic bone disease is caused by abnormalities in the metabolism of calcium and phosphate. Rickets and renal osteodystrophy are the most common forms of metabolic bone disease in children. A thorough understanding of calcium metabolism is required to evaluate affected patients properly (30,138).

The human body is very sensitive to calcium, particularly the cardiovascular and neurologic systems, in which irritability, conductivity, and contractility rely on the precise control of serum calcium levels. Nearly all of the body's calcium is stored in bone in the form of hydroxyapatite, with a small proportion circulating in the bloodstream. Serum calcium levels are regulated by vitamin D and parathyroid hormone (PTH) through their actions on the gut, kidneys, and bone. Calcium is absorbed in the distal duodenum and proximal jejunum by means of a transport mechanism that is activated by the active form of vitamin D (1,25-dihydroxy vitamin D) and by PTH.

Provitamin D is ingested as ergosterol or is produced by the liver as 7-dehydrocholesterol. When they are exposed to ultraviolet light, these compounds become calciferol and cholecalciferol. The first hydroxylation occurs in the liver and the second hydroxylation takes place in the kidney, with the end result being 1,25-dihydroxy vitamin D (233). Conversion to this dihydroxy form is stimulated by hypocalcemia and high levels of PTH.

PTH is produced in the parathyroid glands and is released in response to hypocalcemia. PTH allows for the absorption of calcium from the gut and renal tubules, frees calcium from hydroxyapatite in bone, and activates osteoclasts, an event that takes importance in renal osteodystrophy.

NUTRITIONAL RICKETS

Nutritional rickets is caused by inadequate dietary intake of vitamin D in the growing child. Although the condition is uncommon in the United States (116), it remains a problem throughout the rest of the world. Children who are fed a vegetarian diet or who are breast fed for prolonged periods of time are at increased risk for nutritional rickets (189). Malabsorption of vitamin D due to celiac or hepatic disease results in gastrointestinal rickets, which is more commonly seen in developed countries. In either form, the lack of vitamin D results in the inability to absorb calcium or phosphorus. PTH is released in response to the hypocalcemia, but hypophosphatemia persists. Laboratory studies reveal normal or mildly decreased serum calcium, decreased serum phosphate, elevated PTH, and decreased vitamin D.

Histologic changes are most notable at the growth plate, where loss of columnation occurs in the zone of hypertrophy. Because there is insufficient calcium to mineralize bone, plump chondrocytes persist into the zone of provisional calcification and down into the metaphysis. There is sparse mineralization and elongation of the growth plates. Within trabecular bone, large amounts of unmineralized osteoid surround the fragile trabeculae.

Radiographic findings show marked widening of the growth plate due to the absence of the zone of provisional calcification (Fig. 180.26). The metaphyses are flared or cupped. The long bones may be abnormally bowed because they are unable to withstand mechanical stress. The trabecular pattern of the bone is indistinct. Osteopenia is present. Looser's lines (radiolucuent lines extending transversely across the axis of the bone) are associated with rickets and are present in approximately 20% of patients with all forms of rickets (223).

Figure 180.26. Osteopenia and growth plate widening in the knee of a 1-year-old girl with nutritional rickets.

Most children affected with nutritional rickets are quite young (188). Clinical features include short stature, muscular weakness, and ligamentous laxity. Genu varum and periarticular enlargement of the wrists, elbows, and ankles may be noted. The term "rachitic rosary" refers to the prominence of the costochondral cartilages along the chest wall. The abdomen may be protuberant. Neurologic involvement, such as listlessness and irritability, may be present.

Treatment of nutritional rickets, which should be supervised by a pediatric endocrinologist, consists of vitamin D replacement. Osteotomies are rarely required for residual deformity following medical treatment.

NEONATAL RICKETS

A form of rickets has been described in which premature neonates in intensive care units sustain multiple fractures without antecedent trauma (125). Risk factors include hepatobiliary disease, total parenteral nutrition, diuretic therapy, physical therapy with passive motion, and chest percussion therapy. The fractures require minimal immobilization to heal. The patients are treated by the neonatal intensivists with supplemental feedings (53).

VITAMIN D–RESISTANT RICKETS

Vitamin D–resistant rickets, also known as familial hypophosphatemic rickets, is a group of diseases in which ordinary dietary intake of vitamin D is inadequate in maintaining normal mineral balance (251). The condition usually is inherited in an X-linked dominant pattern, although an autosomal dominant form also exists (69). The genetic locus for the disease has been identified (7,71,184,185). A renal tubular defect leads to the inability to reabsorb phosphate, resulting in phosphate diabes and hypophosphatemia (39,71,101). Laboratory studies reveal near-normal levels of calcium, PTH, and vitamin D but low levels of serum phosphate. Urinary phosphate and serum alkaline phosphatase are elevated.

Affected children present with bowing of the lower extremities, short stature, bone pain, and dental caries (69). The disease becomes clinically apparent after 12 months of age, but it can be diagnosed earlier by laboratory testing for urine phosphate levels in suspected infants (146).

Radiographic changes and histologic findings are similar to those seen in patients with nutritional rickets (Fig. 180.27).
Bowing and physeal widening in the lower extremities of a 4-year-old girl with hypophosphatemic rickets.

Treatment of hypophosphatemic rickets is primarily medical, typically consisting of oral replacement of phosphate and large amounts of vitamin D (247). Nephrocalcinosis is a known complication of medical treatment (227). Growth hormone therapy has been used to improve phosphate metabolism and increase stature in these patients (184,191,282).

Orthopaedic management consists of osteotomies to treat residual deformities of the lower extremities (79,187) (see Chapter 168 and Chapter 169). Careful preoperative planning is required because the deformities are multiplanar and thus may benefit from external fixation that precisely corrects angulation in each plane (123). Bone healing is delayed after osteotomy and may take approximately twice as long as expected in metabolically normal children. Calcification of ligaments and degeneration of articular cartilage may occur in affected adults (79).

MISCELLANEOUS FORMS OF RICKETS

On rare occasions, rickets may occur in patients with neurofibromatosis or fibrous dysplasia (137). Anticonvulsant drug therapy may also produce rickets (236). In addition, certain tumors may produce hypophosphatemic rickets. Patients with no family history of rickets should be suspect. Tumors usually are present in bone or skin (103).

RENAL OSTEODYSTROPHY

Renal osteodystrophy is a more common form of metabolic bone disease (20). Glomerular disease leads to retention of phosphate. The injured kidney is unable to perform the final hydroxylation of vitamin D. Hypocalcemia ensues, which stimulates secondary hyperparathyroidism. It is the secondary hyperparathyroidism that produces most of the skeletal manifestations of renal osteodystrophy.

PTH enables osteoclasts to resorb bone. In renal osteodystrophy, lysis of bone is extensive, resulting in the development of osteitis fibrosa (163). A small number of patients may develop osteosclerosis.

Laboratory studies show elevated levels of blood urea nitrogen (BUN), creatinine, alkaline phosphatase, and PTH. Serum calcium and vitamin D levels are low, whereas the serum phosphate level is high.

Children with renal osteodystrophy are short for their age. Bone pain may be present, and pathologic fractures can occur (11). Hip pain and limp, secondary to slipped capital femoral epiphysis, may be present (203). This occurs in children who are younger than those most often seen with slipped epiphyses, and the condition usually is bilateral. The previously described features of nutritional rickets may also be present. Bowing of the long bones and genu valgum are common.

Radiographic findings are striking. Resorption of bone can be seen at the terminal tufts of the distal phalanges, the symphysis pubis (Fig. 180.28), and the end of the clavicle. Metaphyseal resorption of bone leads to widened physes and slipped capital femoral epiphysis (SCFE; see Chapter 172) (Fig. 180.29). Disturbance of the proximal lateral tibial physes with associated genu valgum has been described (161). Brown tumors appear as large, lucent lesions with indistinct margins within the pelvis or long bones. These tumors can best be seen on MRI (158). “Rugger jersey” spine describes the sclerotic appearance of the vertebral endplates seen on a lateral radiograph. Periarticular soft-tissue calcification may be seen.

Figure 180.28. Resorption of the pubis due to renal osteodystrophy.

Figure 180.29. Physeal widening and slipped capital femoral epiphysis in a 7-year-old boy presenting with hip pain. A diagnosis of renal failure was made.

Treatment is primarily medical and is aimed at correcting the metabolic imbalance. Calcitriol, administered in high doses intravenously, orally, or by dialysis, has been found to be helpful in the treatment of pediatric renal osteodystrophy by lowering PTH levels (193). Pinning of SCFEs may be necessary (107), but osteopenia and continued metaphyseal resorption may compromise fixation (see Chapter 172). The patient's hip pain may resolve simply with medical treatment. Osteolysis of the distal femoral physes has also been described, with cast immobilization and medical treatment sufficient to promote healing and remodeling (231). When an angular deformity of the lower extremities interferes with gait, osteotomy of the femur or tibia is indicated. Best results are obtained if the patient's metabolic state is optimized before surgery (58,260).
GENERALIZED SYNDROMES

DOWN SYNDROME

Down syndrome is one of the most common genetically transmitted diseases, with a prevalence of 9.2 per 10,000 live births (5,159). It results from trisomy of chromosome 21 because of maternal nondisjunction, translocation, or mosaicism. One risk factor for Down syndrome is advancing maternal age. The most notable feature is mental retardation, but a variety of other congenital malformations, including heart defects, commonly occur (120). The IQs of children with Down syndrome vary considerably. About 30% of patients develop orthopaedic problems that require hospitalization (63).

Clinical features include a characteristic facies, with upslanting palpebral fissures, prominent epicanthal folds, mild microcephaly, and a protruding tongue. The child tends to be short. Ligamentous laxity is universal. Development is delayed, with the onset of ambulation usually not occurring until 2 to 3 years of age.

Radiographic findings include a characteristic appearance of the pelvis. The iliac wings are widened, the ischial rami are small and tapered, and the acetabulae are horizontal. Coxa valga is present. Hand radiographs show that all five metacarpals are equal in length, and there is clinopecty of the small finger.

Orthopaedic concerns arise from the ligamentous laxity and its effects on the spine, hips, knees, and feet. Atlantoaxial instability, the most commonly recognized skeletal manifestation of Down syndrome, is caused by laxity in the transverse ligament. The radiographic definition of atlantoaxial instability is an increase in the atlanto-dens interval (ADI), as seen on flexion lateral cervical radiographs (Fig. 180.30). It has been reported to occur in 5% to 31% of persons with Down syndrome (177). Patients with atlantoaxial instability have a particularly high rate of associated congenital cervical spine anomalies (e.g., os odontoideum, hypoplasia of the posterior arch of C-1, and hypoplasia of the dens) that may have an impact on surgical treatment (140,176).

Figure 180.30. The atlanto-dens interval is increased in flexion in this 12-year-old boy with Down syndrome.

Children with Down syndrome are usually screened for cervical instability. The American Academy of Pediatrics Committee on Sports Medicine and Fitness conducted a review of the literature and concluded that greater effort should be directed toward "identification of those patients who already have or who later have complaints or physical findings consistent with symptomatic spinal cord injury" rather than obtaining routine radiographs (6). This report pointed out that almost all children who suffered catastrophic neurologic injury because of atlantoaxial instability had pre-existing neurologic symptoms, and that children rarely develop abnormal radiographic findings following normal films (147).

Activity modification to protect patients with increased ADI from head trauma by removing them from "at-risk" athletic activities is the traditional recommendation. A few authors have proposed that because neurologic abnormalities are so rare even in affected children, activity restriction may be unnecessary (51). Others have found that an equal proportion of patients have neurologic signs with and without radiographic instability of the cervical spine, and they question the need to screen all patients (106). Once atlantoaxial instability is documented radiographically, rarely does it increase significantly over time (172). Neurologic injury following nonsurgical spine surgery has been described; thus, preoperative radiographic evaluation of the cervical spine in patients with Down syndrome is warranted (59,145,249).

Surgical treatment of atlantoaxial instability consists of posterior spinal fusion with halo immobilization (181). A high complication rate with major complications, including nonunion, loss of reduction, neurologic deterioration, late subaxial instability, infection, and wound dehiscence, should be anticipated after posterior arthrodesis of the upper cervical spine in patients with Down syndrome. Ligamentous laxity in patients with precarious preoperative neurologic status increases the neurologic mortality risk during surgery (213). Nonsurgical management is currently recommended for patients with Down syndrome who have atlantoaxial instability but no neurologic signs or symptoms (127,499).

Recent attention has also been directed at instability between the occiput and C-1. Posterior occipitoatlantal hypermobility (POAH), defined as subluxation of the occiput posteriorly during extension of the neck, has been identified in 8% to 63% of patients with Down syndrome (173). Nonsurgical management is currently recommended for patients with Down syndrome who have atlantoaxial instability but no neurologic signs or symptoms (127,499). POAH may be seen in patients with atlantoaxial instability (243). Treatment is based on the child's neurologic status and on the amount of space available for the spinal cord (239). Posterior occipital-cervical fusion has been recommended (146).

The lower cervical spine may also become symptomatic in patients with Down syndrome. Spondylosis of the cervical spine and early degenerative arthritis have been described (239).

Ligamentous laxity may predispose the patient to instability of the joints of the lower extremities, resulting in hip dislocations and patellar subluxation and dislocation. Approximately 7.9% of patients with Down syndrome have some hip abnormality, including dysplasia, dislocation, avascular necrosis, or SCFE (202). Dislocation of the hip in patients with Down syndrome is rarely painful initially but may become so over time. Treatment is difficult, because redislocation is not uncommon. Nonoperative bracing is rarely successful, but prolonged spica casting may allow the hip to stabilize in a reduced position. Open reduction, capsulorrhaphy of the attenuated capsule, and femoral and pelvic osteotomy may result in a stable hip (20) (see Chapter 186).

SCFE is also associated with Down syndrome. Hypothyroidism may be a predisposing factor, so thyroid function tests should be ordered for children with both Down syndrome and SCFE. Treatment is in situ fixation, but hardware failure may occur (see Chapter 172).

Patellofemoral instability is present in more than one third of patients with Down syndrome, but it rarely affects their ability to walk (68). Surgery is advised in selected cases and consists of aggressive realignment and Galleazzi transfer of the semitendinosus to the patella (see Chapter 87).

Planovalgus of the feet is nearly universal in these patients.

ARTHROGYROSIS MULTIPLEX CONGENITA

Arthrogryposis multiplex congenita is a syndrome in which multiple joints are rigid at birth (100). The disorder is nonprogressive, and the cause is unclear. Abnormalities of muscles, joints, and nervous system; teratogens; infection; and environmental factors have all been implicated. Many genetic syndromes include arthrogrypicccontractions and, thus, should be considered when evaluating a child with joint rigidity. The disease can resemble spinal muscular atrophy, and genetic associations between the two diseases have been proposed (56). Arthrogryposis usually is not genetically transmitted, but genetic research is being performed on the less common inherited forms (16,28,36,83,207,217).

Myopathic and neuropathic forms of arthrogryposis exist (178). The neuropathic type is more common (177). Muscle changes include replacement of skeletal muscle by fibrofatty tissue. Neuropathic findings include a decrease in the number of anterior horn cells, with sparing of the posterior columns. Sensation is not affected.

Clinically, most children have contractures of all four extremities. There is occasionally sparing of the upper extremities and rare sparing of the lower extremities. There is a distal form of the disease that consists of hand and foot contractures, including clubfoot (15). Intelligence is usually normal to above normal (217).

Figure 180.30. The atlanto-dens interval is increased in flexion in this 12-year-old boy with Down syndrome.
The affected limbs appear smooth, without transverse creases at the joints. Muscle mass is decreased, but the atrophy may be difficult to appreciate in young infants. Motion in the joints is limited but painless, and a solid block is felt at the extremes of range of motion.

In patients with extensive involvement, the hips are flexed, abducted, and externally rotated. Dislocation is common. The knees may have flexion or hyperextension contractures. Rigid clubfeet usually are present, but vertical talus may occur. The upper extremities, when involved, are adducted at the shoulder and internally rotated. The elbows may have flexion or extension contractures. The wrist may be flexed and ulnarly deviated, with flexion of the fingers and thumb-in-palm deformity. Scoliosis may be seen in young children.

Orthopaedic treatment is individualized. The goal of surgery is to improve function and enable ambulation when possible. With surgery, it has been found that up to 85% of patients with amphiplasia can walk at least on a limited basis by 5 years of age (601). The prognosis for ventilator-dependent babies is less favorable (26). Recurrence of deformities is common following surgery, and orthoses are usually prescribed.

In the neonatal period, focus on establishing a correct diagnosis. Include examination by a geneticist and a pediatric neurologist. Muscle biopsy is occasionally needed. Initiate physical therapy for range-of-motion and developmental skills. Range of motion should always be performed with great care, because pathologic fractures may occur.

Surgery to address hip dislocation has been recommended in patients with arthrogryposis. Pavlik harness treatment is unsuccessful, so open reduction is the treatment of choice. The medial approach has been specifically advocated by Staheli et al. (220) for use in arthrogryposis. Bilateral dislocations may be addressed medially during the same surgery, with good results reported in 80% of a series of 40 dislocated hips in arthrogryopic children (232) (see Chapter 166).

Knee contractures are difficult to treat. Knee flexion contractures require surgery more often than hyperextension contractures (149,215). Surgery is indicated if physical therapy fails to attain less than 30° flexion contracture. Hamstring tenotomy and posterior capsulotomy, with or without femoral shortening osteotomy, are required (234). Sectioning of the cruciate ligaments and resection of intra-articular fibrous tissue often is necessary. Femoral extension osteotomy can increase extension at the knee, but flexion deformity of the distal femur recurs with growth of the child (61). Chronic contractures lead to bony changes, such as squaring off of the femoral condyles and joint incongruity (94). Ilizarov techniques have been used in difficult cases (34) (see Chapter 171). Many children who have undergone knee flexion contracture surgery stop walking in adolescence (149).

Surgical correction of clubfeet should be performed around the age when the child learns to walk, which is nearly always delayed in babies with arthrogryposis. Postmeniscal release, with resection of tendons and capsules, and lateral column shortening, when needed, is the initial surgery of choice. Recurrence of deformity has been seen in 75% of children with arthrogryposis (150). Talarlysis or tarsal medulloectomy is usually reserved for recurrent severe deformity, but the procedure has been performed in primary releases by some surgeons (66,92,144,216) (see Chapter 167).

Upper extremity surgery should be delayed until a complete functional assessment can be performed. Optimally, one elbow should be extended for toileting and use of walking aids, and the contralateral elbow should be flexed to enable the child to self-feed (12). The ability of these intelligent children to adapt to their deformities can be surprising, so care should be taken not to intervene surgically when the child is functioning satisfactorily. Surgical procedures that may be useful for the upper extremities include rotational osteotomy of the humerus, triceps transfer to gain active elbow flexion, capsulotomies at the elbow, and wrist stabilization.

OSTEOPETROSIS

Osteopetrosis, otherwise known as Albers-Schönberg disease and “marble bone disease” is apparently a hereditary disease of bone characterized by abnormal function of osteoclasts. This results in varying degrees of bone remodeling deficiency, the skeleton being predominately composed of primary unremodeled trabecular bone and calcified cartilage. On electron microscopy, there are increased numbers of osteoclasts but their ruffled border is absent or diminished.

This is an exceedingly rare disorder. Most orthopaedic surgeons will not encounter a single case in their lifetime. Pediatric referral centers may see only a few cases at any given time. A recent review of the management of osteopetrosis by Armstrong, Newfield, and Gillespie based upon a review of the literature and a survey of the members of the Pediatric Orthopaedic Society of North America (10a), is highly recommended for readers interested in more details on this rare disorder. They provide an excellent summary of the characteristics of osteopetrosis, list 63 references, and provide clinical details on 79 patients found in their survey.

Osteopetrosis can be classified into an infantile malignant type. It is inherited by autosomal recessive transmission and a more benign adult form, which is autosomal dominant. The latter can be divided into Type I. This is characterized by marked thickening of the cranial vault, and a substantially lesser risk of fractures. Type II is characterized by vertebral end-plate thickening resulting in the classic appearance of “rugger jersey” spine and “endobones” in the pelvis. Type II has a higher incidence of fracture and delayed union as well. There is an extremely rare third form that is autosomal recessive. It is regarded as an “intermediate” form.

The underlying molecular abnormality, which results in dysplasia of the osteoclast, has not yet been established in humans. However, mutations have been found in the mouse and rat that produce an autosomal recessive type of osteopetrosis. In the op mouse and the tl rat, the production of colony-stimulating factor – 1 (CSF-1) appears to be deficient or the factor is inactive.

Patients with infantile malignant osteopetrosis are usually diagnosed during their first year of life and only 30% of patients survive past the age of 6 years, dying of complications resulting from myelophthisic anemia which is due to obliteration of their marrow spaces by unremodeled bone. Clinical characteristics include blindness, failure to thrive, seizures, repeated infections, pathologic fractures, hepatosplenomegaly, hypersplenism, hydrocephalus, mental retardation, cranial nerve palsies, and hemorrhagic diathesis.

The infants are lethargic and underdeveloped with macrocephaly, frontal bossing, hypotelorism, exophthalmos, and flattening of the nasal bridge with chronic rhinitis. Radiographs show increased density in the bone of the entire skeleton and the complete absence of the medullary canal. There is metaphyseal widening producing club-shaped long bones, and the “bone within a bone” phenomenon is seen in the pelvis, vertebrae, hands and feet. Transverse radiolucent bands can be seen in the metaphyseal regions of the long bones. The skull may progressively thicken and show a “hair-on-end” appearance. Transverse or short oblique pathologic-type diaphyseal and metaphyseal fractures are common.

The adult form is compatible with a normal lifespan although patients are prone to long-bone fractures. The age of presentation of these patients can be variable depending upon the severity of the disease. Up to 40% of patients may remain asymptomatic. There may be a family history of the disease or of multiple fractures. Radiographs show increased density in the bone of the entire skeleton and the complete absence of the medullary canal. There is metaphyseal widening producing club-shaped long bones, and the “bone within a bone” phenomenon is seen in the pelvis, vertebrae, hands and feet. Transverse radiolucent bands can be seen in the metaphyseal regions of the long bones. The skull may progressively thicken and show a “hair-on-end” appearance. Transverse or short oblique pathologic-type diaphyseal and metaphyseal fractures are common.

The affected limbs appear smooth, without transverse creases at the joints. Muscle mass is decreased, but the atrophy may be difficult to appreciate in young infants. Motion in the joints is limited but painless, and a solid block is felt at the extremes of range of motion.

In patients with extensive involvement, the hips are flexed, abducted, and externally rotated. Dislocation is common. The knees may have flexion or hyperextension contractures. Rigid clubfeet usually are present, but vertical talus may occur. The upper extremities, when involved, are adducted at the shoulder and internally rotated. The elbows may have flexion or extension contractures. The wrist may be flexed and ulnarly deviated, with flexion of the fingers and thumb-in-palm deformity. Scoliosis may be seen in young children.

Orthopaedic treatment is individualized. The goal of surgery is to improve function and enable ambulation when possible. With surgery, it has been found that up to 85% of patients with amphiplasia can walk at least on a limited basis by 5 years of age (601). The prognosis for ventilator-dependent babies is less favorable (26). Recurrence of deformities is common following surgery, and orthoses are usually prescribed.

In the neonatal period, focus on establishing a correct diagnosis. Include examination by a geneticist and a pediatric neurologist. Muscle biopsy is occasionally needed. Initiate physical therapy for range-of-motion and developmental skills. Range of motion should always be performed with great care, because pathologic fractures may occur.

Surgery to address hip dislocation has been recommended in patients with arthrogryposis. Pavlik harness treatment is unsuccessful, so open reduction is the treatment of choice. The medial approach has been specifically advocated by Staheli et al. (220) for use in arthrogryposis. Bilateral dislocations may be addressed medially during the same surgery, with good results reported in 80% of a series of 40 dislocated hips in arthrogryopic children (232) (see Chapter 166).

Knee contractures are difficult to treat. Knee flexion contractures require surgery more often than hyperextension contractures (149,215). Surgery is indicated if physical therapy fails to attain less than 30° flexion contracture. Hamstring tenotomy and posterior capsulotomy, with or without femoral shortening osteotomy, are required (234). Sectioning of the cruciate ligaments and resection of intra-articular fibrous tissue often is necessary. Femoral extension osteotomy can increase extension at the knee, but flexion deformity of the distal femur recurs with growth of the child (61). Chronic contractures lead to bony changes, such as squaring off of the femoral condyles and joint incongruity (94). Ilizarov techniques have been used in difficult cases (34) (see Chapter 171). Many children who have undergone knee flexion contracture surgery stop walking in adolescence (149).

Surgical correction of clubfeet should be performed around the age when the child learns to walk, which is nearly always delayed in babies with arthrogryposis. Postmeniscal release, with resection of tendons and capsules, and lateral column shortening, when needed, is the initial surgery of choice. Recurrence of deformity has been seen in 75% of children with arthrogryposis (150). Talarlysis or tarsal medulloectomy is usually reserved for recurrent severe deformity, but the procedure has been performed in primary releases by some surgeons (66,92,144,216) (see Chapter 167).

Upper extremity surgery should be delayed until a complete functional assessment can be performed. Optimally, one elbow should be extended for toileting and use of walking aids, and the contralateral elbow should be flexed to enable the child to self-feed (12). The ability of these intelligent children to adapt to their deformities can be surprising, so care should be taken not to intervene surgically when the child is functioning satisfactorily. Surgical procedures that may be useful for the upper extremities include rotational osteotomy of the humerus, triceps transfer to gain active elbow flexion, capsulotomies at the elbow, and wrist stabilization.
